Numerous causes of DIC may be encountered in obstetrics (Fig. 25.6). The most common are placental abruption and dead fetus syndrome. AFE, a rare obstetric catastrophe, often is associated with DIC. Preeclampsia, commonly associated with thrombocytopenia, is not itself a cause of clinical DIC, unless complicated by substantial placental abruption. Other conditions not unique to obstetrics, such as septic shock and transfusion disorders, also may be associated with DIC in obstetrics. The management of acute DIC in obstetrics principally involves resolution of the underlying pathophysiologic process. Although possibly severe, the DIC associated with abruption, dead fetus syndrome, or AFE usually is self-limiting, and its resolution may begin with delivery of the fetus and placenta. In most cases, the replacement of soluble clotting factors or platelets is effective in preventing clinical hemorrhage for the short term while delivery is accomplished; little evidence exists to support the use of heparin or fibrinolytic agents in obstetric DIC syndromes. One exception may be dead fetus syndrome, in which low-dose heparin therapy (5,000 U subcutaneously twice daily) may correct moderate coagulation abnormalities during delivery. When there is bleeding or if surgery is planned, platelet transfusion should be considered for patients with a platelet count less than 30,000 per cubic millimeter, and fibrinogen replacement with fresh frozen plasma is appropriate for the bleeding patient with a fibrinogen level less than 100 milligrams per deciliter or prolonged prothrombin and partial thromboplastin times. In the nonsurgical patient without clinical hemorrhage, clotting abnormalities associated with a mild to moderate intravascular coagulopathy may simply be observed while delivery is accomplished.

FIG. 25.6. Obstetric disorders that initiate disseminated intravascular coagulation. (From Clark SL, Phelan JP. *Critical care obstetrics*, second ed. Boston: Blackwell Scientific, 1990:182, with permission.)

TRANSFUSION THERAPY

Indications for blood or component transfusion include restoration of circulating volume, improvement in oxygen transport, and correction of coagulation disorders. The third indication has been addressed in the preceding paragraphs. This section addresses blood and component transfusion considerations in the patient with massive blood loss.

The incidence of blood transfusion in patients undergoing vaginal delivery is less than 1%, whereas 2% to 12% of patients undergoing cesarean delivery receive blood. To anticipate the potential for peripartum blood loss, blood often is sent for type and screen and, occasionally, type and crossmatch. To type and screen blood, first the ABO group and Rh(D) type of the patient's cells are determined. Her serum is then mixed with reagent red blood cells that contain the antigens with which most clinically significant antibodies will react. An antibody-enhancing solution, such as bovine serum albumin, may be added at this point to enhance the detection of nonagglutinating antibodies. After incubation and washing, the appearance of an agglutination indicates the presence in the recipient serum of antibodies to one or more antigens in the reagent blood cells.

Type and crossmatch procedures are similar to those described for typing and screening, except that potential donor red blood cells are used rather than standard reagent erythrocytes. If blood that has been screened but not cross-matched is used, a transfusion reaction might take place if the recipient serum contains an antibody to an antigen present on the donor cells that was not present on the reagent red blood cells. Because only 0.03% to 0.07% of patients who were determined not to have antibodies on type and screening subsequently are found to have preexisting antibodies determined by crossmatch, the type and screen approach has been about 99% effective in preventing incompatible transfusions. Type and screen testing is much less costly than typing and cross-matching blood and allows blood to be made available for more than one potential recipient, thus decreasing the wastage of banked blood. Therefore, this method is appropriate for both vaginal delivery and most cases of cesarean section and, under these circumstances, is preferred to typing and cross-matching.

Whole Blood

A unit of whole blood contains about 450 milliliters of blood. One unit of whole blood can raise the recipient's hematocrit by 3% to 4%. When stored for longer than 24 hours, whole blood retains few functioning granulocytes or platelets. Clotting factors are maintained in adequate concentrations for the life of the unit, except levels of factors V and VIII, which may be reduced. Because whole blood is not readily available, whole blood transfusion is uncommon in modern obstetric practice; red blood cells plus component replacement is preferred.

Red Blood Cells

Packed red blood cells are prepared from whole blood by separating the cells from plasma by centrifugation or sedimentation. They have a hematocrit of about 70% to 75% (160–275 cc red blood cells per unit). A unit of packed cells contains the same number of erythrocytes as a unit of whole blood; thus, it can raise the recipient's hematocrit by 3% to 4%. Packed red blood cells provide the same oxygen-carrying capacity as whole blood in about one half the volume.

Platelets

Platelets are prepared from whole blood by centrifugation and then are resuspended in 50 to 70 milliliters of plasma. Unlike red blood cells, they cannot tolerate prolonged storage; under special circumstances, however, they may be stored for up to 5 days. The donor plasma in which the platelets are suspended must be ABO compatible with the recipient's red blood cells. A unit of random donor platelets should raise the platelet count by 8,000 to 10,000 per cubic millimeter. Platelets are available in packs of 8 or 10 units. No consensus has been reached regarding minimal platelet levels that indicate the need for transfusion. In the nonbleeding or nonsurgical patient, platelet transfusion seldom is indicated with a platelet count that exceeds 10,000 per cubic millimeter, because antibody formation and platelet destruction are rapid. In the bleeding or surgical patient, the platelet count should be maintained above 30,000 per cubic millimeter to prevent further hemorrhage.

Fresh Frozen Plasma

Fresh frozen plasma contains all soluble clotting factors, similar to those found in whole blood. In addition, it contains significant amounts of factors V and VIII. The plasma is first separated from whole blood and then frozen. The volume of a unit is about 250 milliliters. Fresh frozen plasma is indicated for patients with a consumptive or dilutional coagulopathy in whom replacement of soluble clotting factors, including fibrinogen, is indicated. In the bleeding patient, a fibrinogen level less than 100 milligrams per deciliter associated with prolonged prothrombin and partial thromboplastin times is an indication for fresh frozen plasma infusion. By definition, each milliliter of fresh frozen plasma contains 1 IU of each coagulation factor. One unit will raise the serum fibrinogen level by approximately 25 milligrams per deciliter.

Cryoprecipitate

A unit of cryoprecipitate is prepared by thawing a unit of fresh frozen plasma, removing the supernatant plasma, and then refreezing the precipitate. Cryoprecipitate contains factor VIII:C, factor XIII, von Willebrand factor, fibrinogen, and fibronectin. The sole advantage of cryoprecipitate over fresh frozen plasma is the ability to infuse relatively large amounts of factors in a small volume. In practice, volume restriction seldom is desirable for the hemorrhaging patient; thus, fresh frozen plasma nearly always is preferable to cryoprecipitate in the management of obstetric hemorrhage associated with consumptive or dilutional coagulopathy.

In cases of dilutional coagulopathy, bleeding is more likely to be secondary to thrombocytopenia than to factor deficiency. All the blood and clotting factors contained in cryoprecipitate and fresh frozen plasma carry with them the risk of blood-borne disease transmission, although such a risk is minimal in properly screened and donated blood.

Transfusion Reactions

Acute transfusion reactions are seen in about 5% of blood recipients, and delayed transfusion reactions in up to 7% of recipients. Nonhemolytic febrile reactions may accompany 1% of all transfused units. Most nonhemolytic febrile and allergic reactions are unavoidable. Most hemolytic reactions may be prevented by proper attention to cross-matching procedures.

Hemolytic transfusion reactions may be acute or delayed. Acute intravascular hemolysis most commonly results from the transfusion of ABO-incompatible blood. Such errors are the most frequent cause of fatalities resulting from blood transfusion and usually are related to technical errors in blood specimen labeling and in patient identification. Such hemolysis is complement mediated. Signs and symptoms of acute hemolytic reaction include lumbar pain, facial flushing, chest pain that may be accompanied by fever, tachycardia, hypotension, and shock. In severe cases, DIC associated with oliguria and pulmonary edema may be seen. Acute tubular necrosis or ARDS may be encountered in patients who survive the acute episode. The key laboratory findings in the diagnosis of intravascular hemolytic transfusion reaction are a decrease in the plasma haptoglobin level with an increase in free serum hemoglobin. These findings typically are accompanied by hemoglobinuria if plasma levels exceed 25 milligrams per deciliter.

Acute extravascular hemolytic reactions are not mediated by complement but by the development of immunoglobulin G (IgG) antibodies to antigens such as D or Kell. Clinical findings are less severe and often manifest by simply a fever and hemolytic anemia. Severe clinical symptoms are infrequent.

Delayed hemolytic reactions occur within 3 to 7 days of a blood transfusion. These reactions are caused by a serum antibody that is present in low, undetectable levels at the time of transfusion. The clinical parameters are similar to those seen with acute extravascular hemolysis but are not as severe.

ACUTE RESPIRATORY DISTRESS SYNDROME

Acute respiratory distress syndrome is a complex pathophysiologic process resulting from either primary lung epithelial injury by way of the airways or capillary endothelial injuries initiated by way of the pulmonary vasculature. Such injury results in increased pulmonary capillary permeability, loss of lung volume, and shunting with resultant arterial hypoxemia. The physiologic criteria required for the diagnosis of ARDS are listed in Table 25.4. In pregnancy, the incidence of ARDS is approximately 1 in 6,000. Sepsis, preeclampsia, viral pneumonic processes, hypovolemic shock, and aspiration pneumonia are the most common causes of ARDS.

P_{O_2} <50 with F_{iO_2} >0.6
Pulmonary capillary wedge = 12 mm Hg
Total respiratory compliance <50 mL/cm (usually 20–30 mL/cm)
Functional residual capacity reduced
Shunt (Q_s/Q_t) >30%
Dead space (V_D/V_T) >60%
Alveolar—arterial gradient on 100% oxygen = 350 mm Hg

F_{iO_2}, fraction of inspired oxygen; P_{O_2}, partial pressure of oxygen; Q_s, blood flow to nonventilated areas; Q_t, total blood flow to both ventilated and nonventilated areas; V_D, dead space volume; V_T, tidal volume.

Source: Clark SL, Cotton DB, Hankins GDV, et al, eds. *Critical care obstetrics*. third ed. Boston: Blackwell Scientific, 1997, with permission.

TABLE 25.4. *Physiologic criteria for adult respiratory distress syndrome*

ARDS represents a final common pathway of a cascade of events initiated by the alveolar, epithelial, or endothelial injury (Fig. 25.7). After the initial injury to alveolar epithelial cells or vascular endothelial cells, the complement system, leukocytes, macrophages, and platelets may all play important roles in perpetuating the injury. During the initial lung injury, phospholipids are released from red blood cell membranes, resulting in a secondary mechanism of injury. Free arachidonic acids serve as a substrate for the synthesis of both prostaglandins and thromboxanes by way of the cyclooxygenase system and, possibly, leukotrienes by way of the lipoxygenase system. All of these arachidonic acid metabolites have been implicated in perpetuating the injury of ARDS.

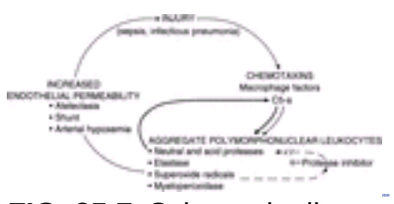

FIG. 25.7. Schematic diagram of the proposed mechanism of lung injury. After the cycle is established, loop 1 feeds back on itself to perpetuate the injury. Amplification of the first loop is provided by the neutral and acid proteases *(bold line);* disruption of the amplification loop is prevented by myeloperoxidases *(dashed line).* PMNs, polymorphonuclear leukocytes. (From Clark SL, Phelan JP. *Critical care obstetrics*, second ed. Boston: Blackwell Scientific, 1990:343, with permission.)

Clinically, the course of ARDS can be divided into four phases. Each is distinguishable by histologic changes in the lungs and reflected in various physiologic parameters in the patient. In phase I, hyperventilation is the only physiologic aberration seen, and arterial oxygenation remains adequate. During phase II (i.e., the latent period), there may be minor auscultatory and radiographic evidence of pulmonary disease. Mild decreases in lung compliance and increases in intrapulmonary shunting of blood are common. Histologically, these stages are characterized by progressive alveolar and interstitial edema formation and the movement of inflammatory cells into the interstitium. Damage to type I alveolar cells occurs, and hyaline membrane formation begins. Phase III is characterized by acute respiratory failure with severe dyspnea, tachypnea, and arterial hypoxemia. During this phase, lung volume is lost, resulting in the deterioration of pulmonary compliance and an increase in intrapulmonary shunting. Chest x-ray films taken during this stage demonstrate marked abnormalities, including bilateral lung opacification. During phase III, intubation and assisted ventilation are required. Histologically, phase III is characterized by thickening of the alveolar septum and marked infiltration by leukocytes, plasma cells, and macrophages. Hyaline membranes begin to form and organize during this phase, and the proliferation of fibroblasts and type II alveolar cells is prominent. In phase IV, interpulmonary shunting in excess of 25% results in hypoxemia refractory to all measures. Dead space during this period may exceed 60% of tidal volume. Metabolic and respiratory acidemia may be found and may result in increased myocardial excitability, which often leads to terminal dysrhythmia. Intraalveolar fibrosis is severe, and pathologic and physiologic derangements are irreversible.

Clinical Management

Four considerations are essential in understanding the clinical management of the pregnant patient with ARDS. These are oxygen delivery and tissue extraction, pulmonary compliance, interpulmonary shunt fraction, and eradication of the underlying cause.

Oxygen delivery is directly proportional to cardiac output; it is also influenced by the oxygen-carrying capacity of the blood. Thus, oxygen delivery can be optimized by maintaining cardiac output and correcting anemia. In the presence of suboptimal cardiac output or significant anemia, marked increases in the inspired concentration of oxygen have little effect on actual oxygen delivery. However, high inspired concentrations of oxygen are toxic to the lung. The goals in caring for a patient with severe ARDS are first to optimize cardiac output and hematocrit and then to maintain a PO_2 of 60 to 70 mm Hg. Because increased body temperature and metabolic acidosis produce a rightward shift in the oxyhemoglobin dissociation curve, these conditions may favorably affect peripheral oxygen delivery. Thus, the patient should not be chilled either in the operating room or through the administration of large volumes of intravenous fluids or blood that is below body temperature. Further, respiratory alkalosis should be corrected. Indeed, a mild metabolic acidemia may result in better tissue oxygen delivery than would be obtained with complete correction of the patient's acid–base status.

Arterial–venous oxygen content difference may be used to assess the adequacy of oxygen delivery. During pregnancy, the arterial–venous gradient narrows.

In the critically ill patient who is receiving assisted ventilation, pulmonary compliance can be calculated by using parameters obtainable from the ventilator. With severe ARDS, pulmonary compliance may fall from a normal value of about 75 milliliters per cm H_2O to as low as 20 milliliters per cm H_2O. Serial calculation of compliance may be useful in evaluating the effects of various therapeutic maneuvers, including positive end-expiratory pressure (PEEP). Longitudinal evaluation of pulmonary compliance may serve as a useful method of following the resolution or progression of ARDS.

The normal shunt in the healthy gravida is 2% to 5% of cardiac output. Mild pulmonary dysfunction may result in shunting of 10% to 15%. A shunt that exceeds 25% suggests and, in the absence of other causes, may be diagnostic of ARDS. The shunt may be estimated either by analyzing an arterial blood sample alone or by analyzing simultaneously obtained arterial and pulmonary artery blood samples. In the former method, the greatest accuracy is obtained by having the woman breathe 100% oxygen. In a patient who is intubated and receiving 100% inspired oxygen, the arterial oxygen pressure should exceed 500 mm Hg; values below 300 mm Hg suggest severe shunting.

During initial treatment of the pregnant gravida with ARDS, the physician should simultaneously conduct an aggressive search for and attempt to eliminate the underlying cause of the lung injury. Early intubation is essential for the patient in incipient respiratory failure (Table 25.5). Mechanical ventilation requires a volume-cycled ventilator. Appropriate initial settings may include a rate of 12 breaths per minute, a tidal volume of about 15 milliliters per kilogram of body weight with a sigh volume of 200 to 400 milliliters above tidal volume, a PEEP of 5 cm H_2O, and 100% inspired oxygen. Fifteen to 30 minutes after the initial therapy, an arterial blood sample is analyzed, and the ventilator settings are adjusted to obtain a PaO_2 of 60 to 70 mm Hg with a PCO_2 of 35 to 45 mm Hg. The level of PEEP often must be increased to optimize PO_2 and oxygen saturation. The use of high levels of PEEP is preferable to the continued use of toxic concentrations of oxygen. If possible, the FIO_2 should be reduced to less than 60% to minimize the potential for long-term oxygen toxicity. The criteria for using higher levels of PEEP include a static compliance less than 40 milliliters per centimeter of water, a shunt fraction exceeding 20%, or an alveolar–arterial oxygen gradient on 100% oxygen exceeding 400 mm Hg. At high levels of PEEP (>20 cm of water), cardiac output may fall; thus, invasive hemodynamic monitoring often is useful in assessing the cardiac output response to high levels of PEEP. Fluid therapy in patients with ARDS may also be facilitated by the use of invasive hemodynamic monitoring, and the PCWP should be maintained as low as is consistent with adequate cardiac and urine output.

	Normal	Intubate
Respiratory rate	12–20	>35
Vital capacity (mL/kg)	65–75	<15
FEV_1 (mL/kg)	50–60	<10
Inspiratory force (cm H_2O)	75–100	<25
Pa_{O_2} (mm Hg)	100–75 air <70 mask	0.4 <300 F_{iO_2}
$Paco_2$ (mm Hg)	35–45	>55
V_D/V_t	0.25–0.40	>0.6

FEV_1, forced expiratory volume in 1 second; F_{iO_2}, forced inspiratory oxygen concentration; H_2O, water; $Paco_2$, arterial carbon dioxide pressure; Pa_{O_2}, arterial oxygen pressure; V_D/V_t, ratio of dead space volume to tidal volume.

TABLE 25.5. *Guidelines for instituting ventilator therapy*

The management of the patient with ARDS often is a long-term process. Ventilation and circulation may be supported by using some of the techniques outlined in this section. After the underlying cause of ARDS has been eliminated, therapy involves support of respiration and circulation while allowing the lungs time to heal. Despite aggressive and optimal management, the mortality rate for pregnant patients is approximately 40%. When ARDS is secondary to sepsis, higher mortality is seen. In many instances, such patients may expire despite optimal therapy. Surfactant replacement as well as nitric oxide therapy have shown promise in the treatment of severe ARDS; however, the use of these agents remains investigational.

AMNIOTIC FLUID EMBOLISM

AFE is an uncommon obstetric catastrophe with a mortality as high as 80%. It is a biphasic process that is triggered by the sudden embolization of amniotic fluid or debris of fetal origin into the maternal venous circulation. The initial physiologic disturbances involve profound alterations in hemodynamics and oxygenation, often followed by the development of a consumptive coagulopathy. Either of these phases may predominate and, occasionally, bleeding may be the initial manifestation. The most common clinical picture consists of sudden dyspnea and hypotension, commonly followed within minutes by cardiorespiratory arrest. In up to 50% of these cases, these initial events may be accompanied by seizure activity. Common signs and symptoms of AFE are presented in Table 25.6. One half of all patients with AFE die within 1 hour after the onset of symptoms; in survivors, neurologic damage or brain death secondary to the initial severe hypoxia is not uncommon. Data from the National AFE Registry suggested an overall mortality rate of 61%; only one half of those who survive do so without significant neurologic sequelae. Women with AFE generally exhibit left ventricular dysfunction or failure accompanied by elevated PCWP and, in most cases, depressed left ventricular stroke work index. Systemic vascular resistance is decreased. Elevations of pulmonary artery pressure and pulmonary vascular resistance often are in the range attributable to left ventricular failure. The existence of an initial but transient phase of pulmonary hypertension and elevated right ventricular pressure is supported by some animal and clinical data. A component of noncardiogenic pulmonary edema (i.e., ARDS) often is present and may become the predominant clinical problem in survivors.

Signs or symptom	No. of patients	%
Hypotension	43	100
Fetal distress	30	100
Pulmonary edema or adult respiratory distress syndrome	28	93
Cardiopulmonary arrest	40	87
Cyanosis	38	83
Coagulopathy	38	83
Dyspnea	22	49
Seizure	22	48
Uterine atony	11	23
Bronchospasm	7	15
Transient hypertension	5	11
Cough	3	7
Headache	3	7
Chest pain	1	2

Source: From ref. 48.

TABLE 25.6. *Signs and symptoms noted in patients with amniotic fluid embolism*

A hemorrhagic phase is reported in at least 50% of patients with AFE. This problem commonly is compounded by the simultaneous occurrence of uterine atony, perhaps as a direct result of a myometrial depressant effect of amniotic fluid. Although AFE has been reported under many conditions, most cases have occurred during labor. In the past, a pattern of vigorous labor or hypertonic uterine contractions associated with oxytocin infusion had often been implicated in the pathogenesis of this condition. Evidence of this association was anecdotal and is clearly invalid. Placental abruption is present in up to 50% of cases, with fetal death reported in some cases before the acute clinical onset.

Early studies suggested that meconium or particulate matter in amniotic fluid is the pathologic agent, but more recent data suggest that a humoral substance, rather than particulate matter, is responsible for the observed hemodynamic changes. It is also clear the infusion of clear amniotic fluid, per se, is innocuous, both in the human and in animal models. Further, the marked similarities between the clinical manifestations of AFE and both septic and anaphylactic shock suggest the involvement of endogenous mediators in the pathophysiology of this condition. Thus term *amniotic fluid embolism* is a misnomer, because the syndrome is not caused by amniotic fluid per se, nor are clinical manifestations those commonly seen with embolic events. Rather, this is yet another example of the increasingly recognized systemic inflammatory response syndrome which characterizes other types of critical illness such as anaphylaxis and sepsis (Fig. 25.8).

FIG. 25.8. Proposed pathophysiologic relationship among amniotic fluid embolism, septic shock, and anaphylactic shock. Each syndrome may also have direct physiologic effects (e.g., fever in endotoxin-mediated sepsis).

Classically, the definitive diagnosis of AFE has been made at autopsy with the demonstration of fetal squamous cells, mucin, hair, or vernix in the pulmonary artery vasculature. More recently, it has been demonstrated that squamous cells and other debris of presumed fetal origin may be demonstrated in blood aspirated from the central venous or pulmonary artery circulation of living patients with AFE. Studies of pregnant women undergoing pulmonary artery catheterization for various medical

indications have suggested that the detection of squamous cells in the maternal pulmonary artery circulation is a common phenomenon that may, in part, be attributable to contamination with adult squamous epithelium from the site of central venous access. Further, such debris is detected in only 50% to 75% of patients with clinical AFE, even when examined with special stains and techniques. Thus, the detection of squamous cells in the maternal pulmonary artery circulation during life is neither sensitive nor specific for the diagnosis of AFE. Such a diagnosis must be made principally on the basis of clinical picture. The differential diagnosis of AFE includes septic shock, aspiration pneumonitis, acute myocardial infarction, pulmonary thromboembolism and, in cases in which coagulopathy is a dominant feature, placental abruption.

Treatment revolves around three goals: oxygenation, maintenance of cardiac output and blood pressure, and resolution of what usually is a self-limiting, albeit severe, coagulopathy. Hypotension usually is on the basis of cardiogenic shock; treatment involves initial optimization of cardiac preload by rapid crystalloid administration followed by pressor support, as necessary. Administer component therapy to treat bleeding secondary to DIC. Packed red blood cells and fresh frozen plasma are the mainstay of such therapy.

It is axiomatic in obstetrics that when maternal and fetal therapeutic interests are divergent, maternal considerations must be primary. Thus, in the presence of an unstable mother, delay in delivery is often necessary despite ongoing fetal asphyxia. On the other hand, once the mother has suffered frank cardiac arrest, maternal prognosis is sufficiently grave to warrant emergency cesarean delivery. Delivery of the fetus beyond 15 minutes from the time of maternal cardiac arrest generally results in newborn death or neurologic impairment.

In patients who survive AFE, recurrence during subsequent vaginal or cesarean delivery has not been reported.

SUMMARY POINTS

- Successful management of the critically ill gravida requires an understanding of both unique maternal physiology, as well as fetal response to critical illness.
- Prompt recognition and aggressive management of shock during pregnancy is essential for optimal maternal and fetal outcomes.
- Invasive hemodynamic monitoring rarely is indicated in the pregnant woman. However, principles learned from such techniques often assist the clinician in the management of critically ill patients without resorting to invasive procedures.

Introduction
Preventive Health Care
Examination
Diagnostic Procedures

The female population of the United States is estimated to grow by approximately 17% over the next 25 years. The over-40 female population will increase by approximately 27% between 2000 and 2020, with the 65- to 80-year-old female population increasing by 52%. Gynecologists have a major role in the provision of primary health care for women, with changes in health care technology, patient expectations, managed care, and health care delivery formats providing new challenges in the area of women's health.

Gynecologists provide more office-based general medical examinations to women 15 years and older than either family practitioners or internists, particularly in those ages 15 to 44. When fellows of the American College of Obstetricians and Gynecologists (ACOG) were queried as to whether they considered themselves primary care providers or specialists, 48.3% designated the former. Office visits to gynecologists and the number, percentage, and characteristics of patients who receive care exclusively from gynecologists are increasing. Thus, gynecologists represent an important resource for general medical examinations, the first step in the provision of health care services for women. However, gynecologists differ significantly from other primary care specialists with respect to the frequency of diagnostic and screening tests that they provide during general yearly examinations. Thus, the complexity and details of the gynecologic history and examination are of great importance in women's health care.

PREVENTIVE HEALTH CARE

Gynecologists spend the majority of their time in the office, and a significant proportion of their patient visits can be classified as preventive medicine visits. A great deal of health care is dependent on the principles of preventive medicine, such as population characteristics, risk profiles, epidemiology, and statistics as they pertain to screening programs. In reviewing the major points of a history and physical examination, gynecologists can address the components of preventive care based on patient demographics, cost, and risk factors. Annual examinations may be recorded on data sheets containing “check-off” lists for preventive services. An example of a form such as this is available at the ACOG Web site (Fig. 26.1). Reminder systems for follow-up visits for Papanicolaou tests (Pap smears) and mammograms can help to integrate disease prevention and health maintenance into gynecologic practice. In addition, gynecologists play a major role in screening for domestic violence, depression, injury, and other psychosocial concerns, as well as sexual dysfunction. Counseling practices for sexually transmitted diseases (STDs) and human immunodeficiency virus (HIV) infection has changed markedly over the past two decades. In addition, genetic testing is becoming an important part of gynecologic practice, including determination of risk for genetic diseases affecting women's reproductive and menopausal care. Rapid advances in genetics, particularly through screening for breast and ovarian cancer, ultimately will result in the assimilation of genetics into the routine gynecologic office practice. In addition, postmenopausal women have a variety of preventive health needs including breast and cervical cancer screening, and general medical needs such as cholesterol screening and smoking advice. Thus, gynecologists have an important role in making preventive recommendations and can make a significant difference in the delivery of women's health care. The beginning of this health care interaction begins with the gynecologic history and follows up with physical examination, along with office diagnostic procedures.

FIG. 26.1. Gynecologic intake history form (http://www.acog.com/).

PATIENT HISTORY

Women want to be actively involved in decisions regarding their gynecologic care and usually expect physicians to use the history to obtain information concerning, not only medical issues, but also concerns regarding family history, cancer risk, sexual partners, or significant personal and social issues. The quality of the medical care provided by a physician, as well as the type of the relationship between the physician and patient, may be determined largely by the depth of the gynecologic history.

New Patients

Time must be taken to obtain a comprehensive history and to perform a comprehensive physical examination for each new patient. It is important to establish a database on each patient, along with a physician–patient relationship based on good communication. Office scheduling should permit dedicated time for new patient bookings to allow sufficient time to obtain the information, perform an examination, provide the management plan, allow for health education, and complete the encounter. Many preprinted history and physical examination forms exist, some of which may be obtained at the ACOG Web site.

Some physicians prefer to use patient-directed history forms, others use an assistant or nurse, and still others prefer to take the history personally. Multiple studies documented that personally directed questioning is more productive than patient questionnaires. Understanding of the predictive health care needs for preventive medicine based on family history, patient history and lifestyle, integrated functional medical investigations, and treatments and development of personal preventive programs all impact the ongoing health and wellness relationship with the gynecologist.

Established Patients

A good database already has been recorded for an established patient, and updates should include any changes in gynecologic or pregnancy history. Additional surgery, accidents or hospitalizations, or new medications should be added. Any changes in family history should be noted. This type of history taking, both for new and established patients, results in a well-organized, problem-oriented medical record. Besides obtaining the historical details, it is important to understand why the patient is seeking care in the gynecologist's office. In addition to understanding and meeting patients' needs, physicians must be prepared to do a medical evaluation in a physically and emotionally comfortable setting, making the visit as comfortable and informative as possible so that women leave the office calm and with their questions answered. This is achieved by an understanding attitude and an ability to listen.

History Taking

Physicians can do several things to obtain a detailed history and reduce patients' anxiety with respect to history taking.

- The history should be obtained in as comfortable and private a setting as possible. Some patients prefer to be clothed and seated at the same level as the physician, especially if they are meeting for the first time. Other patients may choose to change into an examination robe before seeing the physician if the visit is for a follow-up examination. Under most circumstances, patients should be interviewed alone. Exceptions may be made for children, adolescents, and mentally impaired women or at the specific request to have an attendant or a family member present. Even in these situations, it is usually a good idea to give patients the opportunity of speaking privately.
- The initial portion of the interview should be designed to put patients at ease. This often can be accomplished by discussing neutral and nonmedical subjects, such as recent recreational activities, employment, and family. The discussion should be viewed, not merely as a means of relaxing patients, but also as an opportunity for gathering information about their psychological and social backgrounds.
- Physicians should not make assumptions about patients' backgrounds. For example, a clinician usually assumes that all adult female patients are sexually active and heterosexual. Either assumption or both may be incorrect. By asking neutral, open-ended questions (e.g., “Are you sexually active?” and “Are you having sex with men?”), physicians let patients know that these assumptions have not been made.
- An appropriate length of time should be scheduled to allow a patient to tell her story without being hurried or interrupted. Interruptions from phone calls or office staff should be avoided, if at all possible, so that the patients has the physician's undivided attention.
- Patients should be made to feel that they have the respect of the physician. This means that they will have the opportunity of sharing in the decision-making process, will not be forced to endure unwanted pain, will have what they tell the physician held in strict confidence, and are free to ask questions.

In addition to these aspects of the patient–clinician interaction, patient satisfaction is related to the time required to get an appointment, the patient mix in the reception area, the length of waiting time in the reception or examination room, the attitude of the office staff, and the billing procedures.

EFFECTIVE COMMUNICATION

In this age of rapidly expanding medical knowledge, the development of simpler, safer, and more effective techniques of diagnosis and treatment, and an emerging emphasis on preventive health care, it is ironic that there is widespread dissatisfaction in physician–patient relationships. There is increasing evidence that a physician's attitude influences not only patient compliance but also the ultimate effect of therapy. These factors suggest that clinicians must understand the techniques of effective communication.

The first step in effective communication is establishing a good relationship with the patient. Research in human relations has demonstrated that a rapport is most readily established if physicians possess and display certain qualities, including empathy, respect, nonpossessive warmth, genuineness, nonjudgmental acceptance, kindness, and interest. These qualities are common to all effective counselors and can be learned by most clinicians.

Merely possessing the qualities described is not enough; physicians must be able to communicate them to patients through both verbal and nonverbal messages. Physicians convey empathy and respect by listening intently and giving undivided attention. They reinforce these qualities by summarizing their understanding of patients' problems in terms patients can understand.

The communication of warmth, kindness, and interest is, for the most part, nonverbal. Examples of nonverbal communication that convey these qualities include the following measures:

- Maintaining eye contact
- Having a relaxed, open posture
- Facing the patient
- Leaning toward the patient
- Showing a facial expression consistent with the patient's predominant emotion
- Having a modulated, nonmechanical tone of voice

However, forced or excessive expressions of warmth during the early stages of the patient–clinician relationship may be counterproductive and inappropriate.

Once a physician has developed the qualities described and has learned to express them, he or she must put them together to become an effective counselor. The steps involved in doing this are as follows:

- Listening effectively
- Creating a nonthreatening atmosphere in which the patient feels free to express herself
- Creating a relationship based on mutual trust and caring
- Responding to the patient in verbal and nonverbal ways that convey empathy, respect, and warmth by reflecting accurately and fully the patient's feelings, communicating acceptance of the patient as a person, and showing attentiveness and caring through nonverbal behavior
- Defining and agreeing with the patient about the exact role of the physician in the counseling situation

TAKING THE HISTORY

Overview

The history provides information about the total patient and is perhaps the most important part of the gynecologic evaluation. It enables patients to become acquainted with their physicians in a nonthreatening situation. In most cases, it provides the data to establish a tentative diagnosis before the physical examination. In many respects, physicians taking a history are like detectives who keep the various clues that are pertinent and discard those that are deliberately or inadvertently misleading. If the gynecologic history is sufficiently comprehensive, it should in almost all cases permit a physician to narrow the likely possibilities to one or at most two probable diagnoses. The preliminary opinion may not always be correct, but the history-taking session should not end until a tentative diagnosis has been made.

Like a hospital chart, the office chart is a legal, as well as a medical, record. As such, it is subject to subpoena, and whatever is recorded in it may someday need to be defended in court. It should not contain extraneous or casually written material, and the notes should be sufficiently complete that the case can be reconstructed readily.

The gynecologic history should include the following information:

I. Chief complaint
   A. Primary problem
   B. Duration
   C. Severity
   D. Precipitating factors
   E. Occurrence in relation to other events (e.g., menstrual cycle, coital activity, gastrointestinal activity, voiding, other pertinent functions)
   F. History of similar symptom
   G. Outcome of previous therapies
   H. Impact on the patient's quality of life, self-image, relationship with family, and daily activities
   I. Role of other stresses in the chief complaint
II. Menstrual history
   A. Age at menarche
   B. Date of onset of last menstrual period
   C. Timing of menstrual periods
   D. Duration and quantity (i.e., number of pads used per day) of flow
   E. Degree of discomfort
   F. Premenstrual symptoms
   G. Contraception (i.e., current and past methods)
III. Obstetric history
   A. Number of pregnancies
   B. Number of living children
   C. Number of abortions, spontaneous or induced
   D. History of previous pregnancies (i.e., duration of pregnancy, antepartum complications, duration of labor, type of delivery, anesthesia used, intrapartum complications, postpartum complications, hospital, physician)
   E. Perinatal status of fetuses (i.e., birth weights, early growth and development of children, including feeding habits, growth, overall well-being, current status)
   F. History of infertility (evaluation, diagnosis, treatment, outcome)
IV. Medical history
   A. Allergies
   B. Medications currently used
   C. Past and current medical problems
   D. Hospitalizations (reason, date, outcome)
   E. Vaccinations (type, date)
V. Surgical history
   A. Operative procedures (i.e., outcome, complications)
VI. Review of systems
   A. Pulmonary
   B. Cardiovascular
   C. Gastrointestinal
   D. Urinary
   E. Vascular
   F. Neurologic
   G. Endocrinologic
   H. Immunologic
VII. Breast symptoms
   A. Masses
   B. Galactorrhea
   C. Pain
   D. Family history
VIII. Social history
   A. Exercise
   B. Dietary habits (including calcium or folate supplementation)
   C. Drug use
   D. Alcohol use
   E. Smoking habits
   F. Marital status
   G. Number of years married
   H. Sexual history (partners, contraception, protection from STDs)
   I. Occupational history (i.e., exposure to environmental toxins, ionizing radiation, infectious agents)
   J. Emotional, physical, or sexual abuse
IX. Family history
   A. Significant medical and surgical disorders in family members

Chief Complaint

It is often effective to begin the history with an open-ended question concerning the symptoms that patients may have. This gives them the opportunity to describe their symptoms and concerns in their own words. Less information will be obtained if the interviewer asks only focused, closed-ended questions to which patients can answer only yes or no. Some clinicians find it helpful to have an outline of questions about the gynecologic history to obtain all the necessary information.

The following questions are typical of a gynecologic history:

- What were the circumstances at the time the problem began (i.e., time, place, activity, cycles)?

- What has been the sequence of events? (Having a calendar to refer to is often helpful.)
- Have you had this problem before? Can you describe the previous occurrence and what led to its disappearance?
- To what extent is the problem interfering with your daily life and the life of your family?
- Have you had previous evaluations or treatments? (Records from previous physicians may be helpful.)
- Why did you seek evaluation for the problem now?
- What questions do you want answered today? What do you expect and want from today's visit?

Menstrual History

The cycle interval is counted from the first day of menstrual flow of one cycle to the first day of menstrual flow of the next cycle. The range of normal is wide, and a recent change in the usual pattern may be a more reliable sign of a problem than the absolute interval. Although 28-day cycles are the median, only a small percentage of women have cycles of that length. The normal range for ovulatory cycles is between 21 and 35 days.

Estimating the amount of menstrual flow by history is difficult. The average blood loss is 30 milliliters (range, 10-80 ml). The need to frequently change saturated tampons or pads (i.e., more often than one per hour for 6 or more hours) and the passage of many or large blood clots are usually signs of excessive blood flow.

Dysmenorrhea is common. It usually begins just before or soon after the onset of bleeding and subsides by day 2 or 3 of flow. The discomfort is characteristically midline and often is associated with backache and, in primary dysmenorrhea, with systemic symptoms such as lightheadedness, diarrhea, nausea, and headache. Mittelschmerz, or midcycle unilateral pelvic pain at the time of ovulation, is usually mild and seldom lasts for more than 1 or 2 days.

It is important to ask whether or not there is bleeding between menstrual periods and whether this occurs after coitus. Intermenstrual bleeding is a characteristic sign of cervical cancer, although it also is present with benign lesions such as cervical polyps and fibroids or infection.

Finally, physicians should inquire about the presence of premenstrual syndrome (PMS). The symptoms experienced by women with PMS may be physical, emotional, and behavioral. The most common of the physical symptoms are fatigue, headache, abdominal bloating, breast tenderness and swelling, acne, joint pain, constipation, and recurring herpetic or yeast infections. Although these physical symptoms are often uncomfortable, most women with moderate to severe PMS complain most about their premenstrual emotional symptoms, especially depression, anxiety, hostility, irritability, rapid mood changes, altered libido, and sensitivity to rejection. Women with PMS may also experience changes in behavior, including physical or verbal abuse of others, suicide attempts, withdrawal, craving for or intolerance of alcohol, craving for sugar or chocolate, and binge eating.

Many women report that long-standing or severe PMS can cause psychological or social problems that may be as disruptive as the premenstrual symptoms themselves. Psychological reactions to PMS include guilt, shame, decreased self-esteem, unassertiveness, decreased self-confidence, a negative body image, and a sense of hopelessness. In addition, many women with long-standing PMS report that their recurrent emotional and behavioral symptoms have eroded their relationships with co-workers, friends, husbands, and children. Finally, PMS has been an unrecognized factor in poor work records or failed educational pursuits for many women.

Sexual History

Although there are many models for sexual histories, most are not appropriate for the non-sex therapist or in the setting of a brief office visit. A model for office practice has been developed, with two types of sexual histories: a screening history and a problem-oriented history. The screening history is brief and suited for inclusion in the comprehensive medical history that typically is part of a patient's first visit to her gynecologist. The problem-oriented history is more detailed and designed to investigate problems identified by the screening history.

The screening history is designed to determine whether or not major sexual difficulties exist that need in-depth evaluation and therapy, and whether the problem can be dealt with by the physician or should be referred elsewhere for more intensive evaluation. In an attempt to put patients at ease, physicians can begin the sexual history by prefacing questions with statements such as “Most people experience….” or “Because sexual problems can develop as part of other gynecologic problems….” If physicians can convey a willingness to help, patients are more likely to discuss problems. In addition, the screening history should begin with a discussion of topics that are unlikely to provoke anxiety. For example, questions about the occurrence of pain during intercourse are less likely to cause anxiety than questions about orgasmic function or noncoital sexual practices.

With these principles in mind, physicians can begin with a general question, such as “Are you having any sexual problems?” If the response is noncommittal, a more specific question, for example, “Are you satisfied with the frequency of sexual relations?” can be posed. Once a problem is identified, physicians can proceed to the problem-oriented sexual history and ask about the date of onset, severity, previous evaluation and treatment, the results of such treatment, conditions that diminish or exacerbate the problem, the patient's response to the problem, and the effect of the problem on the patient's relationship with her partner. To conclude the screening history, physicians should invite patients to discuss concerns that have not been covered by the screening history. Even if a patient denies having any problems, the screening history is of value because it demonstrates the physician's willingness to discuss sexual problems.

As suggested, the problem-oriented history is designed to differentiate organic from psychogenic sexual problems, determine the complexity of the problem, determine the need for referral of the patient to a more sophisticated sexual counselor, and provide information for the formulation of a treatment program if the physician elects to treat the patient. The problem-oriented sexual history should include the following topics:

- Onset of the sexual problem
- Course of the sexual problem
- Conditions that decrease or increase the severity of the sexual problem
- Previous evaluation of the sexual problem and the results of such evaluation
- Previous treatment of the sexual problem and the results of such treatment
- Severity of the sexual problem
- Patient's reaction to the sexual problem
- Impact of the problem on the patient's sexual relationship
- Patient's sexual attitudes and upbringing
- Patient's sexual practices
- Quality of patient's sexual or marital relationship

A rational treatment or referral plan can be formulated on the basis of discussion of these and related questions.

In addition to screening for sexual dysfunction, it is important to obtain a history of STDs. Physicians should tactfully question patients about past episodes of STDs, sexual practices, number of sexual partners, sociosexual background of sexual partners, use of barrier forms of contraception, use of intravenous drugs, previous blood transfusions, genital lesions, persistent vaginal discharge, and pelvic pain. The discussion of STDs provides an opportunity to discuss modes of prevention, including the practice of safe sex and the use of barrier methods of contraception when the sexual history of a partner is unknown.

Psychosocial History

Health care providers can play a vital role in identifying women who are victims of psychological, physical, or sexual abuse. Unfortunately, women who are abused are often hesitant to acknowledge it. Questions should include the following:

- Are you or have you ever been in a relationship in which you have been physically hurt or threatened by a partner?
- Have you ever been forced to have sex against your will?
- Has your partner ever destroyed things you care about?
- Are you or have you ever been in a relationship in which you were treated badly?

If the answer to any of these questions is yes, the physical examination may reveal signs of physical abuse. In addition, many abused women may report chronic pain, sleep or appetite disorders, and frequent vaginal and urinary infections. One may suspect an abusive relationship if the patient's partner is present at every office visit, insists on staying close to the patient, and answers all the questions directed to her.

Once abuse is recognized, the physician must acknowledge the problem and direct the woman to an appropriate community resource. Inquiry about the woman's safety should be made before she leaves the office. Some physicians obtain wallet-sized cards or brochures from local agencies that provide support and protection for

battered women, and place them in the rest rooms. This provides an option for those women who would not acknowledge abuse when asked by their health care providers.

Depression is another very common condition that may be detected during an annual gynecologic examination. The potential life-threatening nature of depression and the availability of effective antidepressant medications with few side effects make it even more important to diagnose depression. To diagnose depression, physicians can ask the following questions:

- Have you lost interest in the things you used to enjoy?
- Do you feel sad, “blue,” or “down in the dumps”?
- Do you have feelings of guilt or worthlessness?
- Do you have thoughts of death or suicide?
- Are you sleeping too much, or do you have difficulty falling asleep or staying asleep?
- Do you have a loss of energy and feel tired all the time?

An affirmative answer to one or more of these questions may mean the patient is depressed and a candidate for psychotherapy or drug therapy. More than 50% of depressed individuals will respond to antidepressant therapy.

Adolescent History

As the percentage of adolescents increases in practice, gynecologists find themselves dealing with problems unique to the 13- to 19-year-old age group. These include menstrual and breast disorders, pubertal development problems, and the challenges presented by sexually active adolescents. Almost 50% of high school students, male and female, had sexual intercourse and only 57% reported that they had used contraception the last time they had intercourse. The frequency of adolescent sexual activity and its consequences mean that gynecologists caring for adolescents will certainly encounter gynecologic problems such as STDs and pregnancy among their young patients. Gynecologists who provide such care to adolescents, particularly with respect to history taking, need to know their specific needs, with particular importance placed on confidentiality. The gynecologist must be prepared to handle multiple issues related to pubertal development, sexuality, self-esteem, and body image, and approach the adolescent patient in a somewhat different manner than that used for the adult female. This includes having the parent present with young women, 14 years of age or less, during history taking, and speaking to the adolescent first in the office setting when she is fully clothed. If the adolescent refuses to have the parent or mother present, the physician may ask the young woman's permission to speak to her mother or guardian with respect to important issues, especially those requiring treatment.

GYNECOLOGIC EXAMINATION

The pelvic examination is one of the most commonly performed medical procedures and is often considered aversive by women. Aspects of the pelvic examination, such as genital exposure, make it highly likely women will have feelings of anxiety, vulnerability, apprehension, or fear. It is important that the gynecologist observe a woman's behavior, which will communicate her feelings. Behavioral indications of patient anxiety are important, not only because anxiety can hinder communication, but because anxiety can lead to delays in performance of potentially lifesaving pelvic examinations and other preventive screening measures. A complete physical examination is most commonly performed at the first visit. In order to reduce anxiety, patients should be encouraged to give feedback to the physician during the examination, especially when the examination causes pain. Description of the examination, including which portions may include mild to moderate discomfort (such as the rectal examination), should be given to the patient beforehand. When the physician enters the room, the patient should be sitting up on the examination table with the examination gown completely covering her. During the physical examination another female participant, either nurse or medical assistant, must be present. This woman can assist the physician and also lend psychological support to the patient. The patient should be asked to lie down and place her feet in the stirrups, and the physician should be at the level of the patient's head, speaking to her when her position is changed. This dialog may include the physician asking the patient about her symptoms, location of any pain, or other pertinent questions. Studies evaluating anxiety in women with respect to pelvic examinations have found those who have had a less positive first experience have higher anxiety levels with their gynecologists. Patients also come in with other worries about baring themselves, body odor, and personal concerns which should not be unrecognized by the physician. Noting that these behaviors may take place, gynecologists can take necessary measures to reduce patient anxiety and prevent delays and avoidance of gynecologic examinations in the future.

Evaluation of General Appearance

A general impression should be recorded of patients' nutritional state, distribution and proportion of body fat, texture and condition of skin and hair, presence of facial or excessive body hair, acne, abnormal nevi (greater than 5 millimeters, asymmetric outline, variable pigmentation, and indistinct borders), and any specific physical features.

Examination of the Head and Neck

The patient's hair is examined for cleanliness, texture, and scalp health. The eye examination may include ophthalmoscopy to detect retinal aberrations. The patient's nose, throat, and teeth can also be checked. Finally, the anterior cervical, posterior cervical, and supraclavicular nodes, as well as the thyroid gland, should be palpated.

Examination of the Cardiopulmonary System

Hypertension is the most common chronic disease in women over 50. Therefore, every woman, especially those over 50, should have her blood pressure measured with her annual gynecologic examination.

Careful cardiac auscultation may be performed as part of the gynecologic examination, because many patients eventually undergo surgery or childbirth. Mitral valve prolapse (MVP), the most common cardiac condition diagnosed by auscultation in asymptomatic women, can be problematic during surgery or pregnancy. A prolapsing mitral valve is more common in young women than in men. In most cases, it is not associated with other cardiac defects and consists of a large valve with redundant leaves. Although most women with MVP are asymptomatic, others may experience anxiety, chest pain, palpitations, bacterial endocarditis or, rarely, sudden death.

Diagnosis of MVP is made by auscultation of a midsystolic nonejection click and a late systolic murmur. Because alterations in venous return influence the auscultatory findings, they may change in nature from examination to examination and may even disappear, only to reappear at a later examination. The diagnosis of MVP, which can be confirmed by 2-dimensional echocardiography, is important because of its association with bacterial endocarditis, von Willebrand disease, autoimmune connective tissue disorders, and hyperthyroidism. Women in whom this diagnosis has been made probably should have antibiotic prophylaxis at the time of delivery or during invasive diagnostic and surgical procedures. In addition, they may require antiarrhythmic or even anticoagulant therapy and should be followed or evaluated for the systemic conditions noted.

Breast Care

Examination of the Breasts The breast examination begins with a breast-oriented history. Patients are asked whether they have noted any lumps, pain, discharge, or other changes in their breasts. They should also be asked about breast surgery, date and results of the last mammogram, current and past hormone use, and family history of breast cancer. Axillary and supraclavicular nodes are then palpated. The breasts should be examined with patients both sitting or standing and lying supine. In the vertical position, the nipples and inframammary folds are evaluated for asymmetry. The examiner looks for elevation of one nipple, flattening of one breast, dimpling of the skin, or asymmetry by having patients raise both arms above the head and lean forward, and then contract the pectoral muscles with hands on hips. Then, with patients in the supine position with one arm above the head, all quadrants of each breast are felt with the flat part of the distal phalanges of the fingers. The subareolar area should also be palpated, because 15% of carcinomas occur under the areola. The axillary and supraclavicular areas should be palpated for enlarged or tender lymph nodes. The nipples and adjacent areolar tissue are then compressed in an effort to express fluid from the nipple. The examination of the breasts should conclude with a description of the examination results and a recommendation for follow-up physical or radiologic examinations.
Mammographic Examinations Gynecologists as primary care physicians have the responsibility for implementing widespread screening mammography. A diagnostic approach to the breast, including clinical breast examination, possible fine-needle aspiration, and mammography, may be implemented by the gynecologist and performed with findings of a breast mass or suspicious area. Ongoing discussion has addressed the value of screening mammography with respect to breast cancer mortality. A study reported that there was no reliable evidence that screening for breast cancer reduces mortality. A follow-up study from the same investigators showed that breast cancer mortality may be a misleading outcome measure and that screening may lead to more aggressive treatment. Additional studies have noted that mammograms can be lifesaving and that recommendations for gynecologists based on all available information are to urge all women to follow the advice of their physicians and obtain mammograms per guidelines.

Examination of the Chest

From the back, a curvature of the vertebral column can be assessed by observation and palpation. The chest can also be percussed and auscultated.

Examination of the Abdomen

Patients should be positioned supine, with arms against the body to relax the abdominal musculature. If necessary to obtain adequate relaxation, the knees can be elevated and flexed. In a methodical and consistent manner, all quadrants of the abdomen should be examined. Relaxation of the abdomen to evaluate a suspected mass can be assisted by having patients breathe deeply and then exhale. After all quadrants have been examined, the inguinal nodes should be palpated. Asking about abdominal scars may provide information that was not elicited during the history.

Bulging of the flanks suggests free abdominal fluid, but thin-walled ovarian cysts and irregularly shaped uterine leiomyomata may have a similar clinical picture. Although large ovarian cysts and leiomyomata most commonly cause protrusion of the anterior abdominal wall, there are many confusing exceptions. Palpation for a fluid wave through the lateral quadrants of the abdomen is also a useful procedure. Percussion for areas of flatness or tympany and for shifting dullness may aid in determining whether the distension is caused by intraperitoneal fluid or by intestinal gas. Auscultation is especially useful in differentiating among a large tumor, a distended bowel, or an advanced pregnancy as the cause of abdominal enlargement.

Examination of the Extremities

Examination of the lower extremities supplies important information regarding the cardiovascular system. Edema and varicosities should be noted. In a patient with congenital absence of the vagina, evidence of muscle atrophy in the extremities should be sought, because such patients may have nerve root compression secondary to congenital vertebral anomalies. The peripheral pulses and reflexes may also be evaluated at this time. Examination of the calves and ankles for melanomas or dysplastic nevi is advisable.

Pelvic Examination

The first examination of the female genitourinary system often takes place in the neonatal period. An examination is indicated at any age when abnormal bleeding or pelvic symptoms are present, there are questions about primary or secondary sexual development, or sexual activity is being initiated. For teenagers, the first pelvic examination should probably occur at 18 years of age or at the initiation of sexual activity, whichever comes first. Examinations usually are repeated at yearly intervals, at which time a Pap smear should be performed in addition to a pelvic examination and a screening for breast cancer and hypertension.

The pelvic examination provides physicians with an opportunity to dispel myths and misunderstandings and to educate with respect to pelvic anatomy, physical development, and sexual function. Patients often are reassured if the physician carries on a running dialogue, describing the findings, asking and answering questions, and demonstrating on occasion the physical findings with the aid of a hand-held mirror. To maximize the educational aspects of an examination, clinicians can (a) describe all procedures in advance, (b) maintain eye contact with patients during the examination, whenever possible, and (c) explain all findings clearly.

Patient Preparation The pelvic examination is performed with the patient lying on her back with both knees flexed. The buttocks are positioned at the edge of the examining table, and the feet are supported by stirrups. This position allows the necessary exposure of the pelvic organs. Traditionally, patients have been placed with the head and body in a horizontal position. This position does not allow maintaining eye contact and increases a patient's sense of vulnerability. The alternative, assuming the availability of an adjustable examination table, is to elevate the head of the table between 30 and 90 degrees. There are no apparent technical disadvantages to this alternative position, and many patients find it easier to relax, actually making the bimanual part of the examination more accurate. The patient should empty her bladder just before the examination.
Equipment The minimal equipment needed to perform a pelvic examination includes a good light source, a speculum of the correct size, a nonsterile glove, and a water-soluble lubricant. Additional supplies that should be available in the examination room include a variety of speculum sizes, materials to obtain cytologic samples, including fixative, various culture media, large cotton-tipped swabs, pH indicator paper, and a screening test for fecal occult blood. Specialized examinations require other specific equipment.
External Genitalia Examination The pelvic examination begins with inspection of the vulva. Physicians should note and record evidence of developmental abnormalities, as well as the general state of cleanliness, discharge, hair growth and distribution, and abnormalities of the skin, including tumors, ulcerations, scratch marks, rashes, and minor lacerations or bruises. Vulvar varicosities or hemorrhoids should be noted, also. A careful inspection of the skin folds, vulva, and pubic hair may reveal occult disease or infection. The vulva should be palpated for subcutaneous lesions. The labia are then spread, and the condition of the hymen and vulvovaginal skin and the size of the clitoris are noted. The examination should be performed in a systematic manner and include the labia majora, labia minora, vestibule, urethral opening, periurethral glands, Bartholin glands, perineum, anus, and perianal areas. With an index finger in the outer vagina and the thumb on the perineum, the labia and urethra are palpated for masses or tenderness. Patients are asked to contract the muscles of the vaginal opening to assess the tone of the levator muscles and the degree of perineal support, and then to strain to reveal the presence of a urethrocele, cystocele, rectocele, enterocele, or vaginal or cervical prolapse.
Vaginal Examination The vagina should first be inspected with the aid of a speculum. Specula come in various sizes, and an appropriate size should be selected. The largest size that is comfortable often provides the best visualization. Painless insertion of the speculum may be aided by several techniques. First, the muscles at the opening of the vagina may be relaxed by gentle downward pressure with one or two fingers. The speculum may be moistened with warm water before insertion, but other types of lubricants should be avoided if cultures or cytologic samples are to be collected. The speculum blades should be inserted obliquely, not vertically, through the introitus, immediately rotated to the horizontal plane, and then slowly opened after the vaginal apex is reached. The vaginal walls and cervix should be inspected for lesions. The vaginal discharge should be assessed for volume, color, consistency, and odor. The endocervical mucus should also be examined. Samples for cervical or vaginal cytologic examination and cultures, and direct microscopic examination of the vaginal or cervical discharge should be obtained as indicated. Before the speculum is removed, the cervix should be evaluated for ectropion, erosion, infection, discharge, lacerations, polyps, ulcerations, and tumors. As the speculum is removed, with the patient bearing down, the degree of vaginal wall relaxation and uterine prolapse can be assessed. With the speculum removed and the patient still bearing down, one can observe whether or not the patient exhibits stress incontinence.

Bimanual Examination

The technique for the bimanual examination is shown in Figure 26.2, Figure 26.3, Figure 26.4, Figure 26.5 and Figure 26.6. After the speculum has been withdrawn, the physician should gently insert the index and middle fingers along the posterior wall of the vagina. At the same time, the other hand is placed on the patient's abdomen in the midline. The first palpable structure is the cervix. Next is the uterine fundus. The bimanual technique can outline its position, size, shape, consistency, and degree of mobility. Uterine or cervical mobility can be assessed further by placing the fingers on one side of the uterus and moving them to the contralateral side. This can be done on both right and left sides to detect chronic or acute inflammatory changes and fixation. The other hand is then placed on one lower quadrant of the abdomen and slowly worked inferiorly and medially to meet the fingers of the hand examining the vagina. In this way, adnexal structures on that side can be appreciated. The degree of adherence of an adnexal structure to the uterus often can be ascertained. Enlargement, consistency, and position of ovaries and tubes can be noted. The ovary is a sensitive structure, and patients differ in tolerance to palpation. The contralateral side should be examined similarly. Finally, the vaginal walls and adjacent structures (bladder and rectum) are palpated. The glove of the hand used for vaginal examination is then replaced with a clean glove for the rectovaginal or rectal examination.

FIG. 26.2. Bimanual examination, first step. The fingers placed in the vagina feel the consistency and symmetry of the cervix and its axis in relation to the axis of the vagina. They then elevate the uterus toward the abdominal wall, so the total length of the uterus can be determined. (From Duncan AS. In: Bourne A, ed. *British gynaecological practice.* Philadelphia: FA Davis Co, 1955; drawn by G. McHugh, with permission.)

FIG. 26.3. Bimanual examination, second step. The fingers examining the vagina are moved into the anterior fornix to permit palpation of the uterine corpus. If the abdominal wall is thin and well relaxed, it is possible to define even minor irregularities in the contour or consistency of the uterus. Third step: with the fingers still in the anterior fornix and with the aid of the hand palpating the abdomen, the uterus is moved gently toward a retroverted position and then from side to side to determine its mobility and the presence or absence of pain on movement of the uterus. (From Duncan AS. In: Bourne A, ed. *British gynaecological practice.* Philadelphia: FA Davis Co, 1955; drawn by G. McHugh, with permission.)

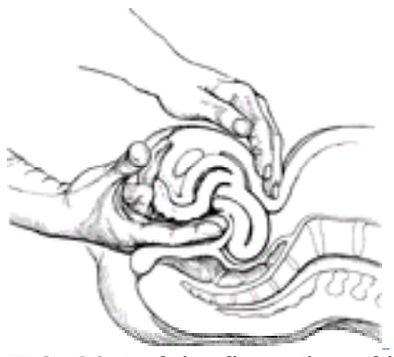

FIG. 26.4. If the fingertips of both hands come together when carrying out the second step of the bimanual examination, it can be concluded that the uterus is retroverted; the fingers in the vagina are then moved to the posterior fornix to outline symmetry, consistency, and mobility of the retroverted corpus. (From Duncan AS. In: Bourne A, ed. *British gynaecological practice.* Philadelphia: FA Davis Co, 1955; drawn by G. McHugh, with permission.)

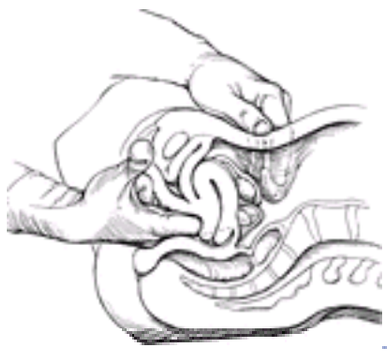

FIG. 26.5. Bimanual examination, fourth step. To outline the adnexa, the fingers examining the vagina are moved to the right fornix, and the examiner attempts to bring the fingers of both hands together at a point presumed to be superior to the fallopian tube and ovary. (From Duncan AS In: Bourne A, ed. *British gynaecological practice.* Philadelphia: FA Davis Co, 1955; drawn by G. McHugh, with permission.)

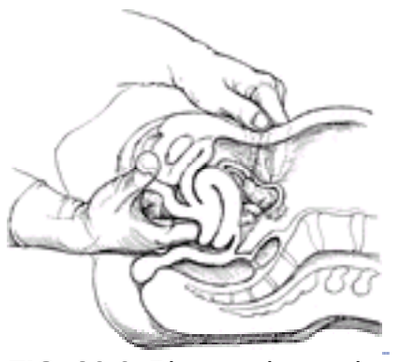

FIG. 26.6. Bimanual examination, fifth step. When the fingers of both hands are quite close together (it is desirable but not always possible to approximate these fingers), they are then moved gently toward the examiner, so the adnexa slip between the fingers as they can be outlined. (From Duncan AS. In: Bourne A, ed. *British gynaecological practice.* Philadelphia: FA Davis Co, 1955; drawn by G. McHugh, with permission.)

Rectovaginal Examination The rectal examination is uncomfortable, but it can be made less so if the physician gently places a finger into the anal opening and waits for the anal sphincter to relax before proceeding. The middle finger is inserted into the rectum and the index finger into the vagina. The tone and symmetry of the sphincter are determined. The parametrial tissue is then palpated between the index finger in the vagina and the middle finger in the rectum. Finally, the posterior uterine surface, adnexal areas, uterosacral ligaments, and pouch of Douglas, along with the anorectal area, are palpated. The rectovaginal examination enhances the evaluation of cul-de-sac or ovarian pathology. Particles of hard fecal material may interfere with an accurate examination.
Rectal Examination Additional information may be gathered from a separate rectal examination. Exerting pressure against the perineum allows introduction of the index finger. Hemorrhoids, polyps, and tumors of the rectum may be felt. The rectal examination can be assisted by placing one hand on the lower abdomen to make it a bimanual procedure. This examination is useful when a vaginal examination is impossible, such as in infants and children. The rectal wall is palpated throughout its circumference and as far as the finger permits. Almost one half of all rectosigmoid cancers can be detected by this palpation. The finger can also explore the surface of each pelvic wall, feeling for enlarged nodes or other abnormalities. Any fecal material can be tested for occult blood. Following the rectal examination, the patient is instructed to slide up on the table while the lower one third of the table is replaced. The examiner can answer any questions about the examination and then step out of the room while the patient dresses. Physicians should always wash their hands after examining a patient.
Recording the Findings Physical examination can be recorded on a preprinted form and should include at least the following elements:

I. Perineum
   A. Old lacerations
   B. Lacerations
II. External genitalia
   A. Stage of development
   B. Color
   C. Evidence of lesions
   D. Bartholin glands
III. Vestibule
   A. Skene glands
   B. Urethral orifice
   C. Hymenal ring
IV. Vagina
   A. Presence of leukorrhea

B. Color
C. Lesions
D. Tone
E. Rugae

V. Cervix
A. Shape
B. Consistency
C. Mobility
D. State of parity
E. Lesions

VI. Uterus
A. Position
B. Mobility
C. Size
D. Shape
E. Consistency

VII. Adnexa
A. Position and mobility of ovaries and tubes
B. Presence of masses or tenderness

VIII. Rectovaginal examination
A. Degree of confirmation of previous findings
B. Statement about additional pathology

IX. Rectal examination
A. Occult blood

Postexamination Discussion

Back in the consultation room, the findings, diagnoses, and plans for therapy are explained to the patient in terms she can understand. It may be helpful to have the patient paraphrase the information to make certain that she understands. This is especially relevant when surgery is contemplated, because the nuances of an operation and its results may be unclear to patients. At this time, the use of medications and the duration of their use are explained. The physician should explain carefully what the patient may expect if any special diagnostic or therapeutic procedures were performed (e.g., heavy leukorrhea after cryosurgery, bleeding after cervical biopsy). In some situations, patients may be instructed to abstain from sexual activity for a specific length of time. The importance of a follow-up examination should be stressed. Prescriptions for medications should be detailed adequately and restrictions on refills stated explicitly.

DIAGNOSTIC PROCEDURES

Pap Smear

The early diagnosis of cervical carcinoma is based on periodic cytologic screening of the cervix. Despite extensive debates regarding the optimal frequency and accuracy of the Pap smear, it has become the standard method of screening for cervical carcinoma. In addition to detecting early cervical cancer, the Pap smear also can be used to assess hormonal status and to assist in identifying sexually transmitted pathogens, such as herpes simplex, human papillomavirus (HPV), *Chlamydia trachomatis*, and *Trichomonas vaginalis*, as well as benign conditions. The presence of cancer of the cervix may indicate infection with HIV.

Pap smears should be obtained at periodic intervals in women when they reach the age of 18 or become sexually active, whichever comes first. They probably should be obtained yearly, especially in women who have had coitus with more than one sexual partner, began to have coitus as an adolescent, or have a history of an STD. A Pap smear should be performed annually in women who have had a hysterectomy for pelvic cancer or *in situ* disease, although it may not be necessary in women who have had a hysterectomy for benign disease.

To visualize the cervix, the largest speculum that is comfortable to the patient is used. The speculum is warmed and lubricated with warm water. The cervix is visualized, and a plastic or wooden spatula is used to scrape the squamocolumnar junction and any areas on the cervix or vagina that look suspicious (Fig. 26.7). In premenopausal women, the squamocolumnar junction is likely to be within the endocervical canal. The spatula is wiped on a clean glass slide, and the slide is sprayed immediately with a fixative (i.e., alcohol and ether) before the cells dry. A second specimen is taken from the endocervix with a cotton-tipped applicator or cytobrush that is placed into the endocervical canal and rotated 360 degrees 3 to 5 times. The cytobrush is more effective than a cotton swab in obtaining endocervical cells. The cells are then transferred to the slide, and the slide is again sprayed with fixative. The slide, previously labeled to identify its source, is then sent for cytologic evaluation.

FIG. 26.7. Pap smear. **A:** Cells obtained from transformation zone using an Ayers spatula. **B:** Cells obtained from the cervix using a cytobrush.

Some well-publicized failures of Pap smears to detect cervical cancer led to an increased interest in technologic enhancements and automated assisted devices to reduce the rate of false-negative smear results. Studies evaluating automated preparation systems versus conventional cervical cytologic preparation have shown excellent cellular presentation and superior sensitivity for automated systems compared with conventional techniques. However, it is important to select carefully the laboratory used for processing, analyzing, and interpreting the specimens.

Thin-layer cytology for Pap smears has become widely accepted during the last decade, addressing some of the imperfections with traditional Pap smear screening. In traditional Pap smear screening there is a 5% to 10% false-negative result rate. Yearly testing decreases the possibility of a false-negative result for any particular woman. The thin-layer cytology, or “thin prep,” appears to decrease the false-negative rate by picking up more potentially precancerous changes. However, it is unclear as to whether decrease in false-negative rate translates to a reduction in the cervical cancer death rate.

With respect to office practice, thin-layer cytologic preparation is made by submerging the sample in a vial of liquid fixative and mixing the cells in the solution. This avoids difficulties with the fixative, piled up cells, and air drying common to smears on glass. The thin prep also appears to decrease the false-positive rate from inflammatory conditions. The atypical squamous cells of undetermined significance-to-squamous intraepithelial cell ratio was reduced by 54% in a thin-prep group.

Vaginitis

Although normal vaginal secretions are clear or white, homogenous, and odorless, with vaginitis there may be an abnormal discharge, vulvar irritation, dysuria, and vaginal odor. The majority of cases of vaginitis are due to bacterial vaginosis, vaginal candidiasis, trichomonas vaginalis, or atrophic vaginitis. Additionally, STDs such as gonorrhea and chlamydia may cause an abnormal vaginal discharge. Detailed history should include the description of the discharge, presence or absence of odor, duration of symptoms, sexual history, and history of infections.

Standard office procedures include preparation of a wet mount, with material from the swab or the speculum placed on each end of a plain microscope slide, and microscopic examination to assess for bacterial vaginosis. Patients with bacterial vaginosis complain of thin white, yellow, or gray vaginal discharge, commonly with a

musty or fishy odor. The pH of the vaginal fluid is usually 5.0 or 6.0. Clue cells on the microscope slide on saline wet mount are described as vaginal squamous epithelial cells that have bacteria adhering to the membrane, giving them a speckled appearance as the focus shifts. Treatment of symptomatic patients and pregnant patients is routinely recommended.

Trichomonas vaginalis may be diagnosed by a saline wet mount showing polymorphonuclear leukocytes and motile flagellating organisms. The female partner complains of copious frothy yellow to green vaginal discharge. The patient and sexual partner should be treated.

Atrophic vaginitis is seen often in postmenopausal women and may be associated with a blood-tinged discharge. Evidence of atrophy on the vulvar vaginal examination may be present. The saline wet mount shows numerous leukocytes with small round epithelial cells. Topical therapy usually is prescribed, although oral therapy with an antifungal agent is considered with resistant infections.

Patients who have vulvar itching and a thick white curdlike discharge usually have vaginal candidiasis. The diagnosis is confirmed by examining a slide treated with 10% potassium hydroxide, with a sample of the discharge showing filaments, hyphae, or spores.

Colposcopy

Colposcopy aids in examining the visible portion of the female reproductive tract (i.e., vulva, vagina, cervix). This technique complements cytologic evaluation and may localize the source of abnormal cells seen on cytologic examination.

Vulvar diseases amenable to colposcopic evaluation include HPV infections, herpes genitalis, and preinvasive cancers. The magnification afforded by the colposcope may aid in the selection of areas for biopsy. The application of 3% acetic acid for 3 to 5 minutes may also help define abnormal areas, which typically turn white and display sharp borders (i.e., acetowhite epithelium). The colposcope may aid in the recognition of clinically inapparent vaginal intraepithelial neoplasia or HPV infection. These lesions also are characterized by acetowhite epithelium.

Colposcopy is used most commonly for evaluating the cervix in a patient with abnormal Pap smear results. After it is visualized and excess mucus is gently removed with a dry cotton ball, the cervix is treated with 3% to 5% acetic acid. As noted, flat condylomata or dysplastic areas turn white or develop a vascular pattern with a mosaic appearance or punctuation. The squamocolumnar junction and transformation zone are then inspected thoroughly, and a biopsy of suspicious areas is performed. In addition, a nonpregnant patient with an abnormal Pap smear result should have an endocervical biopsy. Bleeding occurring as a result of the biopsy can be controlled easily with ferric subsulfate (Monsel solution).

Endometrial Sampling

Advances in devices used for endometrial sampling have simplified the evaluation of abnormal uterine bleeding. Diagnostic dilation and curettage procedures under general or regional anesthesia have been replaced in many situations by outpatient endometrial biopsies, resulting in a savings of money, time, and morbidity. Endometrial sampling is of greatest value in the evaluation of abnormal bleeding when diffuse rather than focal endometrial changes are suspected.

Before obtaining an endometrial sample for biopsy, the physician should have the patient's informed consent. The physician should then rule out intrauterine pregnancy, cervical or endometrial infection, and cervical stenosis.

The size and position of the uterus are determined by a pelvic examination or by ultrasonography, and a speculum is placed in the vagina. If the patient is sensitive to cervical manipulation, a paracervical block can be administered. When endometrial cancer is suspected, an endocervical biopsy sample can be obtained before endometrial sampling. The cervix and upper vagina are then cleansed with an antiseptic such as povidone-iodine.

If the uterus is not anteflexed or retroflexed, a biopsy sample often can be obtained without placing a tenaculum on the cervix. If the degree of flexion is marked, a tenaculum aids in straightening the uterus. It is necessary in some women to anesthetize the anterior cervix with lidocaine 1% (Xylocaine) to avoid discomfort when the tenaculum is applied.

The instrument used to collect the sample is inserted to the top of the fundus, and the length of the uterus noted (Fig. 26.8). It is not necessary to dilate the cervix with sounds before obtaining the biopsy sample in most situations. Several samples are then obtained from the endometrial cavity and submitted for histologic evaluation. If cervical stenosis is present, instruments as narrow as 2 to 3 millimeters in diameter can be used, or the cervical os dilated. There are several instruments available for sampling the endometrium. The most commonly used is the Unimar Pipelle Endometrial Suction Curette (Cooper Surgical, Shelton, CT). Others include the Novak Endometrial Suction Biopsy Curette (Miltex Instrument Company, Lake Success, NY) and Tis-U-Trap Uterine Suction Curette Set (Milex Products, Chicago, IL).

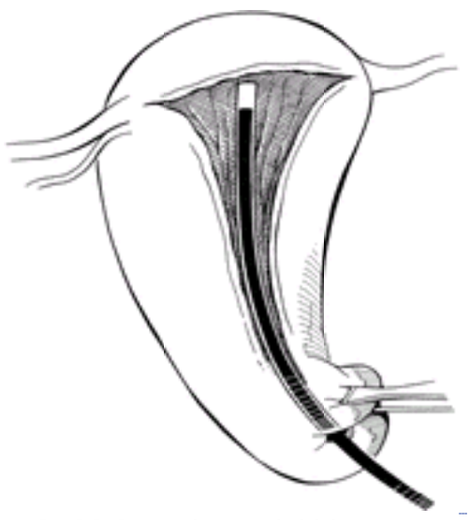

FIG. 26.8. Endometrial biopsy.

Patients may experience vasovagal syncope during the procedure and cramps or bleeding afterward. It is important to consider when sampling the endometrium that the device used can adjust to the shape and curvature of the uterus, which minimizes pressure on the uterine wall, reducing the likelihood of pain and cramping. Bleeding usually stops within 1 to 2 days after the biopsy.

Vulvar Biopsy

In the past, the toluidine blue test was used to direct vulvar biopsies. The vulva was washed with 1% acetic acid, dried, and then treated with toluidine blue dye. After 2 to 3 minutes, the dye was washed away with 1% acetic acid. Areas of possible vulvar intraepithelial neoplasia retained the dye and thus guided physicians to suspicious areas for biopsy. Because of the high rate of false-positive and false-negative results associated with this method, it has largely been replaced by colposcopy. Colposcopy has been shown to be a sensitive tool for diagnosing vulvar lesions such as HPV infections.

The only definitive way to exclude invasion is to perform a biopsy of, and to examine microscopically, suspicious areas of the vulva. Vulvar biopsy samples usually are simple to obtain in the office. The area under suspicion is cleansed with an antiseptic solution and then infiltrated with lidocaine 1% using a 25-gauge needle. Then, a 3- to 6-mm Keyes punch is used to obtain a sample (Fig. 26.9). Any bleeding that occurs can be controlled with silver nitrate or Monsel solution and gentle pressure. For larger areas, a single interrupted suture achieves hemostasis.

FIG. 26.9. Vulvar biopsy using Keyes punch.

Ovulation Detection and Prediction

The confirmation of ovulation is always an important part of the evaluation of patients with infertility or abnormal uterine bleeding. It also is useful in timing donor and homologous artificial insemination.

Methods used to detect ovulation reflect progesterone secretion by the ovary. The simplest among these is the determination of a biphasic temperature pattern by recording the basal body temperature (BBT). The BBT is that taken immediately on awakening and before activity. Persistent elevation in the BBT of 0.5°F to 1.0°F (0.2°C-0.4°C) in response to the secretion of progesterone reflects ovulation. However, ovulation has already occurred, and the BBT does not allow prediction of when it will occur. Measures of serum progesterone or the presence of secretory endometrium can also be used to confirm that ovulation has occurred. As with the BBT, these methods provide confirmation of ovulation but do not make it possible to predict the day of ovulation for the timing of coitus or insemination.

Serial ultrasonographic studies of follicular growth and disappearance and subsequent formation of a corpus luteum is another method of detecting and timing ovulation. The serial sonographic changes associated with ovulation include a preovulatory follicle of 20 millimeters or more, a change in the shape of the follicle, thickening of the follicular wall, disappearance of the follicle, and the appearance of fluid in the cul-de-sac. However, these changes can occur without actual ovulation, and ovulation can occur without these characteristic changes. Only direct observation of ovulation during laparoscopy, or pregnancy, provides definite evidence of actual ovulation.

The introduction of home test kits for detecting the midcycle surge of luteinizing hormone in urine has made it possible for patients to predict when ovulation will occur. A peak in urinary luteinizing hormone typically occurs between 8 a.m. and 3 p.m., and ovulation usually occurs 12 to 36 hours later. This makes it possible for infertile couples to time coitus or insemination more accurately than ever before. False-positive results may occur in women with polycystic ovary syndrome and in those taking ovulation-inducing drugs.

Transvaginal Ultrasonography

Although there is no substitute for a bimanual pelvic examination, transvaginal ultrasonography may enhance and extend the pelvic examination. Ultrasonographic examination cannot replace the physician's physical determination of the mobility and texture of tissues or the presence of tenderness, but it can provide objective confirmation of the size, shape, and location of pelvic organs. The introduction of lightweight, mobile machines with 5- and 7.5-MHz probes has made office-based ultrasonography a valuable diagnostic technique. Compared with other methods of imaging, ultrasonography is unsurpassed in safety and in providing inexpensive images.

Several advantages of ultrasonography available in the gynecology office include picture clarity, ease of operation, and dynamic use of the probe. The probe can be used during almost every pelvic examination to enhance the diagnostic abilities of the bimanual examination and will probably be present in every gynecologist's office within the next 3 to 5 years. The process of transvaginal sonography improves upon the bimanual pelvic examination by allowing the hand on the abdomen to move organs or structures. Structures may be moved or touched to attest for presence of pain, and fluid collections may be observed.

Office-based ultrasonography can be helpful in the following situations:

- Evaluating pelvic masses
- Monitoring follicular growth in response to ovulation-inducing drugs
- Diagnosing and sizing uterine leiomyomata
- Differentiating intrauterine from ectopic pregnancies
- Diagnosing pelvic abscesses
- Evaluating the endometrium in women with abnormal uterine bleeding

Another important area in which ultrasonographic evaluation is valuable is in the postmenopausal woman. In evaluating endometrial abnormalities, endometrial thickness of 5 millimeters is used to determine whether further evaluation is needed. Women whose endometrium measures less than or equal to 5 millimeters are considered to have normal results, and those women whose endometrium measures greater than 5 millimeters are subjected to endometrial biopsy in a screening study performed in a private office setting.

A suboptimal examination or confusion resulting from artifacts may have serious consequences, however. The ultrasonographic image is only as good and as useful as the clinical skills used to relate the sonographic findings to the situation under evaluation.

A variation of pelvic ultrasonography is sonohysterography, in which a clear fluid is infused into the uterus while a vaginal ultrasonographic examination is performed (Fig. 26.10). This technique is a useful adjunct and a less costly alternative to office hysteroscopy in women with abnormal uterine bleeding, Asherman syndrome, and infertility. Using it, one can detect reliably irregularities of the endometrium caused by adhesions or polyps but cannot distinguish hyperplasia from neoplasia.

FIG. 26.10. Sonohysterogram.

A pelvic examination and baseline vaginal ultrasonographic examination are performed to evaluate mobility, size, and position of the pelvic organs. A pregnancy test is done if there is any suspicion of pregnancy. The cervix is cleansed with povidone-iodine or another antiseptic solution and a 5.0- to 5.3-French catheter is introduced with a ring forceps into the cervix. H/S Catheter Set for Hysterosalpingography (Ackrad Laboratories, Crawford, NJ) is commonly used. The speculum is removed, and the ultrasonography probe reintroduced into the vagina. Sterile saline is then infused slowly from either a 30- to 60-milliliter syringe or a bag, while the uterus is scanned from cornu to cornu and from the external cervical os to the fundus. Not only can intrauterine lesions be seen, but tubal patency can be ascertained by observing the accumulation of fluid in the cul-de-sac.

Office Hysteroscopy

The development of small hysteroscopes that use carbon dioxide or saline as a distension medium has made it possible to determine in the office setting, often without

anesthesia, the cause of abnormal uterine bleeding, the size and shape of the uterine cavity, the presence of congenital anomalies of the uterus, the location of a misplaced intrauterine device, and the presence of intrauterine adhesions, polyps, or submucous myomata. Office hysteroscopy is of significant value in evaluating women with abnormal uterine bleeding who have ovulatory menstrual cycles. In such cases, focal rather than diffuse endometrial abnormalities may be present.

The procedure is safe, simple, and quick. It is performed early in the menstrual cycle to avoid an intrauterine pregnancy or a thick endometrium. Patients should give informed consent. The cervix is cleansed with an antiseptic solution, and the hysteroscope is inserted through the cervix (Fig. 26.11). Insertion of the hysteroscope is facilitated by the performance of a bimanual examination before the hysteroscopy to assess the size, shape, and flexion of the uterus. Flexible diagnostic hysteroscopes typically do not require use of a tenaculum on the anterior cervix. Larger flexible hysteroscopes designed for obtaining biopsies usually require dilation. Injection of a local anesthetic to the anterior cervix and paracervical areas and use of nonsteroidal antiinflammatory drugs reduce the discomfort associated with the procedure for most patients. The endocervical canal, endometrial cavity, and tubal ostia are evaluated systematically, and biopsy samples can be taken of endometrial pathology. Patients should be informed that after the procedure they may experience some uterine cramping or bleeding that should subside within 24 hours.

FIG. 26.11. Office hysteroscopy.

Office Microlaparoscopy

Microlaparoscopic procedures may be performed safely under local anesthesia with conscious sedation in the office under selected circumstances. Careful patient selection is critical for the safety of this procedure, which most often is performed for pelvic pain mapping. Improved instrumentation and refined conscious sedation techniques have contributed to the increased interest in this procedure. Pain mapping may identify subtle areas of disease that might have been overlooked if patients had received general anesthesia. Proper patient selection is critical with respect to patient safety, and it is important not to include patients for whom more extensive surgery may be necessary, extensive endometriosis is expected, or when medical problems or obesity are present. In addition, another major obstacle to office laparoscopy is lack of insurance coverage. As gynecologists become more skilled in microlaparoscopic surgery under local anesthesia with conscious sedation, the number of office laparoscopies may increase during the next decade.

Bone Mineral Density Testing

Osteoporosis is a major health threat in the United States, which is particularly prevalent in the postmenopausal woman. The gynecologist often is called upon to assess risk factors for osteoporosis in the menopausal population and in those women who are hypoestrogenic. Although the dual energy x-ray absorptiometry (DEXA) scan of the spine and hip is the gold standard for evaluation of osteopenia and osteoporosis, newer measures of bone strength, such as heel ultrasonography, have been introduced and used in a gynecology office setting. Gynecologists have used office-based heel ultrasonographic bone mineral density-measuring devices. Measurements of bone mineral density are determined as a T score in the heel, as with the spine and hip density measurements. This additional service in the gynecology office will help in screening women for osteoporosis, with appropriate referral for a spine and hip study. In addition, a combination of risk factor evaluation and the bone mineral density measurement in the office may increase the ability to predict the development of osteoporosis and fracture risk and improve evaluation and treatment decisions in the menopausal patient. The efficiency of routine bone density screening in the gynecology office has not been totally established.

SUMMARY POINTS

- An effective history and examination require that physicians understand why patients are seeking medical care.
- A thorough gynecologic history and examination should include an evaluation of personal health habits and psychosocial issues, including sexuality, abuse, emotional disorders, and drug, alcohol, or tobacco addiction.
- A thorough summary of the physician's findings and a discussion of their implications will reduce the patient's anxiety and improve compliance with medial therapies.
- Office hysteroscopy and endometrial biopsy are a valuable alternative to dilation and curettage.
- Transvaginal ultrasonography may enhance and extend the examination of the pelvis.
- Office microlaparoscopy may be useful in specific, selected circumstances for pain mapping in the patient with chronic pelvic pain.
- Office bone mineral density testing with a heel scanner may be useful in combining risk factor evaluation and the scan result with respect to evaluation and treatment decisions.
- The expertise and experience of gynecologists make them excellent agents for consolidating the health care of women, while providing the majority of care for a large female population. The office-based focus of current and future gynecologists is a significant component of their ongoing contribution to the health care of women.

ACKNOWLEDGMENT

The authors wish to thank Mrs. Alyce Soffer for her assistance in the preparation of this manuscript.

As all medical specialties evolve, so has obstetrics and gynecology. Procedures that were once exclusively performed in the hospital setting are now exclusively performed in the office setting. Some office procedures (i.e., endometrial biopsy, transvaginal ultrasound/saline infusion sonography) have decreased the number of hospital surgical procedures a physician needs to perform to make a diagnosis. Additionally, medical therapies are now used that routinely replace surgical therapies (i.e., methotrexate for ectopic pregnancies). All these changes have resulted in shifting care from the hospital setting to the medical office. These changes in the specialty of obstetrics and gynecology coupled with the recent demands placed on the medical community for cost control has helped spark the trend in the development of more outpatient-oriented care and office surgical suites. Although the technology to perform minor gynecologic surgical procedures in an office setting has been available for years, most “simple” gynecologic procedures are still typically performed in the hospital setting. This chapter will discuss the preparation and briefly review a number of minor procedures which can be performed in an office surgical suite.

PREPARING THE FACILITY

Although many procedures can be performed in an office setting, the particular layout, room sizes, equipment availability, and staffing issues may make it difficult for the practitioner to perform certain office surgical procedures. The facility should, at a minimum, allow for easy access of wheelchairs and stretchers. Additionally, the basic medical supplies needed would include pulse oximeters, basic airway management equipment, electrocardiogram monitoring, intubation supplies, rooms equipped with call alarm buttons, intravenous line stands, a crash cart, and waste containers for sharps. An electronic table capable of placing patients in the Trendelenburg position, with cushioned knee stirrups, is preferred for procedures that last over 10 minutes or use anesthesia. It is important to keep in mind that in some states there are regulations for specific facility requirements when conscious sedation is used. Before developing an office surgical suite physicians should check with local regulatory committees so they will be able to meet any local standards and needs assessments.

PREPARING THE PATIENT

For procedures that are performed in the office setting, a clinician should prepare the patient the same way as they would for the similar in-hospital procedure. Important attention should be paid to the medical history and past medical history to make sure the patient is a good candidate for an in-office procedure and is of low anesthetic risk. Patients with multiple medical problems, cardiovascular disease, or neurologic disease may be better served in the hospital setting. Consents similar to what one would obtain for a day-surgery hospital procedure should be signed. It is important to remember that consent will be required not only for the surgical procedure but also for the anesthesia used. Basic preparatory instructions for the individual procedure should be given as well as postprocedure instructions in case discharge planning is needed. Fasting is recommended when conscious sedation is required, which is abstinence from food for 8 hours and clear liquids for 2 hours.

ANESTHESIA

Although some office procedures can be performed without anesthesia, some will require oral or intravenous sedation. The term *conscious sedation* implies a state in which patients can tolerate procedures with adequate cardiopulmonary function and respond to verbal commands. The American Society of Anesthesiologists (ASA) has published guidelines for sedation and analgesia performed by medical staff not trained in the practice of anesthesia. In the office setting nonanesthesia residency–trained physicians should limit patients to ASA classification I or II (Table 27.1). The clinician should avoid procedures on patients with significant cardiac, respiratory, or neurologic disease in the office setting.

Status	Description
I	Healthy patient
II	Mild systemic disease
III	Severe systemic disease, not incapacitating
IV	Severe systemic disease that is a constant threat to life. Moribund, not expected to live 24 h irrespective of operation

TABLE 27.1. *American Society of Anesthesiologists (ASA) patient classification*

Per hospital policy, anesthesia records should be maintained on the patient's ventilatory and oxygenation status. Hemodynamic variables should be recorded frequently and at a minimum it should be recorded:

- prior to the administration of anesthetic agents
- following the administration of sedation
- upon completion of the procedure
- upon recovery
- at the time of discharge.

A designated medical professional (nurse, physician's assistant, or physician) other than those performing the procedure should be present to monitor the patient's vital signs throughout the procedure. A staff member trained in advanced cardiac life support (ACLS) should be immediately available. The patient should have intravenous access. Naloxone and flumazenil should be available when opioids and benzodiazepines are used.

Anesthesia techniques will vary upon the physicians training and facility requirements. Most obstetrician-gynecologists performing office surgical procedures should be versed in conscious sedation, administration of local analgesia, and paracervical blocks. Ideally patients undergoing diagnostic and therapeutic procedures receive

moderate sedation. The definitions within the continuum of sedation are described in Table 27.2.

Minimal sedation: may be achieved with oral or intravenous medication. Cognitive function may be impaired but the patient responds normally to verbal commands. Ventilatory and cardiovascular functions are unimpaired.
Moderate sedation and analgesia: ordinarily referred to as conscious sedation. Medications are usually administered intravenously. Consciousness is depressed but the patient can respond to verbal commands. The patient is capable of maintaining a patent airway and spontaneous ventilation; cardiovascular function is well maintained.
Deep sedation: results in substantial depression in consciousness, the patient is not arousable, except by repeated painful stimuli.
General anesthesia: drug-induced loss of consciousness.

TABLE 27.2. *Explanations of various levels of anesthetic sedation*

Local Anesthesia

Local anesthesia can be a safe and effective means of providing analgesia for office procedures. Local anesthesia is defined as the elimination of sensations, especially pain in one part of the body using topical or regional injections of medications. Most obstetrician-gynecologists are educated in the use of local anesthetics during residency training. The secrets of success with local anesthetic use is injecting slowly, using a sufficient amount of medication and waiting for the medication to take effect. Several agents may be used and include benzocaine, mepivacaine, bupivacaine, and lidocaine. It is important to remember that local anesthetics have cardiac and central nervous system toxicity, particularly with intravasation into the venous system. Local anesthetics are frequently mixed with epinephrine. Symptoms of epinephrine overdose include tachycardia and hypertension, and one should watch for these signs when using local anesthetics containing epinephrine.

Paracervical Block

Most gynecologists should be proficient in performing a paracervical block. Paracervical blocks are useful not only for cervical biopsies, cervical conization, and loop electro-excisory procedures but also for office dilation and curettage (D&C) procedures and office hysteroscopy. In performing a paracervical block, in addition to the supplies needed for the local infiltration, it is useful to have available a needle extender or long spinal needles. The application of 1% benzocaine spray or lidocaine ointment prior to insertion of the needle may relieve some of the discomfort from inserting the needle. For the paracervical block, injecting 10 mL of anesthetic (usually 1% lidocaine) at the 4 and 8 o'clock positions and waiting 10 minutes gives excellent results. This is believed to limit sensation from the uterosacral nerve bundles from S2, S3, and S4. With this technique the only area of tenderness appears to be the fundus of the uterus and providing local anesthesia to this area is difficult as it is supplied by the tenth thoracic nerve (Fig. 27.1).

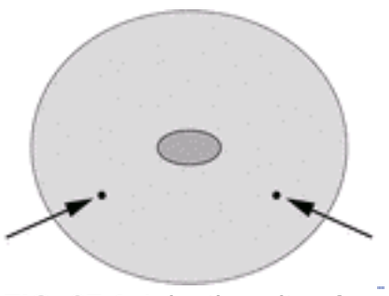

FIG. 27.1. Injection sites for paracervical block at 4 and 8 o'clock positions.

Conscious Sedation

Conscious sedation is defined as a minimally depressed level of consciousness whereby a patient can maintain their own airway independently and respond to verbal commands. The medications used for conscious sedation procedures include local anesthetics, sedatives, and anxiolytic and opioid analgesics. The ideal drugs to use in an office setting would have a quick onset and quick clearance rate. The medications used should have a predictable onset of action and minimal side effects. Anxiolytics and opioids are more commonly used by nonanesthesiologist practitioners for conscious sedation. The window of safety between effect and oversedation is narrow for sedatives and therefore limits their use in the outpatient setting for most physicians. It is important that the surgeon avoids turning a conscious sedation case into general anesthesia, especially in the office setting. There is an approximately a 0.2% mortality rate with conscious sedation, mostly due to oversedation and inadequate monitoring.

Diazepam (Valium) is the most popular of the anxiolytics used; however, midazolam (Versed) has also been used. Diazepam is popular because it can be given both intravenously and orally. The usual dose is 2.5 mg intravenously every 10 minutes to a maximum dose of 0.15 mg per kg or 10 mg. The drawback to diazepam is its long duration of action, which is why some physicians prefer midazolam. Midazolam can also be administered orally, intravenously, or intramuscularly. It has a short half-life. The usual recommended dose is 1 mg intravenously every 5 minutes to a maximum dose of 0.07 mg per kg or 5 mg in the office setting.

The opioids are medications that will decrease the patient's awareness of painful stimuli. These drugs can produce respiratory suppression and should be used cautiously. The preferred drug in this class for conscious sedation is fentanyl. Fentanyl has a quick onset of action and short half-life. In the office setting the standard dose is 25 to 50 µg every 5 minutes, to a maximum of 3 µg per kg, or 250 µg intravenously. Morphine and meperidine have also been used instead of fentanyl, however, they have a longer duration of action. It is important to note that morphine and meperidine appear to work better for patients with visceral discomfort.

Naloxone and flumazenil are two drugs that are essential to have available while providing conscious sedation using opioids and benzodiazepines. Naloxone (40 mg intravenously) is used to reverse the respiratory depression seen with opioids and flumazenil (0.2 mg intravenously) is a benzodiazepine antagonist (Table 27.3).

TABLE 27.3. *Agents approved for conscious sedation and dosing regimens for adults*

PREVENTING COMPLICATIONS

There are two basic groups of complications from surgical procedures:

1. Allergic reaction to the medications used.
2. Technical difficulty with the procedure.

Being prepared is the key to managing procedure complications. Careful history will help eliminate most allergic reactions, but a staff member trained in resuscitation and having agents like Benadryl (50 mg i.v.) and epinephrine may be lifesaving. It is imperative that the recommended limits for in-office sedation for the medication

being used are not exceeded. An approximately 0.2% mortality rate occurs with conscious sedation. Those deaths are mostly due to the lack of adequate monitoring of cardiac and respiratory functions during the procedure. Good judgment is the key to avoiding complications. It is much better to discontinue the office procedure if it appears more complex than originally planned. To help improve outcome after any surgical complication it is important to have an emergency plan available for these unforeseen surgical complications (i.e., local ambulance number, local emergency room number, crash cart, and staff trained in ACLS techniques).

THE PROCEDURES

Office Hysteroscopy

Setup, Equipment, and Preoperative Care Office hysteroscopy is a useful tool for the evaluation of abnormal uterine bleeding, infertility, and recurrent pregnancy loss. Typically an office hysteroscopy can be performed in a regular exam room without much modification. The most common medium used for distention with office hysteroscopy procedures is CO_2. CO_2 is readily available and uses a low-flow insufflator (100 mL/min). It is essential to note that a CO_2 insufflator for laparoscopy is a high-flow insufflator and should *never* be used for office hysteroscopy. Advantages of CO_2 is its low cost, low "mess," and overall performance and safety. It is important to remember however that CO_2 is not a good medium for evaluation of patients with abnormal bleeding while they are bleeding. These patients may be better served with a "liquid" distention medium including high-molecular-weight dextran, sorbitol, normal saline, or lactated Ringer solutions. Several hysteroscopy manufacturers have developed low-cost complete fluid systems for office hysteroscopy procedures that aid in making the procedure safe and simple. When starting to perform office hysteroscopy procedures it is important to make sure you have the correct equipment available. For office hysteroscopy there are two different kinds of hysteroscopes—rigid and flexible. Flexible hysteroscopes tend to be more expensive and have slightly poorer quality images when compared to rigid hysteroscopes. Most physicians prefer rigid hysteroscopes for office procedures. The standard office rigid hysteroscope is 4 mm in size, however, microhysteroscopes with 2.4 mm and 2.7 mm optics are available. The smaller size decreases the need for cervical dilation, which has the advantage of decreasing the pain and bleeding associated with the procedure. In addition to the sheath size for the hysteroscope physicians have a choice of telescope angle. Most physicians prefer to use a telescope at 0, 12, 15, or 30 degrees. Many hysteroscopy systems are available for operating room and office use. All systems have their particular advantages and disadvantages. Several systems should be tested in your office setting to determine which system is the best for you before purchasing a system. Look for a system from a company with reliable service that has the operating equipment you will need (graspers, forceps, scissors) and a telescope with the brightest, clearest image within your budget.
Surgical Technique After the patient has checked in and appropriate vital signs have been taken adequate analgesia should be given (see " Anesthesia" earlier in the chapter). An attempt to pass the hysteroscope without dilation should be made. However, the cervix may need to be dilated. Good techniques for cervical dilation include laminaria or misoprostol. Since these techniques require preplanning it is best at the preoperative appointment to assess the cervix to determine if dilation will be necessary. The problem with laminaria insertion is it requires a visit to the office the day prior to the procedure and many patients experience severe cervical/uterine cramping. Another option is the use of misoprostol 400 mg orally 4 to 6 hours prior to the procedure. The hysteroscope is usually inserted under direct visualization passing through the cervical canal into the endometrial cavity. To aid in visualization during the hysteroscopy, the cervix should be cleared of all blood using a sponge forceps prior to entering the cervical canal. Another way to keep the lens clean when using a liquid distention medium is to start the distention medium prior to entering the cervix. The running fluid at the tip of the hysteroscope upon entering the cervical canal aids in keeping the lens clean and in visualization at the start of the procedure. In addition, if the medium is cloudy upon entry, waiting 15 to 30 seconds to allow the continuous flow process to work will provide a clearer field of vision. In contrast, if CO_2 is used as the distention medium, do not start the CO_2 until after entrance into the cervical canal. This will avoid making blood-tinged bubbles within the cavity which will obstruct the view. Once the hysteroscope is passed through the cervical canal into the uterus a systemic overview of the cavity should be performed prior to performing any operative procedures. Inspect the fundus and locate both tubal ostia first then pull back to the level of the internal os and inspect the entire anterior then posterior wall of the uterus (Fig. 27.2).

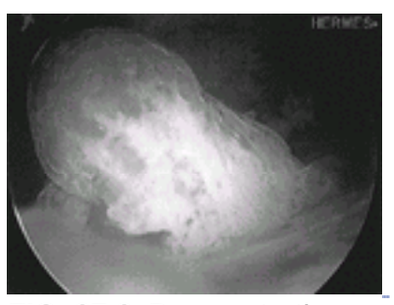

FIG. 27.2. Demonstrating a posterior wall intrauterine mass in an office hysteroscopy evaluation.

Postoperative Care Most patients will have light spotting or light bleeding for up to 5 days after their hysteroscopy procedure and should be advised of such. Intercourse and douching should be restricted for 24 hours. Tampons may be used for the postoperative bleeding that occurs. Patients should be advised that they could have minimal cramping which is best resolved with a nonsteroidal antiinflammatory drug (NSAID) or other analgesic. Patients should be instructed to call if they have heavy bleeding, severe pain unresolved by the NSAID, or fever greater than 100.5°F.

Microlaparoscopy

Setup, Equipment, and Preoperative Care Microlaparoscopy under local anesthesia has raised interest in the medical community due its cost-effectiveness in comparison to in-hospital procedures. Several different microlaparoscopy procedures can be performed in the office setting, however, the difficulty in performing office microlaparoscopy for most physicians is not obtaining the training or equipment needed to do these procedures but rather having adequate office facilities to accommodate a microlaparoscopy suite. In addition to adequate facility size, the following equipment should be available for the office procedure:

- "micro" laparoscope and microlaparoscope lens
- video camera
- video monitor
- trocar sheaths
- laparoscopic scissors, graspers, and bipolar coagulation
- a table capable of accommodating the Trendelenburg position
- resuscitation equipment
- intravenous line supplies

v sterile surgical gowns and drapes. Several "micro" laparoscopes are available for use. The refinements in fiberoptic technology have led to excellent quality 2-mm laparoscopes. Microlaparoscopes range from 25 to 27 mm in working length and have a 0-degree angle of view. There are 2-mm accessories available such as graspers, blunt probes, and biopsy forceps. While concerns remain over optical clarity with these "micro" laparoscopes, comparison of the accuracy of a 1.98-mm microlaparoscope with the standard 10-mm laparoscope (endometriosis scores and adhesions scores) yields no difference between the two. To avoid major complications, candidates for office laparoscopy should have no more than a minimal amount of prior abdominal surgery and no medical history suggestive of a significant risk of abdominal adhesions.
Surgical Technique It is important to realize that even experienced laparoscopic surgeons should perform office microlaparoscopy with an experienced microlaparoscopic surgeon prior to performing these procedures on their own. Even experienced laparoscopic surgeons will find the "micro" equipment more difficult to use at first until a feeling is established for the differences in depth perception and smaller field of view when compared to their full-size counterparts. Procedures best suited for the microlaparoscopic technique include infertility evaluations with chromopertubation, tubal ligation procedures, conscious pain mapping, and second-look procedures. The average length of an infertility evaluation procedure is 18 minutes. Some patients undergoing microlaparoscopy can have the procedure performed strictly under local anesthesia. However, this limits the length of the procedures and the amount of gas that can be used for insufflation. Most patients are better served with some conscious sedation as this often allows the procedure to last 30 to 45 minutes in contrast to only 15 minutes with local anesthetic alone. For the microlaparoscopy procedure, the patient is placed in dorsal lithotomy position on a table capable of performing Trendelenburg. A paracervical block should be give if a uterine manipulator is used such as the Cohen cannula. The patient is sterilely prepped and draped. If conscious sedation is used, this is given according to the guidelines described previously. Local anesthetic is then given in the area of the umbilicus. The use of a Verres needle/sheath combination system allows entry of the Verres needle without reintroduction of a trocar sheath for the procedure. The abdomen is insufflated and the pelvic organs visualized. Remember insufflation pressures will be higher in these patients because they do not have abdominal muscle relaxation. Pressures and gas flow should be titrated to patient comfort. Observation and chromopertubation are performed in a manner similar to that using the 10-mm laparoscope.
Postoperative Care Routine postoperative care for laparoscopic procedures should be followed for patients undergoing in office laparoscopic procedures. Patients should be stabilized prior to discharge and return for a postoperative incision check in 1 to 2 weeks. Patients should be advised to call if they experience heavy vaginal bleeding, pain that is not resolved by NSAIDs, or a fever greater than 100.5°F.

Office Dilation and Curettage (D&C) and Endometrial Sampling

Setup, Equipment, and Preoperative Care The vast majority of office endometrial samplings and D&C procedures can be performed with minimal office

modifications. Most of the equipment needed is readily available and disposable. In addition to the obvious cost savings for office D&C procedures, the office procedures are more time-efficient for the physician. Office D&C procedures may be performed for a variety of reasons but the most common indications include pregnancy termination and management of an incomplete abortion prior to 12 weeks gestation. It is very important to confirm pregnancy status and location by ultrasound prior to performing the procedure. The most common reasons for in-office endometrial sampling include evaluation for abnormal uterine bleeding, postmenopausal bleeding, recurrent pregnancy loss evaluation, and as part of an infertility workup.

Surgical Technique The most popular technique for office D&C uses the Karman cannula. The Karman cannula is a soft catheter and is an efficient suction device as it has two suction ports. The larger the bore of the catheter the more effective is the aspiration procedure. As the soft catheter works so well we find that there is a limited role for the sharp curettage technique. The soft catheter probably reduces the risk of uterine perforation when compared to the traditional sharp curette. In choosing the size of the cannula the diameter of the cannula should equal the size of the uterus using the standard sizing of the number of weeks of pregnancy. Therefore when performing a D&C for an incomplete abortion in a uterus measuring 8 weeks gestation, an 8-mm cannula should be used. Office procedures should be used only on those patients with a uterine size less than 12 weeks gestation. Prior to arrival at the office we usually pretreat the patient with Valium, 5 to 10 mg orally. After check in and routine vital signs are obtained, a bimanual exam is performed to determine the uterine size. A speculum is inserted to perform a paracervical block (see “ Anesthesia” earlier in the chapter for description of this technique). After adequate anesthesia is induced the catheter should be passed through the cervical os. Sometimes cervical dilation is needed and this may be accomplished with dilators, laminaria (or its synthetic counterpart), or misoprostol. Initially the chief purpose of uterine curettage was for endometrial sampling, however, the classic curettage has been essentially replaced with the office endometrial sampling. Endometrial sampling is a diagnostic screening test and the use of an in-office endometrial sampling procedure has essentially eliminated the need for many D&Cs performed in the operating room. During the past 50 years many different instruments have been developed for office endometrial biopsies. Most of the sampling devices used for this purpose have a 5-mm or less outer dimension and are made of plastic. Some of these devices require a syringe or suction pump, however, the most popular endometrial sampling device is the disposable hollow plastic tube with an aspiration port that has a solid plastic obturator (Pipelle).

Postoperative Care Most patients do well after an in-office endometrial curettage or sampling. The patients should be advised that they might have cramping and bleeding for 3 to 4 days after the procedure. Patients often respond well to NSAIDs for uterine cramping. They should be advised to call the office if they develop a fever, have vaginal discharge, or have bleeding past 4 days.

Endometrial Ablation

New technology now allows the physician to perform office endometrial ablation. Several types of endometrial ablation devices are on the market, some using water, balloons, or impedance-controlled bipolar radio frequency. In randomized studies 46% of patients were able to use the balloon technology in the office under local anesthesia (some with i.v. sedation) and 73% using the bipolar radio-frequency system were able to be performed in the office setting.

Novasure (bipolar radio frequency) technology can be performed as an outpatient or office-based procedure. The average treatment time is 90 seconds compared to 8 to 12 minutes for balloon technology. With the Novasure system, the Novasure introducer sheath is introduced through the cervical os (Fig. 27.3). The three-dimensional bipolar electrode expands from the introducer sheath and with the aid of CO_2 conforms and checks the integrity of the uterine cavity. The ablation is accomplished and the electrode is retracted into the sheath and removed. There is a 91% success rate (decrease in flow) and 41% amenorrhea rate (Table 27.4). The endometrial balloon (Thermachoice) is very easy to use (Fig. 27.4). The catheter is primed and tested. The catheter is then introduced into the uterus much like a sound. The balloon is filled and the Thermachoice heats the fluid. After a heating period, 8-minute treatment period, and cooling period the catheter is removed. Temperatures and uterine pressures are measured continuously. This helps confirm uterine integrity.

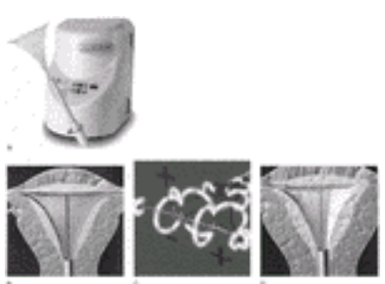

FIG. 27.3. Novasure endometrial ablation technology using a balloon system.

TABLE 27.4. *Endometrial ablation procedures*

FIG. 27.4. Thermachoice endometrial ablation technology using a balloon system. (Reprinted with permission from Gynecare, Somerville, NJ.)

Surgical Technique The surgical technique will depend upon the equipment used. Physicians who desire to use the ablation technology should be trained by those experienced in using the equipment. Contacting your local equipment sales representatives and surgeons to serve as experienced preceptors should be the easiest way to become proficient using ablation equipment. If these procedures are being performed in conjunction with hospital systems, there may be information on credentialed individuals in the medical staff office.

Postoperative Care Most patients will do well after discharge. Generally an NSAID or similar medication is prescribed to control postoperative pain. Patients should be advised to contact the office with excessive postoperative pain that is not relieved by the NSAIDs or if they experience excessive postprocedure bleeding. In order to insure that the patient is satisfied with the ablation results it is important to educate patients about the typical results seen with endometrial ablation. Most patients will not experience a decrease in the menstrual flow for approximately three menstrual cycles after the ablation. The percentage of decrease in flow and amenorrhea rates, which vary with the technology used, should be reviewed prior to the procedure. As many as 30% to 40% of women may need further intervention within 4 to 5 years; however, patient satisfaction remains high if the limitations are discussed preoperatively.

Saline Infusion Sonography

Since the development of high-resolution ultrasound, saline infusion sonography (SIS) has been gaining in popularity. Numerous studies have looked at the benefit of ultrasound in establishing the diagnosis in women with abnormal uterine bleeding. However, it is sometimes difficult to image the endometrial contents and rule out pathology on a reliable basis. The use of fluid instillation into the uterine cavity coupled with ultrasound has become a useful diagnostic tool. SIS is easily performed in the clinical setting and is remarkably well tolerated in most patients. The clinical use of SIS is not in its use to replace surgery but to identify those patients who need surgical intervention. Multiple indications for SIS are listed in Table 27.5.

TABLE 27.5. *Indications for saline infusion sonography*

Setup, Equipment, and Preoperative Care The minimum supplies required to perform SIS include a SIS catheter, instillation medium, a 20-cc syringe, povidone-iodine solution, scopettes, an open-sided speculum, and an ultrasound that preferably has transvaginal capabilities. The most widely used medium for instillation into the uterine cavity is saline; however other contrast media have been investigated, including Echovist and Albunex. These media do not appear to

perform better than normal saline and are more costly. SIS can be performed during any time of the cycle; however performing SIS during the follicular phase will avoid the disruption of an early pregnancy. In addition during the follicular phase there is a thinner endometrium, which may aid in better evaluation of the uterine lining. Instilling saline during menses may lead to poor uterine distention so avoiding the procedure during the menstrual cycle is preferred. There are several SIS catheters on the market (Fig. 27.5, Fig. 27.6 and Fig. 27.7). Alternatively, pediatric Foley catheters, insemination catheters, and pediatric feeding tubes, can be used. The choice of the catheter will depend on the patient and therefore several catheter types should be available to the physician performing the SIS. In particular, one should have a thin, stiff catheter available for nulliparous cervices and a balloon or cone type catheter for multiparous cervices. The balloon should be used in patients with multiparous cervices to occlude the os. This will limit the amount of medium leaking out of the uterus and improve uterine distention.

FIG. 27.5. Placement of the Goldstein catheter for saline infusion sonography using a cone to occlude the cervical os. (Reprinted with permission from Cook Ob/Gyn, Spencer, IN.)

FIG. 27.6. Saline infusion sonography catheter, balloon type.

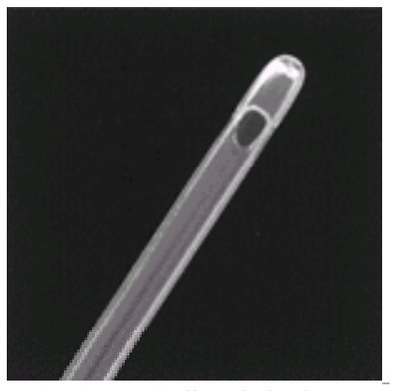

FIG. 27.7. Saline infusion sonography catheter, insemination type.

Technique After performing a bimanual exam or baseline ultrasound to determine uterine position, a speculum is inserted and the cervix is identified. The cervix may be cleansed with povidone-iodine or similar antiseptic solution. The catheter is primed with saline and then inserted through the cervical os. The exact placement will depend upon the catheter used. For a balloon-type catheter, the balloon should be positioned in the cervical canal or lower uterine segment and inflated. However the Goldstein SIS cone-type catheter is inserted to 7 cm, or near the uterine fundus, with the white acorn cone occluding the cervical os (see Fig. 27.5). A ring forceps may be needed to assist in placing the SIS catheter. Once the catheter is in place the speculum is removed with special care taken so that the catheter is not dislodged. The vaginal ultrasound probe is inserted into the vagina and the uterus is imaged as the saline is infused slowly. Usually about 5 to 10 cc of saline is used in order to get good distention. It is important to remember the seal will not be watertight. Although a watertight seal may produce better images, this will result in significantly more cramping with the procedure. When there is a large efflux of saline out the cervix, more saline may be needed to get good images. Visualization in both the longitudinal and transverse axis should be performed. The entire uterine cavity should be visualized from left to right broad ligaments longitudinally and from the cervix to the fundus in the coronal plane (Fig. 27.8). It is important to realize that full distention of the uterus is not necessary to get a good quality evaluation. Indications for SIS are summarized in Table 27.5.

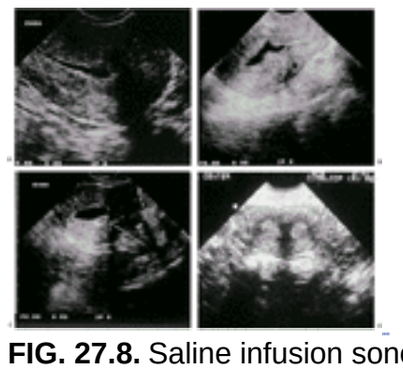

FIG. 27.8. Saline infusion sonography (SIS) evaluation of the uterine cavity. **A:** SIS demonstrating a normal uterine cavity. **B:** SIS demonstrating an intrauterine mass. **C:** SIS demonstrating a localized posterior wall thickening. **D:** Bicornuate or septate uterus visualized prior to instillation of saline.

Postoperative Care Most patients have minimal discomfort after a SIS procedure. Patients usually do well using NSAIDs or similar analgesics for pain control. Patients should be advised to call if they are experiencing heavy bleeding not associated with menses that continues for more than 4 days. Additionally patients should be evaluated if they have a fever greater than 100.5°F or vaginal discharge.

Contraceptive Procedures

As part of residency training most obstetrician-gynecologists will obtain the clinical training needed to perform insertion and removal of an intrauterine device (IUD) and the Norplant system.

Two IUDs are available in the United States: Mirena and Paragard. IUDs are generally recommended as a contraceptive method to women in a stable monogamous relationship who are not at risk for pelvic inflammatory disease, sexual transmitted diseases, or ectopic pregnancies. IUDs are contraindicated in the following situations:

- suspicion of pregnancy
- congenital uterine anomaly
- fibroid uterus which severely distorts the uterine cavity
- pelvic infections
- unresolved abnormal Pap smear
- untreated cervicitis or vaginitis
- genital bleeding of unknown etiology
- women with multiple sexual partners
- leukemia
- acquired immunodeficiency syndrome (AIDS)
- breast cancer
- ectopic pregnancy or history of ectopic pregnancy.

The Mirena IUD consists of a T-shaped polyethylene frame with a steroid reservoir around the vertical stem (Fig. 27.9). The reservoir consists of a cylinder made up of a mixture of levonorgestrel and silicone. There are 52 mg of levonorgestrel within the system which provides levonorgestrel at a rate of 20 µg per day initially. This level declines to half the 52-mg level at 5 years. Levonorgestrel is a progestogen, which is used in a variety of contraceptive products. There is a stable blood level of 150 to 200 pg/mL 3 weeks after insertion of the Mirena device. The T system is 32 mm in length and width. The T-shaped body also has barium embedded which makes it radiopaque. There is a monofilament string attached to the T-shaped body stem. Although the exact mechanism for contraception is not clearly identified it appears that the Mirena IUD has mostly local effects within the uterine cavity. Additionally, Mirena may have an effect on ovulation. In a 1-year study of the system only 45% of cycles were ovulatory; however, in a 4-year study 75% of cycles were noted to be ovulatory. Contraceptive effectiveness is quoted to be 0.2 pregnancies per 100 women and the cumulative 5-year pregnancy rate is 0.7 per 100 women. Half of the pregnancies that occur while using the Mirena IUD are ectopic gestations, at a rate of 1 ectopic pregnancy per 1,000 users per year. It is important to inform patients that the Mirena IUD can alter the menstrual bleeding pattern. During the first 3 to 6 months of use there may be an increase in vaginal spotting. Additionally, it has been noted that approximately 20% of users will amenorrheic after 1 year of use.

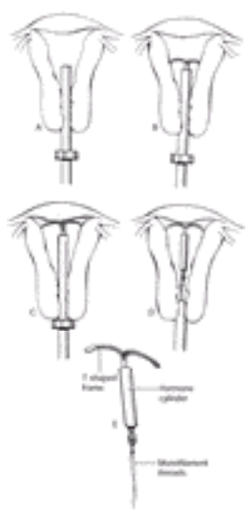

FIG. 27.9. The Mirena intrauterine device. **A:** Insertion of Mirena into uterine cavity. **B:** The arms of the Mirena are released. **C:** Mirena is positioned near the uterine fundus. **D:** Releasing the Mirena IUD and withdrawing the inserter. **E:** The Mirena IUD.

The Paragard IUD has a T-shaped polyethylene body. The vertical portion of the T is wound with 176 mg of copper wire along with a copper collar of 68.7 mg on each of the transverse arms. The exposed areas of copper are approximately 380 mm ^{2}. Paragard has a monofilament thread attached the bulb end of the base of the T-shaped device. The available data indicate that the copper is continuously released into the uterine cavity. The additional copper load to the body from a copper IUD may precipitate symptoms in patients with Wilson disease. The exact mechanism in which the copper provides contraception is unclear; however it is thought that there is interference with sperm transport, fertilization, and embryo implantation. The Paragard should be kept in place no longer than 10 years. Women who use the copper IUD should be advised that blood loss at the time of menses might increase. There is an approximately 35% increase in menstrual blood loss among copper IUD users.

If a woman becomes pregnant while an IUD is in place, the manufacturers recommend removing the IUD if the string is visible. Removal under these conditions is usually simple. It is important to confirm the location and viability of the pregnancy prior to removal of the IUD. Patients in whom the IUD cannot be removed or those who choose not to have the IUD removed should be informed that there is an increased risk of septic abortion and preterm labor/delivery.

IUD Insertion Technique An IUD should only be inserted, managed, and removed only by clinicians trained in IUD use. The Mirena and Paragard have different techniques for preparing the IUD insertion, so clinicians should refer to the package inserts for guidance. IUDs can be inserted at any time during the menstrual cycle. Traditionally physicians have preferred to insert an IUD at the time of menses to insure that the patient is not pregnant. However insertion at the time of menses increases the risk of expulsion of the IUD during the first 2 months of use. It is best to give patients an NSAID 1 hour prior to IUD insertion. After loading the IUD into its insertion device the uterus should be examined by bimanual examination and a speculum inserted into the vagina and the uterus sounded. With both IUDs there is an adjustable flange that should be set to the length to which the IUD should be inserted. A single tooth tenaculum is applied to the anterior lip of the cervix to aid in cervical and uterine straightening. Benzocaine spray or local infiltration of lidocaine may be used prior to tenaculum placement. The IUD must be inserted within 5 minutes of loading so that the arms will spring back open after insertion. The IUD is then passed through the cervical canal to the fundus. The plastic flange should be at the level of the internal os if the IUD is inserted correctly. Once correct placement is confirmed, the insertion device is used to release the arms of the IUD. The insertion device is then removed gently so as not to disturb the placement of the IUD. The monofilament thread should be cut approximately 2 cm from the external os. The risk of uterine perforation is 1 in 1,360 insertions. Insertion immediately in the postpartum period, particularly during lactation has been associated with an increased risk of uterine perforation. However there is no increased risk of perforation if the IUD is inserted immediately after expulsion of the placenta. It is our preference, however, to delay insertion of an IUD until the second postpartum month.
Postoperative Care After insertion of an IUD the patient should be taught how to palpate the strings monthly. Patients should be seen in 3 months to review bleeding pattern and concerns with the IUD. At that time, a speculum examination should be performed to rule out partial expulsion of the IUD. Removal of an IUD is generally easy. It is important to note the type of IUD prior to removal. The strings are grasped with a ring forceps and pulled outward through the vagina until the IUD is expelled. If the strings break off during removal or the strings are not visible, removal under ultrasound guidance is advisable. Under ultrasound guidance, while using packing forceps, the lower stem is located. Using gentle traction, it is removed through the internal then external os. If gentle force does not produce the IUD then the IUD may be embedded and, in such cases, hysteroscopic removal in the operating room may be needed. It is important to note that some IUDs that are used outside the U.S. do not have strings and are designed for permanent placement. These should not be removed in the office setting.
Norplant The Norplant contraceptive system consists of six Silastic capsules each filled with 36 mg of levonorgestrel powder. The capsules should be placed in the subcutaneous layer of the inner aspect of a woman's nondominant arm. Norplant capsules are designed for 5 years of use with a typical first year failure rate of 0.09% and a cumulative failure rate of 1.1% over 5 years. Discontinuation of use prior to 5 years appears to be the major problem with the Norplant system. The major reasons for discontinuation of use include bleeding abnormalities, weight change, headaches, and change in libido. Women with active venous thrombosis, unexplained vaginal bleeding, or history of stroke or breast cancer are not candidates for Norplant. Women using the drugs listed in Table 27.6 should not use Norplant as these drugs increase the metabolic clearance of levonorgestrel, which can decrease its efficacy. The most common side effects of the Norplant system include changes in the menstrual pattern, weight changes, and headaches.

Phenobarbital
Phenytoin
Carbamazepine
Rifampin

TABLE 27.6. *Drugs that decrease the effectiveness of the Norplant system*

Norplant Insertion Technique Both insertion and removal of the Norplant system require formal training to avoid complications. Norplant insertion should be scheduled during the first week after menses. Patients should be told to avoid intercourse during this time to avoid inadvertently becoming pregnant. Location for

placement of the Norplant capsules is the first decision that should be made. Ideally the capsules should not be noticeable. It is important to remember good placement of the capsules translates into easy removal. The location of the Norplant capsules to avoid detection should be on the inner aspect of the upper arm. Ideally the location should be above the level of the nipple and medial enough that it lies on the medial aspect of the arm. The capsules are traditionally fanned, and are placed approximately 15 degrees apart from each other. Once a location is chosen, the physician should use the Norplant template included in the kit and mark a dot for the incision site and a dot for the position of each of the distal tips. The Norplant kit contains all the necessary equipment needed for a standard simple insertion. Patients should be in the supine position when the capsules are inserted. The arm should be placed flat on the examining table with the palm upward and the elbow bent to 90 degrees (as if the patient is signaling to make a right-hand turn). Local anesthesia is given at the incision site, taking care not to use too much anesthesia which may distort the tissue planes. The needle should be advanced its full length just under the skin along the planned tract of each capsule. After adequate anesthesia is obtained, a 3-mm horizontal incision should be made at the incision site that has been chosen. The obturator should be loaded into the trocar provided in the kit. The trocar, with obturator in place, is introduced directly through the incision with the open end of the bevel facing the ceiling. The skin below the incision site should be held in place for traction. The trocar is then advanced until the level of the second line on the trocar is at the incision site. The obturator is removed and the Silastic capsule is introduced. The obturator in then replaced. The obturator is used to push the implant down the shaft of the trocar and into place. Once in place the obturator and trocar are removed gently and slowly. This procedure is performed a total of 6 times at 15-degree angles until all capsules are placed. After all 6 capsules are placed, the edges of the incision should be reapproximated with Steri-Strips.

Postoperative Care of Norplant Patients who have the Norplant inserted close to the time of ovulation should use barrier contraception for 1 week. Patients should be advised to check for signs of infection at the incision/insertion site, which occurs in less than 1% of Norplant insertions.

Norplant Removal The most important thing to remember is that good placement of the Norplant capsules leads to easy removal. One method of removal of the Norplant system is described here. As with other procedures many techniques have been developed to aid with the removal of the capsules. No particular procedure appears to have an advantage over another. It is recommended that removals be scheduled for a 20-minute appointment. Most Norplant removals take 15 minutes, however on rare occasions we have known them to take up to 45 minutes. Patients should be advised that removal is more painful than insertion. The incidence of difficult removal is quoted by the manufacturer to be about 13%. The area should be palpated and the location of the Norplant capsules identified. The following equipment is needed for removal:

- examining table
- sterile gloves
- sterile drapes
- antiseptic solution
- lidocaine or similar anesthetic
- needles and syringes
- scalpel
- marker
- straight and curved mosquito's or a similar clamp
- Steri-Strips, sterile gauze, and tape.

The location of each capsule is marked. If all capsules cannot be identified, localization by ultrasound or radiograph may be necessary. The area is then cleansed with Betadine and a local anesthesia is administered prior to making an incision where all the capsules converge. Additional anesthesia should then be given under the base of each capsule and behind each capsule for about a 1 cm of its length. In addition to providing anesthesia this will serve to raise the capsules. Injection of the anesthetic above the capsules may obscure their location and this should be avoided. Pressure is then applied to the distal end of the implant toward the incision to see if the tip can be “milked” into view. Most of the time, a fibrous sheath will be noted around the implant. This sheath should be nicked and the implant is then “milked out” through this nick and then through the incision on the arm. Unfortunately not all implants can be removed this easily; occasionally the incision will need to be probed and the capsule grabbed. Using a forceps to grab the fibrous tissue over the implant, it may be necessary to nick this tissue prior to removing the implant. Occasionally it is difficult to grab the implant with the forceps and manipulating the skin and implant to an area over the forceps may be easier than fishing for the capsule. Other techniques have been described for Norplant removal and are summarized in Table 27.7. After all the capsules are removed, a Steri-Strip should be applied and the incision dressed with sterile gauze.

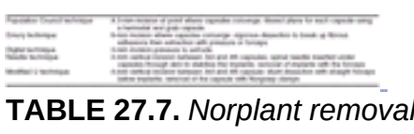

TABLE 27.7. *Norplant removal techniques*

SUMMARY POINTS

- Many gynecologic procedures can be performed in an office setting as they require minimal anesthesia and have minimal risk of complication.
- Performance of office procedures requires a clinician with sufficient training and experience and a facility with proper capabilities and appropriate staffing.
- The facility should allow for easy access, have an electronic table capable of comfortable patient positioning, and have available appropriate medical instrumentation required for local anesthesia and conscious sedation.
- Procedures that can be performed in the office include saline infusion sonography, intrauterine device placement, subcutaneous implant placement, dilation and curettage, hysteroscopy, endometrial ablation, and microlaparoscopy.

Infertility

Historically, assessment of abnormal physical findings in the gynecologic patient was limited to rudimentary plain film x-rays or exploratory surgery. Today, there are multiple diagnostic modalities including ultrasonography (US), computed tomography (CT), and magnetic resonance imaging (MRI) that can be used in the evaluation of gynecologic disorders. This chapter emphasizes the use of US for the initial evaluation of the most common gynecologic disorders for which imaging is indicated. The roles of MRI and CT are also briefly mentioned in this chapter as adjunctive tests in circumstances where sonography is nondiagnostic, or as a means to enhance diagnostic accuracy.

The use of gynecologic sonography has become widespread in gynecologists' offices and in emergency and radiology departments. Its accessibility and high patient acceptance make it applicable as an initial means for assessing many gynecologic disorders. Some practitioners have incorporated transvaginal sonography (TVS) in their routine pelvic assessment, even using it as a surrogate for a pelvic examination, particularly when the patient is obese. Others use it as a problem-solving tool only when a gynecologic disorder is suspected. Without commenting on the wisdom of following either pathway, it can be said that the US machine has become an extremely useful tool found in many, if not most, practitioners' offices. TVS is operator-dependent, and significant clinical experience with pathoanatomic correlation is required for effective use. For those who do not routinely perform pelvic sonograms as part of their practice, but rather order them, it is crucial that they have a working understanding of not only the lexicon of US but also at least a rudimentary ability to interpret the images that are collected.

In selected cases in which standard pelvic sonography is not diagnostic, however, MRI or CT may be used to better delineate anatomic abnormalities. Other advances in the use of pelvic US, such as saline infusion hysterosonography, have eliminated some of the indications for these more expensive examinations. These two imaging modalities are available only in diagnostic imaging departments and are more costly than TVS. However, their selective use may help improve the diagnostic evaluation, especially in disorders that may have only subtle sonographic findings such as adenomyosis. MRI and CT might be better suited for initial staging or workup of certain neoplasms because they can both better delineate retroperitoneal structures such as lymph nodes and images can be obtained in a variety of scan planes that may not be obtainable with US.

This chapter discusses and illustrates the common uses of these imaging modalities in evaluation of a variety of gynecologic disorders. The subsections are divided according to the most common indications for imaging evaluation of gynecologic disorders. Additional information can be found in several texts that provide more extensive coverage of this topic.

SONOGRAPHIC INSTRUMENTATION AND TECHNIQUE

A unique feature of US is that it allows orientation from an internal perspective rather than one based on external landmarks. In other words, the uterus, for example, can be viewed not just in cross-section but in its normal longitudinal orientation, much closer to the real anatomic orientation. US uses sound waves at various frequencies to allow imaging of internal organs or vessels. The sound waves emitted by the transducer are transmitted through the soft tissue and reflect off any perpendicular tissue/fluid interface and return (much like a sonar) to the transducer while a portion of the sound waves continue through until they encounter another perpendicular tissue/fluid interface and send back a reflected echo delayed in time. The US machine collates the information from the returning sound waves based on their return time and intensity and reconstructs a two-dimensional image. Both the origin of the signal, the transducer, and the receiver are contained in the same unit. Simplistically speaking, three-dimensional ultrasonography (3DUS) uses computer software to rapidly collate multiple two-dimensional images into a three-dimensional image.

The most commonly used probe or transducer configurations are those in which transducer elements are rotated (mechanical sector) and those that are made up of multiple send–receive sub-elements, in which the beam is formed by selective electronic activation (curvilinear or phased array). Other recent technologic advances allow newer US machines to make use of the physics principle known as the Doppler effect. This principle states that sound or light waves reflected by a moving object will undergo a change in frequency proportional to the relative velocity of that object, toward or away from the transducer. Detecting these frequency changes can help determine the blood flow through vessels coming to or from a structure being imaged.

US is particularly useful in defining the internal acoustic characteristics of a structure, thus distinguishing fluid-filled structures from solid structures. This makes US the imaging modality of choice in evaluating the ovary and any associated cysts or neoplasms. This imaging technique is not as well adapted to distinguish solid structures from other adjacent, or surrounding, solid structures. A perfect example of this is the ease at which an intrauterine gestational sac can be seen while a comparably sized intracavitary uterine polyp or fibroid can be quite difficult to distinguish from the adjacent endometrium or myometrium.

Diagnostic sonography of the pelvic organs can be performed using the transabdominal sonography (TAS) approach in which the uterus and adnexa are imaged through a distended urinary bladder or transvaginal sonography (TVS), in which the probe is inserted into the vagina for imaging of the uterus and ovaries. In general, the lower the frequency emitted by the US transducer, the further the penetration and the deeper the window of visibility. Therefore, TAS ordinarily uses lower frequency sound waves (3.5–5.0 MHz) to allow for the deeper penetration required to visualize underlying structures beneath a layer of subcutaneous and adipose tissue through the bladder. A TAS is useful in fully assessing the uterus if markedly enlarged or severely anteverted. Due to problems visualizing the pelvic organs through intervening tissues such as small and large bowel as well as the anterior abdominal wall, the transabdominal approach is best performed with a fully distended urinary bladder enabling a better global depiction of the uterus and adnexa (Fig. 28.1). Despite this, TAS is limited by body habitus and intervening bowel or fat that tend to increase artifact and scatter the incident US beam. In general, TAS is best used for large masses such as fibroid uteri that extend out of the pelvis above the urinary bladder. Occasionally, the ovaries of some women can be better imaged transabdominally than with a transvaginal probe, in particular those that are high in the pelvis, are adjacent to an enlarged uterus, and are very anteriorly located.

FIG. 28.1. Transabdominal sonography. **A:** Parasagittal image through right adnexal region showing right ovary (between *cursors*) and normal uterus. **B:** Parasagittal image in the transverse plane showing the transverse dimension of the right ovary (between *cursors*).

TVS uses higher frequency sound (5–8 MHz) which allows higher image resolution at the sacrifice of not being able to penetrate and “see” clearly objects more distant than 10 cm. The higher frequency sound waves used in TVS give much better definition because of the closer proximity of the transducer to the structures being imaged, although there is limited penetration. TVS is also an optimal modality with which to image obese women who have a large amount of adipose tissue in the anterior abdominal wall because the US transducer is positioned immediately adjacent to the uterus and ovaries. For most applications a tightly curved transducer probe that has high line density affords the most detailed image (Fig. 28.2). It becomes increasingly difficult to see the fundal region of the uterus as the uterus leaves the pelvis, as in the case of the large fibroid uterus. By contrast, the transvaginal component of an examination of the uterus and associated fibroids can typically better establish the relationship or proximity of the fibroids to the endometrial cavity than can TAS alone. Visual clarity with TVS is usually superior when imaging ovarian abnormalities as compared to TAS and can also be helpful as a means of distinguishing between ovarian and uterine masses. In addition, TVS with Doppler sonography affords assessment of flow of vessels adjacent to and within the uterus and ovaries.

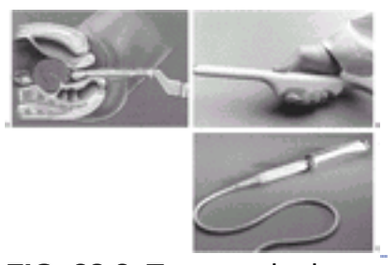

FIG. 28.2. Transvaginal sonography. **A:** Diagram showing transvaginal probe adjacent to cervix in a retroflexed uterus. (Drawing by Paul Gross, MS.) **B:** Picture of tightly curved curvilinear array transvaginal transducer probe. **C:** Flat-faced transvaginal probe with needle guide attached to the shaft.

To perform TVS, the patient is placed in the lithotomy position. After the probe is wiped with a disinfectant, it should be covered by a latex sheath before insertion into the vagina. Nonlatex vinyl covers are also available for those women allergic to latex. For optimal patient comfort, the probe should be inserted into the vagina while the operator's finger gently depresses the posterior introitus. The orientation on the screen for TVS is by convention displayed with the apex of the image at the top of the monitor. A US examination must be thorough and reproducible; for this reason, most would suggest performing each US following the same order and same routine. A complete pelvic US examination begins with images of the uterus as the central pelvic landmark in both long and short axis. The probe can be withdrawn into the midvagina and directed anteriorly to provide short-axis views of a uterus that is anteflexed. The retroflexed uterus is easily imaged without major manipulation of the probe because it is in the anatomic plane of the vagina, though some vaginal probes angle the US beam superiorly making this somewhat more difficult or uncomfortable for the patient. The operator can then orient the probe into the adnexal regions using the internal iliac artery and vein as landmarks for elineation of the ovarian fossa. The normal ovary can usually be found within close proximity to the internal iliac artery and vein but there is substantial variation in the location of the ovaries, particularly in women who have undergone hysterectomy or who have enlarged ovaries. Typically, enlarged ovaries or ovaries with cysts are relatively easy to identify while the normal postmenopausal ovary might be more difficult to visualize. The operator can use one hand to mildly compress the abdominal wall and evaluate the mobility of these organs. If there are no adhesions, the uterus and ovaries should move smoothly away from each other as the probe is advanced. This has been termed the “sliding organ sign” and, if absent, may suggest the presence of agglutinating pelvic adhesions.

Transvaginal color Doppler sonography (TV-CDS) combines the anatomic information provided by TVS with flow information provided by CDS. This probe and attached equipment are more expensive than the standard TVS scanner and do not improve acoustic visualization; rather, they allow detection of flow within blood vessels. However, TV-CDS can provide additional information that is useful in evaluating some patients with pelvic masses (Fig. 28.3). The TV-CDS involves assessment of flow within the uterus and adnexal structures. The flow to or within a structure can be quantified by analysis of the waveform using either resistive index, which is maximum systolic velocity–minimum systolic velocity, divided by maximum systolic velocity. Alternatively, the pulsatility index, which is maximum systolic velocity–maximum diastolic velocity, divided by the mean velocity, can be used. These parameters are unitless values and angle-independent parameters of relative impedance to forward flow. One must obtain signals between 30 and 60 degrees of the angle of the vessel in order to provide optimal waveforms. Waveforms reflect the change in frequency over time, which is related to flow velocity (i.e., the Doppler effect). Standard, frequency-based color Doppler is encoded with red colors indicating flow toward the transducers or blue colors indicating flow away from the transducers. A new type of processing known as *amplitude* or *power Doppler* allows determination of overall blood flow. It is more sensitive than frequency-based measurements but is degraded by motion.

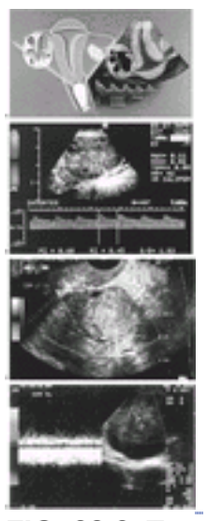

FIG. 28.3. Transvaginal color Doppler sonography (TV-CDS). **A:** Diagram showing the components of a TV-CDS, which include real-time imaging and display of vessels, with subsequent selection of sample volume for Doppler analysis by evaluation of the Doppler waveform. (Drawing by Paul Gross, MS.) **B:** TV-CDS showing low-impedance flow (resistive index = 0.45; pulsatile index = 0.60) within the wall of a corpus luteum. See color figure 28.3.

The technique of TV-CDS is highly operator-dependent but can provide important information as to the character of the blood flow in the uterus and adnexal structures. Depending on the clinical indication, the examination should include evaluation of arterial and venous blood flow to and within the uterus and ovaries. There is a range of sensitivity to flow between scanners from different manufacturers and there is no minimal clinical standard.

Documentation of US studies performed, particularly in an office setting, represents a major issue. Hard copy images should be included as part of the patient's medical record. In the past, hard copy images or videotaping of the study were the only ways to objectively document what was found. More recently, many have begun digitalizing the images and storing them on optical or compact disk devices. This method of documentation and storage of US images has the advantage of being readily available for review without loss of image quality over time. When digital storage of images is used, there should always be safeguards in place to avoid loss or destruction of the information saved, a standard no different than what we should adhere to with hard copy images. US is, to some extent, subjective and attempts to document results of a US are incomplete without a narrative description of the overall impression by the operator.

While becoming more widely available and used in obstetric practice, the clinical value of 3DUS in gynecology over the standard technique has yet to be proven. It has been shown to be efficient and accurate in detecting müllerian abnormalities (Fig. 28.4) and shows promise in some urogynecologic applications. Some investigators have shown 3DUS volumetric measurements of embryonic pole and gestational sacs to be predictive of pregnancy outcome, while others have shown that 3DUS may enhance sensitivity in the diagnosis of ovarian neoplasms. It appears likely that 3DUS will be more frequently used in the future as its role is further clarified and accepted or proven to be of benefit in specific clinical circumstances.

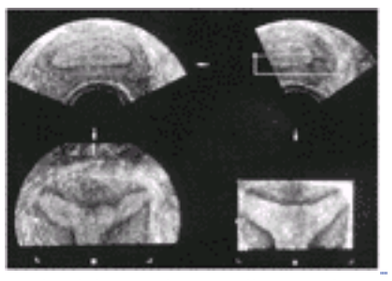

FIG. 28.4. Three-dimensional ultrasound examination of a septate uterus. **Upper left:** Transverse view of the uterus at the plane indicated. **Upper right:** Uterus in the longitudinal plane. **Lower left:** Coronal section. **Lower right:** Composite three-dimensional rendering that can be manipulated with computer software in a variety of ways, enhancing diagnostic accuracy.

Abnormal Uterine Bleeding

TVS has an important role in the evaluation of women of reproductive age presenting with unexplained uterine bleeding. TVS can help distinguish dysfunctional uterine bleeding (i.e., hormonally related) from mechanical or anatomic sources of abnormal bleeding (i.e., uterine leiomyomas, polyps, retained IUD, etc.). Because of the proximity of the transvaginal probe to the uterus, the endometrial and myometrial architecture can be accurately depicted in detail in most patients. However, high resolution delineation of the uterus requires proper imaging technique. For example, because the endometrium is not a precise geometric shape, operator error can account for over- or underestimation of its thickness. Thus, it is of utmost importance to orient the scan of the endometrium for measurement purposes in its greatest long-axis plane and maximal thickness in the fundal region, which optimizes its bi-layer measurement (Fig. 28.5). Saline infusion sonohysterography (SIS) has become an important and effective adjunct to standard TVS and replaced more costly procedures such as pelvic MRI. The endometrial cavity is a potential space where the opposing anterior and posterior uterine walls are normally in contact with, but not adherent to, each other. A fibroid or polyp within the endometrial cavity is often difficult to visualize on standard TVS because its US characteristics are similar to the contacting endometrium or myometrium. SIS uses saline as an acoustic contrast medium that distends the endometrial cavity and that enables visualization of any structures within the space in greater detail than with TVS alone where both uterine walls are in contact (Fig. 28.6). With saline infused into the cavity, the walls of the uterus separate and polyps or intracavitary fibroids that might otherwise have been missed are readily visualized. SIS also has been shown to be useful in evaluating müllerian abnormalities such as distinguishing uterine septa from a bicornuate uterus.

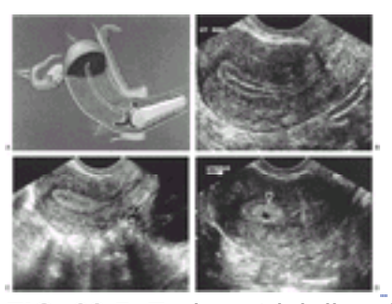

FIG. 28.5. Endometrial disorders. **A:** Diagram showing proximity of the endometrium of an anteflexed uterus to the transvaginal probe. The field of view depicting the long axis of the uterus and endometrium is shown. (Drawing by Paul Gross, MS.) See color figure 28.5A. **B:** Transvaginal sonogram showing multilayered endometrium typical of follicular phase endometrium. **C:** Typical secretory phase endometrium demonstrating increased thickness (between cursors) and homogeneous echogenicity. **D:** Echogenic mass (*arrowhead*) within endometrium containing punctate cystic area representing an endometrial polyp.

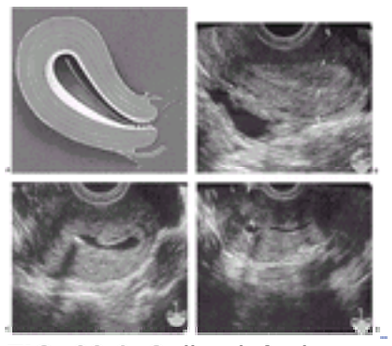

FIG. 28.6. Saline infusion sonohysterography (SIS). **A:** Diagram showing intrauterine catheter used for distension of lumen with saline for detailed evaluation of the endometrium from the inside. (Diagram by Paul Gross, MS.) See color figure 28.6A. **B:** Standard transvaginal ultrasonography showing a secretory phase endometrial stripe. **C:** Same uterus evaluated with SIS revealing an anterior endometrial polyp not seen with standard sonography. **D:** SIS revealing intrauterine synechiae with saline having filled above and below the adhesion. On standard sonography the endometrial stripe appeared normal, with a 6-mm thickness.

Clinically, it is important to remember that the differential diagnosis of premenopausal women presenting with bleeding is different from bleeding seen in postmenopausal women. In general, premenopausal bleeding is usually associated with anovulation or some mechanical factor such as intracavitary fibroids or endometrial polyps, whereas a variety of pathologies including atrophic endometritis, hyperplasia, and endometrial carcinoma are most common in the postmenopausal woman.

In women of childbearing age, the endometrial thickness varies according to the stage of the menstrual cycle. During menses, the normal endometrium is 3- to 5-mm thick with a mildly echogenic texture. Real-time examination of the endometrium while a patient is menstruating will often allow visualization of myometrial contractions associated with an efflux of solvent. As the endometrium proliferates in the periovulatory period, a multilayered texture can be seen with thicknesses ranging from 5 to 8 mm. The outer echogenic layer represents the basalis, whereas the inner layer is the enlarging functionalis. In the secretory phase, the endometrium becomes diffusely echogenic and enlarges up to 12 to 14 mm in thickness.

No specific US findings confirm anovulation as the cause of abnormal bleeding. In essence, all other potential anatomic or pathologic sources of bleeding must be excluded before arriving at the diagnosis of dysfunctional or anovulatory uterine bleeding. There are several US findings that are suggestive of an intracavitary abnormality that might be the source of abnormal bleeding such as a thickened endometrium, an endometrial stripe that is distorted, or an acoustic appearance that is not uniform or is heterogenous.

Uterine fibroids are clonal expansions that disrupt the normal arrangement of the myometrial bundles and are typically hypoechoic or of mixed echogenicity when compared to normal myometrium. Some fibroids contain calcifications that appear as areas of high acoustic reflection similar to that seen in bone. The pedicle of a subserosal fibroid can often be demonstrated during scanning and palpation of the mass relative to actual uterine body. The effect of submucosal fibroids on the endometrium can be assessed by visualizing the endometrial stripe in the area immediately adjacent to the fibroid. Submucosal fibroids typically displace and thin the overlying endometrium, something best visualized with SIS. Occasionally, fibroids may be present as solid masses in the adnexal regions, representing either interligamentary or pedunculated tumors. Endometritis usually produces a thickened endometrium sometimes surrounding intraluminal fluid but neither of these findings is pathognomonic. Intraluminal fluid may be seen in postmenopausal women and is usually a benign finding as long as the single-layer thickness of the endometrium is less than 4 mm. Intracavitary fluid collections due to a hematometra or pyometra may also be seen in the presence of cervical stenosis, particularly in the setting of secondary amenorrhea.

One of the more valuable roles of TVS is evaluating unexplained bleeding in the postmenopausal woman. Typically, an endometrial stripe thickness of less than 3 mm is observed in postmenopausal women not on hormone replacement therapy (HRT) and 2- to 3-mm thicker in those on HRT. In patients with a thickened or highly echogenic endometrium, TVS can suggest the presence of abnormal histology such as hyperplasia or endometrial polyps, but it is not histologically specific. That is to say, there is no endometrial stripe thickness above which carcinoma or hyperplasia is always found and conversely no thickness below which cancer is never encountered. Many studies have been published assessing whether there is an optimal cutoff below which one can safely presume a low likelihood of pathology and avoid invasive diagnostic procedures to assess endometrial histology. Earlier meta-analyses concluded that using 5 mm as the cutoff, irrespective of whether the patient was on HRT, resulted in a sensitivity of 92% in identifying any endometrial pathology and 96% for detecting carcinoma. An endometrial thickness of less than 5 mm was associated with a significantly reduced risk of an underlying carcinoma. More recent literature suggests that this 5-mm cutoff is not as reliable. For this reason,

especially in the face of continued bleeding or in a high-risk patient, tissue sampling should always be considered.

Pelvic Mass

Sonography provides a means to evaluate the size, location, and internal acoustic characteristics of pelvic masses (Fig. 28.7). Larger masses (over 10 cm) may best be delineated using TAS. TVS provides important information about the location of the pelvic mass relative to the ovary and uterus and provides higher resolution for better delineation of the internal architectural characteristics compared with TAS. CDS can assess vascular integrity in cases of possible torsion or detect neovascularity, helpful in predicting whether a mass is benign or malignant. This is less frequently performed in an office setting due to the expense of a US unit with CDS capability and the high level of training required to perform CDS. A general outline of diagnostic considerations according to location and internal acoustic characteristics is shown in Table 28.1.

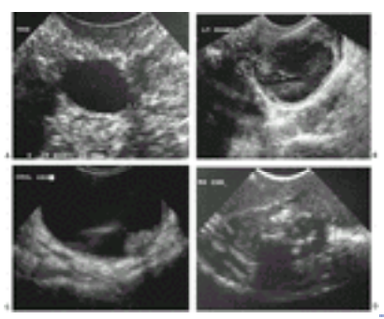

FIG. 28.7. Pelvic masses. **A:** Transvaginal sonogram of a smooth-walled cyst (between cursors) exhibiting the sonographic features consistent with a functional or physiologic cyst. **B:** Hemorrhagic corpus luteum with organized hemorrhage containing thin fibrin strands and internal echoes within the mass. **C:** Papillary excrescence arising from the wall of a mostly cystic ovarian mass. This morphologic feature is highly suggestive of cancer. **D:** Mass containing several echogenic foci and solid areas indicative of a dermoid cyst.

TABLE 28.1. *Differential diagnoses of pelvic masses by TAS and TVS*

Any woman of childbearing age can have a physiologic or functional “cyst” present when undergoing TVS. Most of these functional “cysts” demonstrate fluid free of internal echoes and smooth walls. The cysts have no internal septations and are typically less than 5 cm in size. In the follicular phase, there may be multiple unilocular cysts less than 2 cm in size that represent the pool of available developing follicles from which a dominant follicle is selected. Following ovulation, this dominant follicle becomes a corpus luteum, which is also typically a smooth-walled unilocular “cyst” but with more internal echoes. Labeling these physiologic structures “cysts” is the source of a great deal of unnecessary concern for women that can be best avoided by using terms such as “follicle” instead of “cyst” or by emphasizing the fact that these are completely normal findings in women of reproductive age. In the absence of abnormal or suspicious US findings or in the absence of symptoms such as continuing pelvic pain, repeat sonography of physiologic or functional-appearing cysts found on US is unnecessary.

Up to 15% of asymptomatic postmenopausal woman have been shown to have simple ovarian cysts with acoustic characteristics associated with benign histology. Indeed, one of the pitfalls of the readily available office US may be that incidental masses might be found in this age group, prompting unnecessary surgery. It has been shown that the risk of malignancy in unilocular cysts with a mean diameter less than 5 cm is very low in both premenopausal and postmenopausal women. Conservative management should therefore be the method of choice for women with such cysts identified by TVS. Larger “unilocular” simple cysts have been shown to have higher rates of actually having small papillations or internal growths that were undetectable by TVS and higher rates of malignancy, and thus warrant surgical excision

In the premenopausal woman, it is important to differentiate functional cystic masses that may spontaneously regress from ovarian neoplasms that will persist or continue to enlarge. Hemorrhagic corpus luteum cysts typically exhibit thin fibrin strands of echogenic material within a mostly hypoechoic mass contained by a somewhat thickened and irregular wall. On the other hand, the presence of a papillary excrescence or irregular and thickened internal septations is more indicative of ovarian neoplasms. The morphologic findings of early ovarian cancers can be subtle, but persistent internal septations with irregularity suggesting papillations, especially with any increase in peritoneal fluid, suggests the possibility of malignancy and warrants surgical intervention.

Although the sonographic appearance of masses are typically nonspecific and cannot give a precise diagnosis, there are a few patterns that demonstrate relatively high specificity. One of these is the “ground glass” appearance of an ovarian endometrioma, the other is the echogenic focus seen within benign cystic teratomas. With the improved resolution of modern US scanners, it is not uncommon to see small teratomas that appear as heterogenous echogenic regions within a normal ovary. If a dermoid cyst is found in one ovary, it is important to evaluate the contralateral ovary carefully because approximately 15% of patients have bilateral dermoid cysts.

The TV-CDS provides an adjunctive evaluation of patients with pelvic masses to help lessen the potential of the mass being malignant (Table 28.2). For best results, the TV-CDS findings need to be correlated with morphologic and clinical findings. Although the technique has some limitations, it is helpful in preoperative assessment of women with pelvic masses. Depending on the patient population studied, diagnostic accuracies in the 80% to 90% range have been reported. There is some overlap of impedance values between some functional and neoplastic ovarian cysts. Even so, in the proper clinical setting, TV-CDS improves the confidence in distinguishing benign from malignant lesions over that possible with TVS alone. Malignant lesions tend to have abnormally low-impedance flow, a sign of decreased vascular impedance seen in neovascularity of tumor vessels (see Fig. 28.3) with clusters of vessels in morphologically abnormal areas. The TV-CDS test has better sensitivity in the postmenopausal age group because the prevalence of ovarian cancer is higher at this age and because benign masses, which may also demonstrate low-impedance flow (pelvic inflammatory disease, endometriosis, or hemorrhagic corpora lutea), are far more prevalent in the premenopausal age group.

TABLE 28.2. *Sonographic features of benign and malignant pelvic masses*

To date, no single screening test or combination of surveillance modalities has been shown in a well-conducted clinical trial or even through substantial indirect evidence to reduce ovarian cancer mortality. The major limiting factor in screening for ovarian cancer is its low prevalence. Methods that have been extensively investigated for ovarian cancer screening have included serum tumor markers, primarily serum CA125, and TVS. For women with a known germline mutation (*BRCA1* or *BRCA2*) or with a family history suggestive of a significant possibility of a genetic predisposition to a heightened ovarian cancer risk, an effective screening strategy remains to be developed. Given the high risk in this population, most experts advocate multimodality screening with serum CA125 levels and TVS in patients who elect to delay or decline prophylactic oophorectomy.

Pelvic Pain

TVS plays an important role in evaluating patients with acute pelvic pain (Fig. 28.8). Demonstrably normal-appearing ovaries with no free intraperitoneal fluid on TVS virtually eliminate a primary ovarian source for acute pain. The uterus can be evaluated sonographically and pathologic causes of pelvic pain such as uterine fibroids, with or without degeneration, can be ruled out. TVS is relatively poor at identifying peritoneal endometriosis that is more commonly seen in the setting of chronic pain but is excellent at detecting ovarian endometriomas which can rupture and cause an acute exacerbation. If present, TVS can detect ovarian enlargement with a high degree of sensitivity. Care must be exercised, however, as presence of an enlarged ovary does not necessarily correlate with presence of symptoms. Tuboovarian

abscesses can easily be visualized by TVS and the diagnosis considered in the presence of pelvic pain, fever, and complex adnexal masses.

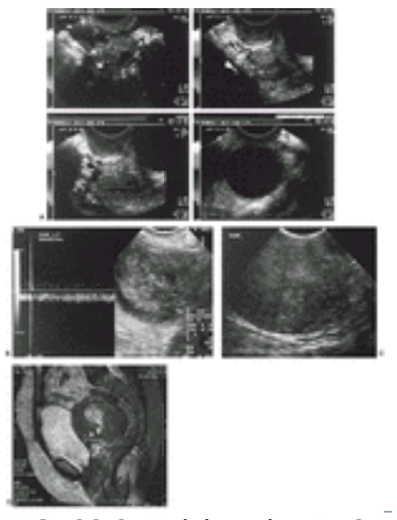

FIG. 28.8. Pelvic pain. **A:** Composite transvaginal sonogram showing enlarged left ovary (*top right* and *bottom left*) without flow and associated with a paraovarian cyst in left adnexa (*lower right*). The right ovary (*top left*) was normal, showing intraparenchymal flow. The left adnexa was found to be twisted three times and was surgically untwisted with good result. See color figure 28.8A. **B:** Doppler sonogram of enlarged left ovary containing venous flow. This finding suggests potential viability of this partial ovarian torsion. **C:** Irregular echogenic area within myometrium suggestive of adenomyosis. **D:** Sagittal T2-weighted magnetic resonance image confirming the presence of adenomyosis in the fundal region.

Ovarian torsion, a surgical emergency, must be eliminated as a cause of acute pelvic pain when a tender mass is noted on pelvic examination. TVS can confirm the presence of a complex adnexal mass and allow assessment of its size and internal acoustic characteristics. CDS provides additional useful information by determining whether there is normal blood flow to the ovary. Because venous flow is the first function affected by torsion, CDS is helpful in determining its presence or absence in an enlarged, edematous ovary. The absence of venous flow suggests the possibility of torsion in a properly performed CDS examination. It is important to examine flow in the contralateral ovary to confirm that the absence of flow is a real finding and not an artifact produced by improper color priority settings on the US machine. The CDS findings in ovarian torsion will also depend on the degree of vascular compromise and chronicity of this disorder. Intermittent ovarian torsion cannot be eliminated as a potential cause of pain even with demonstrable blood flow on CDS, though it will confirm the presence of a pelvic mass without which torsion is unlikely. CDS can also be used to confirm the reestablishment of flow after surgical detorsion. Isolated torsion of a paraovarian cyst is an infrequent event but is manifested on US by a cystic structure separate from, but adjacent to, the ovary that has absent or reversed diastolic flow.

One of the most common causes of acute pelvic pain is a hemorrhagic ovarian cyst. Blood within the hemorrhagic cyst can have several sonographic appearances. Fresh or acute bleeding within an ovarian cyst can appear echolucent. Organized clot has a more heterogenous and echogenic appearance. The hemorrhagic component typically demonstrates no flow, whereas the surrounding normal ovary has both arterial and venous flow. Free peritoneal fluid from a ruptured hemorrhagic cyst can also be observed and is certainly not rare as a cause of acute pelvic symptoms as blood is irritating to the peritoneal lining. Other ovarian neoplasms, such as endometriomas and benign cystic teratomas, can also rupture leading to peritoneal irritation accompanied by acute pelvic pain.

Often, pelvic pain originates in the uterus. Degenerating fibroids may cause severe midline pelvic pain most often seen during pregnancy. TAS or TVS can confirm the presence of fibroids though there is no specific US appearance of a fibroid with degeneration. However, the presence of fibroids on US does not necessarily mean that they are the cause of the pain as asymptomatic fibroids are quite prevalent in the general population. Adenomyosis is a cause of acute pelvic pain and may produce subtle findings that can be seen on TVS which include irregular echogenic areas in the subendometrial myometrium. Rarely, actual cystic spaces within the myometrium are seen. It can be difficult to distinguish adenomyosis or an adenomyoma from an intramural leiomyoma. The vascularity associated with adenomyosis is usually diffuse compared to that of a fibroid, but it can mimic the vascularity surrounding fibroids in appearance. Contrast-enhanced MRI has been most often used to detect the presence of adenomyosis.

When evaluating acute pelvic pain, one must also consider nongynecologic causes of pain such as appendicitis and renal calculi. An understanding of pathologic findings possible in these settings is important. On TAS, an inflamed appendix will appear as a noncompressible fusiform structure in the right lower quadrant that has a thickened (over 6 mm) wall. When ruptured, fluid may be seen surrounding the abnormal appendix. US can also detect hydronephrosis suggestive of ureteral obstruction that may accompany ureterolithiasis. In the hands of skilled operators, TAS may be able to localize renal calculi in the distal ureter in some patients; these will appear as a highly echogenic focus within the ureter. If a ureteral jet is clearly seen within the urinary bladder on CDS, ureteral patency can be confirmed and complete ureteral obstruction ruled out.

Ectopic Pregnancy

Prior to the advent of sensitive ß-human chorionic gonadotropin (ß-HCG) assays and US, the diagnosis of ectopic pregnancy was most often made after the tube had ruptured and the patient became hemodynamically unstable with an acute abdomen, necessitating immediate laparotomy. With TVS and sensitive ß-HCG assays, ectopic gestations are often diagnosed prior to the onset of symptoms, making a ruptured ectopic pregnancy much less common and providing an opportunity for medical management with methotrexate. TVS provides an accurate means for detection of ectopic pregnancy (Fig. 28.9). An ectopic pregnancy will often not be observed on TVS, but its presence may be presumed based on the absence of an intrauterine gestation in the face of a quantitative ß-HCG measurement above a “discriminatory zone,” generally (depending on the assay) around 2,000 mIU/mL. In identifying or evaluating an intrauterine fluid collection, care must also be taken to distinguish a true gestational sac from a collection of blood termed a “pseudosac.” Classically, a “double ring” sign within the uterine cavity is consistent with an intrauterine pregnancy (IUP) but the presence of either a yolk sac or fetal pole within the intrauterine fluid collection is diagnostic. There are certain clinical settings in which this discriminatory zone may be less reliable such as after a recent spontaneous abortion or where there is a multiple gestation. In the absence of assisted reproductive technologies (ARTs) (controlled ovarian hyperstimulation [COH] or in vitro fertilization), finding an IUP effectively eliminates the risk of ectopic pregnancy. In patients who have undergone controlled ovarian hyperstimulation or in vitro fertilization, heterotopic pregnancy rates are as high as 1 in 100.

FIG. 28.9. Ectopic pregnancy. **A:** Unruptured ectopic pregnancy appearing as a “tubal ring” in left adnexa. **B:** Transvaginal color Doppler sonogram showing vascularity of “tubal ring” of an unruptured ectopic pregnancy. See color figure 28.9.

On TVS, ectopic pregnancy should be suspected in the presence of a cystic circular structure in the adnexa separate from the ovary in women in whom an IUP cannot be detected. The “tubal ring” is an indication of an unruptured ectopic pregnancy when not associated with surrounding fluid. One should be able to differentiate a corpus luteum or hemorrhagic ovarian cyst from an ectopic gestation in that the corpus luteum can be delineated to be within the contour of the ovary. Another finding associated with ectopic pregnancy is the presence of intraperitoneal fluid; indeed, this is one of the more sensitive findings in patients who will require surgical intervention. The presence of intraperitoneal fluid combined with an extraovarian adnexal mass in a pregnant patient without an intrauterine gestation should be viewed as a surgical emergency. Careful examination of the uterus with TVS can also help identify cornual and cervical ectopic pregnancies as well as aid in the diagnosis of abdominal pregnancy.

CDS may provide an additional means for delineation of ectopic pregnancies based on blood flow. The CDS provides a vascular “road map” separating the ovary from other adnexal structures. The vascularity of ectopic pregnancies varies from hypovascular to hypervascular depending on the viability of the ectopic gestation. The “tubal ring” of an ectopic pregnancy will most often have increased vascularity with blood flow present circumferentially, or nearly so. If present, this “ring of fire” is highly suggestive of ectopic pregnancy. While there are no specific or unique waveforms that arise from ectopic pregnancies, a waveform showing reversed diastolic

flow can be seen in ectopic pregnancies with necrotic trophoblastic tissue.

Infertility

TVS can provide important information in the evaluation of the infertile patient (Fig. 28.10) and is indispensable in the management of COH induced by parenteral gonadotropins necessary for modern ARTs such as in vitro fertilization. During COH, TVS is used in the serial assessment of follicular maturity as well as for the evaluation of the thickness and texture of endometrium. The number of follicles and their size can be determined, with mature preovulatory follicles measuring between 18 and 20 mm. In the periovulatory period, the endometrial thickness is typically 7 to 11 mm and a trilaminar appearance of the endometrial stripe has been associated with higher rates of implantation. Prior to the widespread use of TVS for oocyte retrieval, egg collection from mature follicles was accomplished by laparoscopy under general anesthesia. Today, oocyte retrieval is routinely accomplished by a TVS-guided, multi-follicle aspiration. In addition, TVS or TAS is used to monitor the transfer of embryos to the uterus at the completion of an in vitro fertilization cycle.

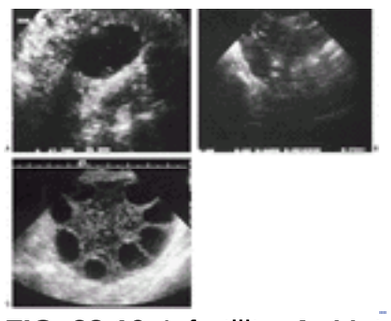

FIG. 28.10. Infertility. **A:** Mature follicle (between cursors) containing a small protrusion from the posterior wall representing the cumulus oophorus. **B:** Image taken during follicular aspiration showing echogenic needle tip within deflating mature follicle. **C:** Classic appearance of ovary seen in women with polycystic ovarian syndrome (“string of pearls”).

More recently, various investigators have used TVS in conjunction with uterine cannulation as a screening tool for assessing the endometrial cavity and tubal patency. Using various contrast media (including saline, as in SIS), the endometrial cavity can be evaluated for the presence of fibroids or polyps that may result in subfertility as well as for müllerian abnormalities such as a uterine septum often associated with recurrent miscarriage. In conjunction with SIS, the escape of saline out the fimbriated end of the tube is readily apparent in women with patent fallopian tubes as the cul-de-sac fills rapidly with fluid. The presence of cul-de-sac fluid during or after SIS confirms that at least one fallopian tube is patent. Attempts have been made to use CDS to assess in real time the efflux of echogenic contrast from each fallopian tube, with varying degrees of success.

SONOGRAPHICALLY GUIDED PROCEDURES

US can be very useful in assisting in difficult gynecologic procedures, particularly those involving the uterus. In cases in which dilation of the uterine cervix has been unsuccessful or more difficult than usual, simultaneous TVS or TAS can decrease the risk of uterine perforation and creation of a false tract. If perforation of the uterus is suspected, the path that the dilator or curette has followed, and its tip, can be readily visualized using sonography, as long as the instrument has not been moved once perforation is suspected. Traditionally, the internal US transducer was placed in the rectum or the abdominal transducer used to assist in directing the dilator as it traversed the cervix or confirmed the correct path to take. With the smaller transducers found on most vaginal US probes today, the transducer can usually be placed next to the cervix through an open speculum, particularly in patients whose cervix is flush with the vagina as in postmenopausal patients, or in those who have undergone cervical conization. Once the dilator is through the internal cervical os, TVS or TAS can localize the dilator or curette within the uterine cavity. Real-time monitoring of the procedure can virtually eliminate the risk of uterine perforation. US can also be helpful in monitoring a curettage being performed for the surgical management of either an incomplete miscarriage or early pregnancy termination. A US done at the end of the procedure can decrease the likelihood of the patient needing a second procedure at a later date by identifying those with an inadequate curettage. TAS monitoring of a mid-trimester abortion is critical to ensure complete evacuation of the uterine cavity and to decrease the likelihood of significant uterine or other organ injury. TAS can also be used to ensure correct placement of a uterine tandem being used for local radiation treatment of cervical or uterine cancer.

TVS can provide real-time delineation of the location of a needle relative to an area of interest within the ovary or adjacent structures (Fig. 28.11). For this purpose, a needle guide with an internal opening can be attached to the shaft of the vaginal transducer, which confines the course of the needle to a prescribed path in the exact plane of the two-dimensional scan. The most common use of this technique is transvaginal oocyte retrieval during an in vitro fertilization cycle, which is accomplished by aspirating individual follicles under direct US guidance. Cystic ovarian or adnexal masses may also be drained in this manner. Ovarian or adnexal masses that are amenable to transvaginal drainage include endometriomas (at the start of a controlled ovarian hyperstimulation cycle or when needed for the short-term relief of acute pain), symptomatic yet relatively small simple ovarian cysts (where there is no concern for malignancy), or hydrosalpinges (at the time of transvaginal oocyte retrieval for an in vitro fertilization cycle, particularly for those in whom surgical intervention is relatively contraindicated). Likewise, tuboovarian abscesses may be drained using the TVS-guided approach. In the case of endometriomas or hydrosalpinges, it is unlikely that transvaginal drainage will be curative, as they typically reaccumulate over time. If a cyst is drained and subsequently reaccumulates, only surgical excision will be curative.

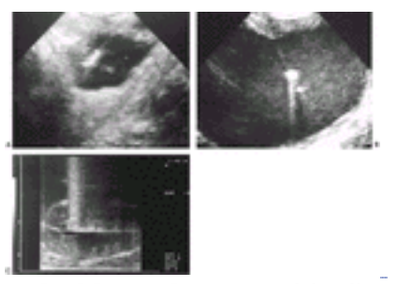

FIG. 28.11. Sonographically guided procedures. **A:** Guided aspiration of complex mass representing tuboovarian abscess. The needle tip is echogenic and within the abscess cavity. The patient defervesced after the procedure. **B:** Guided aspiration of large endometrioma. Note the classic “ground glass” appearance. The needle tip is easily seen within the mass. **C:** Transrectal sonography guidance for dilation and curettage in a patient with cervical stenosis. The curette is clearly within the lumen of the uterus.

OTHER IMAGING MODALITIES

MRI is an excellent, albeit expensive modality for secondary evaluation of a variety of pelvic disorders. These include adenomyosis, endometriosis, and certain pelvic masses such as benign cystic teratomas. The MRI provides global depiction of pelvic structures in selectable imaging planes, and it can identify lymphadenopathy associated with tumors. MRI can be particularly helpful in certain cases where it is not altogether clear if a pelvic mass originates from the ovary or from the uterus on physical examination or on US. MRI is also useful in clarifying müllerian abnormalities such as the bicornuate or septate uterus, although SIS appears to be equally effective. Enhanced MRI can also be helpful in assessing the extent of myometrial invasion in patients with endometrial cancer.

CT scanning is particularly helpful in the evaluation of the bony pelvis and has improved resolution and reduced scan times compared with MRI. Either MRI or CT may be used to delineate intraabdominal abscesses, though CT is often more readily available and less expensive. The presence of a rim-enhancing mass is diagnostic of an abscess.

SUMMARY POINTS

- Transabdominal and transvaginal scanning are both useful in establishing the source of abnormal uterine bleeding, characterizing pelvic masses found on physical examination, evaluating acute pelvic pain, diagnosing ectopic pregnancies, and assessing and treating infertility.
- Advances in technology such as higher transducer frequencies for improved resolution, rapid computerized assembly of two-dimensional images to yield virtual three-dimensional images, and smaller equipment have fostered wider clinical applications and made office use routine.
- US guidance during gynecologic surgical procedures has proved very useful in making difficult intrauterine procedures safer and diagnosing and treating selective pelvic masses by needle aspiration. It is the single most important advance in collecting oocytes for in vitro fertilization.
- Saline infusion sonohysterography has improved the diagnostic capability of TVS in circumstances of abnormal uterine bleeding.
- Pelvic US is the initial diagnostic modality of choice in most circumstances, whereas secondary tests such as CDS, MRI, and CT scanning provide a means to further enhance diagnostic specificity in difficult or nondiagnostic US studies.

Pediatric Gynecologic Examination and Problems
Pediatric Sexual Abuse
Pelvic Masses and Endometriosis
Puberty and Menstrual Disorders

Pediatric and adolescent gynecology is frequently viewed as a single focused aspect of gynecology. In fact, these two areas are reasonably distinct, with a logical division being at the onset of puberty and the activation of the hypothalamic–pituitary–ovarian (HPO) axis. Prepubertal girls differ from postpubertal girls in anatomy, etiologies of similar symptoms, and the spectrum of likely and common syndromes. Both groups however require specific communication skills. Psychosocial and developmental milestones and characteristics help guide the obstetrician and gynecologist in how to communicate with each age group in an effective manner. Involvement of the family or adult caretaker is also critical in achieving the goals of providing excellence in gynecologic care. This chapter will discuss topics in both of these age groups, with an emphasis on the differences in children and teens as compared to mature reproductive women.

EXAMINATION

Examination of the Prepubertal Child

The genital examination of the prepubertal child should be approached quite differently from the gynecologic examination of an adolescent or adult. However, the complete exam may include all of the same elements as the examination of the more mature reproductive female: examination of the external genitalia, examination of the vagina and palpation of the uterus and adnexal structures.

Examination of External Genitalia It is often helpful to examine a toddler on her mother's lap while the mother elevates or abducts the child's hips for the so-called “frog leg position.” It is important to place the child on a towel or chuck pad in case urination occurs. An older child can sit straddling her mother's lap fully clothed while mother places her legs in the stirrups. Children between the ages of 4 and 6, and sometimes as young as 3, can position themselves in classic lithotomy with use of the stirrups. Clinicians can use their hands to provide lateral and downward traction on the area of the labia majora (Fig. 29.1). This will allow full visualization of the hymen and vaginal orifice.

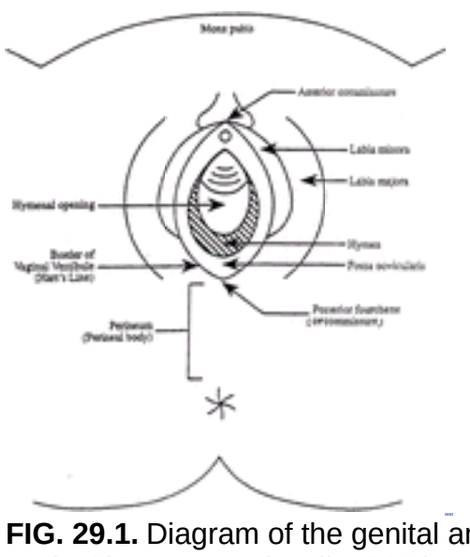

FIG. 29.1. Diagram of the genital anatomy of a prepubertal girl. This drawing shows a crescentic hymen. (From Pokorny SF. *Pediatric and adolescent gynecology.* New York: Chapman and Hall, 1996.)

Care should be taken to inform the child of the necessary steps of the exam. Continuously conversing with the child during the exam will allow her to relax.
Visualization of the Vagina Various positions have been described to visualize the vagina. In the very young infant or toddler a Valsalva maneuver can be helpful in the exam; the child can be asked to pretend she is blowing up a balloon or blowing out her birthday candles. This will often allow visualization of the distal 1 to 2 cm of the vagina. The knee–chest position is very helpful in the older child and can often be used in children 3 years of age and older. The child places her buttocks in the air with knees placed apart and allows her abdomen to sag. The examining physician and one assistant provide lateral and upward traction on the labia and buttocks. An otoscope can also be used as a magnification instrument and light source to shine into the vagina allowing visualization to the level of the cervix even without inserting the instrument. A vaginal speculum is neither appropriate nor indicated in the examination of the prepubertal child in the office (Fig. 29.2).

FIG. 29.2. The knee–chest position can be used to examine the vagina of a prepubertal child: the otoscope is used for a light source and magnification and *not* inserted into the vagina.

Examination of the Uterus and Adnexa Examination of the uterus and adnexa requires a rectal examination and should be reserved for the pediatric gynecology patient in which information regarding the uterus or adnexa is necessary in the evaluation. Rectal bimanual examination should not be done routinely in every child

requiring gynecologic examination. In prepubertal children the adnexa should not be palpable. In children, the ovaries lie at the level of the pelvic brim and drop into the pelvis with the onset of puberty. If an adnexa is palpable there is, by definition, an adnexal enlargement that will require swift and careful evaluation of a possible ovarian neoplasm. In the normal prepubertal child the uterus should be easily palpable on rectal examination. Prior to puberty two-thirds of the uterine volume is cervical in contrast to the one-third proportion in adults. The cervix, therefore, is a relatively easy structure to palpate on rectal examination in prepubertal children.

Examination of the Newborn

The obstetrician/gynecologist should be encouraged to observe the normal genitalia of the female infants that he or she delivers. Under the influence of maternal estrogens, the labia are generous in size, and the hymen is prominent and fimbriated or redundant in appearance. The female infant will sometimes experience an estrogen-withdrawal spotting episode within several days after birth. Mothers should be informed of this normal phenomenon in an effort to preclude maternal anxiety and even unnecessary visits to the pediatric emergency department (ED). In a series of pediatric patients seen in the ED of Cleveland's Children's Hospital for vaginal bleeding, the vast majority of those under the age of 2 were seen for this reason. These ED visits are completely avoidable through parental education.

Observation of the genitalia of female infants at birth allows the detection of various developmental and congenital abnormalities, some of which may be life threatening. If ambiguous genitalia are observed the obstetrician must use excellent communication skills in the delivery room to help set the stage for the evaluation of the infant and help decrease parental anxiety. The parents should be informed that the baby's genitals are not fully developed and a simple examination of the external genitalia cannot determine the actual sex. The parents should be told that they definitely have either a girl or a boy; but because development is not complete, data will have to be collected before they are told what sex the baby is and what treatment is required. Guesses must be avoided. It is critical to wait until all the information allows that the initial sex assignment given to the parents is the final and correct assignment.

The problem of ambiguous genitalia represents a social and potential medical emergency that is best handled by a team of specialists, which may include urologists, neonatologists, endocrinologists, and pediatric gynecologists. The differential diagnosis of ambiguous genitalia includes chromosomal abnormalities, enzyme deficiencies (such as 21-hydroxylase deficiency which is a form of congenital adrenal hyperplasia), and prenatal masculinization of a female fetus resulting from maternal androgen-secreting ovarian tumors or, rarely, drug exposures. The etiology of these problems, as well as intersex disorders that may be discovered in an older child can be complex.

The possibility of congenital adrenal hyperplasia (CAH) is especially critical to exclude. With the salt-wasting form of this disease, death can occur in the neonatal period so electrolytes should be immediately obtained. The presence of gonads in the labial scrotal folds in the infant with ambiguous genitalia eliminates the diagnosis of CAH.

One additional benefit of an observation of the genitalia of female infants at the time of birth is that some genital anomalies such as an imperforate hymen, vaginal agenesis, or other hymeneal anomalies (i.e., bands) may be diagnosed. Hymeneal abnormalities occur in less than 1% of newborn females and include imperforate hymens, cribriform hymens, and septate hymens. Normal hymeneal variations include hymeneal bumps, ridges, or bands. If there is any doubt about hymeneal patency, a rectal thermometer or small plastic catheter may be used to gently test for the vaginal space. Obstructive lesions include imperforate hymen, vaginal agenesis, or vaginal septa. The timing of repair of an imperforate hymen remains controversial. Some experts recommend repair at puberty after full estrogenization. Others repair imperforate hymens after the neonatal interval when convenient for the family. This approach may avoid anxiety during the critical preadolescent years of psychosexual identity if the girl perceives there is something wrong with her genitalia which is awaiting repair. In some cases a mucocolpos develops behind the imperforate hymen. This may be seen in the newborn in which the mucus production is under the direction of maternal estrogens, or at the time of breast budding in which endogenous estrogens orchestrate stimulation of mucus production. Rarely the mucocolpos may cause urinary obstruction that would necessitate urgent hymenectomy. Care must also be taken to delineate the exact anatomic nature of the obstruction and the clinician performing a hymenectomy should be comfortable that the obstruction is at the level of the hymen. Opening a thin imperforate hymen is a relatively easy surgical procedure, whereas the correction of other types of obstructive lesions such as vaginal septae requires careful planning, experience, and a high degree of skill.

Vulvovaginitis

Vulvovaginitis is the most common cause of vulvar symptoms in the prepubertal age group and the most common gynecologic complaint in prepubertal children. In children the primary site of infection is often the vulva; in contrast to mature reproductive women in which the vagina is usually the primary site of infection. Vulvovaginits in prepubertal children may be caused by specific pathogens including *Streptococcus pneumoniae, Neisseria gonorrhoeae, Chlamydia trachomatis, Shigella, Haemophilus influenzae*, and pinworms. More commonly however, the vulvovaginitis is nonspecific with no pathogenic organism responsible.

Cultures of the vagina in children with nonspecific vulvovaginitis will often reveal normal rectal flora such as *Escherichia coli*. Overgrowth of enteric bacteria can cause a primary vulvitis and a secondary vaginitis. In prepubertal children the normal flora may invade and irritate the vulvar area. This invasion in prepubertal children is due to several circumstances. First, the labia minora are thin and unestrogenized. Second, there is no anatomic barrier between the vaginal orifice and the anus since the labia majora are undeveloped and, prior to somatic growth, the anal and vaginal orifices are almost abutting one another. The unestrogenized vulva and vestibule normally appear mildly erythematous and may appear to be infected even when they are not if examined by clinicians unaccustomed to routinely examining prepubertal children. Smegma around and beneath the prepuce resembles patches of candidal vulvitis to the inexperienced examiner. The prepubertal vagina is alkaline in contrast to the acidity of the mature reproductive woman's vagina. At puberty, bacilli in the completely estrogenized vagina begin to produce larger amounts of lactic acid.

Presentation It is often difficult for a young child to describe vulvar sensations, but she may describe pruritis, pain, or a burning sensation. Parents sometimes note that the child cries during urination, scratches herself, touches herself frequently, or squirms when sitting in an effort to rub the sore vulva. Often, the child's pediatrician will have evaluated the child for a urinary tract infection (UTI) and pinworms. Vulvovaginal complaints of any sort in a young child should prompt the consideration of possible sexual abuse.
Diagnosis Most cases of vulvovaginitis are nonspecific. Specific pathogenic organisms should also be considered. When the initial presentation is compatible with nonspecific vulvovaginitis, some clinicians recommend proceeding with therapy without performing diagnostic tests. In cases where treatment was unsuccessful it is important to perform diagnostic testing for specific pathogenic organisms. This may include cultures of the vagina to rule out *S. pneumoniae, N. gonorrhoeae, C. trachomatis, Shigella*, and *H. influenzae.* Both *N. gonorrhoeae* and *C. trachomatis* cause a vaginitis rather than cervicitis in children so a vaginal culture is appropriate to exclude these pathogens. Use of DNA technology to diagnosis sexually transmitted diseases (STDs) in children is currently not recommended as a first-line diagnostic strategy by the Centers for Disease Control and Prevention (CDC). Use of indirect tests for STDs (such as enzyme-linked immunosorbent assay-based technology) is inappropriate in prepubertal children given the high possibility of false-positive results. Several methods of obtaining vaginal cultures from the vagina of children are applicable. One is insertion of a Dacron-tipped swab into the vagina moistened with nonbacteriostatic saline. Avoiding touching the hymen helps avoid any unnecessary discomfort to the child. Another method for obtaining cultures consists of placement of a catheter through which nonbacteriostatic saline can be injected, aspirated, and sent for culture.
Therapy The first step in treatment of prepubertal vulvovaginitis involves attention to vulvar hygiene and toileting. Proper wiping will decrease rectal flora in the vulvovaginal areas. In addition avoidance of vulvar irritants such as shampoo and deodorant soaps decreases the vulvar abrasion and irritation making it more difficult for the rectal flora to invade the vulvar epithelium. Sitz baths are very helpful in relieving symptomatology. Scrubbing the vulvar area should be avoided since this will only abrade the epithelium. Soaking the vulva clean is the preferable hygienic approach. A short course of broad-spectrum antibiotics can eliminate the overgrowth of enteric bacteria; however, unless the child changes her hygienic practices the nonspecific vulvovaginitis is likely to recur when colonization recurs.
Fungal Infections and Vulvovaginitis Fungal infections as a cause of vulvovaginitis are uncommon in prepubertal children. The prepubertal vagina is very alkaline and will not support fungal growth, which requires a more acidic environment. Exceptions to this rule may occur in immunosuppressed children such as organ recipients, children with human immunodeficiency virus (HIV), or children receiving high-dose steroids. Diaper rash, which may present with erythema, excoriations, and satellite lesions primarily outside the vulvovaginal area, is usually fungal related.

Labial Agglutination

Labial agglutination is another common presenting complaint in prepubertal children between 3 months and 6 years of age. These are the years of a nadir in circulating estrogens. The abraded unestrogenized labia minora agglutinate and form a telltale line at the point of the agglutination that is visible on genital examination. These girls sometimes complain of genital discomfort and dripping of urine. Urine can be trapped in the “pouch” behind the agglutination. Despite the fact that the urethra may not be visible on genital examination urinary obstruction is typically not a feature of this pediatric gynecologic problem.

Labial adhesions are extremely common, and usually asymptomatic. Some small degree of adhesions is seen in many 3- to 4-year old girls. Most experts agree that treatment should be reserved for symptomatic adhesions. The treatment consists of a short course of externally applied estrogen cream for several weeks. The area of agglutination will become thin and may spontaneously separate or can easily be separated in the office with the use of topical lidocaine jelly or anesthetic creams. It is critical that the estrogen be applied to the telltale line of adhesion and not lateral to the adhesion line. If pigmentation is seen lateral to the line of adhesion after estrogen application this indicates improper application of the estrogen cream. Manual separation of thick adhesions should not be done in the office, as it is very painful.

Attention must be given to the prevention of subsequent adhesions, as they clearly have a risk of recurring. One option is to recommend the use of a topical emollient,

such as vitamins A and D ointment to prevent reagglutination in a tapering-like manner after initial separation has occurred. Resolution of labial agglutination occurs at the onset of signs of endogenous estrogen production (breast budding).

Lichen Sclerosus et Atrophicus and Other Chronic Skin Conditions

Chronic skin conditions such as lichen sclerosus, seborrhea dermatitis, and atopic dermatitis may occur in young children. Lichen sclerosus et atrophicus (LSA) is a skin dystrophy usually seen in prepubertal girls or postmenopausal women. The appearance of LSA is consistent in both these age groups: a cigarette paper type of appearance in a figure-of-eight distribution around the vulva and anus, ending at the labia majora. Breaks in the integument with small blood blisters and abrasion are common, with inexperienced clinicians misinterpreting the condition as trauma possibly secondary to sexual abuse. LSA is particularly likely to occur in irritated vulvar areas in susceptible children. Appropriate first-line treatment in children is to prevent genital irritation and trauma. This may include avoidance of straddle activities, use of gel bike seats, and so forth. The extremely potent steroid (clobetasol) has been used in adults with success and is being used by experts in children despite a paucity of studies in this age group and the fact that clobetasol is not labeled for pediatric use. When this condition begins in childhood, it may regress with puberty, although this is not invariable.

Vaginal Bleeding

Vaginal bleeding in a prepubertal child warrants a careful investigation. The differential diagnosis of vaginal bleeding hinges on the absence or presence of other signs of pubertal development. In young children with breast development an evaluation for precocious puberty is warranted. Most children with genital bleeding will not have concomitant signs of pubertal development and local causes of the bleeding are probably present. The differential diagnosis in a child with genital bleeding without pubertal development is extensive and includes vulvar irritation/vulvovaginitis, *Shigella* vaginitis, breakdown of labial adhesions, urethral prolapse, malignant tumors of the vagina, foreign objects in the vagina, LSA, and sexual abuse.

Evaluation should include genital cultures, careful genital examination, and vaginal visualization. In cases that the vagina cannot be visualized in the office, or bleeding continues despite a negative exam, an examination under anesthesia is indicated. The exam should rule out foreign objects and rare malignant vaginal tumors (sarcoma botryroides and endodermal vaginal sinus tumors) primarily seen in girls less than 6 years of age.

Sexual Abuse

The possibility of sexual abuse should be considered in children presenting with a variety of presenting complaints including, but not limited to, vulvar vaginal symptoms, vaginal discharge, and genital bleeding. Sensitive but direct questioning of the parent or caretaker and the child by herself should be a part of any evaluation. The parent should be asked about any significant changes in behavior (such as the recent onset of nightmares, difficulties in school, changes in personality) that may accompany sexual abuse. Questioning the child who is verbal can be a useful “teachable moment” in which the physician explains the concept of the genital area as a “private zone,” and the idea that touching in this area should be reported to a parent. One concrete way to explain the “private zone” concept to a young child is to describe this as the areas that are covered by two-piece bathing suits. If the history is suspect or the injuries or physical findings are inconsistent with the reported history, a report must be made to the appropriate social service agency.

The possibility of sexual abuse must also be assessed in children presenting with genital bleeding. However it should be noted that the vast majority of children who have been sexually abused will have normal exams and not present with bleeding symptomatology. Furthermore, hymeneal size is not an accurate way to determine if a child has been abused. The genital examination in abused children usually does not differ from the exam in nonabused children. The child's history is of primary importance in the prosecution of sexual abuse. If forensic evidence is found, the source in the majority of cases is clothing and linens, which should always be collected in cases of recent assault.

Acute trauma and bleeding may result from a straddle injury or from sexual assault. Unintended trauma most commonly results in injury to the anterior vulva or laterally to the labia. Straddle injuries may result in the formation of a large vulvar hematoma, which may require evaluation. Penetrating injuries with transection of the hymen are most commonly the result of sexual assault. Any bleeding laceration of the vulva requires a careful examination to assure that there are no vaginal lacerations and to completely repair the injury. This may require an examination under anesthesia or the use of conscious sedation in the ED.

Precocious Puberty

Precocious puberty should be considered in children presenting with vaginal bleeding with or without other signs of pubertal development or in children presenting with early breast development or adrenarche. The definition of what is early development is changing. Data from a large study involving pediatric office practices indicate that African-American girls have an earlier onset of pubertal development than do Caucasian girls. Precocious puberty has traditionally been defined as pubertal development occurring before age 8. Data from pediatric office practices reveal that 27% of African-American girls and 7% of Caucasian girls had signs of breast budding or pubic hair development at age 7. Thus, the definition for precocious puberty should be reassessed in light of these data. Some experts recommend that precocious puberty be defined as breast budding prior to age 6 in African-American girls and prior to age 7 in Caucasian girls. Others argue that when other neurologic/behavior changes in African-American girls after age 6 or Caucasian girls after age 7 are associated with menarche, evaluation is warranted since these may be hallmarks of serious central nervous system (CNS) lesions. Most gynecologists will refer girls with possible precocious development to specialists for a thorough evaluation because of the rarity of the condition. The causes of precocious puberty include ovarian neoplasm, CNS lesions and tumors, McCune-Albright syndrome, and idiopathic precocious puberty.

ADOLESCENT GYNECOLOGY

Normal and Abnormal Puberty

The average age of menarche in the United States is 12.8 years (Fig. 29.3). Menstrual cycles in the first 2 years after menarche are frequently anovulatory, although the cycle length is typically regular within a range of about 22 to 45 days. Mean duration of bleeding is generally less than 7 days. The patient's estimate of quantity of menstrual flow is typically unreliable, and adolescents may have less basis for comparison than older women. Measurement of hemoglobin/hematocrit provides objective evidence of heavy bleeding.

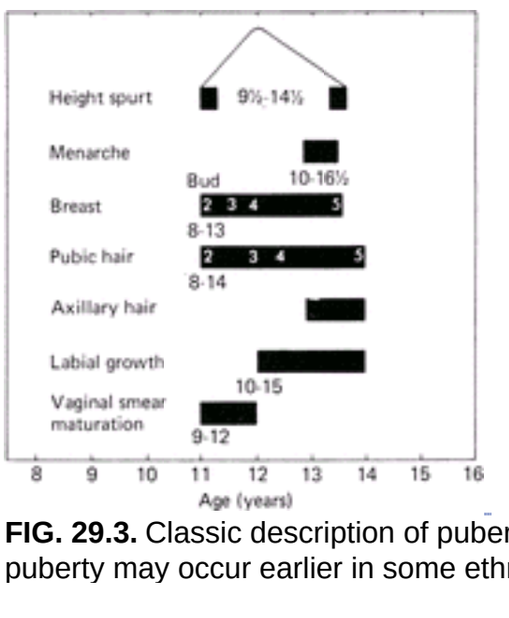

FIG. 29.3. Classic description of puberty. Numbers under each event represent the normal range of ages within which the event may occur. Newer data indicates that puberty may occur earlier in some ethnic groups. (From Tanner JM. *Growth at adolescence*, second ed. Oxford: Blackwell Scientific, 1962.)

First Gynecologic Visit

The American College of Obstetricians and Gynecologists (ACOG) Guidelines for Women's Healthcare indicates that the adolescent's first visit to an obstetrician/gynecologist should take place sometime between the ages of 13 and 15. This is in recognition of the role that obstetrician/gynecologists can potentially

play in providing preventive guidance, screening, and preventive services to adolescents. Obstetrician/gynecologists are uniquely suited to provide these services in that the consequences of adolescent risk-taking behaviors include unintended pregnancies, STDs, ectopic pregnancies, pelvic inflammatory disease (PID), and infertility—all conditions with which the gynecologist is familiar. This initial visit is an ideal opportunity to discuss normal adolescent development and concerns related to adolescents with a girl and her parents. In at least two surveys, adolescents have indicated their desire to discuss health issues such as STDs, contraception, and sexual abuse. These surveys have also indicated that these issues were infrequently addressed by clinicians.

At this visit, issues of confidentiality should be discussed with the adolescent and her parents. Numerous studies have concluded that without assurances of confidentiality, many teens will not divulge their health concerns, particularly those that relate to sex, substance use, and other risk-taking behaviors. However confidentiality does not mean secrecy. Involvement of the parent or guardian should be strongly encouraged and developed. Facilitating a discussion regarding risk behaviors between the parent/guardian and the adolescent (with the adolescent's approval) is an ideal approach.

The initial visit does not necessarily need to include a pelvic examination. The ACOG guidelines state that the provision of additional services beyond guidance and screening should be based on information obtained at this visit. If the adolescent has had intercourse, a pelvic exam, Pap test, and screening for STDs are appropriate.

When a pelvic exam is required careful attention to education and gentle technique at the first exam is particularly critical. Adolescents are less apprehensive if the clinicians describes sensations (i.e., “this will cause a pressure sensation that is not painful but may be a bit uncomfortable”) rather than only describing the purpose of the exam (i.e., “I am now putting the speculum in your vagina”). It is more important that this exam not be traumatic than that it confirm uterine or ovarian dimensions. The exam should be tailored to the needed information. If an adolescent has not been sexually active but is experiencing severe dysmenorrhea, the bimanual and rectovaginal components of the exam are more important than a speculum examination of the cervix. If a speculum exam is deemed appropriate and necessary, as with an adolescent who has had intercourse and thus requires a Pap smear and cervical cultures, an appropriately sized speculum is indicated. The Huffman or “virginal” speculum is quite narrow and can be used with a narrow or rigid hymen. However, visualization of the cervix with the Huffman speculum often requires manipulation that may be more uncomfortable than that required with the more frequently used Pederson speculum. The Pederson speculum should be the most frequently used speculum for adolescents and can be used comfortably for almost all teens. The Graves speculum, which is commonly used for adults, may be necessary for some obese or parous adolescents or when cervical procedures (colposcopy and biopsy) are indicated. Adolescents should be informed about the need for an examination; the amount of information that is provided before the exam should be tailored to the adolescent's wishes. The adolescent should be offered the opportunity to have a parent or friend accompany her during the exam. The exam itself should be performed slowly and gently with forewarning of each successive step of the exam. Pap smears are indicated for adolescents who have been sexually active, and routine screening for STDs is also recommended by the CDC.

The Guidelines for Adolescent Preventive Services (GAPS) is a set of recommendations arrived at by a panel of experts from a number of different disciplines. They are based on the rationale that:

1. The primary health threats to adolescents are behavioral rather than biomedical.
2. An increasing number of adolescents are involved in behaviors with the potential for serious consequences.
3. Adolescents are engaging in these behaviors at earlier ages.

The comorbidities that adolescents experience are related to the risk-taking behaviors of unsafe sexual practices, substance use/abuse, and violence. The GAPS report concludes that many adolescents are engaged in multiple health risks simultaneously, and most adolescents engage in some type of behavior that is a threat to their health and well-being. The multiplicity of risk factors points out the futility of trying to deal with only one specific issue. For example alcohol and drug abuse is related to irresponsible sexuality decisions and motor vehicle accidents. The ACOG guidelines were developed in an effort to screen for and detect the risk-taking behaviors that result in significant morbidities for adolescents and to provide early or preventive interventions and services.

Abnormal Bleeding

Menstrual irregularity is one of the most common presenting problems in the adolescent years. After menarche most adolescents will have an interval of anovulatory cycles. The duration of anovulation varies with the age of menarche. The earlier menarche occurs the sooner ovulatory cycles will occur. If a teen is less than 12 years of age at menarche approximately half of her cycles will be ovulatory within one year, in contrast to the teen who is 12 to 13 at menarche in whom it will be 3 years before half of the cycles are ovulatory.

During this anovulatory interval, menstrual cycles will generally be somewhere between 22 to 45 days apart with great cycle-to-cycle variation. This pattern is due to an intact HPO feedback system creating estrogen withdrawal bleeds. As estrogen climbs, follicle-stimulating hormone (FSH) levels decline, lessening follicular stimulation with a corresponding drop in estrogen. At the estrogen nadir, an estrogen withdrawal bleed is initiated. As puberty proceeds, HPO maturity progresses and levels of estrogen production become high enough to induce a luteinizing hormone (LH) surge with resulting ovulation. Cycles consistently outside the 22- to 45-day range, even in the year after menarche, are often signs of true pathology.

Differential Diagnosis of Menstrual Disorders in Adolescents

The differential diagnosis of menstrual disorders in the adolescent is very extensive and specific diseases are covered in other chapters of this text. However a basic approach is the division of the disorders into two distinct groups: those due to aberrations involving the HPO axis and those unrelated to the HPO axis (Table 29.1).

1. Aberrations in the HPO axis
a. Hypothalamic menstrual disorders
Associations
i. Stress
ii. Dietary practices
iii. Exercise
iv. Body fat
b. Endocrinopathies
i. Prolactinoma
ii. Thyroid disease
iii. Hyperandrogenic anovulation (PCOS)
iv. Congenital adrenal hyperplasia
v. Cushing syndrome
2. Normal HPO axis
a. Pregnancy
b. Bleeding disorders
c. Anatomical bleeding (cervicitis, polyp, endometritis, fibroid, congenital anomaly)

HPO, hypothalamic–pituitary–ovarian; PCOS, polycystic ovary syndrome.

TABLE 29.1. *Menstrual irregularity in the adolescent*

Examples of disorders unrelated to aberrations in the HPO axis include cervical bleeding (from cervicitis), endometritis, polyps, uterine fibroids, bleeding disorders, and abnormal bleeding related to congenital anomalies of the reproductive tract. It is most important to exclude pregnancy.

Every adolescent with a menstrual disorder should be assumed to be pregnant until proven otherwise by pregnancy testing. The potential medical consequences of missing a pregnancy-related complication dictate that a pregnancy test be performed in *all* cases of abnormal bleeding in an adolescent. The adolescent should be questioned privately without her parents about a history of sexual intercourse, whether voluntary or involuntary. In one study in which pregnancies were diagnosed in a pediatric ED, 10% had denied sexual activity. The clinician's skills will certainly be tested in the situation of an unexpected diagnosis of pregnancy. The adolescent should be strongly encouraged to tell her parent(s) or a responsible adult. Counseling about pregnancy options should take place immediately. The clinician must be aware of any relevant state laws that mandate parental notification or consent when an adolescent chooses abortion.

Bleeding from cervicitis is another important consideration. Cervicitis due to *C. trachomatis* can cause abnormal bleeding patterns. Bleeding disorders also deserve careful consideration including idiopathic thrombocytopenic purpura (ITP) and von Willebrand disease. These clotting disorders should be considered in all teens with heavy bleeding but are particularly likely to present with menorrhagia at menarche. In one series approximately half of all girls presenting with menorrhagia at menarche had a bleeding disorder.

Most menstrual irregularity in adolescents is related to aberrations in the HPO axis. These aberrations can be divided into two general groups: hypothalamic menstrual abnormalities and the endocrinopathies (see Table 29.1).

A variety of factors such as stress, body weight, exercise, and diet are related to hypothalamic menstrual disorders. The factors affect neurotransmitter patterns which in turn impact a pulsatile release of gonadotropin-releasing hormone (GnRH).

The endocrinopathies include thyroid disease, hyperprolactinemia, adult-onset CAH, and hyperandrogenic anovulation sometimes referred to as polycystic ovarian syndrome. Other rarer diagnoses include Cushing syndrome and steroid-producing ovarian tumors. All of these disorders are covered in detail in other chapters.

In teens, the hypothalamic disorders are the most common cause of menstrual cycling abnormalities. The diagnosis of a hypothalamic menstrual disorder is a diagnosis of exclusion. Historical questioning will often point toward hypothalamic causes. All teens with menstrual disorders should be specifically questioned about stress, dietary practices, their current, past, and desired body weight, and exercise practices. The physical exam should always include height, weight, temperature, and vital signs. The exam should also include consideration of physical signs of eating disorders. For example, the presence of bradycardia or carotene pigmentation may be critical findings leading to the diagnosis of a serious eating disorder.

The psychiatric definition of anorexia nervosa includes amenorrhea as one criterion. Amenorrhea may even precede severe weight loss. Anorexia nervosa should be managed by a skilled clinician familiar with the medical effects of the disorder, and psychological counseling is always indicated. When the adolescent is in counseling, the approach to the amenorrhea may become a wait-and-watch approach. There is evidence that the bone loss associated with anorexia nervosa may not be rapidly or completely reversible with the use of estrogen supplementation. In one study, approximately 50% of women with bulimia had menstrual abnormalities. Thus, eating disorders should always be considered as a possible cause when adolescents present with menstrual irregularities.

An individual with menorrhagia and signs of hirsutism should be evaluated with hormonal testing for disorders of androgen excess. For individuals without ovarian or adrenal androgen-producing tumors, oral contraceptives usually provide menstrual management and a decrease in acne and hirsutism.

Acute adolescent menorrhagia should initially be managed similarly to acute menorrhagia occurring in older women with hormonal therapy. Curettage is very rarely necessary. Various hormonal protocols have been published for severe menorrhagia including tapering regimens of combination oral contraceptives and intravenous estrogens. Well-controlled studies have not adequately compared these approaches but there is some evidence that there is no additional benefit to intravenous over oral therapy. Some clinicians are adamant that in patients with unopposed estrogens, such as those with polycystic ovary syndrome, the most critical aspect of the hormonal therapy is the progestin. The long-term approach to the patient with menorrhagia is dictated by the diagnosis; a patient with hyperandrogenic anovulation will require different ongoing therapy than the patient with a bleeding diathesis.

Primary Amenorrhea

Primary amenorrhea is defined as the absence of menses by age 15 or 16. The young woman who shows no signs of breast development by age 12 should be evaluated for delayed puberty, as should the young woman with breast development but no menses by age 15 or 16. In one large series from a tertiary referral center, ovarian failure was the most common cause of delayed sexual development. Congenital absence of the uterus and vagina and a physiologic delay of puberty were also frequently diagnosed etiologies. Other etiologies were diverse and numerically less frequent. Only 14% of all patients presenting with abnormalities of pubertal development had subsequent normal reproductive potential. All of these patients were in the physiologic delay category. Thus, the authors concluded that pubertal aberrancy should not be considered a benign entity because it is associated with significant morbidity, mortality, and compromise of reproductive potential.

Pregnancy must always be considered as a possible etiology of amenorrhea, whether it is secondary or primary amenorrhea. Just as with excessive or abnormal bleeding, the consequences of missing the diagnosis of pregnancy are serious, and a pregnancy test should always be performed to confirm the history.

Müllerian agenesis, obstructing vaginal septa and an imperfect hymen are associated with primary amenorrhea and thus are most frequently diagnosed during adolescence. Treatment options may include both surgical and nonsurgical management but should also focus attention on the psychological ramifications of this diagnosis.

Dysmenorrhea

Primary dysmenorrhea, beginning with the onset of ovulatory menstrual cycles, is common, occurring in up to 90% of adolescents. The use of nonsteroidal antiinflammatory drugs (NSAIDs) is usually helpful in relieving the prostaglandin-mediated symptoms, and many adolescents with dysmenorrhea have already tried over-the-counter (OTC) medications, although not always in appropriately therapeutic doses. Adolescents may be unaware that these drugs are more effective in relieving dysmenorrhea than other OTC analgesics. Severe dysmenorrhea and premenstrual molimina can affect the performance of adolescent activities (particularly school attendance, but also athletic endeavors) and these girls can benefit from the use of oral contraceptives. Parents may need to be informed of the potential noncontraceptive benefits of these medications, the rare risk of serious complications, and the fact that oral contraceptive use does not accelerate the initiation of sexual activity in this age group.

Adolescents who have persistent dysmenorrhea in spite of the use of NSAIDs and oral contraceptives should be evaluated for other causes of pelvic pain, such as irritable bowel syndrome and endometriosis. At one time, it was thought that endometriosis did not occur in adolescents. However, when teenagers with severe dysmenorrhea undergo laparoscopy, endometriosis can be found in a significant percentage. The percentage of adolescents with chronic pain who have endometriosis is not well established. In reported series of adolescents undergoing laparoscopy for chronic pain (generally defined as pain unresponsive to oral contraceptives and NSAIDs) up to 75% with this complaint have endometriosis. However, the percentage of teenagers with endometriosis found at laparoscopy depends on the indications for the surgical procedure and the criteria for diagnosis. Traditionally, visual confirmation was deemed sufficient; however, when strict criteria are used for diagnosis, endometriosis is not always confirmed. Endometriosis in adolescents is most frequently minimal or mild and may be atypical, with clear, white, or red lesions rather than the classic “powder-burn” lesion seen most frequently in older women. It has been suggested that there is an age-related change in the appearance and color of endometriotic lesions. There is good evidence supporting a familial occurrence of endometriosis; the evidence is most consistent with a polygenic/multifactorial etiology. An asymptomatic individual with a first-degree relative with endometriosis has a 7% risk of developing the disease.

Pelvic Masses

Pelvic masses in adolescents may be detected as a result of symptoms (pain, pressure, urinary symptoms) or signs (the presence of a pelvic or abdominal mass on examination). Pelvic masses in adolescents are most likely to be ovarian rather than uterine, although pregnancy should always be considered a possibility and ruled out.

Fewer than 5% of ovarian malignancies occur in children and adolescents. Ovarian tumors account for only 1% of all tumors in these age groups. Germ cell tumors make up one half to two thirds of ovarian neoplasms in individuals younger than 20. A review of studies conducted from 1940 until 1975 concluded that 35% of the neoplasms occurring during childhood and adolescence were malignant. In girls younger than 9 years of age, approximately 80% of ovarian neoplasms were found to be malignant. Germ cell tumors make up approximately 60% of ovarian neoplasms in girls, compared with only 20% in adults. Because neoplastic tumors are rare, these studies come from tertiary care centers and may not be representative of the true prevalence of these lesions. Some reports include only neoplastic masses, whereas others include nonneoplastic masses. One community survey of ovarian masses revealed that the frequency of malignancy was much lower; only 10% of masses were neoplastic, and only 6% of all masses were malignant. Another series reported that nonneoplastic masses in individuals younger than 20 constituted two thirds of the total; even in girls younger than 10, 60% of the masses were nonneoplastic, and two thirds of the neoplastic masses were benign.

The mature cystic teratoma (commonly referred to as a “dermoid”) is the most frequent neoplastic tumor of children and adolescents, accounting for more than one-half of ovarian neoplasms in women younger than 20. Ovarian cystectomy with careful palpation of the contralateral ovary is the best approach in order to maximize future reproductive potential in young women. Bivalving the contralateral ovary is not necessary as most contralateral tumors will be palpable.

Functional follicular cysts can occur at any age and have been reported in female fetuses, newborns, prepubertal children, adolescents, and mature reproductive women. Unilocular cysts will usually resolve spontaneously, and surgical therapy should be reserved for symptomatic masses, masses that do not resolve, suspected torsion, or masses that include a solid or multiloculated appearance on ultrasound. Attention to the long-term effects of ovarian function and future fertility dictate a conservative approach to ovarian masses in young girls; preservation of ovarian tissues with oophorocystectomy is a priority for benign tumors. Functional cysts in prepubertal girls may rarely be associated with sexual precocity, particularly when recurrent.

Unintended Pregnancy

The teen pregnancy rate in the United States is significantly higher than those seen in all other industrialized countries. However, a real decline in the U.S. teen pregnancy rate was seen in the 1990s. In 1990 the teen pregnancy rate was 117 pregnancies per 1,000 teen girls; this decreased to 97 pregnancies per 1,000 teen girls in 1996. Approximately 80% of this decline can be attributed to greater use of contraception and 20% to delay of coitus/interval abstinence.

The 1995 National Survey of Family Growth reported that more than 50% of adolescents have had intercourse. Although most of the youngest teens have *not* had intercourse, the percentage of young teens who have had intercourse has been increasing. Some of the adolescents in this survey reported the experience of

involuntary intercourse, and the younger the age at initiation of intercourse the more likely the experience was involuntary. Seventy-four percent of those who reported first intercourse at age 13 or younger reported that they had experienced involuntary intercourse.

At least 75% of adolescent pregnancies are unintended. Most (approximately 80%) adolescents use a method of contraception but do not always use the method consistently, correctly, and continuously. Developmental factors contribute to an adolescent's risk for unintended pregnancy. During early and mid-adolescence, concrete thinking is developmentally normal, and the “personal fable” and magical thinking mitigate against the reality that pregnancy could happen to the individual. Middle adolescents enjoy showing off their new “adult” bodies, frequently seek peer group approval, and feel invulnerable. However, they also have increased mobility and independence coupled with less adult supervision and protection. These factors frequently lead to risk-taking behaviors and experimentation with driving, substance use, and sexual activity. These teens may be unable to anticipate or prevent the consequences of these activities because of inexperience in abstract thinking. While they are developing the ability to perceive causal relationships and future consequences, this ability is variably applied, particularly in stressful situations such as an intimate or sexual relationship. There may be discordance among an individual adolescent's physical, social, sexual, and cognitive development. Thus, adolescents may not be developmentally equipped to use contraceptives effectively. Postponing sexual intercourse therefore is the preferred form of sexual behavior for most adolescents until they are developmentally capable of responsible sexual behavior.

Various approaches to promotion of abstinence have been studied. Curriculum-based approaches have been divided into two groups: abstinence-only and abstinence plus or sometimes labeled “comprehensive sex education.” Abstinence-only education is common given the 1996 federal law that gave states $85 million dollars in funding solely for this approach. Interestingly, in an analysis of published or known U.S. or Canadian studies with an experimental or quasi-experimental design, no programs that were abstinence-only based demonstrated a delay in sexual activity or increased contraceptive use in sexuality active teens. In contrast there have been some abstinence-plus curricula with positive results in delay of sexuality and increasing contraceptive use. It should be noted however that there are only a handful of studies on abstinence-only programs. Fortunately, a well-designed evaluation of the Title V abstinence-only programs will be available in the near future and help resolve the issue of whether abstinence- only education is effective. Given the lack of available evidence, ACOG issued a committee opinion noting the limitation of the abstinence-only approach in 1998.

Contraceptive Patterns in Adolescents

Approximately one third of adolescents wait a year after initiating intercourse before seeking medical contraceptive services, and another one third have not sought medical care. In spite of these figures, however, an increasing percentage of adolescents are using contraception at first intercourse. In 1982, 52% used no method of contraception at the time of first intercourse; in 1988, 35% reported using no method; and in 1995, 23% did not use any method of contraception at first intercourse. Birth control pills and condoms are the most popular methods of contraception among adolescents.

Adolescents generally have higher failure rates of various methods of contraception during typical use, primarily because of problems with compliance—defined for contraception as the use of a method in both a consistent and ongoing manner. Failure rates among adolescents using oral contraceptive pills can be as high as 15% to 18%; as many as 50% or more of adolescents have discontinued the method by the end of 1 year. Missed pills are frequently a problem for women of all ages but are particularly frequent among the youngest adolescents. In one study, only one-fourth of adolescents 14 or younger took their oral contraceptive pill every day. For many adolescents, the longer-term methods of contraception—depot medroxyprogesterone acetate, contraceptive patches, or contraceptive rings—may more appropriate methods, given the problems of compliance.

Sexually Transmitted Diseases

Biologic factors that impact an adolescent's risk of STD acquisition or complications include the active cervical metaplasia and ectopy, which may increase the risk of *Chlamydia* or human papilloma virus (HPV) acquisition. Aspects of adolescent development also affect the risks for STDs. The feeling of invulnerability may result in decreased use of condoms or denial of symptoms. In addition, the clinical presentation of STDs may be affected by both an excessive attention to hygiene (e.g., douching) or excessive neglect of perineal hygiene. When infection is suspected, the adolescent typically reacts with embarrassment and fear, which results in delays in seeking treatment. Once an STD is diagnosed, adolescents may fail to complete therapy, especially if symptoms decrease; they also frequently fail to keep follow-up appointments and have difficulty informing their partners of the STD acquisition.

Behavioral factors placing adolescents at increased risk include the fact that they may be more likely to have multiple sexual partners rather than single, long-term relationships; adolescents may have either concurrent partners or engage in serial monogamy. Almost half of all sexually active women between ages 15 and 19 have had two or more partners during the previous year. Teens may be more likely to engage in unprotected intercourse and may select partners at higher risk for STDs.

Adolescents have the highest rates of gonorrhea and HPV of any age group. Routine screening for *Chlamydia* is recommended by the CDC for all sexually active adolescents, regardless of other risk factors. Routine screening for *N. gonorrhoeae* should at least be done in all high-risk teens (previous STDs, multiplicity of partners), and teens living in areas where prevalence levels warrant routine screening, such as the southern United States. In many areas of the U.S. it is cost-effective to screen for both these STDS in the sexually active teen population. On careful examination the definition of high-risk teens often is the majority of sexually active teens.

Chlamydia screening has been shown in a randomized clinical trial to be associated with a lower risk of PID among those screened when compared to those individuals who were not screened. When control rates of sexual activity are applied (approximately 50% for adolescents between the ages of 15 and 19), adolescents have the highest rates of PID.

Clinicians should be aware that in the United States, all adolescents can legally consent to be screened and treated for STDs and have the right to these services without parental consent or knowledge. Barriers to STD prevention in adolescents and young adults include financial constraints, lack of transportation, discomfort with facilities and services designed for adults, and concerns about confidentiality.

Hepatitis B is the only completely preventable STD. The Advisory Committee on Immunization Practices now recommends the hepatitis B vaccination series at age 11 to 12. However, a cohort of adolescents currently exists who did not receive the vaccine at this age. Based on this finding, the American Academy of Pediatrics and ACOG both recommend that all adolescents receive the vaccine at the time of their next visit to their health care provider.

Treatment of STDs among adolescents is identical to treatment in adults. The difference in STD presentation in adolescents compared with adults relates to the developmental and risk-profile differences noted previously, which place adolescents at increased risk. In addition, problems of compliance with medication are common; single-dose therapies may thus be more appropriate for teens with uncomplicated gonorrhea or *Chlamydia* cervicitis.

SUMMARY POINTS

- This chapter has outlined and summarized the basic aspects of pediatric and adolescent gynecology, highlighting the differences from the manner in which conditions are evaluated and managed in adults. Psychosocial and behavioral factors greatly influence the health of adolescents. Preventive guidance and screening may be able to prevent or minimize these health problems.
- The gynecologic care of children and adolescents requires attention to a set of pathologic entities and treatments as well as psychosocial issues that are different from those of adults.
- A non-specific vaginitis is the most common cause of vulvovaginal symptoms in prepubertal children; sexual abuse must always be considered as a possible etiology.
- Most prepubertal children who have been sexually molested will have normal genital examinations.
- Most health threats in adolescents are related to risk-taking behaviors such as early sexual activity, alcohol, and other substance abuse.
- Menstrual irregularity in adolescents can be divided into two groups: Those due to an aberration of the hypothalamic–pituitary–ovarian (HPO) axis and those with a normal HPO axis. The aberrations are usually due to either the hypothalamic menstrual disorders or endocrinopathies. The most common cause of menstrual irregularity in teens with a normal HPO axis is pregnancy.
- Contraceptive compliance is difficult for adolescents and is the major factor that leads to higher failure rates during typical use for this age group than for older individuals.
- Adolescents with dysmenorrhea unresponsive to nonsteroidal antiinflammatory drugs and oral contraceptives may have pelvic endometriosis.

SUMMARY POINTS

SUGGESTED READINGS

> Reproductive rights embrace certain human rights that are already recognized in national laws, international human rights documents, and other relevant consensus documents. These rights rest on the recognition of the basic right of all couples and individuals to decide freely and responsibly the number and spacing and timing of their children and to have the information and means to do so, and the right to attain the highest standard of sexual and reproductive health.
>
> —Beijing Platform for Action, 1995

All women have a basic human right to determine whether and when they will become pregnant. Sexually active women and men have a wide variety of contraceptive choices for implementing this right, ranging from temporary to permanent methods. Most women have the potential to become pregnant over at least three decades and most men are fertile for an even longer period. Thus, a series of contraceptive decisions may be necessary over a reproductive lifetime. Since 2000, the range of contraceptive choices in the United States has increased, with the approval of four new contraceptive methods: An estrogen–progestogen injectable, a vaginal ring, a contraceptive patch, and a progestogen-releasing intrauterine device (IUD). This chapter focuses on information to help women and men make the contraceptive choices that best address their needs and circumstances.

CONTRACEPTIVE USE IN THE UNITED STATES AND AROUND THE WORLD

Data from the U.S. National Survey of Family Growth indicate that, in 1995, 65% of women between the ages of 15 and 44 used some method of contraception. Among women who used contraception, permanent methods were the most popular; 28% had undergone tubal sterilization and 11% had partners who had undergone vasectomy. Oral contraceptives were the most popular temporary method, but the proportion of pill users decreased from 31% in 1988 to 27% of contraceptive users in 1995, while the proportion of condom users increased from 15% in 1988 to 20% in 1995. Only 3%, 1%, and 1%, respectively, used the injectable depot medroxyprogesterone acetate, levonorgestrel implants, and IUDs. Despite this level of reported contraceptive use, 49% of pregnancies concluding in 1994 were unintended; 54% of those ended in abortion.

Globally, according to the Demographic and Health Surveys, tubal sterilization is the most common method of contraception (in 1997, 20% of couples in which the woman was of reproductive age and who used a contraceptive method, used tubal sterilization), followed by IUDs (15%), oral contraceptives (8%), and condoms (5%).

CHOOSING A METHOD OF CONTRACEPTION

Although sterilization is the most widely used method of contraception in the United States and in much of the rest of the world, it is appropriate only for women and couples who have made a decision to permanently prevent pregnancy. The initial contraceptive choices for most women and men are temporary. Factors that influence the appropriateness of any contraceptive choice include the relative safety and effectiveness of the method for the individual, the frequency and acceptability of side effects, the willingness and ability to use the method consistently and correctly, cost, and the role of religious or cultural beliefs in method acceptability. Other factors include the frequency of coitus, the length of time pregnancy is to be delayed, the impact on lactation and on the breast-fed infant, and any potential impact of the method on future fecundity. In addition, many women are at risk for sexually transmitted infections, including human immunodeficiency virus (HIV) infection, and the need for dual protection against pregnancy and sexually transmitted infections is an issue of great importance for them. Sexually active women at risk for sexually transmitted infections are best advised to consistently and correctly use condoms for both pregnancy and disease prevention, or to use another method of contraception for pregnancy prevention together with condoms for disease prevention.

The need for such dual protection produces special challenges, as there is some evidence that the use of a highly effective method of contraception other than condoms may affect a person's willingness or ability to use condoms for disease prevention.

CONTRACEPTIVE EFFECTIVENESS

Contraceptive effectiveness is measured as reduction in the probability of conception with use of a contraceptive method over a defined period; it cannot be measured directly, largely because studies cannot determine the proportion of women who would have become pregnant during that time had they not been using contraception. By contrast, contraceptive failure rates can be directly determined and are the most clinically useful measures of effectiveness.

Widely used estimates of contraceptive failure rates are shown in Table 30.1. These rates are provided in two categories: “typical use” and “perfect use.” The former is similar to “use effectiveness” and is characteristic of a typical couple starting to use a method (some use the method properly and others do not); the latter is similar to “method effectiveness,” which is the result of consistent and correct use of the method. For some methods, the typical and perfect use rates are substantially different, which indicates that the user's willingness and ability to use these methods consistently and correctly are more important than they are for those methods that have similar typical and perfect use rates. For example, according to Trussell and colleagues (see Table 30.1), although women who take a combined oral contraceptive pill each day should have a near-zero probability of pregnancy, among typical couples in which the woman initiates use of oral contraceptives, 8% experience an unintended pregnancy during the first year if they do not discontinue pill use for any other reason. By contrast, the typical and perfect use failure rates are virtually the

same for IUD users and for users of levonorgestrel implants. Published estimates of contraceptive failure rates apply to groups and may vary substantially among individuals within those groups, particularly among those who use methods with major differences in estimates between typical and perfect use. Most failure rates address the risk of pregnancy within 12 months of starting to use the method. The risk of pregnancy for some methods, particularly those that depend on proper use, is likely to decline over time.

TABLE 30.1. *Percentage of women experiencing an unintended pregnancy during the first year of typical use and the first year of perfect use of contraception and the percentage continuing use at the end of the first year in the United States*

ORAL CONTRACEPTION

Combined Oral Contraceptives

Combined oral contraceptives (COCs), containing both estrogen and progestogen, have been available in the United States since 1960, have been used by millions of women worldwide, and have been extensively studied. Formulations for oral contraceptives have changed over time from higher to lower doses of steroid hormones. Today, most COCs prescribed in the United States contain =35 µg of ethinyl estradiol. The progestogen component of COCs varies and may include norethindrone, norethindrone acetate, ethynodiol diacetate, norgestrel, levonorgestrel, norethynodrel, and the progestogens of “third generation pills”: desogestrel, norgestimate, and gestodene (gestodene is not available in the United States). Monophasic pills have constant doses of estrogen and progestogen, whereas multiphasic pills vary the doses throughout the cycle.

The primary mechanism of COCs is inhibition of ovulation by suppressing follicle-stimulating hormone and luteinizing hormone. In addition, the progestogen thickens and decreases the amount of cervical mucus, which impedes the ascent of sperm into the upper genital tract. COCs may also act by affecting the endometrium and tubal transport. Although COCs are highly effective in preventing pregnancy when used consistently and correctly, 29% of COC users reported missing one or more pills in the last 3 months in the 1995 National Survey of Family Growth. COCs are substantially less effective when used inconsistently (i.e., as seen with many typical users) (see Table 30.1).

Metabolic Effects The estrogen and progestogen components of COCs produce metabolic changes, but for most healthy women, the changes associated with the available low-dose COCs have little or no clinical significance. Estrogens generally produce changes in lipid metabolism that are considered beneficial, including slightly increasing levels of high-density lipoprotein (HDL) and decreasing low-density lipoprotein (LDL). Depending on their level of androgenicity, progestogens can counteract these effects, decreasing HDL and increasing LDL. Therefore, the net effect depends on the doses of both estrogen and progestogen as well as the type of progestogen; however, most changes are within the normal range and not clinically relevant. Although some studies of older formulations of high-dose COCs reported progestogen-associated elevated glucose and insulin levels and higher rates of relative peripheral insulin resistance, clinical studies of low-dose COCs have not found clinically significant effects on glucose metabolism. A large, cross-sectional study of U.S. women found no elevation in hemoglobin A_1C, fasting glucose, insulin, and C-peptide levels among current COC users compared with those who never used COCs. Large, prospective studies have not found increased risks of diabetes mellitus among COC users with either high-dose or low-dose pills.

Cardiovascular Diseases Epidemiologic research confirms that the overall risk of serious cardiovascular complications attributable to COC use is extremely low for the vast majority of users of modern ethinyl estradiol preparations (=35 µg). However, individual user characteristics and the type of COC modify the risk. Cardiovascular complications associated with COC use occur while the pill is being used; once pills are discontinued, risk levels return to baseline.

Hypertension COC use may slightly increase blood pressure among normotensive women, but studies suggest this increase is reversible when COC use is discontinued. Among women with mild hypertension, COC use has also been associated with increased blood pressure. In a cross-sectional study of 94 women with mild hypertension, COC users had significantly increased daytime and nighttime ambulatory systolic blood pressure values (mean 8.3 mm Hg increase for daytime and mean 6.1 mm Hg increase for nighttime). No significant differences in diastolic blood pressure values were found.

Venous Thromboembolism The incidence rate of venous thromboembolism in healthy nonpregnant Caucasian women is estimated to be 5 per 100,000 woman-years. When such women use COCs, the incidence increases to between 15 and 30 per 100,000 woman-years, or three to six times higher than non-COC users, depending on personal characteristics and the type of pill. By comparison, the risk of thrombosis associated with pregnancy is about 60 per 100,000 pregnant women. The case fatality rate of venous thromboembolism is 1 to 2 per 100 and the risk of death from thromboembolism attributable to COC use is extremely low at 1 to 5 per million per year of use. The most important risk factor for thromboembolism is family history of the disease, which is often related to genetic thrombophilia. The most common genetic cause of thrombophilia is resistance to activated protein C (factor V Leiden), which occurs in about 5% of Caucasians but is rare in non-Caucasians. The presence of factor V Leiden substantially increases the risk of COC-associated venous thrombosis; screening for the condition before starting pill use has been considered. However, cost–benefit considerations lead most authorities to recommend against screening before starting COCs unless women have a family history of thrombosis. The third-generation low-dose pills with the progestogens desogestrel or gestodene have been associated with a nearly two-fold increased risk of thrombosis relative to “second- generation” pills, which contain levonorgestrel or norethindrone. Low-dose pills containing cyproterone acetate appear to have risks similar to desogestrel and gestodene pills. Although these elevated risks are noteworthy, they are nonetheless low in absolute terms—an estimated increased risk of 4 deaths per 1 million woman-years of use.

Arterial Diseases Older age, smoking, diabetes, and hypertension are major risk factors for stroke and myocardial infarction. For women with these risk factors, COC use increases their already elevated baseline risk; thus, women with multiple major risk factors for cardiovascular disease generally should not use COCs.

Stroke The annual incidence rates of hemorrhagic and ischemic stroke in healthy, nonsmoking women between 20 and 24 years of age are estimated to be 2 and 0.5 per 100,000, respectively. In women between 40 and 44 years of age, these annual rates are 5 and 1 per 100,000, respectively. Nonsmoking women less than 35 years old with normal blood pressure who use COCs have no extra risk of hemorrhagic stroke and only a marginally increased risk of ischemic stroke. Among such women 35 years or older, the risk of hemorrhagic or ischemic stroke is increased 1.5- to 2-fold during use of COCs. Smoking and hypertension increase the COC-associated risk of hemorrhagic and ischemic stroke. Use of COCs by women with classic migraine further elevates their moderately increased risk of ischemic stroke.

Myocardial Infarction In healthy, nonsmoking women of reproductive age with normal blood pressure, the risk of myocardial infarction is extremely low and the use of COCs causes little, if any, increase in risk. On the other hand, among women who smoke, have hypertension, or have hyperlipidemia, their baseline elevated risk for myocardial infarction is substantially increased by COC use. Myocardial infarction is rare in women under 35 years old, even if they have risk factors; for women 30 to 34 years old who use COCs and smoke, the risk is estimated to be 2 per 100,000 woman-years. By contrast, women 40 to 44 years old who use COCs and smoke have an estimated risk of 25 per 100,000 woman-years. Some studies suggest that women who take pills containing the progestogens desogestrel or gestodene may have an even lower risk of myocardial infarction than that associated with the very low risk of pills containing levonorgestrel or norethindrone, but findings are inconsistent.

Malignant Neoplasia COCs clearly reduce the risk of some cancers and may increase the risk of some others. Most data are based on COCs with higher doses of estrogens and progestogens than in the currently available pills; studies suggest that lower-dose preparations are likely to have similar effects on cancer risk.

Breast Cancer A pooled analysis of 54 studies found a small increased risk of breast cancer diagnosis (relative risk = 1.24) while COCs were being used and recently after use. The excess risk was among women with localized disease, and there was a corresponding decrease in metastatic disease. These findings argue that women who use COCs are:

- simply more likely to have existing breast cancers diagnosed because they are more likely to have clinical exams or mammograms
- more likely to have late-stage promotion of tumors that subsequently are more likely to remain localized to the breast.

The observation that the duration of COC use had no effect on breast cancer risk argues for the former explanation. The excess risk of breast cancer disappears 10

years after cessation of pill use. Thus, women who use the pill from age 15 to age 35 years have the same breast cancer risk at age 50 as comparable women who never took COCs. Because the incidence of breast cancer is low at ages when COC use is most common, any effect would affect a relatively small number of women. For example, among women who stop using COCs at 25 years of age, the cumulative risk from ages 25 through 34 years is estimated to be 1 excess cancer diagnosed per 10,000 women. In women who stop COC use at age 40, when incidence rates are higher, an estimated 19 excess cancers will be diagnosed from ages 40 through 49 years. As noted, even these excess cancers may represent only an earlier detection of existing disease; at worst, they represent a small absolute excess occurrence of localized disease.

Cervical Cancer Several studies in the past suggested that using COCs for 5 years or longer increased the risk of cervical cancer 1.3- to 1.8-fold, but the causality of the association was uncertain. More recent data indicate that COC use may not be associated with cervical cancer in women without persistent genital human papilloma virus (HPV) infection or in women with HPV infection who use COCs for fewer than 5 years. However, in women with persistent HPV infection who have used COCs for 5 or more years, the risk for cancer of the cervix may well increase up to 2-fold. Available data suggest that the increased risk decreases over time after stopping pill use. Questions remain about whether the risk is related to pill use per se, to other characteristics of pill users, such as sexual behavior, or to circumstances associated with pill use, such as cytologic screening. Regardless, where screening services are available, COC users should avail themselves of these services as advised for other women.

Ovarian Cancer Use of COCs reduces the risk of epithelial ovarian cancer, the most common cancer of the ovary. Risk reduction is related to the duration of use. Using COCs for 5 years or longer confers at least a 50% reduced risk that persists for up to 15 years after cessation of use.

Endometrial Cancer COC use reduces the risk of cancer of the endometrium. As with ovarian cancer, risk reduction is related to the duration of use; after about 5 years of use, the risk of endometrial cancer is at least 50% lower than in women who never used COCs. Risk reduction persists for 15 to 20 years after stopping pill use.

Liver Cancer Primary cancer of the liver is rare in populations where hepatitis B or C is not endemic. Some studies in the 1980s pointed to a substantially increased risk of primary liver cancer after long-term use of COCs. Subsequent studies suggest that, among women free of hepatitis B or C, long-term use (>6 years) of mostly less than 50 µg ethinyl estradiol pills may be associated with a modest increased risk of primary liver cancer. In populations where chronic hepatitis is common, pill use has not been associated with primary liver cancer. Liver cancer is rare and usually fatal within 1 year of diagnosis; thus, the fact that there has been no increase in liver cancer deaths in the United States in the four decades that COCs have been in widespread use argues against a substantial risk.

Other Cancers Some studies have found a lower incidence of cancer of the colon among women who have used COCs, but it is unclear whether the association is causal. Previous claims of increased risk of tumors of the pituitary and the skin in users of COCs have not been confirmed.

Medical Eligibility Criteria for COC Use

Most women can safely use COCs. There are some conditions, however, under which COCs should not be used. These conditions include the following:

- breast-feeding and less than 6 weeks postpartum
- age =35 years and smoking =15 cigarettes per day
- multiple risk factors for arterial cardiovascular disease (e.g., older age, smoking, diabetes, hypertension)
- elevated blood pressure of =160 mm Hg systolic or =100 mm Hg diastolic
- current or history of deep vein thrombosis or pulmonary embolism
- major surgery with prolonged immobilization
- current or history of ischemic heart disease
- stroke
- complicated valvular heart disease
- migraine with focal neurologic symptoms (migraine with aura)
- migraine without focal neurologic symptoms and age =35 years
- current breast cancer
- diabetes with nephropathy, retinopathy, neuropathy, vascular disease, or diabetes of more than 20 years duration
- severe cirrhosis
- liver tumors.

In addition, there are several other conditions for which women generally should not use combined oral contraceptives (Table 30.2).

TABLE 30.2. *WHO medical eligibility criteria for contraceptive use*

Noncontraceptive Benefits of COC Use

In addition to protecting against pregnancy, including ectopic pregnancy, and the noted protection against endometrial and ovarian cancers, COC use provides other health benefits including preventing and treating menstrual abnormalities (including bleeding problems and pain); reduced risk of symptomatic pelvic inflammatory disease (PID) relative to use of no contraception (although there is no protection against lower genital tract infection and HIV infection); reduced risk of benign breast cysts; reduced risk of iron deficiency anemia; and treatment of acne. There is also some, albeit inconsistent, evidence that COCs may protect against osteoporosis and uterine fibroids. The protection against ovarian cysts, seen with higher dose COCs, is reduced in low-dose monophasic COCs and may not be present for triphasic COCs.

Return to Fertility After Discontinuing COCs

Women who discontinue COCs have no overall reduction in fertility. There may be a very short delay in time to conception compared with women not using COCs. This delay in time to conception is temporary, and by 3 to 12 months after discontinuation there are no differences in fertility rates.

Side Effects

Nausea and breakthrough bleeding are common side effects of COC use, although they often diminish or disappear after the first 3 months of use. Breakthrough bleeding may be due to the specific pill formulation, but it also may be caused by missed pills. If breakthrough bleeding lasts beyond the first 3 months of use, other gynecologic causes have been ruled out, and the bleeding is a problem for the woman, it may be beneficial to switch to a different COC formulation. Other approaches to managing breakthrough bleeding include adding oral estrogen along with the current COCs (1.25 mg conjugated equine estrogen or its equivalent, daily for 1 week at the time the breakthrough bleeding occurs), doubling up on active pills for 2 or 3 days until the breakthrough bleeding stops, doubling up on active pills through the end of the cycle, or using active pills in a continuous regimen. Nonsteroidal antiinflammatory drugs (NSAIDs) may also help alleviate breakthrough bleeding. Other common side effects associated with COCs are breast tenderness and headaches. Weight changes are often reported but most recent studies suggest that little, if any, weight gain can be directly attributed to COC use.

Progestogen-only Oral Contraceptive Pills

Progestogen-only pills are an appropriate alternative for women who desire an oral contraceptive but who are not candidates for COCs. They are commonly used by women who are breast-feeding after 6 weeks postpartum. Progestogen-only oral contraceptives act on the cervical mucus and may act on the endometrium to prevent pregnancy, but do not consistently inhibit ovulation. Progestogen-only pills are estimated to be as effective as COCs when taken consistently (see Table 30.1), but they are less forgiving of inconsistent use. The most common side effects associated with progestogen-only pill use are changes in vaginal bleeding patterns.

PROGESTOGEN-ONLY AND ESTROGEN–PROGESTOGEN INJECTABLES

Progestogen-only Injectables

Progestogen-only injectables first became available to women in the United States with approval of the U.S. Food and Drug Administration (FDA) in 1992. The injectable, containing 150 mg of depot medroxyprogesterone acetate, inhibits ovulation, produces an atrophic endometrium, and alters cervical mucus to decrease sperm penetration. Intramuscular injections are administered every 3 months (within a window of 2 weeks on either side). Most women who want to use a progestogen-only injectable can safely do so. Women with current breast cancer should not use this method. Several other conditions for which women generally should not use progestogen-only injectables are listed in Table 30.2.

The most common side effects experienced by progestogen-only injectable users are changes in vaginal bleeding patterns. During the first few months of use, many women experience irregular and prolonged bleeding. However, as use continues, bleeding becomes less frequent and up to half the women become amenorrheic by 1 year of use. Some women also report weight gain during the first several years of use; studies suggest a mean weight gain of 3 to 5 lbs per year.

Because of the highly effective suppression of ovulation leading to amenorrhea in many women, there is also a significant delay in return to fertility after discontinuation of progestogen-only injectables. The median time to pregnancy is 6 to 9 months after the last injection. Progestogen-only injectables are the only temporary contraceptives with a substantial delay in return to fertility.

Concern has been raised that progestogen-only injectable use may adversely affect bone mineral density. This question may be particularly important for adolescents, who have not yet reached peak bone mass. A meta-analysis of 12 studies concluded that women who were currently using depot medroxyprogesterone acetate had a lower average bone mineral density than non-users, with some suggestion that women with longer duration of use had greater reductions in bone mineral density. No differences in bone mineral density were found between past users and those who had never been users. One study has found that premenopausal women who discontinue progestogen-only injectables can regain much of their lost bone mass. However, whether adolescents who are still developing peak bone mass can regain bone density to normal levels has not been studied. Likewise, whether perimenopausal use will precipitate the decline in bone mass associated with menopause is unclear.

Estrogen–Progestogen Injectables

In 2001, the FDA approved the first combined estrogen-progestogen injectable for use in the United States. This injectable is administered intramuscularly on a monthly basis and contains 25 mg depot medroxyprogesterone acetate and 5 mg estradiol cypionate. Combined injectables appear to be similar to combined oral contraceptives in their mechanism of action, eligibility criteria, side effects, and safety profile. Vaginal bleeding patterns are more stable with combined injectables than with progestogen-only injectables, and most women experience a monthly withdrawal bleed. Return to fertility is not as delayed as it is with progestogen-only injectables.

LEVONORGESTREL IMPLANTS

Currently, the levonorgestrel implants in use in the United States consist of six capsules containing 36 mg of levonorgestrel for release over 5 years, with potential for effectiveness up to 7 years. A similar system, composed of two rods with 75 mg of levonorgestrel for release over 5 years, has been approved by the FDA but is not yet marketed in the United States. Both systems are inserted subcutaneously in the woman's upper inner arm, under local anesthesia. Although complications with insertions and particularly with removals have been reported, complication rates are related to the training and experience of the provider; studies show significantly fewer complications and faster removal times for the two-rod system than for the six capsules. A woman should have ready access to implant removal on request.

Levonorgestrel implants prevent pregnancy by disrupting normal ovulation in most women, including changes that range from insufficient luteal function to inhibition of ovulation. In addition, the cervical mucus becomes viscous and scanty, which inhibits sperm penetration.

Both systems are highly effective long-term methods, with little action needed by the contraceptive user. However, among the small number of women who become pregnant during use, the proportion of pregnancies that are ectopic is higher than among women who use no contraception.

Most women can safely use levonorgestrel implants. However, women with current breast cancer should not use them. Other conditions for which women generally should not use levonorgestrel implants are listed in Table 30.2.

An international cohort study of over 16,000 women followed for up to 5 years confirmed the safety of levonorgestrel implant use. This study found no significant excess risk of adverse effects for levonorgestrel users compared with controls (IUD users and women with tubal sterilization), other than small excess risks of gallbladder disease and hypertension.

Most levonorgestrel implant users experience changes in vaginal bleeding patterns, including prolonged or irregular bleeding. Although these changes are most pronounced in the first months of use and tend to diminish over time, they persist for many women. As bleeding changes are among the most common reasons for discontinuation of implants, women should be counseled about these bleeding changes before initiating implant use. Other reported side effects include weight gain, headaches, acne, and mood changes. Some women also experience persistent ovarian follicles because of the incomplete suppression of ovulation. These follicles generally disappear within 1 to 2 months and, thus, most do not require surgery.

CONTRACEPTIVE PATCH

In 2001, the FDA approved the first transdermal contraceptive patch. The patch is designed to release 20 µg ethinyl estradiol and 150 µg norelgestromin, the active metabolite of norgestimate, daily for 1 week. The patch acts similarly to oral contraceptive pills in that the user applies the patch weekly for 3 weeks, followed by a patch-free week to allow for menstrual bleeding. The patch is also similar to oral contraceptive pills in effectiveness, side effects, and incidence of breakthrough bleeding. It may be less effective among women who weigh 90 kg or more. In a study that compared the patch with an oral contraceptive, patch users experienced higher rates of breakthrough bleeding or spotting and reported more breast discomfort in the first 2 months of use, but not thereafter. Dysmenorrhea and headaches were infrequent reasons for discontinuation but were more frequent among patch users than among COC users. In clinical trials, patch users have demonstrated high compliance with method use, significantly better than COC users in one study. Over time, the patch may prove to be more effective than oral contraceptives with typical use because of increased compliance.

VAGINAL RING

Most steroid hormones are absorbed efficiently through the vaginal epithelium and can be released from vaginal rings made out of polymers such as Silastic or ethylvinyl acetate. As a delivery system, the vaginal ring is the only long-acting method that is under the user's immediate control. It can be easily inserted, checked, removed, and replaced by the user. Other advantages include the following:

- its use is not related to coitus
- it provides a constant rate of drug release, resulting in a steady plasma level of the minimum dose required for contraception
- metabolic side effects are reduced by avoiding the first-pass effect through the liver
- in the case of accidental pregnancy or if protection is no longer required, plasma levels fall rapidly to zero.

Fertility returns promptly after the ring is removed. In 2001, the FDA approved the first contraceptive ring for use in the United States. The ring, which releases 15 µg ethinyl estradiol and 120 µg etonogestrel daily, is left in place for 3 weeks and then is removed for 1 week to allow for withdrawal bleeding. Like the pill, it acts mainly by inhibiting ovulation and it is highly effective when used correctly. Experience to date suggests that it is well accepted by users and their partners and that it does not cause untoward local effects.

IUDS

Although IUDs are the most commonly used reversible method of contraception worldwide, their use in the United States has plummeted from 7.1% of married women in 1981 to just 0.5% of women between the ages of 15 to 44 years in 1995. Much of the decrease in use of this long-term, highly effective method of contraception can be attributed to concerns about the risk of pelvic infections stemming from studies of IUDs in the 1970s. In particular, the Dalkon Shield IUD was associated with an increased risk of infection and was removed from the market in 1975. Today, pelvic infection among users of modern IUDs is primarily associated with exposure to

sexually transmitted infections; the risk among IUD users at no risk for sexually transmitted infections is extremely low.

Currently, two IUDs are available for use in the United States. The most commonly used IUD is the copper T 380A, which is made of polyethylene with fine copper wire wound around the stem and copper sleeves on the two arms of the “T”. It remains effective for at least 10 years. The copper IUD is the most cost-effective method of contraception in the United States over 5 years of use. The FDA approved a progestogen-releasing IUD in 2000; this IUD releases 20 µg levonorgestrel per day for 5 years. The progestogen plays a role in the mechanism of action and decreases the amount and duration of menstrual bleeding and dysmenorrhea. Both IUDs are highly effective, with typical use failure rates ranging between 0.1% and 0.8% in the first year of use (see Table 30.1). Over the long term, IUD failure rates are similar to those of tubal sterilization, which makes it an ideal reversible alternative to sterilization for many women. Both the copper and levonorgestrel IUDs also protect against ectopic pregnancy. However, among women who become pregnant while using an IUD, the proportion of pregnancies that are ectopic is higher than it is among women who use no contraception.

The primary mechanism of action of IUDs appears to be prevention of fertilization as demonstrated by studies finding significantly decreased numbers of fertilized ova in the fallopian tubes of copper IUD users compared with women who use no contraception. IUDs also act by stimulating an inflammatory response in the uterine cavity, which decreases sperm transport, impedes the ability of sperm to fertilize the ovum, and may be spermicidal. The copper in copper-bearing IUDs enhances this response. In the progestogen-releasing IUD, the hormone also acts on the cervical mucus and ovarian function to prevent fertilization. IUDs may also act to prevent implantation if fertilization occurs.

The primary health concern with the use of IUDs has been the risk of upper genital tract infection. Early studies overestimated the association between IUD use and PID due to inappropriate control groups and lack of control for confounding factors. However, studies of modern IUDs among women at low risk for sexually transmitted infections have shown that the risk of infection is primarily associated with insertion of the IUD, is low (1 per 1,000 woman-years), and is largely limited to the first 20 days after insertion (Fig. 30.1). A randomized clinical trial of 1,833 U.S. women having IUDs inserted compared antibiotic prophylaxis to placebo and found very low rates of infection (1 participant in each group) during the 90 days after insertion. A large international cohort study reported an incidence rate of acute PID of 0.6 per 1,000 woman-years of copper IUD use. Some studies of levonorgestrel IUDs have shown decreased risk of PID compared with copper IUDs, possibly due to thickening of the cervical mucus, which could act as a barrier to bacteria; this finding needs to be confirmed in future studies. In addition, recent studies reduce concerns about any association between IUD use and tubal infertility.

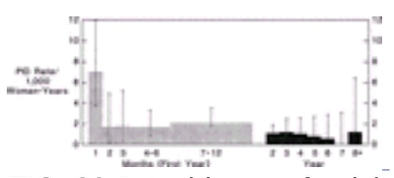

FIG. 30.1. Incidence of pelvic inflammatory disease (PID) by duration of intrauterine device use. The 95% confidence intervals are shown. (From Farley TMM, Rosenberg MJ, Rowe PJ, et al. Intrauterine devices and pelvic inflammatory disease: an international perspective. *Lancet* 1992;339:785–786.)

The IUD is an appropriate method of contraception for many women. Advantages of IUD use include it being a long-term, highly effective, reversible method, with little action required of the user. Exposure to sexually transmitted infections is one of the most important factors to assess when a woman is considering IUD use, and women with current sexually transmitted infections, PID, or increased risk of sexually transmitted infections are generally not appropriate candidates for IUDs. Young age and nulliparity are not by themselves factors that restrict IUD use, although studies have shown a higher risk of expulsion among young and nulliparous women. Some studies have shown that IUD use in nulliparous women is not associated with tubal infertility, and there is no delay in return to fertility after IUD removal. Therefore, young women and nulliparous women may be appropriate candidates for IUD use, if they are at low risk of sexually transmitted infections. Conditions for which women should not use an IUD include the following:

- pregnancy
- puerperal sepsis
- immediate postseptic abortion
- anatomic abnormalities that distort the uterine cavity
- unexplained bleeding, suspicious for a serious condition
- malignant gestational trophoblastic disease
- cervical cancer
- breast cancer (for progestogen-releasing IUDs only)
- endometrial cancer
- uterine fibroids with distortion of the uterine cavity
- PID—current or within the last 3 months
- sexually transmitted infections—current or within the last 3 months
- known pelvic tuberculosis.

Other conditions for which women generally should not use IUDs are listed in Table 30.2.

IUDs can be inserted at any time during the menstrual cycle if the woman is not pregnant. For postpartum women, immediate IUD insertion (within 10 minutes of expelling the placenta) may reduce the risk of expulsion. The IUD can also be inserted after 4 weeks postpartum without an increased risk of perforation or expulsion. However, for breast-feeding women, the progestogen-releasing IUDs generally should not be inserted until 6 weeks postpartum because of theoretical concerns about exposing the newborn to steroid hormones. An IUD can also be inserted immediately after an uncomplicated first trimester spontaneous or induced abortion, but it is recommended that insertion be delayed until involution is complete after second trimester abortions.

A pelvic exam is necessary before IUD insertion to rule out pregnancy and pelvic infection and to identify the position and mobility of the uterus. Accurate determination of uterine position is necessary to prevent perforation; the incidence of perforations with IUD insertion is about 1 per 1,000 insertions. Because the main risk of infection occurs with insertion, careful aseptic technique is required. Randomized clinical trials have not shown differences in infection rates or early discontinuation of IUD use when comparing antibiotic prophylaxis with placebo; however, there was a significant decrease in unscheduled return visits among the group who received antibiotics in one trial. Use of NSAIDs before insertion may reduce discomfort; local anesthesia is another option that is infrequently needed. Once the IUD is inserted, the woman should check for the IUD string so that she will later be able to confirm its presence and length.

IUD users have high rates of continuation—approximately 80% at 1 year of use in the United States. Increased menstrual bleeding and pain are the most common side effects reported with copper IUD use and are a primary reason for discontinuing the method. Because levonorgestrel-releasing IUDs generally reduce the amount of cramping and bleeding, women with heavy menstrual bleeding or dysmenorrhea may benefit from these IUDs. Treatment with NSAIDs has been shown to effectively reduce pain and blood loss. In contrast, amenorrhea is a major cause of discontinuation of the levonorgestrel-releasing IUD; it occurs in about 5% of users in the first year of use.

IUD expulsions occur in about 5% of users. Risk factors for expulsion include young age, nulliparity, and heavy bleeding. IUD users should check for the presence and length of the IUD strings frequently, at least after every menstrual period, to confirm that the IUD is still in place. Although pregnancy in an IUD user is an unusual event, when it does occur and the IUD strings are visible, the IUD should be removed to decrease the risk of spontaneous abortion, preterm delivery, and sepsis.

MECHANICAL BARRIER METHODS

The male latex condom is the only method of contraception proven to be highly effective in preventing both pregnancy and HIV infection when used consistently and correctly. Male condom use also reduces the risk of gonorrhea and chlamydial infection. Inconsistent or incorrect use, however, undermines this great potential benefit. Polyurethane male and female condoms have been less fully evaluated for contraception and disease prevention but consistent and correct use of these methods should also provide substantial dual protection. The potential for condoms to be highly effective if used consistently and correctly is in stark contrast to the long-standing notion that condoms are not highly effective. In fact, as shown in Table 30.1, perfect use of male condoms is more effective than typical use of oral contraceptives, which highlights the role of male condom users. It is now clear that true condom failure is infrequent but that failure to consistently and correctly use condoms is not.

Diaphragms and cervical caps may also provide some protection against some sexually transmitted infections, particularly gonorrhea and chlamydial infections, but there is substantially less evidence for this protection than for male condoms. Pending further evidence, protection against sexually transmitted infections should be

presumed to be less complete than for male condoms and protection against HIV infection should not be assumed at all.

Male Condom

The Centers for Disease Control and Prevention provide the following instructions for correct use of male condoms:

1. Use a new condom with each act of sexual intercourse.
2. Handle the condom carefully to avoid damaging it with fingernails, teeth, or other sharp objects.
3. Put the condom on after the penis is erect and before any genital contact with the partner.
4. Ensure that no air is trapped in the tip of the condom.
5. Ensure adequate lubrication during intercourse, possibly requiring the use of exogenous lubricants.
6. Use only water-based lubricants with latex condoms (oil-based lubricants can weaken latex).
7. Hold the condom firmly against the base of the penis during withdrawal, and, to prevent slippage, withdraw while the penis is still erect.

Condom breakage rates in the United States are low, about 2 broken condoms per 100 used. Proper use reduces the risk of condom breakage. Condom slippage may be more likely to contribute to pregnancies than condom breakage, which highlights the importance of following instruction 7 given above. Most condom failures are the result of inconsistent or incorrect use rather than failures of the product per se.

Female Condom

In 1993, the FDA approved the female condom for marketing and distribution in the United States. The device is a prelubricated, loose-fitting polyurethane sheath that is 17 cm in length and has a flexible ring at each end. One ring is loose inside the condom and is used to insert the condom into the vagina; the other ring lines the opening of the condom, remains outside the vagina, and covers a portion of the external genitalia during intercourse. The woman should insert the condom by holding the sheath at the closed end and grasping the inner ring; the inner ring should then be inserted toward the apex of the vagina by the index finger, making sure that the sheath is not twisted and that the outer ring remains outside the vagina. It is important that the penis is guided into the opening of the sheath to reduce the likelihood that penetration around the sheath occurs during intercourse. Thus, although this condom is female inserted, its proper use, like that of the male condom, requires the cooperation of both partners.

Diaphragm

The diaphragm is a latex, dome-shaped cup with a flexible spring rim. Diaphragms range in size from 50 to 95 mm and require vaginal examination for proper fitting. An appropriately placed diaphragm should completely cover the cervix; the posterior rim should lie in the posterior fornix and the anterior rim should fit posteriorly to the symphysis pubis, with about 1 cm between the rim and the symphysis pubis. In general, the largest diaphragm that is comfortable for the woman should be prescribed. If the diaphragm is too small, it may be displaced during coitus; if it is too large, it may cause discomfort or trauma. Diaphragms are used with spermicidal creams or jellies applied to the inside of the dome. After insertion, the diaphragm substantially reduces the risk of pregnancy for about 6 hours. If coitus occurs after that time, additional spermicidal cream or jelly should be placed intravaginally without removing the diaphragm. Likewise, additional spermicide should be placed intravaginally if coitus is repeated within 6 hours. The diaphragm should remain in place for at least 6 hours after coitus but for no longer than 24 hours to reduce the risk of toxic shock syndrome.

Cervical Cap

The cervical cap is a latex cup with a firm rim that covers the cervix and fits snugly around its base. Four sizes of the cap are available (with inner diameters of 22, 25, 28, and 31 mm). The properly fitted cap has a rim with an inner diameter that is almost the same as the diameter of the base of the cervix, so the cap remains in close contact with the cervix. The cap should be long enough to cover the entire cervix without resting on the cervical os. If the cap is too large, it is more likely to be displaced during coitus; if it is too small, it may cause trauma. The device is used with spermicide placed in the cap before insertion and is effective for 48 hours after insertion. It should be removed no longer than 48 hours after insertion to reduce the risk of toxic shock syndrome.

SPERMICIDES

Spermicides, formulated as vaginal foams, gels, creams, film, suppositories, and tablets, usually contain the surfactant nonoxynol 9 in the United States; the surfactants octoxynol and benzalkonium chloride are widely available elsewhere. Spermicides are not highly effective for contraception when used alone, even when used consistently and correctly. When used alone, or with a mechanical barrier (condoms, diaphragms, or cervical caps), spermicides should be inserted just before coitus.

The hope that vaginal use of nonoxynol 9 would reduce the risk of sexually transmitted infections, including HIV infection, has met with disappointment. Three randomized, controlled trials have failed to demonstrate any benefit in preventing HIV infection and the most recent of these suggests that frequent use of spermicides containing nonoxynol 9 may actually enhance the risk of acquiring infection; the U.S. Centers for Disease Control and Prevention and the World Health Organization now recommend that spermicides containing nonoxynol 9 not be used for prevention of sexually transmitted infections, including HIV infection. Evidence suggests that vaginal spermicides containing nonoxynol 9 are not effective in preventing cervical gonorrhea or chlamydial infection.

FERTILITY AWARENESS-BASED METHODS

Fertility awareness-based methods use signs and symptoms to estimate a woman's fertile period, during which time the couple should refrain from unprotected intercourse. Calendar methods estimate the fertile days based on the length of a woman's usual menstrual cycle; the other three fertility awareness-based methods are based on monitoring physiologic changes throughout the menstrual cycle. About 25% of typical users of fertility awareness-based methods become pregnant in the first year of use. Failure rates are based on couples who abstain from sex during the fertile period and may be different for couples who choose to use barrier methods during that time. The relatively high failure rates are partially due to inconsistent use of the method, but they are also due to the lack of reliability in estimating the fertile window. One study that measured timing of ovulation with daily urine samples found that in only 30% of women did the actual fertile window fall within the days of the fertile window as estimated from calendar calculation. Training in how to use these methods, as well as monitoring the menstrual cycles for several months, is necessary for successful use.

Calendar Methods

Calendar-based methods require abstaining from unprotected intercourse during the woman's fertile period, which is estimated from the typical length of her menstrual cycle and from assumptions about the timing of ovulation, the length of time the ovum is capable of being fertilized, and the length of time sperm can survive in the female genital tract. One method estimates the fertile period to be from the length of the shortest cycle minus 18 to the length of the longest cycle minus 11. For example, if the woman's shortest cycle was 25 days and her longest cycle was 29 days, her fertile period (i.e., when abstinence is required) would be from day 7 through day 18. Another version, the standard days method, simply states that for women whose cycle lengths are between 26 and 32 days, the fertile period is from days 8 through 19 of the cycle.

Cervical Mucus Method

The cervical mucus method entails checking the quality and quantity of cervical mucus each day; the fertile period is indicated by clear, wet, and slippery mucus. Abstinence from unprotected intercourse is necessary during menses, every other day during the preovulatory period (as intercourse interferes with interpreting the cervical mucus signs), and from the time fertile mucus appears through 3 days after the last day of fertile mucus.

Basal Body Temperature Method

The basal body temperature method is based on temperature changes throughout the menstrual cycle. A rise of 0.4 to 0.8 degrees above the mean temperature of the preovulatory phase for 3 days indicates ovulation has occurred. Therefore, abstinence is required from the time of menses until 3 days after the rise in temperature.

Symptothermal Method

The symptothermal method is the use of at least two of the previously described methods and may also rely on other changes during the menstrual cycle, including

midcycle pain and bleeding, as well as position and texture of the cervix.

EMERGENCY CONTRACEPTION

Emergency Contraceptive Pills (ECP)

Emergency contraception was once called “the best kept secret of family planning.” In the early 1970s, Yuzpe and colleagues tested combinations of ethinyl estradiol and norgestrel for postcoital contraception, based on a single dose of 50 µg ethinyl estradiol and 500 µg norgestrel. Subsequent clinical trials led them to conclude that the most successful regimen consisted of two doses of 100 µg ethinyl estradiol and 500 µg levonorgestrel, with the first dose taken within 72 hours of unprotected intercourse, and the second dose taken 12 hours later.

When started within 72 hours of unprotected intercourse, combined ECPs prevent about 75% of pregnancies. About half of users report nausea and about 20% experience vomiting. A randomized clinical trial showed that pretreatment with 50 mg of meclizine significantly reduces the frequency and severity of nausea and vomiting.

Various doses of levonorgestrel have also been tested since the 1970s for emergency contraception. A large multinational, randomized, double-blind clinical trial was conducted comparing the Yuzpe regimen and levonorgestrel treatment (one 750 µg dose followed by a second 750 µg dose 12 hours later) when started up to 72 hours after unprotected intercourse. Results showed that levonorgestrel was not only better tolerated but was also more effective than the Yuzpe regimen, preventing 89% of expected pregnancies among women who correctly used the treatment. It also showed that the earlier either treatment was taken after the act of unprotected intercourse, the more effective it was. Since then, it has been demonstrated that both 750 µg pills can be taken together in a single dose (1.5 mg levonorgestrel) with the same effectiveness and side effects as the two dose regimen.

A primary mechanism of action of ECPs is to inhibit, delay or otherwise interfere with normal ovulation, thereby preventing fertilization. ECPs may also alter the endometrium and impair implantation, although one study found that use of levonorgestrel ECPs did not impair endometrial morphology. ECP use does not disrupt an established pregnancy.

ECPs are safe for use by almost all women. Concerns about ECP distribution have included those regarding advance provision and multiple administrations. Studies have shown that women who were given an advance supply of ECPs had the same rates of unprotected intercourse as controls, followed the treatment regimen correctly, were more likely to use one dose of ECPs, but were no more likely than the control group to use ECPs repeatedly.

Emergency Use of Copper-Bearing IUDs

Copper-bearing IUDs are extremely effective when used as emergency contraception (99%). The IUD must be inserted within 5 days of unprotected intercourse. This method is most appropriate for women who want long-term, highly effective contraception, and have no contraindications to IUD use.

STERILIZATION

Vasectomy and tubal sterilization are intended to be permanent and are appropriate only for women and men who have made a fully informed and well-considered decision to permanently prevent pregnancy. Although some sterilizations are potentially reversible, depending on factors including the sterilization procedure, the length of normal fallopian tube remaining, the age of the woman (tubal sterilization), and the length of time between the sterilization and reversal procedures (vasectomy), many sterilizations are not reversible. Further, the costs of sterilization reversal or in vitro fertilization are prohibitive for many who regret having had a sterilization procedure.

Although vasectomy and tubal sterilization have been shown to be safe and highly effective, vasectomy is somewhat safer, partly because most vasectomies are done with local anesthesia and tubal sterilizations are intraabdominal procedures. Vasectomy is believed to be somewhat more effective than tubal sterilization and its effectiveness is easily assessed by semen analysis. The long-term effectiveness of vasectomy, however, has been less completely studied than that of tubal sterilization; some trials suggest that the effectiveness of vasectomy, like tubal sterilization, may vary according to the method of occlusion.

Counseling of those considering sterilization is critically important. Such counseling should include not only the anticipated risks and benefits of the surgery but also the possibility of later regretting having had the procedure. The strongest predictors of later regretting tubal sterilization are young age at the time of sterilization and substantial conflict between the woman and man at the time of sterilization. Women considering tubal sterilization should understand that pregnancy is possible even remote from sterilization, and they should understand that a high proportion of pregnancies after tubal sterilization are ectopic gestations.

Vasectomy

Vasectomy, or transection and occlusion of the vas deferens, is usually performed in an outpatient setting with local anesthesia and without premedication. After incising or puncturing the skin of the scrotum, the vas is identified, dissected free of its fascial sheath, and divided. The cut ends of the vas are then occluded by ligation, coagulation of the mucosa, or, rarely, clip application. Fascial interposition is frequently performed after ligation or coagulation by pulling the sheath over one of the vas ends and suturing it—to reduce the likelihood of subsequent spontaneous anastomosis. The most frequent complications of vasectomy are hematoma formation and infection, each of which occurs in about 2% of procedures. Death and serious morbidity are rare. No long-term serious adverse health effects have been documented, and the best available evidence suggests no effect on risk of cardiovascular disease, prostate cancer, or testicular cancer.

Although there is a substantial decrease in the concentration of sperm in the semen by 3 days after vasectomy, complete absence of sperm may take 16 weeks or more, depending in part on the number of ejaculations. Semen analysis should be performed, where feasible, after 12 weeks or 20 ejaculations and temporary contraception should be used in the interim. The time to azoospermia after vasectomy is under study and may vary according to surgical technique.

Tubal Sterilization

The proportion of sterilizations done on an interval basis (not pregnancy-associated) varies from country to country. Approximately one half of tubal sterilizations in the United States are performed after vaginal delivery or at cesarean section and the other half are performed at a time unrelated to pregnancy. The timing of the procedure with respect to pregnancy can affect the surgical approach, the method of tubal occlusion, and the choice of anesthetic. For example, interval procedures are usually performed in the United States by laparoscopy using coagulation (the bipolar technique is illustrated in Fig. 30.2), silicone rubber bands (Fig. 30.3), or clips (the spring clip technique is illustrated in Fig. 30.4) under general anesthesia; laparoscopic sterilization can be even more safely performed with local anesthesia. By contrast, procedures at the time of cesarean section require no additional anesthesia and usually involve partial salpingectomies (the modified Pomeroy method is illustrated in Fig. 30.5); procedures postvaginal delivery are performed by minilaparotomy with subumbilical incisions and likewise usually involve partial salpingectomies.

FIG. 30.2. Bipolar method. A 3-cm minimum zone of isthmic tube is desiccated with bipolar forceps. The paddles of the forceps extend across the tube onto the mesosalpinx. (From Peterson HB, Warshaw J, Pollack A. Tubal sterilization. In: Rock JA, Thompson JD, eds. *TeLinde's operative gynecology*, eighth ed. Philadelphia: JB Lippincott Co, 1997:529–547.)

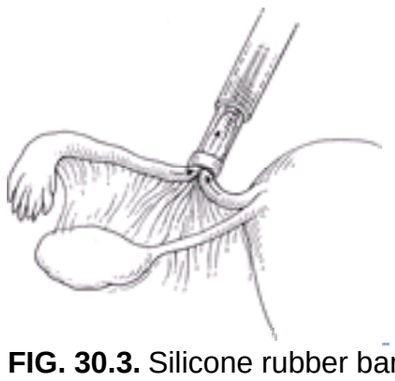

FIG. 30.3. Silicone rubber band method. The isthmic portion of the tube is retracted into the applicator barrel using grasping tongs, which should completely surround the tube. To avoid excessive traction on the tube and its mesentery, the applicator barrel is advanced toward the tube during this retraction process. (From Peterson HB, Warshaw J, Pollack A. Tubal sterilization. In: Rock JA, Thompson JD, eds. *TeLinde's operative gynecology*, eighth ed. Philadelphia: JB Lippincott Co, 1997:529–547.)

FIG. 30.4. Spring clip method. The clip is applied to the mid-isthmus at a 90-degree angle to the long axis of the tube. The hinge of the clip should be pressed against the tube, and the tips of the clip should extend onto the mesosalpinx. (From Peterson HB, Warshaw J, Pollack A. Tubal sterilization. In: Rock JA, Thompson JD, eds. *TeLinde's operative gynecology*, eighth ed. Philadelphia: JB Lippincott Co, 1997:529–547.)

FIG. 30.5. Pomeroy method. **A**: A loop of the isthmic portion of the tube is elevated and ligated at its base with one or two ties of no. 1 plain catgut suture. If performed through a minilaparotomy incision, these ties should be held long to prevent premature retraction of the tubal stumps into the abdomen when the loop of tube is transected. **B**: A fenestration is bluntly created through the mesentery within the tubal loop, and each limb of the tube on either side of this fenestration is individually cut. The cut ends of the tube are inspected for hemostasis and allowed to retract into the abdomen. (From Peterson HB, Warshaw J, Pollack A. Tubal sterilization. In: Rock JA, Thompson JD, eds. *TeLinde's operative gynecology*, eighth ed. Philadelphia: JB Lippincott Co, 1997:529–547.)

The likelihood of pregnancy after tubal sterilization varies according to age at the time of the procedure and sterilization technique (Table 30.3). The chance that pregnancies are ectopic varies by method. Among women in the U.S. Collaborative Review of Sterilization, the highest proportion of pregnancies that were ectopic occurred after bipolar coagulation (65%), followed by interval partial salpingectomy (43%), silicone rubber band application (29%), postpartum partial salpingectomy (20%), unipolar coagulation (17%), and spring clip application (15%). Further, the proportion of pregnancies that were ectopic for all methods combined increased over time, being three times as high (61%) in 4 to 10 years after sterilization as in the first 3 years (20%).

Age at sterilization	Probability of pregnancy (%) (Range)
18–27 y	
Bipolar coagulation	54.3 (28.3–80.4)
Unipolar coagulation	3.7 (0.0–11.1)
Silicone rubber band application	33.2 (10.6–55.9)
Spring clip application	52.1 (31.0–73.3)
Interval partial salpingectomy	9.7 (0.0–28.6)
Postpartum partial salpingectomy	11.4 (1.6–21.1)
28–33 y	
Bipolar coagulation	21.3 (9.6–33.0)
Unipolar coagulation	15.6 (0.0–31.4)
Silicone rubber band application	21.1 (6.4–35.9)
Spring clip application	31.3 (15.1–47.5)
Interval partial salpingectomy	33.5 (0.0–74.3)
Postpartum partial salpingectomy	5.6 (0.0–11.9)
34–44 y	
Bipolar coagulation	6.3 (0.1–12.5)
Unipolar coagulation	1.8 (0.0–5.3)
Silicone rubber band application	4.5 (0.6–8.4)
Spring clip application	18.2 (0.0–36.4)
Interval partial salpingectomy	18.7 (0.0–39.6)
Postpartum partial salpingectomy	3.8 (0.0–11.4)

[a]Cumulative probability per 1,000 procedures and 95% confidence interval.

Source: Adapted from Peterson HB, Xia Z, Hughes JM, et al. The risk of pregnancy after tubal sterilization: findings from the U.S. Collaborative Review of Sterilization. *Am J Obstet Gynecol* 1996;174:1161–1170, with permission.

TABLE 30.3. *Life-table cumulative probability of pregnancy among women undergoing tubal sterilization in the U.S. collaborative review of sterilization by age* [a]

Death from tubal sterilization is rare, 1 to 2 deaths per 100,000 procedures, with most deaths attributable to complications of general anesthesia. Major complications, principally unintended laparotomies, occur in 1% to 2% of procedures.

The potential for late sequelae of tubal sterilization has been assessed. There is strong evidence against a purported post-tubal ligation syndrome of menstrual abnormalities. Sterilized women in the U.S. Collaborative Review of Sterilization were no more likely than women whose partners underwent vasectomy to have menstrual abnormalities within 5 years after sterilization. In the same study, sterilized women were more likely to undergo hysterectomy than women whose partners were sterilized, but nonbiologic factors were likely explanations.

Young age at sterilization, regardless of the number of children, is a strong predictor of later regretting having had the procedure. Among women sterilized at 18 to 24 years who were followed in the U.S. Collaborative Review of Sterilization, the cumulative probability of requesting information about reversal within 14 years was 40%.

SUMMARY POINTS

- The effectiveness of some contraceptive methods—including oral contraceptives, barrier methods, and fertility awareness-based methods—is highly dependent on whether they are used consistently and correctly. The effectiveness of other methods—including IUDs, implants, and injectables—is less dependent on user characteristics.
- Oral contraceptives have been studied more extensively than any other method. They are nearly 100% effective if taken daily, but they are substantially less effective with typical use. For healthy, nonsmoking women, the health benefits of oral contraceptive use far exceed the health risks.
- Four new contraceptive methods are available in the United States—a contraceptive patch, a combined injectable, a vaginal ring, and an IUD. The first three deliver both an estrogen and a progestogen; the fourth delivers a progestogen alone.
- Many women who desire contraception are also at risk for sexually transmitted infections, including HIV infection. For such women, consistent and correct use of a male latex condom is highly effective in protecting against both pregnancy and some sexually transmitted infections, including HIV infection. Spermicides containing nonoxynol 9 are no longer recommended for preventing sexually transmitted infections, including HIV; frequent use of spermicides may actually enhance the risk of acquiring HIV infection.
- IUDs are highly effective and provide long-term protection against pregnancy. Women at no risk of sexually transmitted infections are at exceedingly low risk of pelvic inflammatory disease from IUD use.
- Male and female sterilization are highly effective but should be chosen only by those who wish to permanently prevent pregnancy. Young age at sterilization is a key risk factor for regretting having had a tubal sterilization.

Approximately 1.18 million abortions were performed annually in the United States in 1997. This number has decreased from the 1.61 million abortions in 1990. Each year, 2% of women of reproductive age (15–44) terminate a pregnancy legally in the United States. With the rate of abortion in the 1980s, it was estimated that 43% of women in the United States would have a pregnancy termination at some point in their reproductive life. The most recently published rate of abortion is approximately 20 per 1,000 women between the ages of 15 to 44. This rate has decreased from 25 per 1,000 women in 1990. The abortion ratio is about 306 per 1,000 live births. This ratio has decreased from 345 abortions per 1,000 live births in 1990 (Table 31.1). Regardless of contraceptive availability, about half the 6 million pregnancies occurring each year are reportedly unplanned. Of the unplanned pregnancies, approximately half are terminated by induced abortion. This rate has remained fairly constant since 1980. The typical patient seeking an abortion has been young, white, unmarried, and poor. Statistics from 1972 are indicative of the period prior to *Roe v. Wade* and the legalization of abortion in the United States (Table 31.1 and Fig. 31.1, Fig. 31.2 and Fig. 31.3). Worldwide, 53 million abortions are performed annually with 20 million reportedly being done illegally. Illegal abortions remain very unsafe and may account for 50,000 to 100,000 deaths each year.

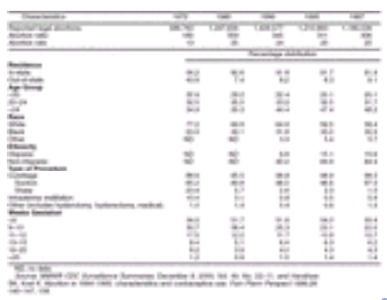

TABLE 31.1. *Legal abortions, abortion ratios, and abortion rates in selected years from 1972 to 1997 and characteristics of women who obtained legal induced abortions in those years*

FIG. 31.1. Fertility rate and abortion ratio and rate, by year—United States, 1972–1995. (From Koonin LM, MacKay AP, Berg CJ, et al. Pregnancy-related mortality surveillance—United States, 1987–1990. *MMWR CDC Surveill Summ* 1997;46:10.)

FIG. 31.2. Abortion ratio (per 1,000 live births) by age group (in years) of women who obtained a legal abortion, selected states—United States, 1974–1997. (From: Koonin LM, Strauss LT, Chrisman CE, et al. Abortion surveillance—United States, 1997. *MMWR CDC Surveill Summ* 2000;49:1–11.

FIG. 31.3. Rate of induced abortion by gestational week for 1997. *MMWR CDC Surveill Summ* 2000;49:1–11.

Abortion remains primarily a surgical procedure with 97% being done by suction curettage. The first medical abortion (in the U.S.) was done in the 1960s with antimetabolites. A medical abortion is accomplished by drug induction without primary surgical intervention. In September 2000, the U.S. Food and Drug Administration (FDA) approved a more effective yet more complex regimen, which includes mifepristone (initially developed under the manufacturer designation RU-486), an antiprogestin, as the initiating medication, followed by off-label use of misoprostol to be administered in the physician's office. Mifepristone, even if given with newer evidence-based medicine protocols using an equally effective 200-mg dose, carries a cost of $270 per 600-mg dose. This high cost has been one factor that has hampered the widespread use of this medical regimen for abortions. Nonetheless, about half of abortion providers were offering medical abortions within the first 6 months of 2001, and some centers reported that 10% to 15% of their terminated pregnancies were medical abortions. Drug protocols, with greater flexibility in dosage, timing of medication to decrease the interval from initiation to completion of the abortion, and home administration protocols to lower costs, will likely increase the number of providers offering medical abortions. These drug protocol modifications should also produce an overall shift from surgical to medical abortions.

LEGALIZATION

Since the landmark 1973 Supreme Court decision legalizing abortion, hundreds of laws, both federal and state, have been proposed or passed. This makes induced abortion the most actively litigated and highly publicized area in the field of medicine. The two most controversial topics of legislation involve debate on an appropriate definition for “viability” and the need for legislating parental involvement in a minor's decision-making process.

ABORTION COUNSELING

Some patients find the decision to have an abortion an easy one; for others it takes time and the consultation of a variety of providers and counselors. It may also take time to filter through multiple layers of providers to find a facility that performs pregnancy terminations, as over 80% of U.S. counties have no abortion providers. Statistics from the Alan Guttmacher Institute indicate that almost half of the women having abortions beyond 15 weeks of gestation state their procedure was delayed because of problems in funding or locating abortion services. Preoperative counseling for abortions should include a discussion of all options regarding the pregnancy within the context of the patient's concerns driving her decision to abort (Fig. 31.4). This should include discussion of medical versus surgical procedures, continuing the pregnancy, and the various options for legal adoption. Discussion should focus on the decision-making process and the patient's support system. Of utmost importance is to ensure that patients are not being coerced into their decision.

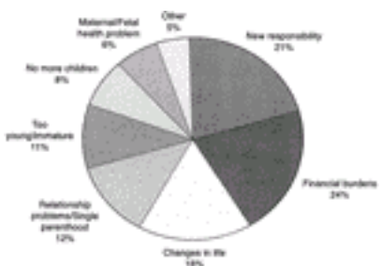

FIG. 31.4. Most important concerns driving the decision to abort. (From Torres A, Forrest JD. Why do women have abortions? Fam Plann Perspect 1988;20:169–176, with permission.)

Counseling sessions should also provide medical information, review pertinent medical and gynecologic history, and specifically discuss any previous abortion procedures. Statistics show that 47% of women who have an abortion have had a least one previous abortion. Medical personnel, such as obstetricians, perinatologists, and nurses, should be enlisted to review medical risks and benefits within the context of the patient's medical and pregnancy history. Patients should be informed of the risks of the procedure selected, and full isclosure of information includes discussing the risks of the abortion process as well as the risks of continuing the pregnancy. A full disclosure of methods regarding surgical versus medical abortions is mandatory. If a surgical abortion is preferred, the patient must then understand that the procedure is most often done under local anesthesia. Because the patient is awake during the procedure, she may verbalize a change of intent at this time. If this occurs, consent must be reestablished before the abortion may proceed.

The medical abortion counseling process takes longer than the surgical abortion counseling session. In the event the patient chooses a medical abortion, a description of the FDA protocol or any other evidence-based protocol must be presented to the patient. The patient will need to sign the mifepristone medication consent form. If the patient's medical abortion process will differ from the process described in this consent form, she must fully understand the differences. The patient needs to clearly appreciate that the passage of fetal tissue will present with bleeding, cramping, nausea and, in some cases, vomiting. There will also be some pain with the procedure. Patients will be told that they will be provided with sufficient pain medication and antiemetics. The patient needs to be given clear instructions on how to insert the misoprostol dose vaginally and to be taught how to differentiate bleeding from hemorrhage. This disclosure of information must be part of the consent process. There is a 2% to 8% chance of an incomplete abortion, which would require a follow-up surgical dilation and curettage for completion. Counselors must, therefore, indicate to the patient that follow-up examination visit(s) is (are) encouraged to ensure the completion of the pregnancy termination and the health of the patient. Finally, patients undergoing a medical abortion need telephone access and, more importantly, assistance with transportation in the event of an emergency during the abortion process (i.e., hemorrhage). Providers need to comply with all relevant applicable local, state and federal laws and ordinances.

In conclusion, the intent of the counseling session is to make sure that as much information as possible is available to the woman requesting a pregnancy termination in order for her to make an appropriate, informed, and independent decision. Counselors need to remain involved in caring for the patient throughout the abortion process. Preabortion counseling should also explore the subjects of future contraception and protection against sexually transmitted diseases (STDs).

INDICATIONS FOR ABORTION

Medical Indications

Medical indications for abortion have narrowed with advances in perinatal care. If data are available for a given indication, most perinatologists and abortion counselors prefer to put the risks in statistical perspective. In particular, these professionals are opposed to the concept of “recommending abortion” even in cases where maternal death is a possibility. Induced abortion is safer, with respect to mortality and morbidity, than a term delivery. The relative risk of death associated with childbirth may be ten times higher than that associated with abortion although the absolute risks for either are low (Table 31.2). Medical abortions in early pregnancy circumvent surgical and anesthetic risks associated with either delivery or surgical abortion. However, there is no evidence in the literature that suggests this makes medical abortion safer than surgical abortions. In the 1980s, it was estimated that maternal mortality was reduced seven-fold by a first trimester abortion compared to women carrying their fetus to term. More recent data indicate that a first trimester abortion may be even safer now; consequently, any discussion of risk must always be put in perspective.

Vacuum curettage[a] ≤12 weeks	0.05
Dilation and evacuation 13–15 wks[a]	2.00
Dilation and evacuation 16–20 wks[a]	6.5
Dilation and evacuation >21 wks[a]	11.9
Overall abortion mortality[b,c]	0.8
Overall maternal mortality[b]	10–20

[b]Maternal deaths per 100,000 live births; range accounting for reporting variances.
[c]*MMWR, CDC Abortion Surveillance—United States*, August 8, 1997, Vol. 46, No. ss–4.

TABLE 31.2. *Case-fatality rates for induced abortion and pregnancy*

Maternal conditions that may be considered a medical indication for an abortion include: renal failure, diabetic retinopathy, sickle cell disease, cardiac disease, neoplasia, autoimmune disease, and psychiatric disease. Cardiac conditions that may result in maternal death include severe mitral stenosis, coarctation of the aorta with vascular involvement, uncorrected tetralogy of Fallot, aortic stenosis, previous myocardial infarction, myocardial infarction during pregnancy, artificial heart valves, and Marfan syndrome with aortic involvement. A cardiac anomaly with potentially greater mortality is the Eisenmenger syndrome with pulmonary hypertension. Other medical indications include intrauterine infections, chorioamnionitis, and preterm premature rupture of membranes. Radiation treatments, chemotherapy, and live virus immunizations given inadvertently in early pregnancy are other reasons to discuss the risks and options of an abortion. However, nondirective factual counseling in this area is essential.

Fetal Indications

Despite progress in prenatal diagnosis, most anomalies identified have no real means of treatment other than abortion or, otherwise termed, *selective termination.* Maternal–fetal surgery involves surgical correction of fetal anomalies in utero. These anomalies are more easily detected with newer ultrasound technology increasing fetal assessment capabilities. Yet, this type of surgery remains experimental and controversial with little long-term outcome data. At present, fetal indications for induced abortion include those anatomic conditions incompatible with life (e.g., anencephaly) and major congenital abnormalities (e.g., hypoplastic left heart, severe neural tube defects). Recent literature studied the most common indications for selective termination. Parents are more likely to electively abort if a central nervous system (CNS) anomaly was discovered in utero compared to a non-CNS anomaly (Table 31.3.). This was true for all grades of severity within the CNS anomaly classification compared to all grades of severity for the non-CNS anomaly classification.

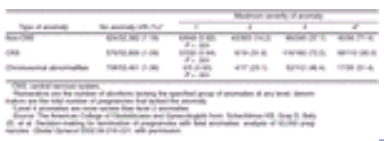

TABLE 31.3. *Abortion rate, by maximum severity of non-CNS anomalies, CNS anomalies, and chromosomal abnormalities*

When an anomaly is diagnosed in time to have a legal abortion, 50% to 80% of women selected abortion, although even the most severe cardiac conditions can theoretically be treated by cardiac transplantation. Most serious anomalies are not diagnosed until well into the second trimester as that is when complete anatomic surveys, by ultrasound, are performed.

SURGICAL ABORTION

Preoperative preparation for most women, after the focused history and consent process, can be fairly simple. The pregnancy is assessed for gestational age. (The abortion facility must be capable of performing the procedure for the gestational age.) Evaluation includes adequate cervical visualization, uterine palpation, and whether a local or general anesthetic is required. Testing for STDs is considered optional but may be beneficial for patients at high risk for an STD. A targeted physical examination is sufficient for a healthy woman. Laboratory analysis must include assessment of the hemoglobin or hematocrit and establishment of a patient's Rh factor status. Pap smears are recommended per usual protocols but are not specifically necessary for the abortion.

Ultrasonography establishes the pregnancy dating, as well as confirming fetal number, placental localization, and the presence of any uterine anomalies or fibroids. Sonography can guide the performance of the procedure by continually imaging the instruments as they are being manipulated within the uterine cavity (Fig. 31.5). For very early terminations, so little placental tissue exists that postprocedure ultrasound imaging is not always helpful in confirming the completeness of the procedure.

FIG. 31.5. Abdominal ultrasound anteroposterior view of 16-mm, straight vacuum curette visualized in an intrauterine location during a dilation and evacuation procedure for pregnancy termination.

Anesthesia for first trimester and early second trimester procedures is typically local infiltration paracervically with lidocaine, 12 cc of 1% to 2%, or chloroprocaine, 12 cc of 1% to 2%, with the physician and an assistant speaking to the patient to relax and reassure her throughout the procedure. Approximately 80% of women receive only local anesthesia during surgical termination. Preoperative preparation may include acetaminophen, or a nonsteroidal antiinflammatory drug (NSAID) or diazepam. Conscious sedation can be provided with 2.5 to 3.0 mg midazolam. In addition, rapid-acting narcotics, such as fentanyl, are occasionally used.

Cervical Dilation

Forceful cervical dilation can cause cervical lacerations, damage, or permanent incompetence of the internal os, all of which are extremely rare with modern techniques. Early first trimester procedures often require no dilation for the multiparous patient and little dilation with primigravidas. Initially, 400 µg of misoprostol, a cervical dilating agent, may be administered orally a few hours prior to the surgery. For procedures performed at less than 9 weeks from the last menstrual period (LMP), dilation is accomplished with progressive use of graduated cervical dilators. Pratt-type or Teflon Denniston dilators 3 mm and larger, are used serially to enlarge the cervical canal. Beyond this gestational age, medical or mechanical aids for dilation are very helpful. Most commonly employed is the seaweed *Laminaria japonica* (in singles or multiples), which expands over a 3- to 24-hour period to enhance dilation. Successive applications of increasing numbers of *L. japonica* can be effective and used for longer than 24 hours. Once the dilators are inserted, patients should understand that the abortion process has begun and must be completed, and failure to do so can result in life-threatening infection. Failure to be able to dilate the cervix is rare, but if the os is so stenotic that it cannot admit even a 3-mm dilator, preoperative use of misoprostol 400 to 800 µg intravaginally or 200 to 400 µg orally, up to 24 hours prior to the surgical procedure, can be helpful. When the cervix is easier to dilate, be aware that misoprostol has a fairly rapid onset so its use, earlier than 4 to 6 hours prior to the procedure, may lead to a spontaneous pregnancy expulsion. Another option is waiting until the pregnancy progresses to a later gestational period when the cervix may be more easily dilated.

First Trimester Abortion Procedure

Early first trimester abortions are almost exclusively performed by suction curettage. The earliest surgical abortions are performed between 3 to 5 weeks after the LMP. In some institutions, early abortion is performed before sonographic visualization of the gestational sac, but most are performed after the intrauterine location of the pregnancy is confirmed by ultrasound.

To rule out ectopic pregnancy, two to three ß-human chorionic gonadotropin (ß-hCG) titers should be taken at 48-hour intervals. Beta-hCG titers greater than 2,000 IU/L for a patient without an intrauterine sac visualized sonographically suggest an ectopic gestation. A sonogram should again be performed to definitely ascertain presence or absence of an intrauterine gestational sac. If an ectopic pregnancy is still suspected, the woman may undergo a medical abortion using the methotrexate protocols, which will treat an ectopic pregnancy as well.

To begin the suction curettage procedure, the anterior lip of the cervix, optionally anaesthetized at 12 o'clock first, is grasped with a single-tooth tenaculum that effectively stabilizes the cervix and straightens the cervical–uterine axis to facilitate cannula insertion. Local anesthetic is circumferentially infiltrated submucosally in the paracervical region. The cervix is dilated commensurately with the length of gestation and the need of cannula aperture. For a 7- to 9-week post-LMP gestation,

cannulas of 5 to 9 mm in width are used; they can be soft, flexible cannulas or rigid plastic, either straight or bent. Use of a uterine sound should be avoided, as it increases the incidence of uterine perforation, and depth of the endometrial cavity can be assessed by other means. The actual evacuation is accomplished by suction generated by a self-locking, handheld syringe or a machine aspirator; both may generate pressures of 60 to 70 mm Hg. Completeness of the procedure is confirmed by the appearance of bubbles in the suction cannula and the characteristic uterine sound of the catheter against the uterine wall, denuded of the decidual tissue. Completeness of the procedure can be confirmed by looking at the uterine cavity under ultrasound (Fig. 31.6A, Fig. 31.6B and Fig. 31.6C).

FIG. 31.6. A: Longitudinal view of the uterine cavity within minutes after a surgical abortion showing the endometrial stripe and constricted endocervical canal. **B:** Transvaginal ultrasound image taken in a longitudinal view of an 11-week gestation 1 hour after uterine evacuation shows evidence of procedure completion, but the endometrial stripe is less prominent due to the natural accumulation of blood within the endometrial cavity. **C:** Two weeks after suction curettage, transvaginal endometrium shows 16 mm of endometrial tissue, likely to be decidua and a few chorionic villi consistent with the normal involution process and warrants observation if clinically stable.

After the procedure, a surgeon can reliably confirm the pregnancy contents were obtained by inspecting the tissue. Washing the villi for the early suction curettage and then observing them through backlighting can enhance tissue visualization (Fig. 31.7). For procedures farther along in pregnancy, assessment of the primary skeletal fetal parts must be done. Visual confirmation of tissue must be done before the patient leaves the facility. Histologic evaluation of the products of conception can identify the rare woman with gestational trophoblastic disease (i.e., a molar gestation). In cases of known fetal anomalies, pathologic tissue examination is even more important. Blood loss is usually low, varying from 15 to 50 mL in most cases.

FIG. 31.7. Transillumination of villi floating in saline allows visualization for placental tissue confirmation after pregnancy termination.

Second Trimester Abortion Procedure

Dilation and Evacuation Dilation and evacuation (D & E) is the most common method of second trimester abortion. The procedure requires additional dilation of the cervix (up to 2 to 3 cm), and some of the evacuation needs to occur with the use of Sopher and Beirer type forceps. The forceps are most safely manipulated in the lower portion of the uterus or the midcavity region. Occasional use of uterotonic agents enhances the ability to reach the products of conception. Blood loss with these procedures is typically in the 100- to 300-mL range. Vasopressin, 4U, added to the paracervical block, significantly reduces bleeding. The use of ultrasound during the procedure to ensure the forceps are within the uterine cavity and afterward to verify complete removal of the products of conception may be helpful.
Intact Dilation and Extraction Procedures removing an essentially intact fetus have been termed *intact dilation and extraction.* Very few of these procedures have been performed in the United States.
Saline- and Prostaglandin-induced Abortions After 16 weeks gestation, abortions can still be performed with intrauterine abortifacient injection. Several solutions have been used for intrauterine injections, including hypertonic glucose, saline, urea, or uterotonics, such as prostaglandins or oxytocin. The uterus is relatively resistant to oxytocin induction at this point in the gestation, thus high doses of oxytocin are typically required and even those may not cause adequate uterine contractions. Labor induction with prostaglandins is the preferred strategy for second trimester pregnancy evacuation. The most widely used prostaglandin is PGE_2, dinoprostone, 20-mg suppositories, or 15-methyl-PGF_2, carboprost 250 g and tromethamine, for intramuscular injection. Misoprostol protocols using 25 g to 800 g orally or intravaginally, 4 to 8 hours prior to the procedure, can speed up delivery, although this drug regimen alone may take 24 to 72 hours. As saline and urea are hypertonic, the instillation procedure kills the fetus. Isolated reports of fetal survival in cases of prostaglandin induction exist. To avoid delivery of a nonviable but living fetus, intracardiac injection of digoxin or potassium chloride can be given prior to induction. Induction techniques may offer some advantages for the postmortem evaluation of fetal anatomic abnormalities, but 97% of anomalies can be evaluated after D & E. Preoperative karyotyping through amniocentesis is the best assurance of accurate chromosomal evaluation as this avoids more terminal cell contamination (i.e., the deciduas) and the requirement for optimal handling of the tissue to maintain viability.
Hysterotomy Hysterotomy may rarely be required for some cases of induced abortion. An indication for a hysterotomy would be large leiomyomata blocking cervical access. However, D & E procedures, even preceded by laminaria insertion, can safely be done in cases of placental previa as the laminaria do not need be inserted through the internal os to dilute the cervix. It is important to note that all hysterotomies are done with the classic uterine incision because the uterine segment is not developed well enough early in pregnancy to put the incision in the lower uterine segment.
Surgical Sterilization At the time of first or second trimester induced abortions, bilateral tubal ligation (using minilaparotomy), tubal fulguration, or tubal device occlusion are all considered to be safe. This option should be discussed during preoperative counseling.
Postoperative Care Antibiotic prophylaxis against infection reduces the incidence of postoperative salpingitis and endometritis, since cultures are not typically available preoperatively. Doxycycline has a broad spectrum of coverage and is the agent of choice. If the patient is allergic to doxycycline, metronidazole or ampicillin can be considered as alternatives. Prophylaxis regimens vary, but two doses of 100 mg of doxycycline should be administered with termination and again in 12 hours. Postoperative pain management is relatively straightforward. Contraction pain is usually mild and responsive to acetaminophen. An alternative regimen includes the use of NSAIDs. Both the acetaminophen and the NSAIDS, if over-used, can potentially mask a postoperative fever. Prior to the procedure, the provider must take note of the Rh(D) antigen status of the patient. Then immunoglobulin D must be offered to all Rh(D)-negative women. Rho(D) immunoglobulin should be administered to the Rh-negative patient on the day of the procedure or within 72 hours. For gestations less than 13 weeks, a dose of 50 µg is given. This amount is effective in preventing sensitization. For gestations =13 weeks, a dose of 300 µg is required. This dose may be excessive, but is considered the standard dose used in the United States. An intrauterine device, or intrauterine system, can be inserted immediately after a first trimester procedure, although the expulsion rate is slightly higher than if it is inserted after complete uterine involution. Injections of the contraceptives medroxyprogesterone acetate or estradiol–medroxyprogesterone as well as inserting levonorgestrel implants can be done on the day of the procedure or within the next 5 days. Postoperative appointments, 1 to 3 weeks later, can ensure and confirm that the induced abortion has been completed, evaluate for complications, reassess psychological status, and continue contraceptive and gynecologic care. As the ß-hCG has a long half-life, sensitive pregnancy tests may stay positive for weeks after an adequately evacuated pregnancy. However, compliance with follow-up visits is low due to a variety of factors. These include the distances patients have to travel, the fact that most women usually feel very well after their abortion, and the negative emotional response associated with a return to the site of the procedure. Women often seek care elsewhere but do not verbalize they had an abortion due to possible negative feedback.

MEDICAL ABORTION

Medical abortions can benefit a woman seeking pregnancy termination by increasing her control over the process and may allow abortions to be more widely available

in terms of the number of physicians that could provide this service in their offices. Both providers and patients can be shielded from the highly politicized abortion debate, allowing women to have an abortion without delay compared to waiting for an assigned scheduled surgery. Medical abortion reduces the risk of cervical laceration and uterine perforation and eliminates any anesthetic risk. Three abortifacients are currently being used for medical abortions: Prostaglandins (misoprostol), antiprogesterones (mifepristone), and antimetabolites (methotrexate). Misoprostol has been reported to be a teratogen when used in the first trimester. The mechanism of misoprostol action may be due to alteration of transplacental oxygenation or possibly a direct effect of the drug. The most common anomaly reported is a frontal facial set of lesions, termed *Möbius syndrome*, but over two dozen healthy pregnancies have been reported after failed medical abortion regimens. Mifepristone may be a teratogen but its effects have not been well studied. Methotrexate is a potent teratogen and its use in the first trimester is associated with major congenital malformations.

The FDA-approved regimen is initiated with mifepristone, followed by misoprostol (Table 31.4). This protocol is for women up to 49 days from the first day of the LMP. The literature, establishing the safety and efficacy of procedures up to 63 days from the LMP, indicates the procedures are less effective at this time but safe if clinicians and patients completely understand the process and the need to intervene with surgical uterine evacuation when necessary. Although the counseling process has been reviewed earlier in this chapter, patients given methotrexate and misoprostol need to comprehend that neither medication has been formally approved for medical abortions.

Visit 1: day 1—clinic or office
▪ Counseling and signing informed consent ▪ Medical history and physical examination, specific attention to medical contraindications ▪ M.D. and patient signing the provided medication agreement and patient receiving copy ▪ Blood samples taken for determination of hemoglobin level and Rh factor ▪ Pregnancy dating with sonogram or hCG titers if no gestational sac present ▪ Make sure no ectopic pregnancy ▪ Administer Rho_(D) immunoglobin if patient is Rh-negative ▪ Administer mifepristone 600 mg p.o.
Visit 2: day 3—clinic or office, 4-h observation
▪ Use sonography to check if patient has aborted ▪ If incomplete, administer 400 µg misoprostol orally and observe until heavier bleeding or passage of fetal tissue ▪ Repeat sonography for completion at end of 4-h observation ▪ If complete, schedule follow-up visit ▪ If still incomplete, discharge home ▪ Instruct patient on self-care
Visit 3: day 12–20—clinic or office
▪ Confirm abortion by sonography ▪ Surgical abortion, if necessary ▪ Assess level of bleeding and cramping since last visit, evaluate hemoglobin if medically indicated ▪ Administer birth control of patient's choice

ß-hCG, human chorionic gonadotropin.

TABLE 31.4. *U.S. Food and Drug Administration-approved mifepristone and misoprostol regimen summarized*

Misoprostol

Misoprostol, an E_1 prostaglandin analog, is FDA-approved as a treatment to aid in the prevention of gastric ulcers in persons taking NSAIDs. For pregnancy termination, the pharmacologic consequence of misoprostol administration is two-fold, softening the cervix and causing uterine contractions. The strong uterine contractions aid in the expulsion of the intrauterine contents. Misoprostol has excellent absorption orally or with vaginal administration. Oral absorption peaks in 30 minutes and then significantly drops at 120 minutes. The vaginal absorption does not peak for almost an hour, but high levels are sustained. The primary side effects of misoprostol are nausea, vomiting, diarrhea, abdominal pains, chills, fever, and shivering (Table 31.5). Misoprostol has been used for well over a decade with the antimetabolite methotrexate for medical abortions based on evidence-based protocols. As a single agent, misoprostol is considered less than adequately effective in terminating a pregnancy. Contraindications to misoprostol are glaucoma, anemia, mitral stenosis, and hypersensitivity.

	Mechanism of action	Side effects	Contraindications	Pharmacokinetics
Prostaglandins Misoprostol 400–800 µg p.o. or p.v.	Interact with myometrial cell receptors causing strong myometrial cell contractions leading to expulsion of embryonic or fetal tissue. Also causes cervical softening and dilation.	Diarrhea Vomiting Nausea Cramping Bleeding	Glaucoma, sickle cell anemia, hypotension, mitral stenosis, pregnancy not intended for termination, hypersensitivity to misoprostol	Half-life = 30 min p.o.: Time to peak plasma concentration =30 min Onset of uterine tonus = 8 min Time to peak uterine tonus = 25 min p.v.: Time to peak plasma concentration = 80 min Onset of uterine tonus = 21 min Time to peak uterine tonus = 86 min Time to peak serum levels = 90 min Half-life = 20 h Percent protein bound = 88% Oral bioavailability = 88%
Antiprogesterones Mifepristone (RU-486) 200–600 mg p.o.	Five times greater affinity for progesterone receptors. Binds to progesterone receptors and blocks progesterone from binding thus inhibiting its action and leading to increased uterine contractility. Also softens and dilates cervix.	Abdominal pain Uterine cramping Nausea Vomiting Diarrhea	Severe anemia, adrenal disease, chronic corticosteroid administration, severe kidney disease, severe liver disease, severe pulmonary disease, cardiovascular disease, inherited porphyria, clotting disorder, anticoagulant therapy, ectopic pregnancy, undiagnosed adnexal mass, IUD in place, hypersensitivity to mifepristone	
Antimetabolites Methotrexate 50 mg/m² i.m. 25–50 mg p.o.	Blocks dihydrofolate reductase thus inhibiting folate production and DNA synthesis. Affects rapidly dividing cells first (including trophoblast cells).	Nausea Vomiting Diarrhea Hot flushes Headache Cramping Dizziness	Severe anemia, inflammatory bowel disease, clotting disorder, acute liver or kidney disease, alcoholism, immunodeficiency syndrome, bone marrow hypoplasia, leukopenia, thrombocytopenia, hypersensitivity to methotrexate	Time to peak serum levels = 1–2 hours Terminal half-life = 10–17 hours Percent protein bound = 30%

IUD, intrauterine device.

TABLE 31.5. *Medications used in pregnancy termination*

Mifepristone (RU-486)

In 1988, the French released the progesterone antagonist RU-486, later named mifepristone, a derivative of norethindrone, for use as an abortifacient. It was noted that efficacy was improved if mifepristone was given in combination with a prostaglandin analog. Mifepristone has a potent receptor affinity for the progesterone receptor and a less potent affinity for glucocorticoid receptors. Once bound, it does not activate the progesterone receptor, rendering the progestin receptor inactive, thus making it an effective antiprogestin. Many prostaglandin analogs have been successfully used worldwide, but the FDA, in approving the drug, specifically mandated the requirement for mifepristone administration to be in conjunction with the misoprostol. The fundamental principle is that progesterone support of trophoblast attachment to the decidua in early pregnancy is essential, and withdrawal of this support causes detachment. Once trophoblastic separation occurs, ß-hCG levels will begin to decline. Mifepristone softens and dilates the cervix causing decidual necrosis, increasing uterine contractions, and enhancing the sensitivity of the uterus to prostaglandin administration.

Medical abortions have long been available in France, China, Sweden, and the United Kingdom. Before mifepristone was available for medical abortions in the United States, regimens in use worldwide varied. The FDA regimen specifies the dosage and timing of both the approved mifepristone and the misoprostol; the drugs are not currently individually approved for abortion (see Table 31.4). The regimen also specifies that the mifepristone is given on day 1 after the provider and the patient sign the informed consent. Then on day 3, misoprostol administration occurs in the provider's office with 4 hours of observation. The mifepristone must be directly purchased from the manufacturer after the provider signs a statement that he or she is capable of diagnosing an ectopic pregnancy and can arrange for the patient to receive a surgical abortion in the case that the medical abortion is not complete. Evidence-based medical abortion protocols provide equal efficacy with greater patient convenience and lower medical costs. Many regimens have been reported in the literature as shown in Table 31.6. The regimen most widely used is shown in Figure 31.8.

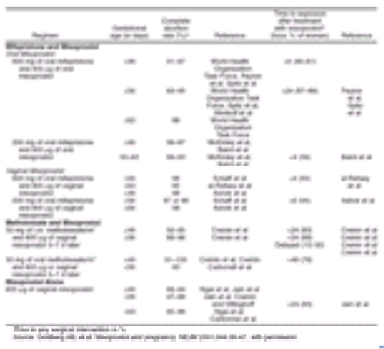

TABLE 31.6. *Efficacy of misoprostol regimens for medical abortion in the first trimester of pregnancy*

FIG. 31.8. Nonsurgical evidence-based mifepristone/misoprostol abortion sequence.

Patients undergoing medical abortion should be told to anticipate cramping, pain, and bleeding, and a third of patients may experience nausea, vomiting, diarrhea, dizziness, or fatigue (see Table 31.5). Abdominal/uterine cramping has been noted in 83% to 95% of patients; nausea has been observed in 12% to 61% of patients; vomiting in 9% to 47% of patients; diarrhea in 7% to 67% of patients; headache in 12% to 27%; dizziness in 1% to 37% of patients; chills in 14% to 89% of patients; mild to moderate pain in 50% to 95% of patients; and finally bleeding in 100% of patients. These symptoms are usually self-limiting and it is not necessary to treat them prophylactically. Narcotic-based analgesics are used, but many patients do well with NSAIDs.

The preabortion workup can be straightforward but should include a medical and obstetric history, allergies to medications, current patient medications, a pelvic exam, and a physical exam to obtain height and weight and blood pressure. All patients should be evaluated by pelvic ultrasound as all published studies to date have done this and it remains the standard of care. If a gestational sac is not seen, a clinical evaluation for an ectopic pregnancy should be initiated. A ß-hCG titer of = 2,000 IU/L and the absence of an intrauterine sac are consistent with either an ectopic pregnancy or an early spontaneous abortion. While patients could be treated based on ß-hCG titers alone (without the use of ultrasound), misdiagnosis of an ectopic pregnancy may occur and this clinical regimen is not generally recommended. Finally, Rho(D) immunoglobulin for Rh-negative patients can be administered on day 1.

Methotrexate

Methotrexate is an antimetabolite that blocks dihydrofolate reductase, an enzyme essential for the production of the DNA nucleotide thymidine during DNA assembly. As rapidly dividing cells are most affected, it causes trophoblastic cell death. Methotrexate has been used clinically for the treatment of gestational trophoblastic disease (i.e., molar gestation, ectopic pregnancy, and early medical abortion). Although methotrexate is not FDA-approved for early medical abortion, the protocols for abortion have been extensively studied. Toxicity is dose-dependent, and in the dosages given for these regimens, blood levels of methotrexate are undetectable 2 days after administration. At the low doses used in regimens for ectopic pregnancy, side effects of methotrexate are primarily gastrointestinal, with nausea, vomiting, and diarrhea, although there have been isolated reports of marrow suppression (leukopenia) and alopecia (see Table 31.5). At high doses, methotrexate can cause renal toxicity or damage to the gastrointestinal lining. Methotrexate in the 50- to 150-mg range should not induce ovarian toxicity and has no known long-term toxicity with regard to reproductive function. The protocols with methotrexate are more complex than those for surgical abortions, requiring more evaluation and more provider visits (Table 31.7 and Fig. 31.9). Failure rates are marginally higher than with mifepristone/misoprostol protocols.

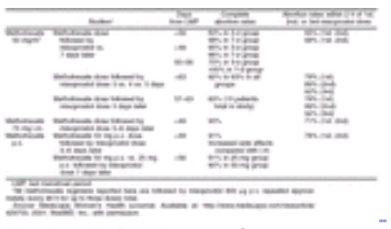

TABLE 31.7. *Methotrexate regimens used in pregnancy termination*

FIG. 31.9. Nonsurgical methotrexate/misoprostol abortion.

The National Abortion Federation (NAF) has revised the methotrexate/misoprostol protocol for early abortion. Two options have been recommended as guidelines for early medical abortion with these two abortifacients. Prior to the initiation of either of these protocols, counseling, education, and consent are completed. In addition, a medical history, physical exam, and sonography to confirm gestational age are necessary. The first option protocol begins on day 1 when methotrexate is administered. The dose can be 50 mg/m ^{2} intramuscularly (i.m.) or 50 mg p.o. Rho(D) immunoglobulin for Rh-negative patients can be administered on day 1 also or can be given any day prior to the misoprostol administration. The patient is provided with sufficient analgesic information and prescriptions and is also provided with 800 µg misoprostol, with instructions for self-insertion vaginally on either day 3, 4, 5, 6, or 7. On day 8 the patient returns to the office for a visit and the patient history is

obtained and ultrasound performed. With ultrasound, if a gestational sac is absent, treatment is complete. If a gestational sac is still present, repeat the misoprostol dose. This can be administered by the physician, self-administered in the clinic, or self-administered at home later that day. For follow-up, the cardiac activity in the gestational sac must be considered. If there is no cardiac activity in the gestational sac, the patient must return in 3 to 4 weeks. If there is cardiac activity, the patient should return in 1 week following this clinic visit. The visit on day 15 will include obtaining an interval history and an ultrasound. If a gestational sac is absent, the medical abortion is complete. If the gestational sac is present, with cardiac activity, a surgical evacuation is necessary at this time. If the gestational sac is present, with no cardiac activity, the patient should be given instructions on what to expect with regard to a delayed passage of the products of conception and scheduled for an appointment in approximately 3 weeks. On visit day 29 to 45 following methotrexate administration physicians must obtain another interval history and perform an ultrasound. If a gestational sac is absent, the treatment is complete. If a gestational sac is *still* present, a surgical evacuation is necessary at this time.

The other NAF-supported protocol is similar to the first protocol, but allows for an additional misoprostol administration (two 800 µg misoprostol doses total) for the patient (see Fig. 31.9). As a result, this may reduce the number of required clinic visits. Again this protocol begins on day 1 with 50 mg/m ^{2} methotrexate given i.m. or 50 mg p.o. The Rho(D) immunoglobulin for Rh-negative patients can be administered on this day or any day prior to the administration of misoprostol. The patient is provided with sufficient analgesic information and prescriptions and two doses of misoprostol at 800 µg each with instructions for vaginal insertion on day 3 to 7. The second dose of the misoprostol should be administered 24 hours later if little or no bleeding has occurred after the first misoprostol dose. The day 8 visit is optional if the patient has had bleeding. If the patient has not had bleeding at this point, then the day 8 visit includes obtaining an ultrasound to determine the status of the gestational sac and provide the woman with support and reassurance that all is well. On day 15, if a complete medical abortion process has not yet taken place, an interval history is obtained and an ultrasound is performed. If a gestational sac is absent, the treatment is considered complete. If a gestational sac is present with cardiac activity, a surgical evacuation is required at this time. If a gestational sac is present without cardiac activity, the physician should make arrangements to follow up with this patient in 3 to 4 weeks. At this next visit, the patient should be given adequate information with regard to a delayed passage of the pregnancy. At a subsequent visit between day 29 and 45, if a completed abortion has yet to be confirmed, the physician must obtain the interval history and perform an ultrasound. If the gestational sac is absent, the medical abortion process is then complete. If a gestational sac is still present, a surgical evacuation is necessary at this time.

With these two protocols, some patients take as many as 4 weeks to complete the abortion, and 4% to 6% of women will require surgical evacuation of the products of conception. Complication rates are similar to those with the mifepristone/misoprostol regimen. Although the ultrasonography assesses the presence or absence of an intrauterine pregnancy, the patient must be continually reevaluated clinically for stability and amount of blood lost. Contraception counseling is always given upon the completion of any medical abortion.

Contraindications for Medical Abortion

Contraindications to mifepristone include anemia, adrenal disease or chronic corticosteroid use, severe liver, cardiovascular, kidney or pulmonary disease, clotting disorders, anticoagulation therapy, pregnancy with an intrauterine device, or hypersensitivity to this drug (see Table 31.5). Preprocedure assessment of a hemoglobin or hematocrit, as well as Rh typing is required. Rho(D) immunoglobulin is to be given on day 1 of the regimen if the patient is Rh-negative. Patient selection for medical regimens should focus on the certainty of the decision to terminate the pregnancy, a willingness to comply with the instructions, and access to 24-hour emergency services. Factors that may affect a patient selecting a medical abortion are a desire to avoid a surgical procedure, falling within the medical dating criteria for the procedure, having no medical contraindications to the medications, access to telephone and transportation, a good support system, the ability to return for follow-up visits, being able to tolerate pain as it may be intense when passing tissue products, and the ability to give informed consent.

Patient Follow-Up for Medical Abortions

Patients who are undergoing a medical abortion are told that they must expect bleeding and cramping, especially after misoprostol administration. About 5% of women abort in the first 24 hours after mifepristone alone. About another 5% of patients abort within a few hours of the misoprostol (day 3), and almost 80% of patients have aborted within the next 24 hours. Patients are asked, however, to be patient as longer times to completion do occur and are not accompanied by a greater risk of complications. Once the sequence of events in Figure 31.8 has begun, ultrasonography assessments are essential in visualizing completeness of the medical abortion procedure as shown in Figure 31.10A, Figure 31.10B, Figure 31.10C. At the 8- to 10-day visit, ß-hCG levels may be measured. A decrease in ß-hCG levels more than 50% has been shown to be associated with a complete abortion process. Sonography is performed and is necessary to confirm absence of gestational sac. Some publications have indicated that bleeding, on average, lasts 14 days. Yet, bleeding may persist for 60 days in some patients, without untoward effects. More important, the patient must realize that heavy bleeding and severe cramping does not necessarily indicate a complete abortion has taken place. Therefore, the patient must realize that a third follow-up visit (day 12 to 20) is compulsory to confirm the completion of the procedure and observe the absence of a gestational sac. Sonography is again used for this confirmation. A further decrease in ß-hCG levels to more than 90% at this visit suggests, almost certainly, that the termination process is complete.

FIG. 31.10. A: Transvaginal ultrasound of a 42-day pregnancy 4 hours after misoprostol ingestion. Heavy bleeding and passage of tissue indicated the pregnancy termination had probably completed, the ultrasound confirms the absence of a gestational sac and that the medical abortion was effective. **B:** Day 14 after a medical abortion of a 47-day pregnancy. Transvaginal ultrasound shows retention of gestational sac although no fetal development or fetal cardiac activity is seen. This is consistent with an incomplete medical abortion. Follow-up or surgical termination are both options if the patient is medically stable at this point. **C:** Three-and-a-half weeks after medical abortion of a 35-day pregnancy. Transvaginal ultrasound shows a sac in the endocervix, not in the uterine cavity. Abortion is not yet complete.

In general, continuing pregnancy rates are low, and less than 1% of patients require curettage due to hemorrhage. However, one of the most important assessments the provider needs to ensure is a set of instructions for the patient to address severe bleeding. Because bleeding is expected, the provider needs to recognize, although rare, an actual episode of hemorrhage requiring surgery may be indicated. If the provider's bleeding threshold is low, it may be that potentially unnecessary surgical procedures are performed, and consequently an increased complication rate for the medical abortion procedure may result. Other indications for surgical intervention include a continuing intrauterine gestation of a retained nonviable pregnancy. A medical abortion is considered a failure if there is viable cardiac activity 2 weeks following the regimen. Additional rounds of misoprostol may be effective in accomplishing completeness at this time, but studies have yet to establish useful clinical guidelines. If the pregnancy is retained and nonviable, the patient will likely spontaneously abort within the next 3 weeks. Because there is always a risk, albeit low, of viable cardiac activity 2 weeks following the medical regimen, the provider must have arranged for a surgical evacuation as a back-up plan. It is important to note that surgical evacuation may be offered at any point in the medical abortion process if the pregnancy has not been spontaneously expelled and the patient is unwilling to wait any longer for completion.

COMPLICATIONS OF ABORTION

An induced abortion is a very safe procedure. Complications are rare (Table 31.8). During the abortion counseling session, the counselor should clearly state the known risks and benefits. The lay literature erroneously states that abortion causes cancer and reproductive dysfunction. Current medical evidence gives no indication that abortion causes either. There has also been no proven link between abortion and breast cancer. Future reproductive health is not affected by having a medically supervised legal abortion.

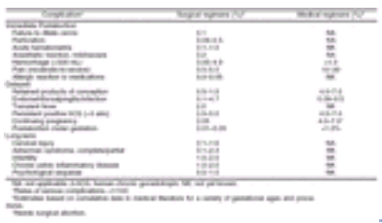

TABLE 31.8. *Complications of abortion and complication rates*

Surgical Procedures

Abortion procedures are extremely safe in the United States, with serious complications developing in only 1 in 100 patients and a mortality rate of less than 1 in 100,000 patients (see Table 31.2). The safest abortions are those performed at 7 to 10 weeks after the LMP (Table 31.9). Death rates for D & E have been reported at approximately 7 per 100,000, comparable to a term delivery. Concomitant sterilization, preexisting medical conditions, and general anesthesia may all contribute to an increase in postabortion complications. Immediate complications include acute cervical laceration, failure to dilate the cervix, failure to obtain the pregnancy tissue, postoperative pain, acute uterine hematometria, and, rarely, pulmonary embolism (Table 31.8 and Table 31.10). Other immediate complications can include moderate to severe pain, and allergic reactions to medications. More delayed complications include persistent bleeding secondary to retained products of conception, endometritis or salpingitis, and a continuing viable pregnancy. Longer-term complications include intrauterine adhesions and Rh sensitization. No long-term effects causing cervical incompetence have been documented in the literature. Rates of all the complications are extremely low.

TABLE 31.9. *Mortality rate with respect to gestational age*

Complication	Percentage	Number[a]
Hemorrhage	18.5	10
Embolism	11.1	6
Pregnancy-induced hypertension	1.2	1
Infection	49.4	25
Anesthesia	8.6	4
Other/unknown	11.1	6

TABLE 31.10. *Abortion-related deaths: United States 1987–1990*

Uterine Hemorrhage

Rates of uterine hemorrhage (more than 500 mL blood loss) are low, occurring in less than 5% of cases, and the need for transfusion is exceedingly rare. Uterine atony can be decreased by complete evacuation of the uterus with the use of vasopressin injection in the paracervical block (4 U or 0.2 mL), or use of postoperative oral or intramuscular methylergonovine maleate (0.2 mg). Failure to respond to acute management of bleeding can be treated with carboprost tromethamine, oxytocin, or misoprostol. Continued atony can be treated with insertion of a large intrauterine Foley balloon to tamponade the uterine cavity.

Uterine Perforation

Uterine perforation is uncommon, occurring in approximately 1.3 in 1,000 terminations. It is usually not recognized even by an experienced surgeon at the time of the procedure. In first trimester fundal perforations, observation is all that is required. If the nature and extent of the perforation are unknown or if suction was applied during the perforation, evaluation by laparoscopy is necessary. In early first trimester abortions the procedure may be safely completed, even after perforation in experienced hands with sonographic guidance of the catheters. A perforation during D & E is a more serious complication, and the amount of bleeding may necessitate a laparotomy for uterine wall repair. One study from the literature established that 14 of 15 perforations during D & E were associated with major organ injury. Organs damaged include the uterus, bowel, and bladder. Surgical interventions, when necessary, should not be delayed.

Endometrial Adhesions

Asherman syndrome, or the development of endometrial surface adhesions or scaring, should be suspected in a patient with no menses for several cycles following a surgical abortion. This is a rare complication and may be avoided through the prevention of endometritis. This is done by complete evacuation of the products of conception.

Retained Tissue

Evaluation of the products of conception at the time of abortion can significantly reduce the number of cases of retained tissue. There have been case reports of very delayed retention of incompletely removed tissue, but a new pregnancy must be the first consideration in these cases. Persistence of a positive pregnancy test can signal retained products of conception, but careful postoperative evaluation by those experienced with the normal involution process typically reveals that this is a self-limited process. Normal resolution of the pregnancy test depends on the length of the pregnancy at the time of abortion and the sensitivity of the ß-hCG tests used. Beta-hCG persistence for a few weeks is not uncommon. A rapid decline in the quantitative ß-hCG is the rule. Sonography can be helpful, but many pregnancies have some intrauterine fluid accumulation that appears within a few hours of abortion and does not dissolve for several days in a first trimester pregnancy. Retained products of conception may be most effectively handled by endometrial aspiration (3- to 5-mm suction pipettes), which is also useful for treatment of hematometria and can be diagnostic for retained tissue. Alternatives that may be useful in selected cases are observation, uterotonics (with methylergonovine maleate or misoprostol), or repeat suction curettage. In some cases, the retained tissue can cause uterine hemorrhage and increase the incidence of infection.

Infectious Complications

Endometritis can occur with or without retained products of conception. Clinical signs are abdominal pain, increased cramping, fever, and increased bleeding. Endometritis is difficult to diagnose but can be presumed to be present when tenderness, especially associated with febrile morbidity (fever >38°C), or an elevated white blood cell count is present. It is expected to occur in about 0.5% of suction curettage procedures, 1.5% of D & E procedures, and 5% of uterine instillations, despite the use of prophylactic antibiotics. The organisms most likely responsible for endometritis are vaginal flora. A broad-spectrum oral antibiotic with anaerobic coverage is usually sufficient therapy. Repeat curettage may be indicated when it seems likely that retained products of conception are responsible for the endometritis.

Complications of Medical Abortions

Complications due to medical abortions exist but are rare. The most common complication from a medical abortion procedure is an incomplete abortion. Surgical evacuation is then required to complete the procedure. The incidence of hemorrhage is less than 1%. Bleeding from a medical abortion procedure can be heavy but only in rare instances does this bleeding become so severe that transfusion is warranted. In some instances, copious amounts of bleeding may need treatment with vasoconstrictor medications, curettage, and saline solution administration. More often less serious complications arise as indicated in Table 31.5. The incidence of intrauterine infection after surgical abortions is 0.1% to 5%, likewise infections after medical abortions are rare, occurring 0.09% to 0.5% of the time. Patients having experienced both medical and surgical abortion report greater satisfaction with the low risk of complications associated with medical abortion protocols.

Psychological Consequences of Abortion

Improvement in emotional health is the most common psychological consequence following abortion. However, women with a prior mental health diagnosis of depression may be at risk for depression following an induced abortion. The proportion of women experiencing clinical depression, up to 2 years after the induced abortion, is not significantly different from the population in general for this same age group (approximately 15–35 years old). Although occasional reports of posttraumatic stress disorder are documented, the incidence of posttraumatic stress disorder in the postabortion population is less than in the general population for

this age group. There is a subset of patients who do feel sadness, guilt, and regret after an abortion. Studies show this subset of patients to be 10% to 30% of all women who have experienced an abortion, but these feelings are usually mild. It is the job of abortion providers to be sensitive to the emotional support requirements for each woman undergoing pregnancy termination. Preabortion counseling should increase awareness for all patients with regard to their possible feelings after the abortion. Younger women (<24 years old) and women who have other children may be at higher risk for feelings of regret and distress after an abortion. It has also been noted that emotions of regret, sadness, and guilt may increase over time (years after the abortion). But whether these feelings were due directly to the abortion years before, or from another completely different emotionally draining event occurring since the abortion procedure, is difficult to ascertain.

SUMMARY POINTS

- An estimated 1.2 to 1.6 million elective abortions have occurred in the United States in each of the past 10 years, making this a very common procedure and choice for women with unwanted pregnancies.
- Extensive research indicates that induced abortions continue to be requested by women regardless of religious conviction or socioeconomic status.
- The most common surgical approach in the first trimester is suction curettage and in the second trimester, dilation and extraction.
- Medical abortion is performed by initial administration of mifepristone followed by misoprostol. A non-FDA approved alternative is the use of methotrexate.
- The complications of induced abortion are relatively few and the death rates remain less than 1 woman per 100,000, comparing favorably to maternal mortality.
- It is important for health care providers to understand the process of induced abortion and to recognize and be able to counsel women regarding the potential risks, benefits, and complications of both surgical and medical abortion procedures to keep these procedures safe and widely available.

SUMMARY POINTS
SUGGESTED READINGS

A large number of microbes are present in the female reproductive tract, and pelvic infections are common. Many pelvic infections are sexually transmitted (Table 32.1). This chapter provides data on usual presentations and updated treatment of pelvic infections.

Organisms	Diseases
Bacteria	
Neisseria gonorrhoeae	Gonorrhea
Chlamydia trachomatis	Chlamydia
Treponema pallidum	Syphilis
Haemophilus ducreyi	Chancroid
Calymmatobacterium granulomatis	Granuloma inguinale
Gardnerella vaginalis, anaerobes	Vaginitis
Group B β-hemolytic streptococcus	Group B streptococcal infection
Mycoplasmas	
Mycoplasma hominis	Mycoplasmosis
Ureaplasma ureatyticum	Mycoplasmosis
Viruses	
Herpesvirus hominis (herpes simplex virus)	Genital herpes
Cytomegalovirus (CMV)	CMV infection
Hepatitis B virus	Hepatitis B
Human papillomavirus	Condyloma acuminatum
Molluscum contagiosum virus	Molluscum contagiosum
Human immunodeficiency virus	Acquired immunodeficiency syndrome
Protozoa	
Trichomonas vaginalis	Vaginitis

Fungi	
Candida albicans	Vaginitis
Parasites	
Sarcoptes scabiei	Scabies
Phthirus pubis	Pediculosis pubis

TABLE 32.1. *Sexually transmitted infections*

The impact of pelvic infections on women ranges from minor annoyance to serious illness and, rarely, even death. The cost of treating pelvic infections is enormous from both direct medical costs and indirect costs, including time lost from work. Using pelvic inflammatory disease (PID) as an example, previous estimates were that, by 2000, one of every four women who reached reproductive age in the 1970s had an episode of PID. Of women with PID, 25% will be hospitalized, 25% will have major surgery, and 20% will have tubal sterility.

Upper genital tract sites (endometrium, fallopian tubes, ovaries) formerly considered sterile are subject to ascending microbial traffic and occasionally infection from lower genital tract microbes. Some microbes preferentially infect certain sites and give rise to characteristic symptoms while other microbes cause few symptoms until major pathologic changes occur or until congenital neonatal infection or male-partner infection ensues. Clinicians should have special knowledge of the infections caused by *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, group B streptococci, *Treponema pallidum*, anaerobic bacteria, bacteria associated with bacterial vaginosis, and *Mycobacterium tuberculosis*; these infections either are common or potentially produce severe sequelae. It is now appreciated that most viral infections of the genital tract are asymptomatic. Several viruses are common and produce severe disease in both adults and neonates, including herpesvirus, cytomegalovirus, hepatitis B virus, human papillomavirus, and human immunodeficiency virus (HIV).

VULVA

Herpes

Type-specific serologic assays indicate that one third of women 20 to 45 years of age have been exposed to herpes simplex virus type 2 (HSV-2). Between 60% and

85% of women with HSV-2 antibodies never have a recognized genital infection. Despite the frequency of asymptomatic infection, HSV infection is a common cause of vulvar ulcers. Genital ulcers also are caused by syphilis and chancroid. Ulcers from HSV usually occur 3 to 7 days after exposure. Symptomatic primary (first) genital infections typically consist of multiple vesicles that rapidly produce ulcerations of the vulva that can be exceedingly painful. The cervix and vagina may also be involved, producing a gray, necrotic cervix and profuse leukorrhea. External dysuria is common, and bilateral inguinal lymphadenopathy is usual. Vulvar lesions may last for 3 or more weeks before complete healing. Constitutional symptoms of fever, malaise, headache (i.e., aseptic meningitis), and urinary retention (i.e., myelitis) may persist for a week.

After primary infection, latent HSV usually localizes in the sacral ganglion and perhaps the dermis. Periodic asymptomatic viral shedding occurs, particularly in the first 6 months after primary infection. HSV is isolated on 1% of the days with no symptoms or physical evidence of infection. Most patients develop a secondary (recurrent) infection from latent virus weeks to months after the primary infection. Secondary lesions are less painful and more localized and last for a shorter time (3 to 7 days) than the lesions of primary infection. Systemic manifestations are unusual with secondary infection.

From 75% to 85% of genital herpes infections are caused by HSV-2, with the remainder caused by HSV-1, the primary cause of oral herpes. The two types of herpes infections are clinically indistinguishable except that genital recurrence is unusual from HSV-1. Vesicles and ulcers contain many highly infectious virus particles, and viral shedding occurs until the lesions disappear. Thus, direct contact with either genital or oral HSV lesions leads to a high rate of infection. Transmission usually occurs by direct contact with ulcerative lesions. Transmission is greatest during a primary infection, intermediate during a secondary infection, and probably least with asymptomatic shedding.

The diagnosis of herpes can be made clinically if typical, painful, shallow multiple vulvar ulcers are present. However, many HSV lesions are atypical. Laboratory confirmation of atypical lesions and lesions that appear during pregnancy is best attained by virus isolation (which can usually be achieved within 48 hours) or by polymerase chain reaction (PCR) identification. Other direct HSV identification methods, including Pap smear, fluorescein tagging, and immunoperoxidase staining, are insensitive. Accordingly, a negative direct Pap smear does not exclude HSV infection. Complement fixing and neutralizing antibodies appear within 1 week of the onset of infection; failure of an experienced laboratory to identify antibodies within 3 weeks is evidence against HSV infection. However, even high antibody levels do not protect against recurrent HSV infection, although antibody passively transferred to the fetus offers considerable protection against neonatal infection.

The rising incidence of herpes infection and the potentially serious fetal infection caused by HSV make this an important infection in pregnancy. New guidelines for herpes are discussed in Chapter 19.

Oral acyclovir (Zovirax), 400 mg three times daily, famciclovir (Famvir), 250 mg three times daily, or valacyclovir (Valtrex), 1 g twice daily all for 7 to 10 days, shortens the ulcerative phase. Antiviral therapy does not eradicate HSV or prevent recurrence. Patients with episodic recurrent herpes should be provided a supply of drugs to take for 5 days beginning with prodromal symptoms or within a day of the lesion appearance. Patients with six or more yearly recurrences may benefit from suppressive therapy of acyclovir, 400 mg twice daily, famciclovir 250 mg twice daily, valacyclovir, 500 mg daily, or valacyclovir, 1 g daily for up to 1 year. The expense of this drug limits routine or prolonged use. Local therapy of genital herpes is limited to pain relief. Local treatment neither penetrates into virus-containing cells nor influences epithelial damage from HSV. Corticosteroids and antimicrobial ointments offer no benefit as they prevent drying and, thus, delay healing. Wet-to-dry therapy is often helpful (i.e., 10-minute sitz bath three or four times daily followed by drying with hair dryer).

Human Papillomavirus

Genital human papillomaviruses (HPV) are DNA viruses that are distinct from papovaviruses that cause the common wart. HPV thrives in the moist genital area and usually is sexually transmitted. HPV infection is common and typically subclinical. HPV DNA is found in the genitalia in 30% to 45% of women by PCR DNA amplification. The vulva is positive for HPV DNA in more than 40%, and the cervix in over 30%. Only 1% of the women have visible warts, and only 9% have a history of genital warts. The average incubation period for visible warts is 3 months. Genital warts most commonly occur on the labia and posterior fourchette (Fig. 32.1). They originally appear as individual lesions, although large confluent growths can occur if neglected. Vaginal and cervical warts are even more common than labial warts, although most of these are flat lesions visible only by colposcopy. Over 30 HPV types infect the genital tract. Visible genital warts are usually caused by HPV types 6 and 11; 3% of college women had these types. The flat-wart variant is caused by HPV types 16, 18, 31, 33, and 35 (found in 22% of college women tested) and is visible only by colposcopy. A biopsy of flat or atypical-appearing cervical warts is required to exclude cervical neoplasia. Biopsies of warts also should be performed for pigmented, unresponsive, or fixed lesions, or in immunocompromised patients. HPV types 16, 18, 31, 33, and 35 are associated with high-grade cervical dysplasia and cervical cancer where the HPV DNA is integrated into the cancer cell. Women with flat warts should have frequent Pap smears. At present, routine typing of HPV is not recommended to aid PAP smear interpretation or predict cervical dysplasia.

FIG. 32.1. Condylomata acuminata of the vulva.

Vulvar warts must be differentiated from the less verrucous, flatter growths of syphilitic condyloma latum (Fig. 32.2) and from carcinoma in situ of the vulva; dark field examination or punch biopsies may be required to differentiate these lesions. Small to medium-sized verrucous lesions can usually be treated with patient-applied podofilox (Condylox), imiquimod (Aldara), or by providers (cryotherapy, podophyllin, or trichloroacetic acid). Intralesional interferon and laser surgery represent alternative regimens. Small amounts of podophyllin (0.25 mL) should be used to avoid severe burns. Podophyllin, imiquimod, and podofilox are contraindicated during pregnancy. Large amounts of podophyllin have produced coma in adults and fetal death in pregnancy. A biopsy should be done on atypical lesions before therapy is initiated because podophyllin causes bizarre histologic changes that persist for months. Cryotherapy, trichloroacetic acid, or laser ablation can be used on vaginal warts during pregnancy. Recurrence rates of 50% probably relate to the failure of these methods to kill the virus in adjacent untreated areas. Severe burns have occurred from the use of 5-fluorouracil (5-FU) to treat warts; as a result its use is not recommended. Large warts may not respond to surgical or laser removal alone but also may require regional interferon therapy. Examination of sexual partners is unnecessary because most are already infected.

FIG. 32.2. Condylomata lata of the vulva and perineum. (From Curtis AH, Huffman JW. *A textbook of gynecology*, sixth ed. Philadelphia: WB Saunders, 1950, with permission.)

Vestibulitis

Patients with vestibulitis characteristically have pain with vaginal penetration (i.e., intercourse or tampon insertion) and, in extreme cases, have difficulty sitting or wearing tight clothing. This condition is frequently treated as vaginitis because acidic vaginal discharge increases local irritation. Patients typically have an erythematous area, most commonly at the 4-o'clock and 8-o'clock positions just outside the hymenal ring. There is no clear evidence that HPV or bacteria cause the inflammation, but an accelerated inflammatory response to *Candida* is suspected in many patients. Treatment is often not effective, but regimens include topical corticosteroids (i.e., without an alcohol base), local corticosteroid injection, oral tricyclic antidepressants, pelvic floor muscle physical therapy, and, in severe cases, skinning vulvectomy.

Furunculosis

Hair follicles or areas of hidradenitis in the vulva may become infected by staphylococci or other bacteria, giving rise to pustules. This condition must be distinguished from herpetic and syphilitic lesions. The diagnosis can be made by culture or by the finding of Gram-positive cocci in Gram stains of pus. If only a few small lesions are present, treatment with hot, wet compresses or hexachlorophene scrubbing helps. If a larger area is involved, administration of antistaphylococcal antibiotics is required until infection subsides, which may take weeks. Daily low-dose suppressive antibiotic therapy (e.g., erythromycin, 250 mg) can reduce frequent recurrences.

Bartholinitis

Two stages of Bartholin gland infection occur. The first is an acute infection of the duct and gland, usually caused by either *N. gonorrhoeae* or *C. trachomatis*. If infection causes obstruction of the duct, an abscess stage can result. Anaerobic bacteria can be isolated from most abscesses. Rarely, synergistic vulvar gangrene results from bartholinitis.

Cultures and a Gram stain of material expressed from the duct may identify gonococci. Cervical gonococcal and chlamydial cultures should be obtained, and treated, if present. Patients with an abscess usually require abscess marsupialization or incision with placement of a catheter in the abscess cavity for 3 to 6 weeks to establish a new duct. Simple incision and drainage should be avoided, since it does not address the drainage of mucus from a functioning gland. Recurrent infection from vaginal flora and mucus cyst formation are common sequelae of bartholinitis.

Chancroid

The soft chancre of chancroid is a painful ulcer with a ragged, undermined edge and a raised border. In contrast, the syphilitic chancre is painless and indurated. “Kissing ulcers” on opposing surfaces of the vulva occur. Tender, unilateral adenopathy is common, and node suppuration occurs in about 50% of patients with lymphadenopathy. The incubation period of this sexually transmitted disease (STD) is 2 to 5 days. The infection is caused by *Haemophilus ducreyi*, a Gram-negative bacterium that forms a school-of-fish pattern on Gram-stain preparation. The organism is fastidious, and it is best identified by culture of material from aspirated lymph nodes or from the chancre using special selective media or PCR tests. The differential diagnosis includes syphilis, genital herpes, and lymphogranuloma venereum.

Preferred treatment is azithromycin (Zithromax), 1 g orally, or ceftriaxone sodium (Rocephin), 250 mg intramuscularly, in single doses, or ciprofloxacin, 500 mg twice daily for 3 days or erythromycin, 500 mg three times daily for 7 days. Sexual partners should be examined and treated.

Granuloma Inguinale

Granuloma inguinale is rare in temperate climates and is usually considered an STD, although gastrointestinal transmission can occur. The initial papular lesion typically ulcerates and develops into a soft, painless, progressive granuloma that may be covered by a thin, gray membrane. The granuloma may spread over the course of many months to involve the anus and rectum (Fig. 32.3). Lymph nodes are moderately enlarged and painless, but they do not suppurate. The infection can become chronic, and long-standing disease may cause genital scarring and depigmentation, as well as lymphatic fibrosis with consequent genital edema.

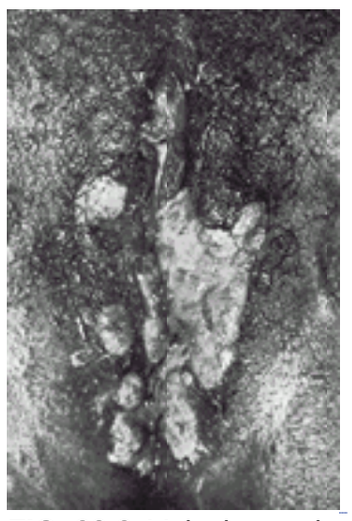

FIG. 32.3. Vulval granuloma inguinale of relatively recent origin. Some lesions are separate, others confluent. The margin of lesion is raised and scrolled; the base is granular and covered imperfectly by thin, gray slough. (From Demis DJ, Crounse RG, Dobson RL, et al, eds. *Clinical dermatology*, Vol 3. Hagerstown, MD: Harper & Row, 1972, with permission.)

Infection is caused by a gram-negative bacillus, *Calymmatobacterium granulomatis*, which is difficult to culture because it is an intracellular parasite. The identification is usually made from scraped material or a biopsy specimen obtained from the periphery of the lesion. Bipolar-staining bacteria are best identified within mononuclear cells (i.e., Donovan bodies) by Wright or Giemsa staining.

Therapy of choice is a 3-week course of doxycycline, 100 mg, or trimethoprim/sulfamethoxazole (double strength) or ciprofloxacin, twice daily. Erythromycin and azithromycin offer alternative therapies.

Lymphogranuloma Venereum

The incubation period for lymphogranuloma venereum (LGV) is 2 to 5 days. Thereafter, a transient, primary, painless genital or anorectal ulcer develops. Multiple, large, confluent inguinal nodes develop 2 to 3 weeks later and eventually suppurate. Acute infection may cause generalized systemic symptoms. If untreated, the infection enters a tertiary phase that can lead to extensive lymphatic obstruction. This development, together with continued infection, causes fistulae or strictures of the anal, urethral, or genital area. Women with LGV are particularly susceptible to rectal stricture. Edema and elephantiasis of the external genitalia and lower extremities are other serious sequelae.

The infection is caused by the sexually transmitted organism *C. trachomatis*, an intracellular bacterium. Only L $_{1\text{-}3}$ Chlamydia serovars, which produce accelerated in vitro tissue destruction, typically cause LGV. The diagnosis can be made by culturing chlamydiae from genital lesions or lymph nodes. The most specific and sensitive serologic test is the microimmunofluorescent antibody test, in which the specific L immunotypes are identified. The results of complement fixation (CF) tests are positive in 95% of patients with LGV, but the CF test lacks specificity; test results are often falsely positive in patients who do not have LGV but have previously been exposed to *Chlamydia.* High (=1:64 CF) titers offer some specificity.

LGV responds to 3-week regimens of doxycycline or erythromycin in the usual doses. Large lymph nodes should be aspirated to avoid chronic drainage. Surgical excision of scarred areas may be necessary.

ACUTE URETHRAL SYNDROME

Acute cystitis is present in approximately 50% of women with symptoms of dysuria and urinary frequency. Cystitis is defined by pyuria and midstream urine cultures that contain more than 10^5 organisms per milliliter of coliform or staphylococcal organisms. It is now apparent that about one-half of the remaining symptomatic women also have cystitis, but with less than 10^5 coliforms or *Staphylococcus saprophyticus* organisms per milliliter of urine obtained by suprapubic aspiration or urethral catheterization. Virtually all of these women have pyuria of eight or more leukocytes per high-power field of urine. The pyuria that occurs among another 25% of women with recent onset of internal dysuria and urinary frequency and negative urine cultures is termed acute urethral syndrome. These patients usually have *C. trachomatis*. The remaining 25% of patients with these symptoms have no pyuria, bacteriuria, or chlamydial infection and a variety of diseases are involved, including candidal or herpetic vulvitis, or no infection origin. Treatment of acute urethritis consists of therapy for the infectious agent, whether it is coliform or *S. saprophyticus* cystitis, or *C. trachomatis* urethritis.

VAGINITIS

Vaginitis is the most common reason for a gynecologic visit. Symptoms of vaginitis include increased vaginal discharge, vulvar irritation and pruritus, external dysuria, a foul discharge odor, and a yellow discharge color. However, symptoms are very poor indicators of the specific cause of vaginitis. Women with infectious vaginitis have either an STD (i.e., trichomonads) or a quantitative increase in normal flora (i.e., *Candida*, *Gardnerella vaginalis*, anaerobes). At least four types of infectious vaginitis are found: candidal, trichomonal, bacterial vaginosis, and, in children, gonococcal. Every effort should be made to establish the diagnosis of one of these specific infections and to avoid the diagnosis of a nonspecific vaginitis. A specific diagnosis is mandatory to select effective therapy. Treatment of nonspecific vaginitis inevitably fails.

Other conditions that may cause excessive vaginal discharge include cervicitis, normal cervical mucus from cervical ectopy, vaginal foreign bodies (most commonly, retained tampons), and allergic reactions to douching or vaginal contraceptive agents. Atrophic vaginitis among postmenopausal women can produce burning and dyspareunia, but an infectious cause is not established.

A small amount of vaginal discharge may be normal, particularly midcycle, when large amounts of cervical mucus production produce a clear vaginal discharge. A normal vaginal discharge should not have a foul odor or produce irritation or pruritus.

Examination

External genitalia may be normal or edematous, erythematous, excoriated, or fissured. Local vulvar disease, especially vestibulitis, must be excluded from a secondary effect of vaginitis.

On speculum examination, the vaginal mucosa may be erythematous. Discharge characteristics that are important to observe are viscosity, floccular appearance, color, and odor. Vaginal pH status must be determined. A pH less than 4.5 indicates *Candida* or a normal vaginal discharge. A potassium hydroxide (KOH) odor test and a microscopic examination consisting of a normal saline and 10% KOH wet mount should be done. A drop of each solution is mixed with discharge. Before placing a cover glass over the two separate drops, the KOH portion is tested for the presence of a fishy amine odor. Microscopic examination of the KOH portion is made for hyphae under the 100× objective, and examination of the saline portion is made for trichomonads and clue cells under the 400× objective. Multiple causes of vaginitis are frequent.

Vaginal cultures are not particularly helpful except when used selectively to identify Candida. Microscopy is specific, but only 80% sensitive in identifying various types of vaginitis. When infectious vaginitis is suspected in patients in whom a specific diagnosis cannot be established, a repeat examination should be performed 2 weeks later.

Candidiasis

The most prominent symptom of candidiasis is vulvar and vaginal pruritus. Increased vaginal discharge is infrequent. Vulvar signs of edema, geographic erythema, and fissures may occur. Classically, the vaginal walls are red and contain adherent, white, curdy plaques. However, most women with candidiasis have atypical symptoms, little discharge, and no erythema.

Candida albicans causes about 90% of vaginal yeast infections. Noncandidal species cause the remaining infections. These saprophytic fungi are isolated from the vagina in 15% to 25% of asymptomatic women. Thus, the mere presence of vaginal *Candida* does not always identify an infection, but large numbers of organisms lead to symptomatic vaginitis. However, severe symptoms develop in some women with only a few organisms but with an accelerated immune response to *Candida.* Candidiasis occurs because changes in host resistance or immune response allow organism detection or cause inflammation. The most widely accepted risk factors for candidiasis include pregnancy, diabetes, and use of immunosuppressive drugs and broad-spectrum antibiotics. Frequent vaginal intercourse and vaginal douching also are risk factors. Because cellular, not humoral, immunity is required to resist candidal infections, pregnant women and patients receiving immunosuppressive drugs that decrease cellular immunity are predisposed to candidiasis. Candidal overgrowth is also favored by high urine glucose levels that can occur in diabetes or pregnancy. Broad-spectrum antibiotics cause suppression of the normal vaginal and gastrointestinal bacterial flora, allowing fungal overgrowth. The role of oral contraceptives in candidal infection remains controversial.

Most women have uncomplicated infection defined as a sporadic, mild, *C. albicans* infection in a host with normal immunity. About 5% of women have complicated infection defined as recurrent, severe, or non- *albicans* infection. Many of these occur in immunosuppressed women (pregnant, diabetic, or debilitated or immunosuppressed).

Candidiasis is best diagnosed in KOH wet-mounts. Vaginal plaques, vaginal discharge, or vulvar scrapings from the edge of the erythematous border are mixed with 10% KOH (Fig. 32.4). The mycelial form is usually found only during an infection; mycelia can be identified by KOH wet mount in 80% of cases. The pH of vaginal discharge is normal (i.e., 4.7 or less). Fungi can readily be isolated on various media. However, Candida is part of normal vaginal flora, and a positive culture does not necessarily indicate infection. Cultures for Candida should be limited to KOH wet-mount–negative patients with symptoms or signs of candidiasis. In fact, 50% of women with candidiasis have a negative wet mount, but a positive Candida culture.

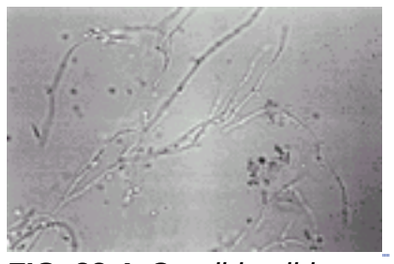

FIG. 32.4. *Candida albicans* growing as hyphae and pseudohyphae within infected tissue (×320). (From Monif GRG. *Infectious diseases in obstetrics and gynecology*. Hagerstown, MD: Harper & Row, 1974, with permission.)

Local vaginal therapy is used because most antifungal preparations are not absorbed from the intestinal tract. For uncomplicated infection, various intravaginal azole agents used for 3 to 5 days are equally effective for women with primary and infrequent candidal vaginitis. These agents include miconazole, clotrimazole, butoconazole (Femstat), tioconazole (Vagistat-1), and terconazole (Terazol). Azole drugs are not absorbed to any degree from the vagina, and the same local regimens can be used safely in pregnancy. The insertion of boric acid powder in capsules into the vagina is also effective. A one-time dose of fluconazole (Diflucan), 150 mg orally, or itraconazole (Sporanox), 400 mg initially then 200 mg for 2 days, is also effective for those with uncomplicated infection. Patients with complicated infection from severe symptoms need 7 to 14 days of intravaginal azole therapy or fluconazole 150 mg with the dose repeated in 4 days. Oral nystatin administration to decrease gastrointestinal colonization does not markedly improve therapeutic cure rates or diminish recurrence rates. About 15% of male sexual contacts of women with candidiasis have symptomatic balanitis; symptomatic males should be identified and treated to prevent recurrent female infection.

The number of non- *albicans* candidal infections appears to have increased. These infections respond poorly to azole therapy, including fluconazole. Boric acid or nystatin therapy works best. Even gentian violet 1% aqueous solution has a limited place in such patients.

Patients with frequently recurrent candidiasis represent the most difficult problem in treatment. Extended 2- to 3-week vaginal therapy, male therapy, and reduction of sugar intake are usually ineffective. A glucose tolerance test and HIV testing should be performed in recurrent or resistant cases to exclude unrecognized diabetes and HIV infection. In addition, some women with candidiasis have other concurrent vaginal infections; a repeat physical and wet-mount examination may clarify the problem.

Complicated infection from frequently recurring candidiasis (four or more times a year) should be treated first with standard anticandidal therapy for 2 weeks, followed by suppressive therapy with an intravaginal azole or boric acid twice weekly or an intravaginal azole daily for 5 days once a month, oral fluconazole, 150 mg weekly, or oral itraconazole, 400 mg monthly. Suppressive treatment should continue for at least 1 year; recurrent candidiasis is usually reduced to no or one infection yearly, but recurs in 30% to 40% of patients upon cessation of suppression.

Trichomoniasis

Characteristic symptoms of trichomoniasis include a profuse, yellow, malodorous, often uncomfortable vaginal discharge with vulvar irritation. *Trichomonas vaginalis* is a common sexually transmitted organism, present in 3% to 15% of asymptomatic women and in up to 20% of women who attend clinics for STDs. *T. vaginalis* is most likely identified in symptomatic women with recent acquisition. However, about 50% of all women with trichomoniasis are asymptomatic. Most male contacts of women with trichomoniasis asymptomatically carry the organism in the urethra and prostate.

A classic profuse, frothy, yellow vaginal discharge is present in only about one-third of women. The vulva may be edematous and inflamed by the discharge. Sometimes, subepithelial redness of the cervix (i.e., strawberry cervix) is seen with the naked eye; smaller red areas are more commonly identified colposcopically. The discharge in women with symptomatic trichomoniasis often has a pH greater than 4.5 and forms an amine odor with 10% KOH. Motile trichomonads are demonstrated in the saline wet-mount smear (Fig. 32.5). Trichomonads are larger than white blood cells (WBCs) and have a jerky motility. The wet mount usually also contains many polymorphonuclear leukocytes. Although the wet mount can identify trichomonads with 80% sensitivity among symptomatic women, less than 50% of all women with trichomoniasis by culture have positive wet mounts. Trichomonads also can be seen occasionally on a Pap smear.

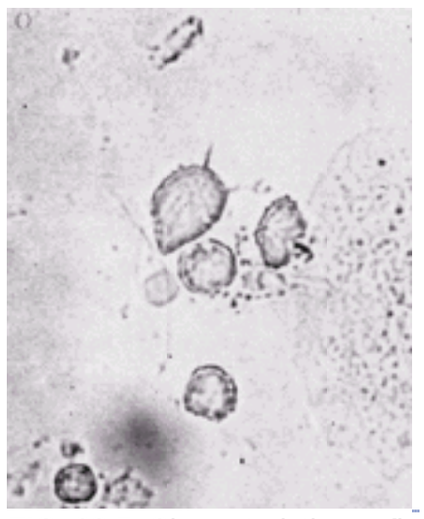

FIG. 32.5. Characteristic configuration of a trichomonad seen in wet smear at high-power magnification. (From Monif GRG. *Infectious diseases in obstetrics and gynecology.* Hagerstown, MD: Harper & Row, 1974, with permission.)

T. vaginalis is an anaerobic protozoan. A culture of this organism is easy to perform but not readily available, and culture should be limited to cases where the diagnosis is suspected, but cannot be confirmed by wet mount. Screening cultures in asymptomatic women are not recommended, except for certain high-risk populations. Women with trichomoniasis should also be cultured for *N. gonorrhoeae* because of a close association between the microbes.

T. vaginalis resides not only in the vagina but also in the urethra, bladder, and Skene glands, so systemic, rather than local, therapy is needed. Metronidazole is effective in treating trichomoniasis; the preferred regimen is 2 g in one dose because of complete patient compliance and high effectiveness. Extended 7-day metronidazole therapy, 500 mg twice daily, does not increase the 95% cure rate of a single dose. Simultaneous treatment of the male sexual partner is recommended. Recurrent trichomoniasis is usually attributable to either a lack of compliance or reexposure to an untreated sexual partner. A single recurrence should be treated with the recommended regimens. However, increasing in vitro and in vivo resistance of *T. vaginalis* to metronidazole exists, and repeated treatment failure should be treated with metronidazole, 2 g daily for 3 to 5 days. The Centers for Disease Control and Prevention (CDC) has consultation available for patients who fail this regimen (see Sexually Transmitted Disease Treatment Guidelines, 2002).

Metronidazole therapy is controversial because of its tumor-causing potential in humans. In animals, large doses (equivalent to 350 to 1,000 human doses) cause tumors. The drug also causes mutation of salmonellae associated with carcinogenic potential. No increased tumor rates were found in a small series of women evaluated for up to 10 years after metronidazole therapy for trichomoniasis. However, these data are only slightly reassuring that the drug does not cause cancer because longer, larger studies are needed to exclude this possibility. A meta-analysis and other studies show no consistent evidence of teratogenesis from use of metronidazole in pregnancy. The CDC Sexually Transmitted Disease Treatment Guidelines, 2002 no longer advise avoiding metronidazole in pregnancy. Treatment of asymptomatic *T. vaginalis* has not reduced prematurity and should be limited to symptomatic women. Persistent discharge after adequate treatment for trichomoniasis should lead to repeat examination for *Trichomonas*, candidiasis, and gonorrhea.

Bacterial Vaginosis

Bacterial vaginosis describes the vaginal condition resulting from overgrowth of both anaerobic bacteria and *G. vaginalis*. Both anaerobes and *G. vaginalis* are normal inhabitants of the vagina, but overgrowth of the normal Lactobacillus-dominant flora by these bacteria results in a thin, homogeneous, fishy-smelling, gray vaginal discharge that adheres to the vaginal walls and often is present at the introitus. In contrast to findings in other causes of vaginitis, the vaginal epithelium appears normal, and WBCs are usually not present. The fishy amine odor produced by anaerobes is accentuated when 10% KOH is added to the discharge.

The diagnosis of bacterial vaginosis is based on the presence of three of the following four characteristics of the discharge: pH greater than 4.5, a homogeneous thin appearance, a fishy amine odor with the addition of 10% KOH, and clue cells. Clue cells are vaginal epithelial cells with many organisms attached. The cell border of clue cells is so obscured by adherent bacteria that it is not identifiable. In bacterial vaginosis, 20% to 50% of the epithelial cells are clue cells. Polymorphonuclear leukocytes and lactobacilli are notably absent. Gram stains used for diagnosis rely on a reduction in *Lactobacillus* morphotypes and an increase in small Gram-negative rods and Gram-positive cocci. Commercially available card tests for high concentrations of *G. vaginalis* (Affirm), pH and trimethylamine (FemExam), and proline aminopeptidase (PIP Activity Test Card) are available. Cultures are not helpful because anaerobes and *G. vaginalis* can be recovered from women without bacterial vaginosis. In fact, up to 40% of asymptomatic women without vaginitis carry *G. vaginalis*. The distinguishing feature of bacterial vaginosis is the 10- to 1,000-fold increased concentration of anaerobic bacteria and *G. vaginalis*.

Factors leading to the overgrowth of anaerobes and *G. vaginalis* are poorly established but include the absence of Lactobacillus and a new sexual partner. Sexual transmission of the infection is considered a risk factor, but is unproven, especially since the treatment of sexual contacts does not prevent recurrence.

Treatment is not advocated for most asymptomatic women with bacterial vaginosis because it can spontaneously disappear. However, the 10- to 1,000-fold increased concentration of potentially virulent bacteria in the vagina is related to upper genital tract infection after surgery. A significant, increased relative risk (RR) of postoperative infection has been reported in patients with bacterial vaginosis following cesarean section (RR = 6), hysterectomy (RR = 3 to 4), and induced abortion (RR = 3). Bacterial vaginitis has also been associated with spontaneous PID and postpartum endometritis after vaginal delivery. Treatment of bacterial vaginosis is particularly beneficial for those undergoing elective surgery. Bacterial vaginosis in pregnancy has also been related to premature delivery (RR = 2 to 4), amniotic fluid infection (RR = 2 to 3), and chorioamnionitis (RR = 2 to 3); treatment of women with prior preterm delivery has reduced the incidence of preterm delivery, but treatment of low-risk asymptomatic women had no effect on preterm delivery.

Metronidazole, 500 mg orally twice daily for 7 days, metronidazole gel, intravaginally once daily for 5 days, and clindamycin cream, intravaginally at bedtime for 7 days are the recommended regimens for bacterial vaginosis. Alternative regimens include 2 g oral metronidazole in a single dose, 300 mg oral clindamycin twice daily for 7 days, and clindamycin ovules intravaginally at bedtime for 3 days. Metronidazole and clindamycin are particularly effective against the anaerobes. Fluoroquinolones, tetracycline, sulfonamides, and erythromycin are ineffective. Treatment of the male sexual contact with metronidazole does not prevent recurrent bacterial vaginosis and is not recommended.

Toxic Shock Syndrome

Toxic shock syndrome is an acute illness caused by toxin-producing *Staphylococcus aureus*. About 6% of women carry *S. aureus* in the vagina, but only 2% of women have *S. aureus* capable of producing the toxic shock toxin. The syndrome is highly associated with menstruation and probably with tampon use, but it has also occurred from *S. aureus* infection of the breast and endometrium after delivery and from abdominal surgical wounds. Characteristic features include a high fever (>102°F [38.9°C]), a diffuse rash, hypotension, skin desquamation (usually 1–2 weeks later), and a wide variety of systemic effects, including gastrointestinal (vomiting, diarrhea), muscular (myalgia), mucous membrane (hyperemia), renal (elevated blood urea nitrogen or creatinine level), hepatic (enzyme abnormalities), hematologic (thrombocytopenia), and neurologic (disorientation, coma). Vaginal or specific-site cultures recover *S. aureus*. Blood, throat, and cerebrospinal fluid cultures, together with serologic tests for Rocky Mountain spotted fever, leptospirosis, and measles, are usually indicated to exclude diseases with similar clinical presentations.

A vaginal tampon, if present, should be removed. Patients should be hospitalized and, when indicated, given large fluid volumes for blood pressure maintenance. Beta-lactamase–resistant antibiotics are recommended, and if other causes of bacterial sepsis such as meningococcemia cannot be excluded, additional antibiotics are necessary. Other life-supporting measures such as intubation, vasopressor administration, and dialysis are often necessary. The case:fatality ratio has been reduced from 15% to 3% with supportive therapy. Antibiotics are of no proven benefit in the acute stage, but they do reduce recurrence rates from 30% to 5%.

Although the effectiveness is uncertain, it is prudent for all women to avoid the prolonged and overnight use of tampons. It is recommended that postpartum women not use tampons for 6 to 8 weeks after delivery. Women with toxic shock syndrome should be warned of recurrent episodes and advised against resuming tampon use.

SYPHILIS

Physicians must constantly be aware of possible syphilitic infection, particularly in populations with high rates of HIV infection. Most women with syphilis are asymptomatic and have only serologic evidence of infection. *T. pallidum* rapidly enters lymphatics after exposure, but a primary chancre lesion usually takes about 3 weeks to develop. The classic chancre ulcer is painless and firm with sharply defined, raised edges; however, most syphilitic ulcers are atypical. Any suspicious genital ulcer should be studied by dark field examination. Serous material expressed from the ulcer base is mixed with saline solution, and because *T. pallidum* is an anaerobe, this mixture must be immediately placed under a cover slip with the edges occluded by petroleum jelly. Identification of typical spirochetes by dark field microscopy establishes a diagnosis of primary syphilis. Dark field examination of ulcer material from possible syphilitic ulcers should be done on 3 consecutive days. VDRL test or rapid plasma reagin (RPR) and fluorescent treponemal antibody (FTA) serology should be performed for a patient with a suspicious lesion. If the serologic results are nonreactive and spirochetes cannot be demonstrated by dark field examination, serologic tests should be repeated in 1 month.

Secondary syphilis appears 6 or more weeks later and is characterized by a symmetric, macular, papular, or papulosquamous rash and generalized, nontender lymphadenopathy. Condylomata lata (see Fig. 32.2) are highly infectious, hypertrophied, wartlike lesions of secondary syphilis that usually occur in moist areas such as the vulva or perineum; they must be distinguished from other vulvar lesions. Superficial, painless mucosal erosions of the mouth or vagina, called mucous patches, develop in one-third of patients. Systemic symptoms of fever, weight loss, and malaise may occur. Serologic tests are positive in the secondary stage.

Untreated patients will enter a latent phase of syphilis during which clinical and physical manifestations are absent. Diagnosis in the latent phase is established by serologic tests. Intermittent spirochetal bloodstream invasion may occur in the early latent phase (first 4 years). In pregnancy, the risk of congenital fetal infection in the primary and secondary phases of syphilis is 80% to 95%; the risk during the early latent phase is 70%. During the late latent phase, immunity develops, which reduces blood invasion, and the risk of congenital syphilis decreases to 10%. Congenital syphilis is reported to be on the rise, affecting 1 in 10,000 live-born infants. Fetal or perinatal death occurs in 40% of those with congenital syphilis. About one-third of adult patients with untreated late syphilis manifest central nervous system or cardiovascular symptoms of tertiary syphilis.

VDRL and RPR tests detect a nontreponemal, nonspecific reagin antibody. The tests can be titrated, and the titer either falls or disappears after therapy for early or secondary syphilis. Thus, the VDRL test can be used to judge the activity of either a first episode or reacquired infection in a patient with documented syphilis. Treated patients with latent syphilis may retain high, stable VDRL titers. Acute bacterial or viral infections can give rise to acute false-positive serologic reactions that last for up to 6 months. Several conditions, such as aging, addiction to drugs, autoimmune disease, and pregnancy, can lead to chronic, nonspecific, false-positive VDRL reactions. False-positive VDRL titers usually are 1:8 or less. By contrast, the FTA test involves a specific antitreponemal antibody, and false-positive FTA reactions are rare. Patients with a positive VDRL reaction must have a confirmatory FTA test to exclude a false-positive VDRL reaction. Patients with a false-positive VDRL reaction will have a negative FTA reaction. In patients with syphilis, the FTA test remains positive indefinitely, and because the test is not titrated, repeat FTA testing should not be done in a known positive patient.

The treatment schedules for syphilis currently recommended by the U.S. Public Health Service's CDC are as follows:

- Early syphilis: Early syphilis is defined as primary, secondary, or latent syphilis of less than 1 year's duration. The drug of choice is penicillin G benzathine, 2.4 million U intramuscularly in a single dose. Alternative choices for penicillin-allergic patients include 2-week regimens of doxycycline, 100 mg twice daily, or tetracycline, 500 mg four times daily. Ceftriaxone, 1 g daily intramuscularly for 8 to 10 days, may be used if close follow-up can be ensured.
- Syphilis of longer than 1 year's, or of unknown, duration: Penicillin G benzathine, 2.4 million U intramuscularly each week for 3 successive weeks (7.2 million U total), is the drug of choice in this situation. Alternative choices for the penicillin-allergic include doxycycline and tetracycline for 4 weeks. Intravenous aqueous penicillin G or penicillin G procaine is recommended for neurosyphilis. Erythromycin is not recommended for neurosyphilis. Spinal tap to exclude asymptomatic neurosyphilis is recommended for those with neurologic or ophthalmologic signs, other evidence of active disease (aortitis, gummas), HIV infection, treatment failure, and infection for more than 1 year with a titer of 1:32 or greater. Neurosyphilis and syphilis in HIV-positive patients should be treated by infectious disease specialists.
- Syphilis in pregnancy: Parenteral penicillin is the only documented efficacious treatment in pregnancy. Treatment with penicillin is the same as for the corresponding stage of syphilis among nonpregnant women. For pregnant patients who are allergic to penicillin, tetracycline is not used because of toxicity and erythromycin is not used because of high failure rates to cure the fetus. Penicillin is so superior to other antibiotics for treating syphilis in pregnancy that pregnant, penicillin-allergic patients should be desensitized. The Jarisch-Herxheimer reaction commonly occurs in early syphilis, and pregnant women should be hospitalized in anticipation of this possibility for monitoring of themselves and the fetus. The reaction is ascribed to the sudden massive destruction of spirochetes by antibiotics; it is marked by fever, myalgia, tachycardia, and occasionally hypotension. The reaction usually begins within 24 hours and subsides spontaneously in the next 24 hours. All patients need to be followed with quantitative serologic tests to monitor treatment results and offered HIV testing. All sexual partners need to be contacted and tested for syphilis.

CERVICITIS

Acute cervicitis is defined as the presence of yellow cervical mucopus or an increased number of WBCs in cervical mucus. Symptoms are usually limited to a purulent vaginal discharge. Physical findings include mucopus in the endocervical canal or bleeding after swabbing of the cervix. Organisms that infect the cervical columnar epithelium, *C. trachomatis* or *N. gonorrhoeae*, can be isolated separately or in combination from about one-half of women with purulent cervicitis. Unknown microbes cause the other cases. The diagnosis can also be established by the finding of more than 10 WBCs per 1,000× microscopic field.

Infectious ulcers of the cervix caused by herpesvirus, syphilis, and chancroid must be distinguished from erosion and the other conditions described in Chapter 33. Depending on the nature of the lesion, Gram stain, Pap smear, culture, dark field examination, colposcopy, and, in some cases, biopsy may be required.

If *N. gonorrhoeae* is found by culture or DNA technique, treatment should be the same as for gonorrhea, including treatment for coexisting *C. trachomatis*. If *N. gonorrhoeae* is not found, azithromycin or doxycycline regimens used for *C. trachomatis* are recommended. Ofloxacin or levofloxacin can also be used.

ENDOMETRITIS

Lymphocytes and neutrophils normally appear in the endometrium in the second half of the menstrual cycle; their presence does not necessarily constitute endometritis. However, plasma cells are not normally in the endometrium, as they represent an immune response, usually to a bacterial antigen.

Endometritis produces nonspecific symptoms, and it should not be diagnosed unless plasma cells, neutrophils within glands, or a specific causative infection is found. Endometritis may occur in the following situations:

- puerperal endometritis (see Chapter 19)
- chlamydial or gonococcal endometritis, often occurring among patients with salpingitis
- endometritis after endometrial instrumentation or surgery
- tuberculous endometritis
- purulent endometritis, occurring in pyometra caused by a cervical stricture or after radium insertion
- endometritis occurring characteristically in the presence of an intrauterine device (IUD).

The fact that chronic endometritis is associated with the use of IUDs is well documented; it results from organisms attached to the IUD surface rather than from the foreign body per se. Transfundal endometrial cultures of hysterectomy specimens from women who had used tailed IUDs for more than a few weeks uniformly recovered bacteria, while cultures from women who did not use an IUD were negative. Bacteria that can be recovered are usually of low pathogenicity, but more virulent intrauterine bacteria occasionally cause malodorous discharge and salpingitis. In addition, an anaerobe, *Actinomyces israelii*, has been found in Pap smears from about 5% of women using IUDs, but not in those who do not use IUDs. This organism appears to colonize the IUD, and when it is found on a Pap smear, asymptomatic patients should be warned of abnormal discharge or abdominal pain, representing infection. If symptomatic infection occurs, the IUD should be removed, and patients treated with ampicillin for 2 to 4 weeks. Asymptomatic patients should not have the IUD removed because of *A. israelii*.

Chronic plasma cell endometritis in nonpregnant women who do not use an IUD is often related to endometrial infection with *C. trachomatis* and, to a lesser extent, *N. gonorrhoeae*. Plasma cell endometritis occurs in up to 50% of women with acute cervicitis and over 80% of women with acute salpingitis. Symptoms are abnormal uterine bleeding and mild uterine tenderness. Untreated endometritis can progress to clinically evident salpingitis.

GONORRHEA

Gonorrhea is caused by the Gram-negative diplococcus *N. gonorrhoeae* which attach only to columnar or transitional cells by pili and are rapidly brought intracellularly by pinocytosis. They attract leukocytes, commonly giving rise to purulent discharge. Gonorrhea is usually sexually transmitted, although organisms can be acquired by neonates passing through an infected cervix, causing gonorrheal ophthalmia.

Course of the Disease

N. gonorrhoeae in the lower genital tract infects the urethra, Bartholin glands, and endocervix. The anus and rectum can also be infected either from cervical infection or during anal coitus. Urinary frequency, dysuria, and a purulent vaginal discharge are the first symptoms to appear 2 to 5 days after exposure. At least 50% of women with *N. gonorrhoeae* infection have no symptoms. Many women do not seek medical attention if these symptoms are mild. The discharge occasionally is locally irritating and causes vulvar edema and soreness. Pharyngitis may result from gonorrheal pharyngeal infection. In 2% of infected women, disseminated gonococcal infection occurs, causing fever, septicemia, dermatitis, arthritis, endocarditis, or meningitis, in various combinations. Untreated gonorrhea is associated with premature delivery and premature rupture of membranes.

In 10% to 17% of women with untreated gonorrhea, the organisms ascend to produce upper genital tract infection or acute PID (Fig. 32.6). Acute PID is the most common serious sequela of gonorrhea. The mechanical and antibacterial properties of cervical mucus probably provide a barrier against upward extension, but during menstruation the mucus barrier is lost, and gonococci can disseminate to the uterus and fallopian tubes. A transient endometritis occurs as the organisms pass through the uterine cavity and reach the fallopian tubes, where they produce an acute and usually bilateral inflammatory reaction of tubal mucosa. The tubes characteristically become swollen and reddened when the muscularis and serosa become inflamed. If exudate drips from the fimbriated ends of the tubes, pelvic peritonitis occurs that ultimately can cause peritoneal adhesions. The swollen and congested fimbriae may adhere and produce tubal occlusion.

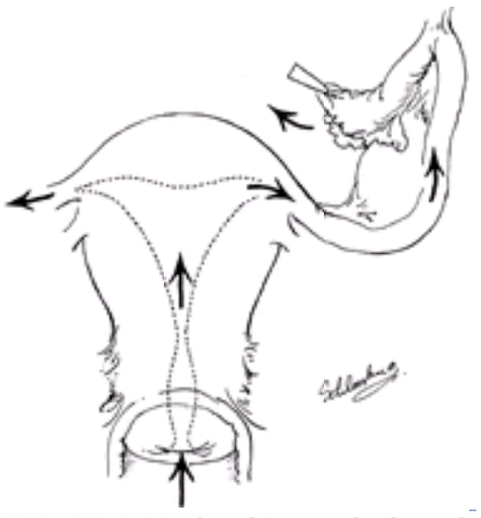

FIG. 32.6. Mode of transmission of gonococcal pelvic infection. Portal of entry is external genitalia. The organism enters cervix, following mucous membrane, passes up through the uterine cavity, and attacks the fallopian tube. Pelvic peritonitis results from escape of pus from tubal fimbria. (From Wharton LR. *Gynecology and female urology.* Philadelphia: WB Saunders, 1943, with permission.)

The process can take any of the following courses. With prompt, appropriate antibacterial therapy, the infection may subside with little permanent damage to the reproductive tract. The fimbriae may occlude, producing permanent tubal infertility. The swollen and congested fimbriae may adhere to one another or to the ovary, trapping the exudate in the tube and giving rise to pyosalpinx or, if the ovary becomes infected, a tuboovarian abscess. The mucosal folds may adhere to one another, forming glandlike spaces that are filled at first with exudate and later, as the process becomes chronic, with watery secretion in follicular salpingitis (Fig. 32.7). If the infection subsides after agglutination of the fimbriae and closure of the distal tube, watery secretion accumulates and distends the tube, forming a hydrosalpinx (Fig. 32.8).

FIG. 32.7. Follicular salpingitis, an end stage of gonorrheal salpingitis. Mucosal folds are adherent, giving rise to innumerable round or irregular cystlike cavities lined by cuboidal epithelium. (From Kelly HA. *Operative gynecology*, Vol 2. New York: Appleton, 1898: plate XI; drawing by Max Brodel, with permission.)

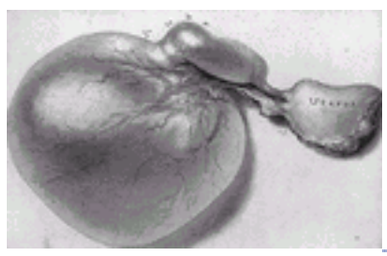

FIG. 32.8. Hydrosalpinx. (From Curtis AH, Huffman JW. *A textbook of gynecology*, sixth ed. Philadelphia: WB Saunders, 1950, with permission.)

Symptoms and Signs

Except for the discharge, which can be milked from the urethra or is present in the vagina or cervix, there are few signs of acute gonococcal infection in women. Bilateral, mild to severe lower abdominal pain may occur with acute salpingitis. Pelvic peritonitis can cause pain on movement of the cervix, direct and rebound abdominal tenderness, muscle guarding that prevents abdominal palpation, and tender adnexa to various degrees on bimanual examination. However, a sizable proportion of women with salpingitis experience either mild or no symptoms. In subacute salpingitis, infection continues with signs and symptoms that are even less overt than those of the acute stage. In the end stage of salpingitis, the uterus and the adnexa can be fixed by pelvic peritoneal adhesions. The adnexa may be either adherent to the posterior aspect of the uterus or prolapsed in the cul-de-sac, which may pull the uterus into a retroverted position. Notable features are dyspareunia, sterility, and chronic, aching pelvic pain that increases before menstruation.

Diagnosis

The diagnosis of gonorrhea depends on a culture of *N. gonorrhoeae* or identification of *N. gonorrhoeae* by DNA tests. The finding of intracellular Gram-negative diplococci in the Gram stain of cervical or urethral exudate points to gonorrheal infection, but Gram stains for gonorrhea are insensitive. Gonococcal testing should be performed on women with positive Gram stains, symptoms or signs suggestive of gonorrhea (e.g., cervicitis, undiagnosed vaginitis, dysuria), other STDs, bartholinitis or skenitis, acute lower abdominal pain suggestive of acute salpingitis, or suspected disseminated gonococcal infection, as well as on women with male sexual contacts with gonorrhea.

Sites to be tested in order of importance are: cervix, anal canal, pharynx, and urethra. Vaginal discharge should be wiped away from the cervix before mucus is obtained for testing. Genital samples must be cultured on Thayer-Martin or similar media containing antimicrobial agents that inhibit growth of the normal bacterial and fungal flora. Patients with gonorrhea should also receive a test for chlamydial infection because 10% to 30% of women with *N. gonorrhoeae* also have *C. trachomatis*.

Because gonorrhea is an STD, it usually is present in the male partner. The fact that more than 40% of the male contacts of women with gonorrhea are asymptomatic carriers who otherwise do not seek treatment underscores the importance to identify and treat male sexual contacts.

Drug Therapy of Uncomplicated Lower Genital Tract Gonorrhea

The CDC-recommended treatment schedules for gonorrhea reflect increased resistance to penicillin and tetracycline and in Asia, the Pacific rim, and the West Coast to quinolones, frequent coexistence of chlamydial infection with gonorrhea, potentially serious complications, and frequently no testing for *C. trachomatis*. Penicillin is no longer recommended to treat gonorrhea because ß-lactamase production by extrachromosomal plasmids destroys ß-lactam antibiotic activity in a large number of gonococcal strains. Resistance to quinolones will likely increase.

The recommended drug therapy regimens are given in Table 32.2. A loading dose of cephalosporin or quinolones is used to inhibit *N. gonorrhoeae*. Patients allergic to penicillin should receive spectinomycin (Trobicin) or other cephalosporins or quinolones. If *C. trachomatis* is not excluded, azithromycin or doxycycline is indicated. Quinolones and doxycycline should not be given to pregnant women. Special antibiotic regimens are recommended for patients with complicated gonococcal infections. These regimens are published in the widely circulated CDC Sexually Transmitted Disease Treatment Guidelines 2002. Prophylactic regimens to prevent ophthalmia neonatorum include silver nitrate, erythromycin, and tetracycline applications.

Gonorrhea
Recommended loading dose regimen (choice of one plus treatment for chlamydia)
Ceftriaxone (Rocephin), 125 mg i.m.
Cefixime (Suprax), 400 mg p.o.
Ciprofloxacin (Cipro), 500 mg p.o.
Ofloxacin (Floxin), 400 mg p.o.
Levofloxacin (Levaquin) 250 mg p.o.
Alternative regimen (choice of one)
Spectinomycin (Trobicin), 2 g i.m.
Ceftizoxime (Cefizox), 500 mg i.m.; cefotaxime (Claforan), 500 mg i.m.; or cefoxitin (Mefoxin), 1 g i.m. with probenecid
Norfloxacin (Noroxin), 800 mg p.o. or gatifloxacin (Tequin) 400 mg p.o.; all in a single dose
Chlamydia
Follow-up regimen to treat chlamydia (choice of one)
Azithromycin (Zithromax), 1 g p.o., in a single dose, *or*
Doxycycline, 100 mg p.o., b.i.d. for 7 d
Alternative regimen (choice of one)
Ofloxacin, 300 mg p.o., b.i.d. for 7 d
Erythromycin (see "Pregnant patients" below)
Levofloxacin 500 mg p.o. for 7 days
Pregnant patients (choice of one)
Preferred regimen
Erythromycin base 500 mg p.o. q.i.d. for 7 days, *or*
Amoxicillin 500 mg p.o. t.i.d. for 7 days, *or*
Azithromycin, *or*
Erythromycin base, 250 mg p.o., q.i.d. for 14 d, *or* azithromycin
Alternative regimen
Erythromycin ethylsuccinate, 800 mg p.o., q.i.d. or 400 mg q.i.d. for 14 d

TABLE 32.2. *Treatment regimens for gonorrhea and chlamydia*

The first-choice regimens are so effective that test-of-cure cultures are not recommended. A rescreening culture in 1 to 2 months is reasonable. Patients treated with alternative regimens should have a test-of-cure culture in 4 to 7 days after therapy. All male sexual contacts need referral for evaluation and treatment.

Patients with gonorrhea should have serologic tests for syphilis. Those with incubating syphilis (i.e., seronegative, without clinical signs of syphilis) are likely to be cured by all the regimens mentioned, except for quinolones and spectinomycin. Patients treated with these regimens need a follow-up serologic test for syphilis.

CHLAMYDIAL INFECTION

C. trachomatis is a sexually transmitted bacterium that is often associated with gonorrhea. Chlamydiae infect the same tissues and produce the same symptoms and

diseases as gonorrhea. Chlamydial infection causes urethritis, bartholinitis, cervicitis, endometritis, salpingitis, Fitz-Hugh and Curtis syndrome (i.e., perihepatitis), and LGV. Treatment of *C. trachomatis* in pregnancy reduces premature delivery. Neonates born of mothers with chlamydial cervical infection have up to a 40% risk of chlamydial conjunctivitis and a 20% risk of chlamydial pneumonia. As with gonococcal infection, male sexual contacts have both symptomatic and asymptomatic urethritis.

C. trachomatis is an obligate intracellular bacterium that attaches to columnar or transitional epithelial cells, is engulfed by pinocytosis, and remains within a phagosome membrane that protects it from host defense mechanisms. The bacteria replicate until they replace most of the cell and, ultimately, cause the cell to rupture. Infective particles are released into the extracellular space, and the process is repeated. Replication time is a relatively slow 24 to 48 hours, explaining the characteristically long latent period between the time of exposure and the onset of symptoms, which ranges from weeks to months.

C. trachomatis is three to five times more common than *N. gonorrhoeae* in developed countries because it is not routinely sought in asymptomatic patients. Chlamydial infection is most often asymptomatic and frequently not identified until overt infection occurs. Infection is particularly common among teenagers. *C. trachomatis* is associated with serious sequelae, including tubal infertility and ectopic pregnancy and it appears able to produce permanent tissue damage more readily than *N. gonorrhoeae*. Permanent tissue damage appears largely related to the immune response to infection. Reinfection, chronic infection, and infection in the presence of antibody to chlamydial heat shock protein are particularly associated with tissue damage.

Chlamydial infection should be suspected with acute urethritis, mucopurulent cervicitis, and salpingitis. The rate of chlamydial salpingitis approximates that of gonorrhea. Chlamydial infections can be diagnosed by culture, a direct monoclonal antibody slide test, an enzyme-linked immunosorbent assay, or DNA techniques. New DNA methods using ligase chain reaction or PCR offer both sensitivity and specificity not achieved with older tests. Samples should be taken from the cervix or from urine with DNA tests.

Azithromycin and doxycycline are the most effective drugs to treat chlamydial infection (see Table 32.2). Erythromycin, ofloxacin (Floxin), and levofloxacin (Levaquin) are alternatives. In pregnancy, erythromycin and amoxicillin are preferred, but reports document the effectiveness and safety of azithromycin.

GENITAL MYCOPLASMAS

Genital mycoplasmas have often been thought a microbe in search of a disease because they are ubiquitous and not highly virulent. *Mycoplasma hominis* is recovered from the vagina in 15% to 70% of women, and *Ureaplasma urealyticum* is recovered from 40% to 95% of women. A third isolate, *Mycoplasma genitalium*, is now associated with endometritis. These organisms are phylogenetically positioned between bacteria and viruses.

The most convincing role for mycoplasmas in human female infections is as a pathogen in postpartum fever. Mycoplasmas are recovered from the blood of 10% to 15% of women with postpartum fever, and antibodies to *M. hominis* are demonstrated in 50% of such women. Their role in salpingitis is less clear. Mycoplasmas are recovered from the tubes of 5% to 15% of women with salpingitis, but in primate model studies, *M. hominis* produces an adnexitis and not salpingitis.

Maternal lower genital tract *U. urealyticum* is not associated with low birth weight, and treatment of *U. urealyticum* does not reduce preterm births. However, organisms are found in intraamniotic infection and cause cerebrospinal fluid and lung infection in premature neonates. Recovery of *U. urealyticum* from fetal tissue of mid-trimester spontaneous abortuses also suggests a relationship with abortion. The role of *U. urealyticum* in fertility is unsettled, but in some reports, mycoplasmas were not related to infertility or to higher pregnancy rates in infertile women.

Both *M. genitalium* and *M. hominis* are sensitive to tetracycline. Erythromycin inhibits *U. urealyticum* in vitro but not *M. hominis*. However, neither antibiotic very effectively eradicates mycoplasmas from the vagina.

ANAEROBIC BACTERIA

Anaerobic bacteria are highly associated with pelvic infections. Multiple anaerobic species, usually together with one or more aerobic bacteria, typically combine to form a polymicrobial infection. Intraabdominal abscess and postoperative, postpartum, and bacterial vaginosis infections are the most important examples of anaerobic infection.

Anaerobic bacteria are part of the normal vaginal flora. Although many mechanisms by which anaerobic bacteria become pathogenic are unknown, two mechanisms known to cause anaerobic infection include (a) reduction of the redox potential that occurs with tissue trauma from surgery and (b) antibiotic selection that preferentially inhibits aerobic bacteria. Clinicians can virtually assume the presence of anaerobes in infections with a foul-smelling odor as only anaerobes produce odorous metabolic products. Anaerobes are virtually always isolated from an abscess. Anaerobic infections can also produce gas and cause thromboembolism.

The anaerobic bacteria most commonly found in genital infections include anaerobic Gram-positive cocci (*Porphyromonas* and *Peptostreptococcus* species), gram-negative rods (*Prevotella* [*P. melaninogenicus, P. bivia*], *Bacteroides* [*B. fragilis*], and *Fusobacterium* species), and Gram-positive rods (*Clostridium* species).

Cultures should be obtained before antimicrobial therapy is begun. Because anaerobes are part of the normal flora, deep tissue cultures are required that are not contaminated by surface bacteria. Because 48 or more hours are required for anaerobe isolation, antibiotic selection is usually based on clinical signs. Anaerobic infection should be particularly suspected with abscess formation, a foul odor, gas formation, tissue necrosis, sterile cultures from obviously infected sites, and thromboembolism. Antibiotic sensitivity testing is only a rough guide to antibiotic susceptibility, but in vitro and in vivo experience has shown that clindamycin, metronidazole, imipenem/cilastatin sodium (Primaxin), second- and third-generation cephalosporins (cefoxitin sodium [Mefoxin], cefotaxime sodium [Claforan]), and extended-spectrum penicillins (ticarcillin disodium/clavulanate potassium [Timentin], amoxicillin/clavulanate potassium) are effective to treat anaerobic infections.

SALPINGITIS

Acute primary salpingitis results when pathogenic bacteria in the cervix invade the fallopian tubes. *N. gonorrhoeae*, *C. trachomatis*, normal flora aerobic and anaerobic bacteria, and, perhaps, *M. genitalium* are known causes of tubal infections. Virtually all primary salpingitis occurs among sexually active, menstruating, nonpregnant women. Gonococcal and chlamydial infections account for 50% to 60% of cases. Tuberculous, parasitic, or fungal salpingitis is rare in industrialized countries. Salpingitis usually occurs without instrumentation or trauma to the genital tract; however, approximately 15% of cases occur after instrumentation (e.g., IUD insertion, dilation and curettage, abortion, hysterosalpingography). Perisalpingitis secondary to acute appendicitis or other intraabdominal infections accounts for less than 1% of cases.

Acute salpingitis is a common event that annually develops in up to 1% of women between 15 and 39 years of age. Young, sexually active women between 15 and 24 years of age have the highest rate of infection. This infection has tremendous cost consequences. At least $1 billion is required to treat the 800,000 women with acute salpingitis in the United States annually, and $40 billion is spent to diagnose and treat tubal infertility.

Epidemiology

Most women are infected with sexually transmitted organisms. The rate of salpingitis is increased in women with multiple sexual partners. The high rate of salpingitis in young women is due to their increased rates of gonorrhea and chlamydial infection. Routine screening for *C. trachomatis* and *N. gonorrhoeae* has reduced salpingitis in Europe and the United States. Sexually active women at increased risk for STDs, especially women younger than 25 years and with multiple sexual partners, should be annually screened for chlamydial infection and gonorrhea. Such screening will prevent salpingitis and subsequent tubal infertility and ectopic pregnancy more effectively than any other measure. Previous salpingitis also predisposes women to subsequent salpingitis, probably because mucosa damaged from prior infection is more susceptible to infection than normal tissue. Patients with previous uncomplicated gonorrhea have a high rate of subsequent salpingitis, in part because of increased rates of subsequent gonorrheal infection. Prior chlamydial infection predisposes patients to salpingitis if a second chlamydial infection occurs. Repeated chlamydial infections produce a hyperimmune response that increases the chance and severity of tissue damage.

The presence of an IUD is an independent risk factor for salpingitis. IUD users have a two-fold to four-fold increased rate of both salpingitis and tubal infertility, compared to non–IUD users. The highest rate of salpingitis in IUD users occurs within a few weeks of insertion as a result of the introduction of cervical bacteria into the endometrial cavity along with the IUD. Most infections in IUD users, however, occur long after insertion, probably because bacteria wick along the IUD tail from the vagina to the uterus and adhere to the IUD surface. IUDs also appear to enhance anaerobic bacterial growth, and their use is associated with *Actinomyces* and bacterial vaginosis infection. Because IUD use is also associated with tubal infertility, an IUD should not be inserted in women who desire future pregnancy. By contrast, barrier or oral contraceptive methods appear to protect against salpingitis. The protective effect of oral contraceptives on salpingitis appears to exist only for patients with chlamydial infection, possibly due to a down-regulation of the hyperimmune response caused by the organisms.

The role of male contacts with untreated gonococcal or chlamydial urethritis is often ignored by gynecologists. Only 25% of male contacts of women with gonococcal salpingitis are treated by the time the female partner develops symptomatic salpingitis. Over 50% of the male contacts with gonococcal urethritis are asymptomatic, and *N. gonorrhoeae* is isolated from 40% of these asymptomatic males. Men with nongonococcal urethritis represent reservoirs of chlamydial salpingitis. To reduce the rate of new and recurrent salpingitis, all male contacts of women with any type of salpingitis should be examined and cultured. If infectious organisms are found, males should be appropriately treated.

Bacteriology

Neisseria gonorrhoeae In most studies in the United States, *N. gonorrhoeae* is recovered from 40% to 50% of women with acute salpingitis. However, gonococcal prevalence varies greatly: *N. gonorrhoeae* is isolated from less than 20% of salpingitis cases in Sweden and from 80% of cases in certain urban populations in the United States. In women with both cervical gonorrhea and salpingitis, *N. gonorrhoeae* is the most frequent intraabdominal isolate, but the sole isolate in only 30% of these cases. The remainder have either no organisms or other organisms isolated alone or together with *N. gonorrhoeae* in the abdomen. Chlamydial infection frequently coexists with gonorrhea; in some studies, more than 50% of women with gonorrhea also had *C. trachomatis* in the cervix. Positive tubal gonococcal cultures are usually obtained during the early stages of infection, but not in the later stages of infection.
Chlamydia trachomatis *C. trachomatis* is as important as the gonococcus in causing acute salpingitis. From 30% to 60% of women with salpingitis have *C. trachomatis*, and in most of these women the organisms can be isolated from the fallopian tube. Application of new DNA tests for *C. trachomatis* identifies even more chlamydial infections. Chlamydial salpingitis is under-diagnosed because many patients have mild symptoms and are not identified. It is now evident that women with mild symptoms and signs have the same amount of severe tubal damage as those with severe symptoms. Chlamydial salpingitis often produces mild symptoms and signs but may produce more severe tubal damage compared to gonococcal salpingitis.
Nonsexually Transmitted Aerobic and Anaerobic Bacteria Nonsexually transmitted aerobic and anaerobic bacteria are normally present in cervical and vaginal flora and particularly include organisms associated with bacterial vaginosis. These organisms can be a direct cause of salpingitis, but they also cause secondary infection in combination with *N. gonorrhoeae* and *C. trachomatis*, IUD use, or instrumentation. Polymicrobial infection with these agents is common in salpingitis. In such cases, many different Gram-positive and Gram-negative aerobic and anaerobic organisms are isolated, particularly *Porphyromonas*, *Prevotella*, and *Bacteroides* spp, including *B. fragilis*. Anaerobic organisms are especially common in serious infections, and they are virtually always found in abscesses.
Mycoplasmas Genital mycoplasmas have been recovered from the tubes or cul-de-sac in 2% to 20% of patients with salpingitis. In addition, more than 20% of patients with salpingitis have changes of mycoplasmal antibody titer suggestive of invasive infection. These organisms lack the virulence of *N. gonorrhoeae* and *C. trachomatis*, and they appear to cause an adnexitis rather than salpingitis. *M. genitalium* identified by DNA technology is related to endometritis.

Pathogenesis

Salpingitis occurs from vaginal and cervical bacteria ascending into the endometrium and fallopian tubes. The ascent of bacteria probably increases during menses, as evidenced by the onset of pain within 7 days of starting menses in one-half to two-thirds of patients with gonococcal salpingitis. Virulent gonococci also proliferate at menstruation, and less virulent gonococci are present at other times of the cycle. Other risk factors for salpingitis exist. Virulent bacteria in the cervix are more likely to cause salpingitis than nonvirulent bacteria, and *C. trachomatis* and *N. gonorrhoeae* are two virulent organisms capable of causing salpingitis. Virulence is occasionally evidenced by bacteria in the normal flora.

Specific bactericidal antibodies to *N. gonorrhoeae* appear to reduce salpingitis. Clinically recognized salpingitis develops in only 10% to 17% of women with cervical gonorrhea, and most of these women probably develop tubal infection during the first one or two menstrual periods between gonococcal acquisition and the development of specific bactericidal antibodies.

C. trachomatis may not depend on menses for ascent into the endometrium. Endometritis caused by *C. trachomatis* appears to be a common chronic intermediate infection that exists through several menstrual cycles. Tubal damage from chlamydial infection appears to occur from the immune response to infection. As mentioned, repetitive chlamydial infections elicit a hyperimmune response that accelerates tissue damage. The presence of chlamydial heat shock protein also contributes to an acceleration of tissue damage.

The usual route of infection with either organism is the contiguous spread along mucosa from the cervix to the endometrial cavity and fallopian tubes (see Fig. 32.6). Lymphatic or hematogenous dissemination of organisms from the uterus to the adnexa is uncommon in nonpregnant women. It also is possible that organisms may be transported along the fallopian tubes by cilia or even carried by their attachment to spermatozoa or to other organisms.

Fitz-Hugh and Curtis Syndrome Perihepatitis consisting of liver capsule inflammation without liver parenchymal damage is referred to as Fitz-Hugh and Curtis syndrome (Fig. 32.9). Swelling of the liver capsule produces pain with inspiration, usually in the right upper quadrant. A purulent or fibrinous exudate appears on the capsular surface. Violin-string adhesions between the liver capsule and the anterior abdominal wall are a late manifestation of capsular inflammation.

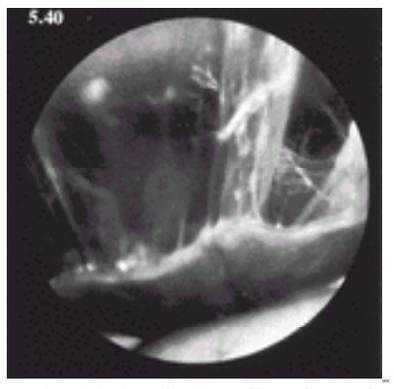

FIG. 32.9. Liver adhesions in Fitz-Hugh and Curtis syndrome.

Perihepatitis was formerly believed to be caused solely by *N. gonorrhoeae*, but *C. trachomatis* also causes this syndrome. Chlamydial heat shock protein is associated with perihepatitis, indicating that the syndrome is another manifestation of a hyperimmune response to chlamydiae. Some organisms travel transperitoneally from the fallopian tubes to reach the liver surface, but organisms may also reach the liver by lymphatic and hematogenous routes. The syndrome occurs virtually exclusively in women, although two men with this syndrome have been reported. Salpingitis is invariably the source, but the syndrome occasionally follows appendicitis and other causes of peritonitis. The Fitz-Hugh and Curtis syndrome is frequently misinterpreted as cholecystitis, viral pneumonia, or pyelonephritis. Liver enzyme levels may be mildly elevated. In women with salpingitis, 5% to 10% developed symptoms, but another 5% of women have asymptomatic perihepatitis. This latter group may have the violin-string adhesions recognized as an incidental finding at a subsequent surgery. Many women with Fitz-Hugh and Curtis syndrome note the onset of lower abdominal pain before or with the upper abdominal pain, but some develop such severe upper abdominal pain that they fail to complain of lower abdominal pain. Given the frequency of salpingitis and the infrequency of acute cholecystitis in women 15 to 30 years of age, Fitz-Hugh and Curtis syndrome is a more likely cause of upper quadrant pleuritic pain than cholecystitis and should be suspected in any woman with pleuritic upper quadrant pain and physical signs of salpingitis. Laparoscopy is useful to diagnose unclear cases.

Diagnosis

The largest unsolved problem with salpingitis is the lack of sensitive and specific diagnostic criteria. For an estimated one-half of women, salpingitis does not cause sufficiently typical symptoms to be diagnosed. In Table 32.3 women are presented who, despite not having a recognized episode of salpingitis, had severe enough tissue damage to cause infertility from tubal obstruction. Thus, patients with mild abdominal pain and other mild manifestations are often not identified. An emphasis must be placed on increasing the sensitivity for the diagnosis. The problem is the very broad spectrum of clinical severity among patients with salpingitis. Although severe manifestations are usually recognized as salpingitis, they occur in only 30% of patients. Insistence on rigid criteria, such as fever, severe tenderness, leukocytosis, and an elevated erythrocyte sedimentation rate (ESR), leads to a failure of diagnosis in nonovert cases.

TABLE 32.3. *Proportions of patients with tubal occlusion from salpingitis with no history of salpingitis*

On the other hand, a clinical diagnosis of salpingitis that relies on the history, physical examination, and nonspecific laboratory tests also has a large false-positive error rate. Several studies demonstrate that a clinical diagnosis of salpingitis can be confirmed by laparoscopy in about 65% of patients (Table 32.4); about 20% of patients had no disease observed, and another 15% had other pelvic conditions, most commonly ovarian cyst, ectopic pregnancy, appendicitis, or endometriosis.

TABLE 32.4. *Laparoscopic observations in patients with a clinical diagnosis of pelvic inflammatory disease*

History

Important history and physical findings in patients with presumed PID are listed in Table 32.5. However, none of these findings distinguish women with salpingitis from those with other causes of pelvic pain. Lower abdominal pain is the most consistent symptom in women with overt salpingitis, although it may be mild or even absent. Acute pain is present for less than 15 days in 85% of patients who present with PID. Most women with gonococcal salpingitis experience acute pain during menses; in chlamydial salpingitis, the onset of pain is often insidious and not associated with menses. The abdominal pain is usually continuous and most severe in both lower quadrants. It increases by movement, the Valsalva maneuver, and intercourse. Abnormal vaginal bleeding occurs in 15% to 35% of women with salpingitis. Symptoms of appendicitis and ectopic pregnancy overlap with those of PID. The risk of STD can be helpful in forming a tentative opinion. An increased risk of PID would be expected for women with multiple sexual partners, other STDs, symptomatic male partners, and prior gonorrhea or prior PID.

TABLE 32.5. *Clinical findings in 176 women with suspected acute pelvic inflammatory disease (PID)*

Physical Examination

Most patients with salpingitis have lower abdominal, cervical, and bilateral adnexal tenderness (see Table 32.5). Cervical motion tenderness is a sensitive indicator of salpingitis. However, none of these findings is specific for PID and patients with other disease or with no apparent disease may have similar physical findings. Other associated findings lack the sensitivity to be useful. For example, although a temperature of 100.4°F (38°C) or higher is present more often in patients with than in those without salpingitis, only 45% of patients with laparoscopically confirmed salpingitis have a temperature greater than 100.4°F.

Laboratory Tests

Nonspecific tests as the peripheral WBC count and the ESR are helpful only if the results are abnormal, but they are often normal. Of patients with laparoscopically confirmed salpingitis, 50% have a normal WBC count and 25% have a normal ESR. C-reactive protein levels may be more useful.

Laboratory signs such as yellow cervical mucopus and a cervical Gram stain with an increase of polymorphonuclear leukocytes of more than 30 per high-powered field appear to offer a more specific indication of salpingitis in patients with pelvic tenderness. It is mandatory to obtain a culture for gonorrhea and a test for chlamydial infection. Cervical culture for other organisms is not recommended.

Endometrial Biopsy

Endometrial biopsies are easy and safe to obtain. Histologic evidence of endometritis is based on finding plasma cells and polymorphonuclear leukocytes migrating through the epithelium. Histologic endometritis has a 90% sensitivity and specificity for diagnosing salpingitis, compared to laparoscopy.

Ultrasound and Computed Tomography

Abnormal vaginal ultrasound findings correlate with a diagnosis of salpingitis made by laparoscopy, but these findings remain too insensitive with mild tubal abnormalities and too nonspecific for a certain diagnosis. Ultrasound is useful to distinguish an abscess from an inflammatory mass within the adnexa, define a mass in obese or excessively tender patients, and follow the size of a mass with treatment. Computed tomography has successfully been used for the same purposes; it may be especially helpful if ultrasound is difficult to perform, as in peritonitis or a recent abdominal incision.

Laparoscopy

Laparoscopy provides the most accurate way to diagnose salpingitis. It should be used when the diagnosis is unclear, particularly in patients with severe peritonitis, to exclude a ruptured abscess and appendicitis. It is estimated that for every 100 times a clinical diagnosis of PID is made without visual confirmation, three patients with appendicitis are treated for PID (see Table 32.4), resulting in a critical delay in the correct diagnosis. Pain and tenderness from acute PID should abate 3 or 4 days after antibiotics begin. Patients without reduced tenderness on antibiotic therapy also benefit from laparoscopy. About 20 of 100 women with a clinical diagnosis of PID have no abnormality at laparoscopy. All cases where laparoscopy is performed should have cultures taken from the fimbriated ends of the tubes, regardless of the findings, to detect the small number of patients with endosalpingitis and normal-appearing tubes.

Open laparoscopy is used to identify and percutaneously drain pelvic abscesses. The abscess is visualized, and a 14-French catheter is placed into the abscess, which is drained of pus and carefully rinsed with sterile bacteriostatic water. A closed drainage system is then connected to the catheter for 1 to 3 days until drainage ceases. About 90% of abscesses are successfully treated by percutaneous drainage.

Examination of the Male Partner

Examination of the male sexual partner helps establish the diagnosis of PID and treat STDs. At least 80% of male contacts of women with PID are not treated by the time PID occurs in the female partner. If there is no urethral discharge, a Gram stain and urethral material for *N. gonorrhoeae* and *C. trachomatis* identification should be obtained.

Treatment

Adequate treatment of salpingitis includes an assessment of severity, antibiotic therapy, additional general health measures, close patient follow-up, and treatment of the male sexual partner. Patients with the mildest manifestations can be treated as outpatients. Specific indications for hospitalization include severe manifestations of salpingitis (i.e., severe peritonitis, severe nausea, or fever higher than 100.4°F [38°C]), a suspected abscess, outpatient antibiotic failure, and an uncertain diagnosis

with severe symptoms.

Patients should be examined within 2 to 3 days and again at 7 and 21 days later to verify a satisfactory response to treatment. If an IUD is in place, it should be removed 24 to 48 hours after therapy is started. Ideally, the antibiotic should be selected according to the organism isolated, but, in salpingitis, empiric therapy is used. The treatment regimens recommended by the CDC were designed to treat gonococcal and chlamydial salpingitis and anaerobic salpingitis. Inpatient regimens include either intravenous cefoxitin or cefotetan disodium (Cefotan) and oral doxycycline or intravenous clindamycin and gentamicin, followed by oral clindamycin or doxycycline for a total of 14 days. The clindamycin regimen is also effective for patients with chlamydial infection. Parenteral therapy can be stopped 24 hours after clinical improvement. Outpatient regimens include a loading dose of an antibiotic recommended for gonorrhea and treatment of Chlamydia with an option to treat for anaerobic infection. One treatment regimen consists of ofloxacin 400 mg twice daily or levofloxacin 500 mg once daily for 14 days with or without metronidazole. A second regimen includes ceftriaxone or cefoxitin with probenecid in a single dose plus doxycycline with or without or metronidazole, 500 mg twice daily for 14 days. It is also possible to use other antibiotic regimens with similar antimicrobial activity. Gonococcal salpingitis responds more rapidly to antibiotics than nongonococcal salpingitis. Recommended agents must be used in full doses because partially treated, subacute salpingitis may result from the use of lower doses.

Hospitalized patients with peritonitis but no adnexal abscess usually respond rapidly to the regimens. An adnexal abscess, even if systemic manifestations are mild, should be treated with antibiotics that inhibit *B. fragilis* because of its frequency in pelvic abscesses. Clindamycin, metronidazole, cefoxitin, or imipenem/cilastatin should be used to treat a known or suspected pelvic abscess.

Abdominal surgery is indicated for a ruptured abscess. Colpotomy drainage is usually preferable for an unruptured midline abscess filling in the cul-de-sac. If laparotomy is performed for a presumptive diagnosis of appendicitis but instead acute salpingitis is found, the procedure should be limited to taking a tubal culture and closure of the abdomen. If laparotomy is required for an unresolved abscess or adnexal mass, surgery should be limited to the most conservative procedures that will be effective. Unilateral abscesses respond to unilateral salpingo-oophorectomy if appropriate antibiotic regimens are used; routine hysterectomy and bilateral salpingo-oophorectomy are seldom needed to treat acute salpingitis in young women. As mentioned, percutaneous drainage of abscesses is usually successful.

When chronic pain occurs, surgery should be deferred as long as possible to allow maximum healing. Analgesics and oral contraceptives to prevent ovulation may suffice until the swelling and fixation decrease. Surgery may be indicated for persistent pain that does not respond to conservative measures, for recurrent attacks of pelvic pain, or for a pelvic mass that does not resolve. Laparoscopy with lysis of adhesions usually suffices, but adnexectomy or, rarely, even hysterectomy is required. Surgery is also necessary for infertile patients.

OOPHORITIS

Most cases of oophoritis are secondary to salpingitis. The ovary becomes infected when purulent material from the fallopian tube enters the ovary. If the tubal fimbriae are adherent to the ovary, the tube and ovary together may form a large retort-shaped tuboovarian abscess. Antibacterial therapy, as previously outlined, is immediately indicated, and surgery is mandatory if the mass is considered to be leaking or ruptured or if it fails to resolve. Ovarian abscess after gynecologic surgery is particularly resistant to antimicrobial treatment.

Oophoritis may occur without accompanying salpingitis in mumps and septicemia. Oophoritis of this type usually results in lower abdominal pain that lasts for only a few days during an acute infectious illness. The ovarian infection usually subsides without incident, although abscesses may occur. If bimanual examination is not satisfactory, ultrasound scans may be used to detect abscesses.

GENITAL TUBERCULOSIS

Female genital tuberculosis remains relatively uncommon in the United States. Less than 1% of salpingitis cases can be attributed to *Mycoplasma tuberculosis*. Pulmonary tuberculosis remains a problem in many impoverished areas, and its rate is rising in parallel with the number of female patients with HIV infection. Although the spread of tuberculosis from the primary pulmonary infection to the pelvis usually occurs early in tubercular infection, early detection of genital infection is seldom feasible. Genital tuberculosis develops in about 10% of patients with pulmonary tuberculosis.

Pathogenesis

Virtually all genital infections are secondary to a pulmonary infection, which usually spreads by the bloodstream from the lungs to the fallopian tubes within 1 year of the primary pulmonary infection (Fig. 32.10 and Fig. 32.11). Direct extension occurs from the tube in several directions: to the pelvic peritoneum and ovary, to the endometrium, and to the cervix. Less common lymphatic extension to the genitalia can occur from abdominal sources or by direct extension from the intestinal tract. Genital tuberculosis is seldom caused by an ascending infection from a sexual partner with tuberculous epididymitis.

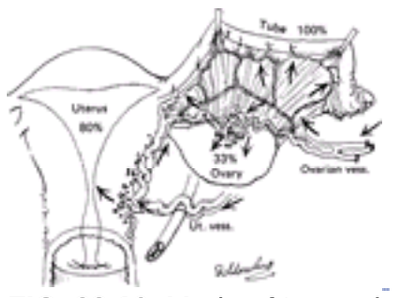

FIG. 32.10. Mode of transmission of tuberculous pelvic infection. Tubercle bacillus invades pelvic organs by way of bloodstream from distant focus in the lung or other organ. (From Wharton LR. *Gynecology and female urology.* Philadelphia: WB Saunders, 1943, with permission.)

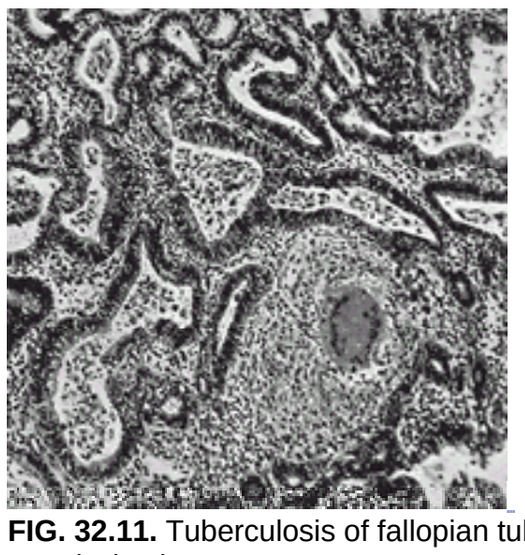

FIG. 32.11. Tuberculosis of fallopian tube (×105). (From Curtis AH, Huffman JW. *A textbook of gynecology*, sixth ed. Philadelphia: WB Saunders, 1950, with permission.)

The initial tubal lesion may remain localized for a considerable time (in some cases years), or it may extend to the interior tubal mucosa. Endosalpingitis results either in an exudative phase where ulcer formation at the site of caseous degeneration produces a typical moth-eaten pattern hysterosalpingogram, or in an adhesive phase, where large tubercles are present within the tubes. Dense perisalpingian adhesions are characteristic. In contrast to bacterial salpingitis, tubal occlusion, particularly fimbrial closure, does not occur early in tuberculous disease, and the tubes may remain patent despite relatively marked destruction of the tubal wall.

Tubal infection is present in virtually all women with genital tuberculosis. Endometrial infection is present in 50% to 80% of cases. Infected endometrium is shed monthly at menses and the endometrium becomes reinfected from tubal seeding. Myometrial infection occurs but only in advanced cases. Cervical infection occurs in

only 10% to 25% of patients, resulting in either a papillomatous or ulcerative lesion that grossly resembles cervical carcinoma.

Clinical Forms

Latent Genital Tuberculosis In the latent form, genital tuberculosis appears partially or completely arrested after the initial tubal infection, and patients have few or no pelvic complaints. Pelvic physical findings are normal. The diagnosis is usually made in the course of an investigation of infertility (by endometrial biopsy or dilation and curettage) or by chance at laparotomy. In the latent phase, a precarious balance exists between the disease and the host defense mechanisms. Active but latent infection has been documented 30 years after an initial infection.
Tuberculous Salpingitis Tuberculous salpingitis is a more advanced infection that may develop immediately after the primary hematogenous tubal spread, or it may follow a prolonged latent phase. The tubes are grossly enlarged by the inflammatory reaction. Although the symptoms and findings can mimic those of acute bacterial salpingitis, clinical manifestations are usually indolent and prolonged. Additionally, tuberculous salpingitis does not respond to the antibiotic therapy used for acute bacterial salpingitis. Despite these differences from bacterial salpingitis, tuberculosis is often discovered only by histologic examination of an excised tube.
Tuberculous Peritonitis In tuberculous peritonitis, widespread infection of all peritoneal surfaces produces ascites, adhesions, and innumerable small nodules (i.e., tubercles) throughout the abdomen. The serosal surfaces of the pelvic organs are typically involved, and the tubes are often patent. This form results from hematogenous or lymphatic spread.

Diagnosis

A history of pulmonary tuberculosis is often present in patients with genital tuberculosis, but simultaneous active pulmonary infection is uncommon. A normal chest film does not exclude genital tuberculosis because pulmonary lesions are found in only 30% to 50% of genital tuberculosis cases. The most common complaints are sterility and pelvic pain. Deteriorating health and menstrual abnormalities may also occur. Menorrhagia may be associated with abdominal pain, but amenorrhea or oligomenorrhea also occurs with tuberculous peritonitis. Most women with genital tuberculosis are in their 20s and 30s, but because of the frequent tendency for long latency periods, the disease may become active even after menopause. As mentioned, tubal tuberculosis may mimic acute bacterial salpingitis. However, when a pelvic problem does not conform to expected rules, the first consideration should be ectopic pregnancy and the second pelvic tuberculosis. Pelvic tuberculosis should be strongly considered when salpingitis occurs in a woman who is considered to be virginal.

A first-strength, purified protein derivative tuberculin skin test is important because a negative result virtually rules out the possibility of tuberculosis. Diagnosis is best established by endometrial biopsy, which should be performed in the week preceding menstruation, when the endometrium is thickest and is most likely to contain tubercles. A portion of the specimen should be cultured, and the remainder submitted for histologic examination. Repeated cultures of the menstrual blood can also be obtained. If cultures of either biopsy specimens or menstrual blood are negative, curettage may yield results. Antimicrobial susceptibility testing should be performed to predict drug resistance.

Endometrial biopsy, curettage, and culture of menstrual flow or endometrial tissue can provide an exact diagnosis of genital tuberculosis if the results are positive; if the results are negative, tuberculosis cannot be excluded. Diagnostic laparotomy is indicated if these measures fail to verify a diagnosis in a patient with a history and pelvic findings suggestive of genital tuberculosis. Diagnostic laparoscopy may be performed if there is minimal likelihood of tuberculous peritonitis, but caution must be used because of the possibility of perforating a loop of adherent bowel. Hysterosalpingography may reveal a characteristic tubal pattern, but it may also cause severe exacerbation of disease and should not be used if tuberculosis is possible.

The incidental discovery of reproductive tract tuberculosis may be the first indication that the patient has tuberculosis. In such patients, it must be determined whether or not other sites (e.g., lungs, urinary tract, bone, and gastrointestinal tract) also are infected.

Treatment

A three-drug therapy consists of isoniazid, 300 mg daily, rifampin, 600 mg daily, and pyrazinamide, 1,500 mg daily, for 18 to 24 months. In areas of high resistance, streptomycin or ethambutol (Myambutol) is added as a fourth drug. Patients without adnexal masses should have an endometrial biopsy for culture and microscopic examination 6 and 12 months after starting therapy. Persistent organisms need to be susceptibility-tested to identify drug-resistant strains. Laparotomy is performed if adnexal masses persist for 4 months and rifampin or streptomycin should be given preoperatively. Bilateral salpingectomy and removal of other tuberculous foci may be performed in young women with minimal disease. A bilateral salpingo-oophorectomy and total hysterectomy are indicated in those with advanced disease or advanced age. Pregnancy after tubal tuberculosis is rare, even in women with minimal disease. If the tubes are damaged by genital tuberculosis, efforts to improve fertility by tubal operations are usually futile.

SUMMARY POINTS

- STDs are common, particularly in young sexually active women with multiple sexual partners. However, most STDs occur among the larger population of women not at high risk for STDs.
- STDs are often asymptomatic for both women and their sexual partners.
- Many classic symptoms associated with various STDs are common in women without infection and, conversely, they are not present in many women with STDs.
- Many signs present in women with STDs also are common and they are present in women with no identifiable infection. Specific laboratory tests are usually required to confirm infection.
- The best course of treatment of STDs incorporates a combination of antimicrobial therapy directed at the patient and her partner, education about reducing STD exposure, and, when appropriate, careful follow-up examination and testing.

Additional Books and Book Chapters

This chapter addresses benign diseases of the vagina and vulva. Vaginal disorders including vaginal inflammation, vaginal adenosis, vaginal granulation tissue, and vaginal prolapse of the fallopian tube are discussed. Benign diseases of the vulva are presented in four major categories: nonneoplastic epithelial disorders, including vulvar lichen sclerosus and squamous cell hyperplasia; other inflammatory dermatoses, including vulvar vestibulitis; vulvar and vaginal ulcers, including infectious conditions that may cause ulceration; and a section on dark lesions of the vulva, including melanosis, lentigo simplex, nevi, and other benign pigmented lesions. The last section discusses the differential diagnosis of cysts of the vulva, including Bartholin cysts, and reviews common benign tumors of the vulva.

BENIGN DISEASES OF THE VAGINA

Vaginitis

Vaginitis may be of various causes and these have been classified in various ways; however, the classification outline of Sobel has been adapted for use here (Table 33.1).

Cause	Approximate % of total
Bacterial vaginosis	50%
Gardnerella vaginalis	
Mycoplasma hominis	
Mobiluncus curtisii	
Candidiasis	25%
Trichomonas vaginitis	20%
Other	5%
Atrophic vaginitis	
Postmenopausal	
Postpartum	
Physical agent-related	
Foreign body	
Allergic	
Chemical/caustic agents	
Desquamative inflammatory vaginitis	
Idiopathic	
Behçet syndrome-related	
Dermatosis-related or dermatosis-like	
Lichen planus, erosive	
Cicatricial pemphigoid	
Pemphigus	
Linear IgA disease	
Lichenoid vaginitis	
Ulcerative vaginitis/acute bacterial vaginitis	
Staphylococcus aureus infection	
Toxic shock syndrome	
Streptococcal vaginitis	
Beta-hemolytic streptococci	
Idiopathic vaginitis	
Causes unrelated to the above	

TABLE 33.1. *Causes of vaginitis in adults*

Lichenoid Vaginitis

Lichenoid vaginitis is primarily a descriptive diagnosis. Clinically these patients are usually of reproductive age and have symptoms of dyspareunia or vulvovaginal discomfort and pain. On examination vaginal mucosal atrophic-like changes are usually seen associated with punctate red areas.

Histopathologic findings include superficial chronic inflammation at the mucosal–submucosal interface (lichenoid in character), atrophic-like changes within the mucosa, and microscopic submucosal hemorrhagic areas. A number of these patients have had associated vulvar vestibulitis or a vulvar dermatosis. Treatment is directed toward the underlying cause of the inflammatory process, if known. If atrophy is present, vaginal estrogen cream may be effective.

Congenital Vaginal Adenosis

An association between a specific lesion of the lower genital tract and intrauterine exposure to diethylstilbestrol (DES) and related nonsteroidal synthetic estrogens has been established. Clear cell adenocarcinoma (carcinoma) of the vagina or cervix has been the most ominous but least frequently encountered sequel related to maternal administration of these drugs, with an estimated incidence of no more than 4 per 1,000 exposed young women. Benign anatomic anomalies, however, are exceedingly common and include vaginal adenosis and cervical vaginal ridges, including a cervical “hood” of vaginal tissue about the apparent ectocervix. Transverse vaginal septum and large cervical ectopian (eversion) involving the cervix and the upper vagina are also recognized abnormalities. The uterus may be small and the uterine cavity “T”-shaped.

Vaginal adenosis is defined as the presence of benign glandular epithelium in the superficial vaginal wall usually of endocervical and, more rarely, endometrial type. It is frequently accompanied by squamous metaplasia that may be extensive and can, over time, completely replace the columnar epithelium, leading to a “remodeling” of the upper vagina and cervix which results in a relatively normal-appearing vagina and cervix. The endometrial type of adenosis is more commonly associated with clear cell adenocarcinoma.

Acquired Vaginal Adenosis

Acquired adenosis of the vagina (columnar cell metaplasia, mucinous metaplasia, and ciliated cell metaplasia) represents an acquired metaplastic change of the nonkeratinized squamous epithelium of the vulva vestibule to columnar epithelium of mucinous or tubal–epithelial type. This has also been described within the vulvar vestibule (see “ Vulvar Cysts”).

Vaginal columnar cell metaplasia (acquired adenosis) presents as a somewhat red area in the upper vagina that may be associated with a mucoid vaginal discharge. This has been described associated with Stevens-Johnson syndrome as well as after vaginal laser or 5-fluorouracil (5-FU) therapy for vaginal intraepithelial neoplasia.

Within the vagina, topical estrogen cream and acidification of the vagina can promote squamous metaplasia of the columnar epithelium, with resulting squamous mucosa. Surgical excision is not necessary in such cases.

Vaginal Granulation Tissue

Granulation tissue within the vagina may be found in the vaginal suture line following hysterectomy or other vaginal operative procedure. It can also occur following vaginal treatment that ulcerated or resulted in the loss of the vaginal mucosa, such as laser therapy. The patient may complain of postcoital bleeding or of an unusual mucoid-appearing discharge.

On physical examination granulation tissue is relatively red to violet in color as compared to the normal adjacent squamous mucosa. The surface may be slightly elevated and have a granular or mucoid appearance as compared to the adjacent squamous epithelium. The tissue may be friable and bleed easily on contact or following biopsy. Histopathology demonstrates characteristic granulation tissue with small clustered capillary-like vessels and loose-appearing edematous stroma with acute and chronic inflammatory cells.

Treatment usually consists of excisional biopsy or electrofulgeration. Monsel solution can control bleeding and be used if the granulation tissue recurs. Acidification of the vagina can promote vaginal mucosal healing.

Vaginal Prolapse of the Fallopian Tube

Prolapse of the fallopian tube through an apical vaginal suture line following hysterectomy may occur. The patient may experience pain with coitus and postcoital bleeding. On examination a red elevated mass is usually identified within the suture line, and the mass may be tender or painful on palpation or with pressure. In some cases the entire fimbriae may protrude from the suture line. If biopsy is performed the findings are of tubal epithelium usually with associated tubal muscle or typical fallopian tube plical architecture. Treatment is vaginal excision of the prolapsed portion of the tube.

VULVAR NONNEOPLASTIC EPITHELIAL DISORDERS

As classified by the International Society for the Study of Vulvovaginal Disease (ISSVD), vulvar nonneoplastic epithelial disorders include lichen sclerosus, squamous cell hyperplasia (formerly hyperplastic dystrophy), and other dermatoses. This terminology replaced the ISSVD terminology, as reported in 1976, and does not use the term “vulvar dystrophy”.

Lichen sclerosus and squamous cell hyperplasia usually present as white lesions of the vulva. They are both symptomatic, associated with pruritus or burning pain. Biopsies, usually taken from several sites bearing the white epithelium, are necessary to definitively distinguish these lesions. Diagrammatic representation of vulvar anatomy is included in Fig. 33.1.

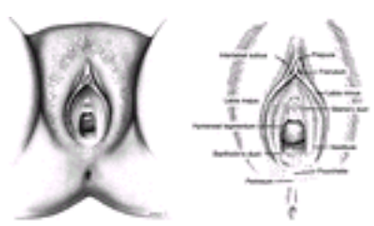

FIG. 33.1. Diagrammatic representation of vulvar anatomy. (From Wilkinson, Stone. *Atlas of vulvar disease.* Philadelphia: Lippincott, Williams and Wilkins, with

permission.)

Lichen Sclerosus

Lichen sclerosus often presents as white, thin, parchment-like skin. Ecchymosis and superficial erosions or ulcerations may be seen, secondary to scratching (Fig. 33.2).

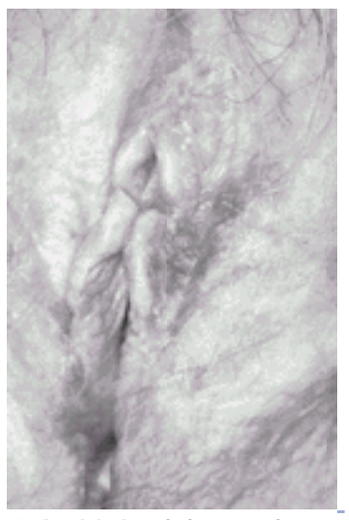

FIG. 33.2. Lichen sclerosus of the vulva with excoriation. (From Wilkinson, Stone. *Atlas of vulvar disease.* Philadelphia: Lippincott, Williams and Wilkins, with permission.)

Long-standing lichen sclerosus may result in marked introital stenosis with atrophy of the labia and agglutination of the labia minora and frenulum of the clitoris. Perianal and perineal involvement is common and the involved areas are typically symmetric in location. Lichen sclerosus may occur at any age, including childhood. The involved skin is often thin and wrinkled, and areas of ecchymosis and ulceration may be seen. In children, perianal lichen sclerosus may present with pain or bleeding on defication, and may be misinterpreted as sexual abuse.

On histopathologic examination, lichen sclerosus is characterized by loss of rete ridges with marked thinning of the epithelium. Within the dermis loss of cellularity with subepithelial dermal fibrin deposition, edema, and chronic inflammation in the deeper dermis are characteristic features. The cause of lichen sclerosus is unknown; however there is a recognized familial occurrence. It is recognized that women with vulvar lichen sclerosus have some risk of squamous cell carcinoma within the vulvar areas involved. In prospective evaluations the frequency of squamous cell carcinoma arising within vulvar lichen sclerosus has been observed to be 3.5% or higher. The precursor epithelial changes are not well recognized, however epithelial hyperplasia is commonly associated. One known neoplastic change in the epithelium is referred to as “vulvar intraepithelial neoplasia; differentiated type.” This type of vulvar intraepithelial neoplasia (VIN) lesion is associated with keratinizing squamous cell carcinoma, but is not associated with human papillomavirus (HPV) as are the other VIN types and their associated carcinomas. Any suspicious lesion, such as an ulcer or markedly hyperkeratotic area, identified within an area of lichen sclerosus is best biopsied to exclude carcinoma.

Therapy for lichen sclerosus of the vulva includes topical high potency corticosteroids (e.g., halobetasol 0.05% or clobetasol propionate 0.05%). Application is usually once per day and continued until a response occurs. Tapering of the topical medication to one or two times per week is considered for long-term therapy, but does require medical observation. Therapy is continued indefinitely, recognizing that lichen sclerosus is not cured, but is controlled by this therapy. Topical testosterone is generally only used with topical high-potency corticosteroids in women with severe atrophic changes who do not respond to the topical corticosteroid alone. Topical testosterone is not recommended in children or those who may have unacceptable reactions to testosterone because it is absorbed systemically. Topical progesterone can be considered as a supplement to topical corticosteroid in children or in individuals where the side effects of testosterone exposure are not acceptable. In addition to the topical corticosteroid, sitz baths and mild tranquilizers or antihistamines may be needed initially to relieve acute symptoms.

Squamous Cell Hyperplasia

Squamous cell hyperplasia (formerly hyperplastic dystrophy) typically presents as white thickened skin, often with accentuated skin markings (Fig. 33.3). The skin is thickened with prominent wide and deep rete ridges (acanthosis), a nonspecific term used as a diagnosis only when HPV infection, fungal infection, and other known causative conditions have been excluded.

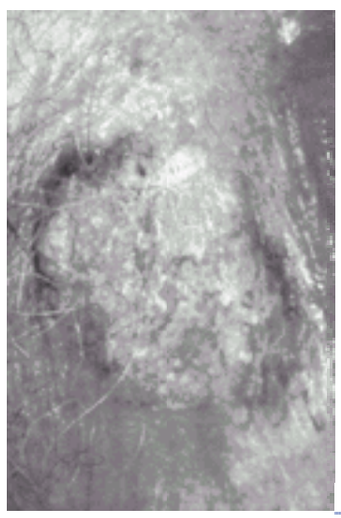

FIG. 33.3. Squamous cell hyperplasia of the vulva. Pruritic vulvar hypertrophied plaque of squamous cell hyperplasia with associated postinflammatory hyperpigmentation. (From Wilkinson, Stone. *Atlas of vulvar disease.* Philadelphia: Lippincott, Williams and Wilkins, with permission.) See color figure 33.3.

Squamous cell hyperplasia (can include lichen simplex chronicus and neurodermatitis and previously referred to as hyperplastic dystrophy) is also characterized by white epithelium. The epithelium usually appears thickened with an irregular surface. Unlike lichen sclerosus, the process is typically not symmetric, and may be localized to a single site. Shrinkage and agglutination of the labia is not seen, nor are the focal areas of submucosal ecchymosis that may occur in lichen sclerosus secondary to scratching.

Squamous Cell Hyperplasia and Granular Cell Tumor

Squamous cell hyperplasia can be associated with granular cell tumor of the vulva. In some cases the hyperplasia is so marked as to resemble well-differentiated squamous cell carcinoma (pseudoepitheliomatous hyperplasia). Although this is a rare event, biopsy of the hyperplastic area, including some underlying dermis containing the tumor, is usually diagnostic. Granular cell tumors are usually benign tumors, although rare cases with recurrence and malignant behavior have been reported. The tumor is thought to be of nerve sheath origin. Treatment is local excision.

The pathologic changes seen in squamous cell hyperplasia include prominent acanthosis, with elongation, widening and deepening of the rete ridges, and thickening of the epidermis. Hyperkeratosis may be present. A mild chronic inflammatory infiltrate may be present within the dermis. This diagnosis is one of exclusion and if a specific histopathologic diagnosis such as lichen simplex chronicus or lichen planus can be made, a specific diagnosis should be given. Chronic candidiasis or dermatophyte infection may result in similar epithelial changes. The identification of the causative organisms by clinical evaluation and culture of skin scrapings, or

silver fungus stains on histologic sections, permits a precise diagnosis and specific therapy.

Squamous cell hyperplasia is responsive to topical corticosteroids (e.g., betamethasone valerate 0.1% ointment). Lesions usually respond within 2 weeks, and treatment can be tapered and discontinued after the lesion regresses. Long-term therapy is not necessary and may lead to problems related to chronic topical corticosteroid use such as epithelial atrophy. The avoidance or elimination of exogenous contact irritant factors is also beneficial.

Lichen Planus

Lichen planus (LP) presents most commonly in women over 40 years of age. Symptoms include pruritus and burning but some patients may be asymptomatic. The oral and vaginal mucosa also may also be involved by white, lacelike plaques (Wickham striae). Women with the vulvovaginal-gingival syndrome have an erosive form of LP and present with involvement of the oral, vaginal, and vulvar mucosa. Women with LP may present with vulvar pain, dyspareunia, burning, as well as postcoital bleeding. The bleeding is apparently related to vulvar vestibular or vaginal adhesions. Long-term changes include anal and vaginal stenosis.

Clinical findings may involve both the vulvar vestibule as well as the vagina (Fig. 33.4). The findings may initially be minimal with foci of reticulated papules. In later or more severe stages, LP may present as an erosive or desquamative process, with loss and agglutination of the labia minora, frenulum and prepuce, and shrinkage with stenosis of the vagina. Postinflammatory hypopigmentation of the involved vulvar skin may occur, resembling advanced lichen sclerosus. Vaginal and oral mucosal involvement help distinguish LP from lichen sclerosus. Histopathologic findings are related to the severity, age, and location of the process. Vaginal and vulvar vestibular mucous membrane findings may differ somewhat from cutaneous changes.

FIG. 33.4. Lichen planus of the vulva. The lichen planus involves the vagina and vestibule and was associated with severe dyspareunia for 8 months. (From Wilkinson, Stone. *Atlas of vulvar disease.* Philadelphia: Lippincott, Williams and Wilkins, with permission.)

Microscopic features identified in the involved skin or mucosa include a bandlike, predominately lymphocytic, inflammatory infiltrate. Plasma cells are usually rare or absent in the skin, but may be found in mucosal lesions. Lichenoid inflammation involves the superficial dermis and overlying epidermis. Basal epithelial cells have liquefaction necrosis. Colloid bodies (Civatte bodies) are degenerated keratinocytes and valuable in the diagnosis of LP. Acanthosis, with wedge-shaped hypergranulosis and hyperkeratosis without parakeratosis, are typical findings. Immunofluorescent studies of a skin or mucosal biopsy submitted in Michelle fixative, or other appropriate fixative, or snap frozen, can be studied and characteristically will demonstrate fibrinogen deposits in the dermal–epidermal junction. Complement C3 and granular immunoglobulin M (IgM) and immunoglobulin G (IgG) deposits may be found. In the mucosa of the vestibule vagina, LP changes may include thinned epithelium, erosion, ulceration, and bullae.

The most common differential diagnoses include lichen sclerosus, plasma cell vulvitis, cicatricial pemphigoid, localized scleroderma (morphea), and contact dermatitis. Clinical history, examination of the patient's skin and oral mucosa, and biopsies of specific lesions, including unruptured bullae, for light and immunofluorescent studies are needed to definitively distinguish these processes. The treatment of LP is best undertaken with a dermatologist as consultant. The most difficult issue is the adhesion formation that leads to scarring and stenosis of the vestibule and vagina. Topical corticosteroids are the usual initial approach, and may include high-potency, fluorinated corticosteroids to gain initial response and relief. Other treatment may include topical or oral cyclosporine, oral dapsone, and oral griseofulvin.

Cicatricial Pemphigoid

Cicatricial pemphigoid can involve the vulva and the vagina and usually presents clinically with subepithelial blisters, which clinically may resemble the blisters of pemphigus vulgaris. Eosinophils are prominent in the vesicles of cicatricial pemphigoid. Immunofluorescence studies are needed to distinguish this bullous lesion from others, including pemphigus and linear immunoglobulin A (IgA) disease. Cicatricial pemphigoid has linear IgG and complement C3 deposits, which are usually absent in LP. Clinical management is complex and consultation with a dermatologist is recommended.

Psoriasis

Psoriasis affects about 2% of the U.S. population. It is inherited as an autosomal dominant trait with incomplete penetrance. When it involves the vulva, it often involves the lateral labia majora and genital intertriginous areas. Sharp-bordered, silvery-crusted erythematous papules and plaques characterize psoriasis (Fig. 33.5). Removing the loose silvery scale reveals multiple small punctate bleeding points. This finding is referred to as *Auspitz sign.* Presentation of psoriasis on the vulva may not demonstrate the typical silvery scales but rather red erythematous plaques, with the red plaques being the primary clinical finding. The lesions of psoriasis usually are somewhat symmetric. Without treatment the psoriasis typically has a long protracted course. The presentation of psoriatic lesions developing related to localized trauma is referred to as the *Koebner phenomenon.* The lesions present within 7 to 30 days following the localized trauma. Reiter syndrome may occur related to psoriasis although it not common in women.

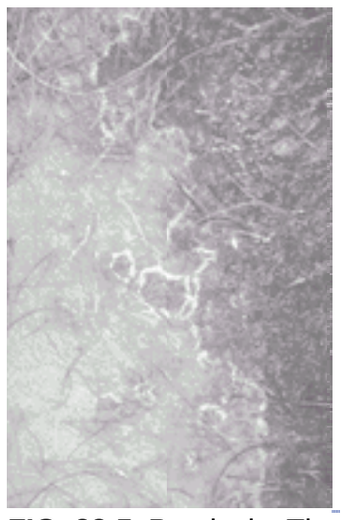

FIG. 33.5. Psoriasis. There is marked erythema and the lesion has sharply demarcated borders. (From Wilkinson, Stone. *Atlas of vulvar disease.* Philadelphia: Lippincott, Williams and Wilkins, with permission.)

Histopathologic features of psoriasis include hyperkeratosis and parakeratosis, with uniform acanthosis evidenced by a relatively uniform increase of length of the rete ridges. The rete, at their base, are wide and “club-shaped.” There is a decreased granular layer, and intraepithelial abscesses, composed predominately of

granulocytes, are within the epidermis and referred to as *Munro abscesses.* There is increased epithelial turnover reflected in increased numbers of mitotic figures in the basal and parabasal areas. The dermal papillae have prominent vessels and also may be club-shaped. The associated papillary dermis is edematous with little or no significant inflammatory cell infiltrate.

The differential diagnosis includes squamous cell hyperplasia, seborrheic dermatitis, and chronic eczema. Although these all have acanthosis, unlike psoriasis, the rete ridges are not relatively uniform in length and Munro abscesses are not present. Seborrheic dermatitis usually has granulocytes about follicular ostia that can clinically resemble psoriasis, therefore biopsy is usually necessary for definitive diagnosis (Fig. 33.6). The clinical presentation and distribution of the cutaneous lesions can be similar when comparing psoriasis and seborrheic dermatitis and their distinction can be difficult.

FIG. 33.6. Seborrhea. The involved vulvar skin is somewhat reddened. (From Wilkinson, Stone. *Atlas of vulvar disease.* Philadelphia: Lippincott, Williams and Wilkins, with permission.) See color figure 33.6.

Plasma Cell Vulvitis (Vulvitis of Zoon)

Women with plasma cell vulvitis typically have symptoms of pruritus and burning. It should be distinguished from other red lesions including those of known etiology (Table 33.2). An erythematous macular lesion that is red to orange in color and may be hemorrhagic characterizes plasma cell vulvitis. The macular areas may be single or multiple, and may involve relatively large areas of the vulva.

Red lesion	Cause
Candida infection	*Candida albicans*
Tinea cruris	*Trichophyton rubrum*
Pityriasis versicolor	*Pityrosporum orbiculare*
Erythrasma	*Corynebacterium minutissimum*
Reactive vulvitis	Local irritants

TABLE 33.2. *Inflammatory red lesions of the vulva with known etiology*

Histopathologic features include a thinned epithelium with reduced rete ridge length and without a granular layer or keratinized surface. The horizontally orientated parabasal squamous cells have been referred to as “lozenge-shaped keratinocytes.” Superficial dermal inflammation is present involving the dermal–epithelial interface, and is lichenoid in character. The inflammatory cells present consist predominantly of plasma cells. Prominent blood vessels are found in the dermis, often associated with intradermal hemorrhagic areas and hemosiderin-laden macrophages.

The differential diagnosis includes lichen planus and related dermatosis, as well as some infectious conditions, especially syphilis. The prominent plasma cell infiltrate may include perivascular plasma cells, however the plasma cells are not associated with spirochetes or other organisms on silver stain and serologic studies for syphilis are negative. The cause of plasma cell vulvitis is not known.

Treatment is primarily topical corticosteroids but may include intralesional corticosteroids, as well as etretinate. Supportive care, to relieve acute symptoms, is also recommended.

Vulvar Vestibulitis

Vulvar vestibulitis is one of a number of conditions associated with vulvar vestibular pain. There remains controversy regarding the definition, diagnosis, and treatment of vulvar vestibulitis. For the purposes of defining vulvar vestibulitis it is defined in this chapter as originally described (Friedrich 1987), specifically as a symptom complex characterized by severe external dyspareunia (dyspareunia on entry), inflammation of the vulvar vestibule, and exquisite tenderness of the vulvar vestibule in the areas of inflamed minor vestibular glands. It is recognized that asymptomatic women may have some minor redness or pressure tenderness within the vulvar vestibule and this should not be interpreted as vulvar vestibulitis.

Histopathologic findings associated with vulvar vestibulitis are not specific. Within biopsies, or specimens obtained from partial vestibular excisions performed to relieve vestibulitis, a superficial inflammatory cell infiltrate is present consisting predominately of lymphocytes, but also usually also includes plasma cells, mast cells, and complement C3. The inflammation is within the superficial submucosa. If minor vestibular glands are present, the inflammation is also seen around the minor vestibular glands. The minor vestibular glands are simple glands lined by tall, mucus-secreting columnar epithelium. The inflammation usually does not involve the gland lumens.

No specific etiology has been identified as a cause of vestibulitis, and studies for HPV have not demonstrated a causal association.

Although no uniformly effective medical therapy has yet been defined, clinical management, including biofeedback, is sometimes effective in relieving symptoms. A list of some of the more common treatments follows. None of these treatments, however, have been proven to be uniformly effective in controlled trials.

Vaginal and introital lubricants with or without the use of vaginal dilators.
Vaginal and introital lubricants with or without the use of biofeedback.
Interferon local injections (3 million U/mL), 1 million units per injection site with up to 12 injection sites distributed about the vestibule. Injections are with a fine 25- or 33-gauge needle and an insulin syringe. Three courses of injections are given per week for 4 weeks.
Topical anesthetics (5% Xylocaine ointment or 2% lidocaine gel) applied to the tender sites p.r.n.
Systemic antifungal therapy is advocated as initial therapy by some (e.g., Diflucan, or similar medications).
Amitriptyline (Elavil) started at a low dose 10 to 25 mg orally, with increased doses up to 3 times per day in protracted or unresponsive cases.
Local excision of the involved inflamed vestibular areas has been used; however, long-term follow-up studies show recurrence or persistence of symptoms in about one half of the cases.

Pruritic Vulvar Squamous Papillomatosis

Pruritic vulvar squamous papillomatosis is a clinical complex that includes vestibular papillae and pruritus. Vulvar pain or burning may also be present and dyspareunia is common. On examination of the vulva, multiple small clustered squamous papillae are present on the medial aspects of the labia majus (Fig. 33.7). In some cases the papillae present following the onset of symptoms. The papillae are sometimes so small that magnification is necessary for identification (colposcopic magnification ×10).

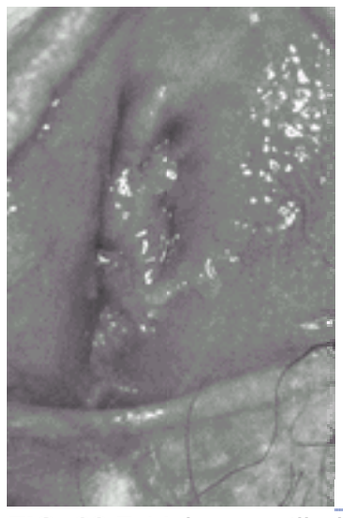

FIG. 33.7. Vulvar vestibular papillomatosis. Clustered vulvar vestibular papillary projections of squamous papillomatosis. (From Wilkinson, Stone. *Atlas of vulvar disease.* Philadelphia: Lippincott, Williams and Wilkins, with permission.)

Histopathologic examination demonstrates small (1–2 mm) squamous epithelial covered papillae supported on delicate vascular stalks. The papillae usually are multiple and occur in clusters on the vestibule. Although initially thought to be secondary to HPV infection, more recent work does not support this association.

Contact Dermatitis

Contact dermatitis may be an allergic or an irritant-related entity. Allergic dermatitis is a cell-mediated response related to sensitizing agents. Topical medications and rubber are example agents. Irritant agents can include urine, stool, soaps, deodorants, perfumes, or other agents related to such reactions within the skin. Irritant dermatitis is more common than allergic dermatitis in most settings. The cutaneous or mucosal areas involved are usually confined to the area of exposure and the dermatitis often persists for weeks to months following exposure.

Histopathologic findings may be quite variable, and are related to whether it is an allergic or irritant-related process, the severity of the reaction, duration of the exposure, and length of time the inflammatory process has been present. Epithelial spongiosis with microvesiculation is usually present, and if the lesion is more severe or long-standing, erosion and ulceration may be seen. A superficial perivascular inflammatory infiltrate consisting predominantly of lymphocytes and histiocytes is often present. Eosinophils may be present, especially in allergic reactions. In long-standing contact dermatitis, epithelial thickening (acanthosis) with parakeratosis and hyperkeratosis can occur resulting in histopathologic features of squamous cell hyperplasia with or without features of lichen simplex chronicus.

Atopic Dermatitis

Atopic dermatitis of the vulva is usually associated with pruritus and burning. On examination the vulvar skin may appear dry and scaling. Scratching related to the pruritus can result in excoriation and thickening of the vulvar skin. Vulvar biopsy is generally not needed unless significant epithelial thickening or a questionable lesion is identified.

The histopathologic findings of atopic dermatitis may include epithelial thickening with features of squamous cell hyperplasia. The findings may be nonspecific with epithelial spongiosis and associated superficial dermal inflammation. The inflammatory infiltrate predominately includes lymphocytes and macrophages, however, eosinophils and mast cells also may be present. The extent of the inflammatory cell infiltrate tends to correlate with the severity and duration of the dermatitis. Immunofluorescent studies are generally not necessary but if performed may identify immunoglobulin E (IgE) on epidermal Langerhans cells.

Fixed Drug Eruption (Dermatitis Medicamentosa)

Fixed drug eruptions typically are related hypersensitive reactions to systemic drugs. The eruptions typically can recur at the same skin sites upon reexposure to the same drug. Multiple reexposure can be associated with lesions in new sites as well in the original locations. After the drug is stopped, the lesions usually heal completely in the mucosa, but in the skin, postinflammatory hyperpigmentation is common. Cutaneous fixed drug eruptions are a complex group of drug hypersensitivity reactions. They are subclassified into four distinct types that can be summarized as follows. Type I usually presents as urticaria and is mediated through IgE antibodies. Type II presents as purpura or bullous lesions and is mediated through IgG and IgM antibodies. Type III may present as an urticarial or maculopapular reaction and may be associated with vasculitis and is related to immune complexes. Type IV may present as a contact dermatitis, exanthem, or a maculopapular eruption.

The histopathological findings of fixed drug reaction may include epithelial interface vacuolar changes with associated necrotic keratinocytes. Within the dermis eosinophils may be identified. These findings may be otherwise nonspecific or only suggest drug eruption. Other testing, including patch testing for the suspect offending drugs, indirect and direct Coombs testing, as well as other laboratory testing, all maybe useful. In cases of suspect fixed drug eruption, a complete drug exposure history is essential.

Behçet Syndrome

Behçet syndrome is of unknown etiology and includes oral aphthous ulcers, genital ulcers, and ophthalmologic inflammation. In addition these patients may have colitis, acne, cutaneous nodules, thrombophlebitis, and, in severe cases, encephalopathy. Some cases lack the ocular changes (Table 33.3, on vaginal and vulvar ulcers). When Behçet syndrome involves the vulva, deep ulcerations are usually seen that, in severe cases, result in fenestration of the labia, and occasionally labial gangrene (Fig. 33.8). The disease is of unknown cause and may wax and wane, with vulvar ulcerations healing and then recurring. The vulvar ulcers are usually associated with oral ulcers

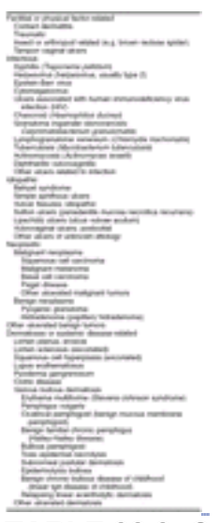

TABLE 33.3. *Causes of vulvar and vaginal ulcers*

FIG. 33.8. Behçet disease. Painful vulvar ulcer in a woman who also had oral ulcers of a similar appearance. Serologic and microbiologic studies for other potential pathogens were negative. (From Wilkinson, Stone. *Atlas of vulvar disease.* Philadelphia: Lippincott, Williams and Wilkins, with permission.)

On histologic examination the involved vulvar skin or mucosa is involved with a necrotizing arteritis. This is associated with a chronic inflammatory infiltrate that is typically perivascular and may involve the vessel wall with damage to the arterial media. The arteritis is associated with endothelial cell swelling and can result in arteriolar occlusion or venous thrombosis.

Hidradenitis Suppurativa

Hidradenitis suppurativa is an apocrine gland–related chronic inflammatory disorder. The initial presentation is of a painful, tender, deep-seated subcutaneous nodule or nodules in the vulva as well as axillae and other sites where apocrine glands occur. Subcutaneous spread of the inflammatory process results in confluent masses that, in some point in their course, involve the overlying skin and result in ulceration and draining sinuses. This process, over time, subsequently causes extensive scarring of the vulva or other involved sites. Fox-Fordyce disease may be associated in some cases.

Histopathologic features in the early stages of hidradenitis suppurativa include perifolliculitis associated with acute and chronic dermal inflammation. In advanced cases severe inflammation results in the loss of the epithelial appendages with squamous epithelial ulceration with sinus tract formation.

Management includes medical as well as surgical approaches. Medical treatment may include long-term retinoids (e.g., isotretinoin), anti-androgen therapy, or treatment with leuprolide. Surgical approaches may include laser ablation by unroofing of the sinus tracts, or excision of involved areas. Surgical approaches are usually appropriate in severe or refractory cases.

Miscellaneous Inflammatory Conditions

Inflammatory infectious conditions that may occur in the vulva, that present as red lesions, with their known causative agent, are listed in Table 33.2.

ULCERS OF THE VULVA AND VAGINA

Table 33.3 lists the predominant causes of ulcers within the vulva and vagina.

Dark Lesions of the Vulva

Dark or pigmented lesions of the vulva are listed in Table 33.4.

Nevomelanocytic lesions
Lentigo simplex
Melanosis vulvae
Nevomelanocytic nevi
Junctional
Intradermal
Compound
Compound nevus without atypia
Atypical vulvar nevomelanocytic nevus
Malignant melanoma
Superficial spreading melanoma
Nodular melanoma
Lentigo maligna melanoma
Metastatic melanoma
Vulvar intraepithelial neoplasia
Seborrheic keratosis
Reactive hyperpigmentation
Dermatofibroma
Malignant fibrous histiocytoma

TABLE 33.4. *Dark lesions of the vulva*

Lentigo Simplex Lentigo simplex is one of the most common pigmented lesions biopsied on the vulva. Lentigo simplex clinically is a flat, non-elevated pigmented area on the skin that has normal surface skin markings (Fig. 33.9). Lentigo simplex represents an area of skin with increased melanin with associated melanocytes. The epithelium may be slightly hyperplastic and hyperkeratotic. Lentigo simplex by definition is 5 mm or less in diameter. Larger flat pigmented lesions with essentially identical histopathologic features are referred to as *melanosis vulvae.* No treatment is needed although biopsy is performed to determine the basis of the pigmented lesion.

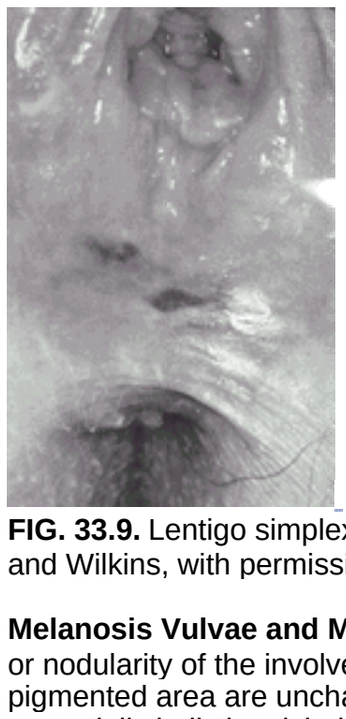

FIG. 33.9. Lentigo simplex. Several small flat pigmented lesions of lentigo simplex. (From Wilkinson, Stone. *Atlas of vulvar disease.* Philadelphia: Lippincott, Williams and Wilkins, with permission.) See color figure 33.9.

Melanosis Vulvae and Melanosis Vaginae Vulvar melanosis is a benign pigmented condition that is characterized by pigmentation of the vulvar skin without elevation or nodularity of the involved skin in an area that is, by definition, larger than 5 mm in diameter. Like lentigo simplex the melanosis is flat and the skin markings over the pigmented area are unchanged and similar to the adjacent skin. Histopathologic examination of vulvar melanosis and lentigo simplex demonstrate that they are essentially indistinguishable. Therefore the size of the lesion is important and influences the clinical diagnosis and the pathologic interpretation. Similar pigmentation with similar findings when found in the vagina is referred to as *melanosis vaginae*, and in some cases melanosis of both the vulva and the vagina may be found.
Vulvar Nevomelanocytic Nevi The types of nevomelanocytic nevi identified on the vulva include junctional, compound, and intradermal. In most series compound and intradermal nevi are more common. Atypical vulvar nevi are a special category of nevus and these often have some features of compound nevi.

Junctional Nevi Junctional nevi have the nevus cells located within the epidermis as well as the dermal–epidermal junction. The nevus cells are immediately adjacent to the squamous keratinocytes. Junctional nevi are young and somewhat undifferentiated.

Compound Nevi

A compound nevus represents a continuum of maturation from a junctional to an intradermal nevus. In compound nevi, the nevus cells are within both the epidermis and the dermis. Nevus cells are seen within the dermal–epidermal junction, but also within the dermis, where dermal reticulum, collagen, and elastic fibers envelop the nevus cell nest. Compound nevi have elevated surfaces as compared to the surrounding skin.

Intradermal Nevi Intradermal nevi do not have a dermal–epidermal component and the nevus cells are completely surrounded within the dermis by connective tissue elements. Over time an intradermal nevus may entirely regress, or evolve into an acrochordon (fibroepithelial polyp).
Atypical Vulvar Nevi Of special interest are the atypical vulvar nevomelanocytic nevi that may clinically and histopathologically resemble malignant melanoma (Fig. 33.10). Atypical nevi are found predominately in adolescent and premenopausal women. Pathologically they have features of compound nevi, having both a junctional and an intradermal component, but they also have cytoatypia, especially in the more superficial nevomelanocytes.

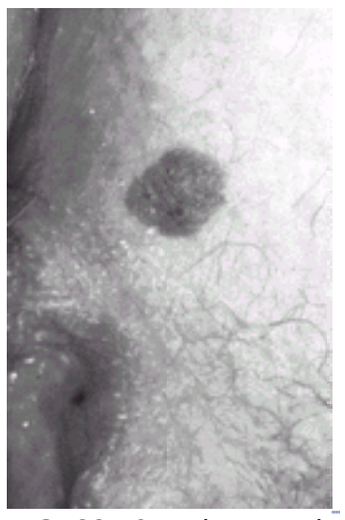

FIG. 33.10. Vulvar atypical nevus in an adolescent patient. The lesion is raised and has somewhat irregular borders. (From Wilkinson, Stone. *Atlas of vulvar disease.* Philadelphia: Lippincott, Williams and Wilkins, with permission.)

They can be distinguished histopathologically from malignant melanoma by three specific features. These include symmetry in horizontal and vertical dimensions, decrease in cell size with maturation of the nevus cells in the deeper levels, and lack of pagetoid single cell spread in the upper one-third of the epidermis.
Congenital and Giant Nevomelanocytic Nevi Congenital nevi occur in approximately 10% of newborns and most of these nevi are less than 4 mm in diameter. Giant nevomelanocytic nevi, which by definition are 20 cm or larger in diameter (“garment type” nevus), are rare but are associated with increased risk of developing malignant melanoma in prepubertal individuals. The frequency of involvement of the vulva by these types of nevi is uncertain.

Other Benign Pigmented Lesions

Other benign pigmented lesions of the vulva include seborrheic keratosis, postinflammatory (reactive) hyperpigmentation, and dermatofibroma (benign fibrous histiocytoma).

Seborrheic Keratosis Seborrheic keratosis often presents as a macular or papular pigmented lesion that usually feels waxy on palpation (Fig. 33.11). The lesions are usually multiple and may be seen in other sites as well as the vulva in a given patient. In some cases the surface of the lesion can be peeled away to reveal punctate bleeding points at the base. In most cases, however, biopsy is necessary to establish the diagnosis. Biopsy is especially useful to distinguish seborrheic keratosis from vulvar intraepithelial neoplasia, which can also present as pigmented macular or papular lesions.

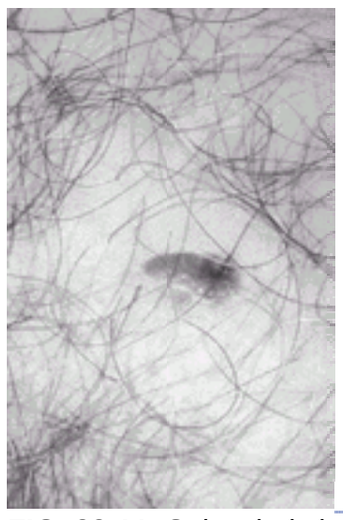

FIG. 33.11. Seborrheic keratosis. Typical appearance of a waxy-appearing, elevated, pigmented lesion. (From Wilkinson, Stone. *Atlas of vulvar disease.* Philadelphia: Lippincott, Williams and Wilkins, with permission.)

On histopathologic examination seborrheic keratosis has a thickened epithelium (acanthosis) with a hyperkeratotic surface. The deeper tips of the rete tend to have uniform length. No significant dermal compression or inflammatory infiltrate is present in most cases. Treatment of seborrheic keratosis is usually local superficial excision or cryotherapy.
Reactive Hyperpigmentation Reactive hyperpigmentation is usually preceded by chronic inflammation (postinflammatory) or injury. Although the skin is pigmented in the involved areas, the surface of the skin maintains its normal character, without surface elevation. Biopsy is usually not necessary to establish the diagnosis although the usual evaluation for the cause of the inflammatory process is necessary. No therapy is needed.
Dermatofibroma/Fibrous Histiocytoma Dermatofibroma is rare on the vulva, however, it may present as a slightly raised, nonpolypoid pale brown to red solitary subcutaneous mass. The term *dermatofibroma* is reserved for those lesions 1.5 cm in diameter or less. Masses larger than this, or that are polypoid in appearance, are referred to as *fibrous histiocytoma.* Biopsy is necessary to establish the diagnosis and to distinguish these benign histiocytic tumors from dermatofibrosarcoma protuberans or malignant fibrous histiocytoma.

Management of Pigmented Lesions

As a general rule, any elevated pigmented lesion of the vulva that is 5 mm or larger in greatest dimension, or otherwise clinically suspicious, should be excised. In these cases, excision, with submission of the specimen for histopathologic examination is both diagnostic and therapeutic. If malignant melanoma is suspected, and outpatient biopsy is considered reasonable, wide and deep excision is needed to properly diagnose and pathologically stage the lesion if it is a melanoma. Three centimeter (3 cm) margins of excision, both wide and deep, can be considered in such cases. Immediate consultation with a specialist familiar with the diagnosis and treatment of melanoma of the vulva may be the best alternative for management of patients with a lesion suspected of being melanoma, rather than attempted excision or biopsy in the outpatient setting.

Depigmentation Disorders

Depigmentation disorder include vitiligo, albinism, and postinflammatory hypopigmentation. Vitiligo is the loss of melanocytes from where they were once present, and is due to an inherited disorder. Albinism is a congenital inability of melanocytes to produce melanin. Postinflammatory hypopigmentation is the loss of melanocytes in the skin secondary to inflammation or injury (Fig. 33.12).

FIG. 33.12. Postinflammatory hypopigmentation. The white area has lost melanocytes and melanin. (From Wilkinson, Stone. *Atlas of vulvar disease.* Philadelphia: Lippincott, Williams and Wilkins, with permission.) See color figure 33.12.

BENIGN TUMORS OF THE VULVA

Condyloma Acuminatum

HPV infection is the viral cause of vulvar and vaginal condylomata acuminata. HPV is also associated with VIN, a lesion that is a known precursor of certain types of vulvar carcinoma. Condyloma acuminatum (genital wart) is a benign neoplasm that is usually sexually transmitted and can involve the vulva as well as the vagina, cervix, urethra, anus, and perianal skin. HPV-6 and HPV-11 are the usual HPV types associated with genital condyloma acuminatum; HPV-11 is observed in about one-fourth of cases.

On clinical examination condylomata acuminata of the vulva are usually papillary, verrucous, or macular in character and can involve the skin as well as the vulvar vestibule, vagina, and cervix. The lesions are usually multiple. They may be asymptomatic but can be pruritic and may result in the patient coming to the clinic when she observes or palpates the lesion or lesions. Condylomata acuminata of the vulva and vagina may be associated with pregnancy, diabetes mellitus, perineal hygiene problems, immunosuppression, and other related problems. Approximately one-third to one-half of the women with vulvar condyloma acuminatum have associated cervical HPV-related lesions (cervical intraepithelial neoplasia/dysplasia). In children, genital HPV infection may be evidence of sexual abuse.

Magnification of the vulva and vagina with a ring light, or colposcope, and the application of 3% to 5% acetic acid can greatly aid identification of smaller lesions because the HPV-related lesions that involve the mucosa are aceto-white, becoming white in color with the application of the acetic acid. Lesions detectable only by colposcopic examination are considered subclinical HPV infections.

Histopathologic examination of a typical vulvar or vaginal condyloma acuminatum demonstrates epithelial thickening usually associated with acanthosis, koilocytosis, and parakeratosis. Lesions arising in the vulvar skin often have hyperkeratosis and a prominent granular layer. Superficial dermal or submucosal chronic inflammatory cells may be seen beneath the condyloma.

Vulva condyloma acuminatum may persist for years however regression may occur and has been observed following pregnancy. Presentation following pelvic radiation therapy or with immunosuppression has also been observed.

Differential Diagnosis Within the vulva there is an important distinction made between typical condyloma acuminatum and vulvar intraepithelial neoplasia of high grade (VIN 2 or VIN 3/moderate or severe dysplasia or carcinoma in situ). Many pathologists would prefer to refer to macular condyloma acuminatum (condyloma plana) of the vulva as VIN 1, as referenced in leading texts on vulvar pathology, but this is not a uniform practice. Unlike most VIN lesions, typical vulvar or vaginal condylomata are not usually associated with HPV-16 or other high risk HPV types as are VIN 2 or VIN 3 lesions. They are typically DNA-diploid whereas VIN 2 or VIN 3 lesions are usually DNA-aneuploid.
Fibroepithelial Polyp Fibroepithelial polyps may clinically resemble large condylomata, however, the epithelium of a fibroepithelial polyp lacks significant proliferation, unlike the epithelium of typical condyloma acuminatum (Fig. 33.13). This proliferation can be demonstrated immunohistochemically using Ki-67 (MIB-1) immunohistochemistry, where the proliferative cells of condyloma are seen throughout the epithelium, while fibroepithelial polyps only have proliferative cells in the basilar epithelial layers. Condylomata lata or secondary syphilis can suggest condylomata acuminata clinically; however, biopsy demonstrates inflammation and arteritis with many plasma cells. Spirochetes can be demonstrated by immunofluorescence on air-dried scraping of the surface of the lesion, or on Warthin-Starry silver stain of a tissue section. Syphilis serologic studies are appropriate in cases where there is question regarding the differential diagnosis.

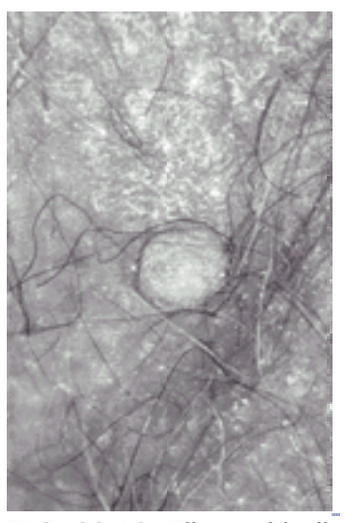

FIG. 33.13. Fibroepithelial polyp (acrochordon) with a pedunculated appearance. (From Wilkinson, Stone. *Atlas of vulvar disease.* Philadelphia: Lippincott, Williams and Wilkins, with permission.)

Squamous cell carcinoma can arise in vulvar condyloma acuminatum, and vulvar verrucous carcinoma may resemble a large condyloma. In addition, the so-called giant condyloma of Buschke and Löwenstein is now recognized to be a variant of verrucous carcinoma. The association of vulvar and vaginal condyloma acuminatum with invasive squamous cell carcinoma has been associated with lymphoproliferative disorders, such as Hodgkin disease, as well as chromosomal disorders with immunosuppression related to Fanconi anemia.
Therapy There are many methods to treat vulvar condyloma acuminatum. These include clinician-applied topical concentrated trichloroacetic acid or bichloracetic acid. This treatment method may be effective for small vulvar condylomata. Larger lesions are more commonly treated with surgical excision, electrodesiccation with surface curettage, or electro-loop excision. Cryosurgery and laser ablation have also been used for larger lesions, however these two techniques are usually not the treatments of choice for larger lesions unless the clinician is experienced in their use on the vulva. Topical application by the clinician of a dilute podophyllin toxin preparation is also effective for small lesions, but contraindicated in pregnancy and should not be used in the vagina. These medications inhibit cell proliferation and can be neurotoxic if systemically absorbed through mucosal surfaces. Imiquimod is a topical, immune-enhancing medication that has also been successful in treating small and nonkeratinized condylomata. This medication can be applied by the clinician, or by a well-informed patient who is capable of doing the applications. Approximately 40% to 60% of children with laryngeal papillomatosis are born from mothers with a history of genital condyloma acuminatum. Laryngeal papillomas of infancy and childhood are thought to be acquired at delivery. Although the incidence of HPV infection of the larynx of the newborn from maternal genital papillomavirus infection is unknown, no correlation has been established between the volume of maternal wart tissue and occurrence of infantile laryngeal papillomatosis. Approximately one-half of patients with laryngeal papilloma have HPV-11.

Leiomyoma of the Vulva

Leiomyoma is a benign smooth muscle tumor and is the most common vulvar soft tissue tumor (Fig. 33.14). In children, vulvar leiomyomata may be associated with

esophageal or gastric leiomyomatosis. Histopathologic examination demonstrates that the tumor is composed of smooth muscle cells that can have myxoid change or epithelioid features, both are especially noted in pregnancy. Leiomyoma, in contrast to leiomyosarcoma, has a low mitotic count, lacks significant cytologic atypia, and is not infiltrative or metastatic. Immunohistochemical studies can distinguish these tumors from rhabdomyosarcoma and rhabdomyoma. Therapy is local excision. Gonadotropin inhibition medical therapy may be of value to reduce tumor size before surgery.

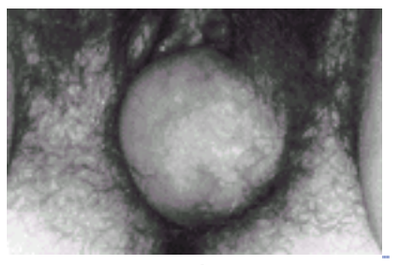

FIG. 33.14. Leiomyoma. Large, firm, and somewhat mobile nontender tumor. (From Wilkinson, Stone. *Atlas of vulvar disease.* Philadelphia: Lippincott, Williams and Wilkins, with permission.)

Benign Vulvar Tumors of Sweat Gland Origin

There are several benign epithelial tumors of sweat gland origin that occur in the vulva. The two most important are papillary hidradenoma and syringoma. Other important benign epithelial tumors include mammary-like tumors and clear cell hidradenomas.

Papillary Hidradenoma

Papillary hidradenomas of the vulva may present as a nodule or a papillary mass. They may form a papillary-like mass that bleeds easily if the tumor mass everts from its subepithelial location. These tumors are usually located in the interlabial sulcus and occur after puberty (Fig. 33.15). They are usually under 2 cm in diameter and are not infiltrative. The tumor is currently thought to arise from specialized mammary-like anogenital glands that are found predominately in the interlabial sulcus.

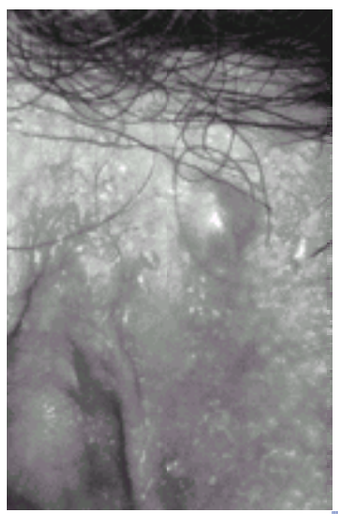

FIG. 33.15. Papillary hidradenoma, asymptomatic, located in the sulcus between the labia minus and majus. (From Wilkinson, Stone. *Atlas of vulvar disease.* Philadelphia: Lippincott, Williams and Wilkins, with permission.)

On histopathologic examination the deep relationship of the tumor with the underlying dermis reveals a circumscribed papillary tumor with a pushing, noninfiltrative boarder. The epithelial component of the tumor is composed of superficial secretory apocrine cells with a second deeper layer of myoepithelial cells below the secretory cells. Local excisional biopsy as a form of treatment is both diagnostic and therapeutic. Excision should be sufficiently deep to encompass the deep portion of the tumor margin. This will provide diagnostic pathologic material as well as be adequate therapy. Superficial biopsies can be somewhat misleading in some cases if the two cell layers of the papillary elements are not apparent and the relationship with the dermis is not seen.

Mammary-like Tissue: Arising from the Specialized Anogenital Glands

Mammary-like tumors were once considered to be from ectopic breast tissue in the vulva, however current evidence supports that the vulva is not in the human milk line and does not contain breast tissue. These tumors may be hidradenoma papilliferum, or resemble benign or malignant breast tumors. Metastatic breast adenocarcinoma is in the differential diagnosis in such cases. For the benign tumors the treatment is as for hidradenoma papilliferum.

Clear Cell Hidradenoma

Clear cell hidradenoma is rare on the vulva, however the histologic appearance, consisting of large regular cells with prominent clear cytoplasm, may present a diagnostic problem for the pathologist. As with the papillary hidradenoma, diagnostic excisional biopsy will be both therapeutic and will greatly aid in the pathologic diagnosis. These tumors, although usually solid, are well defined, with a pushing border at the tumor stromal interface without an infiltrative pattern.

Syringoma

Syringoma usually presents as multiple small, skin-colored papules often occurring bilaterally on the vulva. Pruritus may be a presenting symptom. Syringomas are considered to be benign adenomas of the ducts of the eccrine sweat glands.

The histopathologic diagnosis can be made from a representative biopsy of one of the papules. The comma-shaped, dilated duct elements within the dermis usually contain an inner myoepithelial layer and luminal epithelial cell layer. Syringomas are benign tumors; however, malignant variants of skin appendage tumors that may contain syringoma-like elements (mixed tumors of the vulva) have been reported. Syringoma is usually not treated surgically unless there is a specific mass in question that needs excision for diagnostic purposes. Topical or medical treatment is preferred.

Vascular Lesions

Capillary hemangioma occurs in infants and children. It is a slightly elevated, well-defined, red-to-violet lesion with an irregular surface. Ulceration may occur.

Capillary hemangiomas can be diagnosed clinically without biopsy. They typically regress over time without treatment. On microscopic examination the lesion consists of well-demarcated, clustered, small capillaries in a fibrous tissue.

Cavernous hemangiomas also may occur in children but are rare in the vulva. They are larger, deeper, and more complex than capillary hemangiomas. They can be associated with pelvic hemangiomas. They can involve the clitoris or labia and resemble hypertrophy. Cavernous hemangiomas will usually regress over time and therefore do not require treatment unless they bleed or otherwise become symptomatic.

Acquired hemangioma, also known as senile hemangioma, is common in the vulva in adults. The lesions are usually small, red-to-violet-to-purple papules, and are usually multiple. They do not require therapy but may resemble pigmented lesions and therefore may be biopsied. On microscopic examination acquired hemangiomas

are composed of clustered capillary-like vessels within the dermis, with fibrous tissue about the vessels that may be rich in collagen.

Differential diagnosis of hemangiomas includes hemangiomatous-like changes that may be seen in the vulva after radiation therapy. In addition, angiokeratoma, pyogenic granuloma, bacterial angiomatosis, hemangiopericytoma, angiosarcoma, and Kaposi sarcoma are all vascular lesions that can be included in the differential diagnosis.

Angiokeratoma

Angiokeratoma is a benign vascular tumor that is a variant of hemangioma. They are relatively common on vulva and present as a dark red to purple to black, papular lesion that may have an appearance of a condyloma acuminatum (Fig. 33.16). These vascular lesions are often multiple and usually asymptomatic although they may ulcerate and bleed. They can be associated with Fabry disease. Their elevated and dark appearance may result in them resembling a nevus and this prompts excisional biopsy.

FIG. 33.16. Angiokeratoma. Multiple angiokeratomas in a woman with Fabry disease. White blood cell a-galactosidase of 36 nm per hour per mg (normal = 50–80). (From Wilkinson, Stone. *Atlas of vulvar disease.* Philadelphia: Lippincott, Williams and Wilkins, with permission.)

On microscopic examination the lesion has a warty appearance with acanthosis and usually some hyperkeratosis. A distinctive feature is that the basal layer of the overlying epithelium is nearly contiguous with the endothelial cells lining the underlying vascular channels of the angiokeratoma. This benign vascular lesion is confined to the superficial dermis and is not infiltrative, as seen with Kaposi sarcoma or angiosarcoma. Angiokeratoma is a benign lesion and does not require treatment unless bleeding or ulceration occurs, or excision is prompted because of its clinical appearance.

Pyogenic Granuloma (Granuloma Pyogenicum)

Pyogenic granuloma typically presents as an elevated, papular, red lesion that in the fully developed state is ulcerated. It is a variant of hemangioma and is analogous to the epulis tumor of pregnancy. Pyogenic granulomas on the vulva occur usually related to pregnancy but may arise in vulvar skin wound infection. The vascular tumor can have rapid growth and can become secondarily infected. Histologically, the findings resemble granulation tissue with inflammation. In fully developed cases at the ulcer edge a “collarette” of elevated dermis and epithelium surrounds the lesion.

Bacillary Angiomatosis

Bacillary angiomatosis clinically presents as a macular and papular red skin lesion or lesions that may resemble Kaposi sarcoma or hemangioma. These lesions are apparently caused by infection with the bacteria *Bartonella henselae* and *B. quintana* (formally, *Rochalimaea henselae*) and *R. quintana*. The bacterial organisms can be detected in tissue with appropriate silver stains.

Kaposi Sarcoma

Kaposi sarcoma is a vascular tumor associated with human immunodeficiency virus (HIV) and herpesvirus (herpesvirus VIII). Neoplastic-appearing, endothelial-appearing cells grow as spindle-shaped cells that form “slit-like” spaces that are filled with red blood cells.

VULVAR CYSTS

Bartholin Cyst and Bartholin Abscess

The Bartholin cyst is a result of distal obstruction of the Bartholin duct. Obstruction results in accumulation of secretion and cystic dilation of the duct (Fig. 33.17). The lining of the Bartholin cyst is epithelium that can be squamous, transitional, low cuboidal mucinous epithelium, or otherwise not classifiable. The Bartholin cyst is filled with mucoid sialomucin that is sterile and stains with mucicarmine, periodic acid-Schiff (PAS) with and without diastase digestion, and Alcian blue at pH 2.5. The cyst epithelium is immunoreactive for carcinoembryonic antigen (CEA).

FIG. 33.17. Bartholin cyst. Bartholin duct cyst expanding the left labium majus. (From Wilkinson, Stone. *Atlas of vulvar disease.* Philadelphia: Lippincott, Williams and Wilkins, with permission.)

Bartholin cysts are usually treated with marsupialization, using a Word catheter or equivalent to establish a new duct exit to the vestibular surface. In postmenopausal women, a persistent Bartholin mass after drainage or recurrent cysts may require surgical excision to resolve the process and exclude adenocarcinoma of the Bartholin gland.

Bartholin Abscess

Bartholin abscess may be caused by *Neisseria gonorrheae* infection, or related to infection with *Staphylococcus* or anaerobic organisms. The presenting symptoms are pain and sometimes fever. The physical findings demonstrate tenderness, redness, and swelling in the Bartholin gland area.

Microscopically, the Bartholin duct has acute inflammation within the duct as well as within the gland stroma about the duct. The abscess, when fully developed, contains purulent exudate. Treatment of choice is excision and drainage. Antibiotic therapy that the related organism is sensitive to is part of the treatment. In some cases the infection may subside without abscess formation. Persistent chronic inflammation may occur in some cases. Bartholin duct cyst may follow stenosis of the distal Bartholin duct secondary to chronic inflammation of the duct.

Keratinous Cyst (Epithelial Inclusion Cyst)

Keratinous cysts are relatively common on the vulva and can involve the majora, clitoris, perineal body, as well as other vulvar sites (Fig. 33.18). These cysts usually range in size from 2 to 5 mm, but may be larger, and they are typically superficial and can be multiple. They may occur at any age, and can occur in newborns. Milia, a type of multiple keratinous cysts, can occur in the vulva. Keratinous cysts may occur in episiotomy scars and have been observed as a complication of female circumcision. Keratinous cysts contain keratinous material that is white to pale yellow in color and grumous or cheesy in character. Hair is not present in these cysts. Keratinous cysts are not considered premalignant, although carcinoma arising in keratinous cysts may occur.

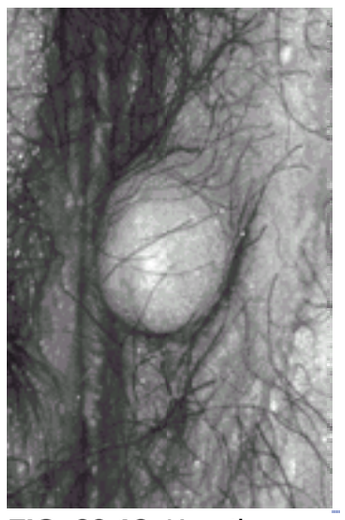

FIG. 33.18. Keratinous cyst (epidermal inclusion cyst). The cyst is firm but compressible. (From Wilkinson, Stone. *Atlas of vulvar disease.* Philadelphia: Lippincott, Williams and Wilkins, with permission.)

On microscopic examination, the cyst lining is flattened, stratified squamous epithelium that is immunoreactive for high-molecular-weight keratin. These cysts may be associated with occluded sebaceous gland ducts that have undergone squamous metaplasia. In the adjacent tissue to the cyst wall, foreign body-type giant cells associated with keratinous material that has leaked into the dermis can be found. Treatment is not necessary if the cysts are asymptomatic. Surgical excision is considered if the diagnosis is in question or if the cysts are enlarging, symptomatic, or become infected.

Mucous Cyst

Mucous cyst occurs primarily in the vulvar vestibule (Fig. 33.19). These cysts apparently arise from occlusion of minor vestibular glands. These cysts are typically simple cysts, superficial, and lined by mucus-secreting, cuboidal-to-columnar epithelium without associated myoepithelial cells. Metaplastic squamous epithelium may be present with the columnar epithelium lining the cyst. The epithelial cyst lining stains with both Alcian blue and Mayer mucicarmine. This distinguishes them from cysts of mesonephric origin that do not stain with these agents.

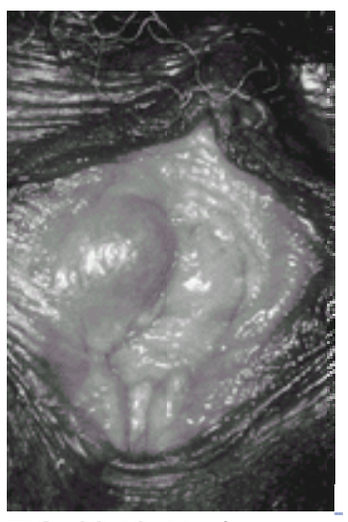

FIG. 33.19. Mucinous cyst of the vulvar vestibule. (From Wilkinson, Stone. *Atlas of vulvar disease.* Philadelphia: Lippincott, Williams and Wilkins, with permission.)

Columnar Cell Metaplasia

Columnar cell metaplasia has been described within the vulvar vestibule epithelium, as well as within the vaginal mucosa. Columnar cell metaplasia presents as a solitary flattened red area of the labia minora, or as persistent redness of the upper vagina. In one reported case the process responded to topical estrogen cream. Columnar cell metaplasia of the nonkeratinized squamous epithelium of the vulva vestibule or vagina is a condition where columnar epithelium of mucinous or tubal–epithelial type replaces the squamous epithelium. This has been described after Stevens-Johnson syndrome as well as after laser and 5-FU therapy.

Columnar cell metaplasia appears to be the origin of vulvar ciliated cysts. These cysts are lined with columnar epithelium resembling müllerian epithelium (tubal–endometrial epithelium), consisting of ciliated, secretory, and undifferentiated type cells. The cysts within the vestibule are considered acquired, since the müllerian system does not contribute to the development of the vestibule, which is of urogenital sinus origin. The cysts are distinguished from endometriosis by the absence of associated endometrial stroma or hemosiderin-laden macrophages.

Therapy for these cysts in the vestibule is generally not needed and they can be followed by observation alone. If the cyst or cysts persist, enlarge, or become symptomatic, they can be excised.

Vulvar Endometriosis

Vulvar endometriosis represents ectopic endometrial epithelium. The origin may be from endometrium implanted following vulvar or vaginal tears, or at the time of delivery, or endometrium shed at menstruation. Vascular spread of endometrium to the vulva or vagina may also be a consideration.

On clinical presentation, superficial vulvar or vaginal endometriosis usually presents as a mass that is blue-black to violet in color. In the vulva the mass is often in the posterior fourchette. Deeper endometriosis usually has no associated skin or mucous membrane discoloration. Cyclic pain and enlargement with the menstrual cycle

may be noted.

Diagnosis may be made using fine-needle aspiration cytology or local excision. On histologic examination endometrial glands and stroma are usually identified, often associated with hemosiderin-laden macrophages.

Apocrine Hydrocystoma/Cystadenoma of the Vulva

Apocrine hydrocystoma is a cyst with an epithelial lining with apocrine differentiation. The lining cells are apocrine in character with pink cytoplasm and apical snoutlike secretion. Apocrine cystadenoma is a cyst lined with apocrine-differentiated cells with an epithelial lining that has micropapillary projections. These cysts typically arise in the apocrine gland–bearing areas of the vulva.

Mesonephric-like Cyst (Wolffian-like Duct Cyst)

Mesonephric-like cysts occur on the lateral walls of the vagina, and occasionally within the lateral vulvar vestibule. These cysts are typically thin-walled, translucent in appearance, and contain a clear fluid. The cuboidal to columnar epithelial lining is not ciliated. Using immunohistochemistry for smooth muscle, such as smooth muscle actin, smooth muscle can be seen deep and surrounding these cysts.

Cyst of the Canal of Nuck (Mesothelial Cyst)

Entrapped peritoneum (processus vaginalis) within the round ligament may result in a cyst of the canal of Nuck, causing labial enlargement. These cysts apparently arise from inclusions of the peritoneum at the inferior insertion of the round ligament into the labia majora.

Cysts of the canal of Nuck typically occur in the superior labia majora or inguinal canal. Therefore they are analogous to spermatic cord hydrocele. These mesothelial-lined cysts can achieve substantial size and a concurrent inguinal hernia, which occurs in approximately one-third of cases, and sometimes obscures their diagnosis. These cysts may mimic inguinal hernia on clinical examination.

Polycystic Ovarian Syndrome

Amenorrhea is the absence or cessation of menses and may result from a wide variety of pathologic conditions. It is a common symptom of an underlying abnormality in the reproductive system that may be anatomic (developmental or acquired), organic, or endocrinologic in nature. This chapter outlines the differential diagnosis of amenorrhea, discusses the indications and methods for evaluation, and describes options for treatment once a diagnosis and the patient's goals are clearly defined. However, the most common cause of amenorrhea in women of reproductive age is pregnancy and that should be ruled out before considering other etiologies.

THE NORMAL MENSTRUAL CYCLE

Normal menstrual function involves a complex multilevel integration of endocrine signals, local autocrine and paracrine mechanisms, and target cell receptors, all operating at four distinct levels: the genital tract, the ovary, the pituitary gland, and the hypothalamus. First, normal menstrual function requires a normal genital outflow tract. The uterus must have a functional endometrium capable of response to estrogen and progesterone, and be continuous with the cervix, vagina, and introitus. Second, the ovaries must contain follicles responsive to pituitary follicle-stimulating hormone (FSH) and luteinizing hormone (LH) stimulation. Progressive follicular development and ovulation further require the normal operation of local intraovarian regulatory mechanisms that are sensitive to changes in the endocrine milieu. Third, pituitary gonadotrophs must have the capacity to synthesize and secrete gonadotropins in response to hypothalamic gonadotropin-releasing hormone (GnRH) stimulation. The relative amounts of FSH and LH released reflect changes in the pulsatile pattern of GnRH secretion and the feedback modulation of ovarian steroid and peptide hormones. Finally, specialized neurosecretory cells located in the medial basal hypothalamus (arcuate nucleus) must have functional communication with the pituitary gland and be able to synthesize and release GnRH in a pulsatile pattern that varies in response to stimuli from the environment and feedback signals from the periphery.

Amenorrhea may result from congenital or acquired disease or dysfunction at the level of the genital tract, the ovary, the pituitary, or the hypothalamus. In fact, the single most common cause of amenorrhea—chronic hyperandrogenic anovulation (polycystic ovary syndrome; PCOS)—involves a number of interrelated pathophysiologic mechanisms that operate at the ovarian, pituitary, and hypothalamic levels, and does not fall neatly into any one specific category. The wide array of disorders that may be responsible suggests that amenorrhea may present a daunting diagnostic challenge but, in truth, evaluation is relatively straightforward, logical, and requires only tests and procedures with which all gynecologists should be quite familiar. With few exceptions, an accurate diagnosis can be confidently established in very little time and without great expense.

Differential Diagnosis of Amenorrhea

Although the list of potential causes of amenorrhea is long, the majority of cases relate to one of five conditions: pregnancy, PCOS, hypothalamic amenorrhea, hyperprolactinemia, and ovarian failure (Table 34.1). All of the remaining causes are relatively uncommon and only occasionally encountered in a lifetime of clinical practice.

Pregnancy
Genital tract abnormalities
Congenital
Hymeneal obstruction
Congenital absence of all or a portion of the vagina or cervix
Congenital absence of the müllerian duct system
Androgen insensitivity syndrome
Acquired
Cervical obstruction/stenosis
Intrauterine adhesions
Ovarian failure
Gonadal dysgenesis (45X, 46XX, and 46XY)
Premature ovarian failure (postpubertal)
Pituitary disorders
Functional hyperprolactinemia (including hypothyroidism and drug-induced)
Prolactin-secreting and other pituitary tumors (including craniopharyngioma)
Empty sella syndrome and Sheehan syndrome
Hypothalamic disorders
Congenital (Kallmann syndrome)
Stress (weight loss, excercise, emotional)
Polycystic ovary syndrome

TABLE 34.1. *Causes of amenorrhea*

Genital Tract Abnormalities

The embryology of the female genital tract involves the medial migration and midline fusion of the paired müllerian (paramesonephric) ducts to form the uterus, cervix, and upper vagina, and the vertical fusion of that developing ductal system with the invaginating urogenital sinus to form the lower vagina and the introitus. Outflow tract abnormalities that result from failure of müllerian duct development include *vaginal/müllerian agenesis* and *androgen insensitivity syndrome (AIS)*, where the uterus is altogether absent. Abnormalities caused by failure of vertical fusion include *imperforate hymen, transverse vaginal septum*, and *cervical atresia.* These conditions result in an accumulation of menstrual effluent above the level of obstruction (cryptomenorrhea). With two notable exceptions, all outflow tract abnormalities are developmental in origin and therefore cause primary amenorrhea. *Asherman syndrome* and *cervical stenosis/obstruction* are acquired conditions and therefore are causes of secondary, rather than primary, amenorrhea. Asherman syndrome results from intrauterine adhesions that obstruct or obliterate the uterine cavity as a consequence of inflammation (postpartum endometritis, retained products of conception) or trauma (curettage). Severe cervical stenosis with complete outflow

obstruction is a rare complication of cervical conization procedures or other surgical treatments for cervical intraepithelial neoplasia.

Ovarian Disorders

Ovarian failure occurs when few or no follicles remain that are capable of producing estradiol in response to pituitary gonadotropin stimulation. Follicular depletion may occur during embryonic life with no follicles remaining by infancy or early childhood, after puberty has begun but before menarche, or at some later time before menopause would normally be expected. Therefore, depending on when the available supply of ovarian follicles is functionally depleted, puberty may not occur, it may begin normally but stop before the first menses, or it may progress normally to and beyond menarche with secondary amenorrhea having onset at some later point in time.

Gonadal dysgenesis is among the most common of all causes of primary amenorrhea (approximately 30%–40%) and results from an absence of ovarian follicles or accelerated follicular depletion during embryogenesis or the first few years of life. The gonads of affected individuals contain only stroma and appear as fibrous streaks. The most common form of gonadal dysgenesis is Turner syndrome, classically associated with a 45,X karyotype, but also with an assortment of other structural X chromosome abnormalities (deletions, ring, and iso-chromosomes). These X chromosomal anomalies may be present in all or only in some of the cells of the body (mosaicism), depending on the stage of embryonic development at the time that they arise. Although less common, individuals with gonadal dysgenesis also may have a normal 46,XX or a 46,XY karyotype *(Swyer syndrome)* in all cells or in one or more cell lines in mosaic individuals (e.g., 45,X/46,XX; 45,X/46,XY). Most, in the absence of ovarian follicles, have no significant secondary sexual development. A few may have transient normal ovarian function, the extent depending on when the limited supply of ovarian follicles is depleted. Approximately 15% begin but do not complete pubertal development and approximately 5% have sufficient follicles to complete puberty and begin spontaneous menstruation. Spontaneous pregnancies rarely occur and are associated with a relatively high risk for sex chromosome aneuploidy and spontaneous abortion.

Premature ovarian failure (POF) results in secondary amenorrhea at some time after puberty has been completed. It is distinguished from gonadal dysgenesis on the basis of ovarian morphology and histology; instead of streak gonads, the ovaries in POF more closely resemble those of postmenopausal women. Approximately 1% to 5% of women will develop POF before the age of 40 years. The karyotype in individuals with POF is most often normal (46,XX), but also may reveal mosaicism (e.g., 45,X/46,XX). A specific cause for early follicular depletion in POF frequently cannot be determined and is presumed to result from inadequate germ cell migration during embryogenesis or accelerated atresia. POF is frequently associated with *autoimmune disorders* and in some cases (e.g., Addison disease) appears to result from an autoimmune lymphocytic oophoritis. *Radiation* and *chemotherapy* are two other important causes of ovarian failure. The effects of both are dependent upon dose and the age at time of treatment. *Galactosemia* is an autosomal recessive disorder of galactose metabolism caused by a deficiency of the enzyme galactose 1-phosphate uridyltransferase and another, albeit very rare, cause of POF. Affected women have fewer primordial follicles presumably due to the cumulative toxicity of galactose metabolites on germ cell migration and survival.

Other, very rare, ovarian disorders that may cause amenorrhea include *17a-hydroxylase deficiency, aromatase deficiency*, and the *gonadotropin-resistant ovary syndrome.* Unlike in ovarian failure, the ovaries of individuals with these disorders contain follicles and oocytes, but cannot produce estrogen. The enzyme 17 µ-hydroxlase mediates an early step in steroid hormone synthesis, without which progesterones cannot be converted to androgens and subsequently, estrogens. The enzyme aromatase mediates the conversion of androgenic precursors to estrogens; individuals with aromatase deficiency generally exhibit sexual ambiguity at birth, virilization at puberty, and multicystic ovaries. The gonadotropin-resistant ovary syndrome results from genetic mutations in the FSH or LH receptor or post-receptor signaling defects that prevent the ovaries from responding normally to gonadotropin stimulation; although present, ovarian follicles fail to develop beyond the early antral stage and therefore produce little estrogen.

Pituitary Disorders

Pituitary tumors may cause amenorrhea by directly compressing pituitary gonadotrophs or distorting the portal venous network that delivers hypothalamic GnRH stimulation, resulting in decreased FSH and LH secretion. They also may cause inadequate or excessive production of other pituitary hormones, via compression of pituitary tissue, interference with the portal venous circulation, or autonomous secretion (functional pituitary adenomas). Directly or indirectly, these endocrinopathies may disrupt normal ovarian function, thereby causing amenorrhea. Although metastatic lesions may occasionally be seen, malignant pituitary tumors are extremely rare. Virtually all pituitary tumors are benign adenomas that may be functional or nonfunctional; functional tumors may secrete prolactin, growth hormone (GH), thyroid-stimulating hormone (TSH), or adrenocorticotropic hormone (ACTH).

Other uncommon pituitary disorders that may cause amenorrhea include the *empty sella syndrome* and *Sheehan syndrome.* The empty sella syndrome results from herniation of the subarachnoid space containing cerebrospinal fluid into the sella turcica with compression of the pituitary gland against the sellar floor, giving the sella an “empty” appearance when viewed by computed tomography (CT) or magnetic resonance imaging (MRI). Sheehan syndrome results from acute infarction and necrosis of the pituitary gland as a rare complication of shock due to obstetric hemorrhage. Depending on the extent of pituitary damage, clinical consequences may be limited to disorders of reproductive function (failed lactation, amenorrhea), or more general, with multisystem failure due to panhypopituitarism.

Hypothalamic Disorders

Absent or abnormal patterns of pulsatile hypothalamic GnRH secretion that fail to stimulate normal levels or patterns of pituitary gonadotropin secretion are the most common cause of amenorrhea. Both *PCOS* and *hypothalamic amenorrhea* that may result from emotional, nutritional, or physical stress are basically hypothalamic disorders, but their pathophysiology and clinical presentations differ considerably. Women with PCOS exhibit an increased frequency of pulsatile GnRH secretion that results in increased LH synthesis, hyperandrogenism, and impaired follicular maturation. In contrast, the inconsistent and generally low frequency pattern of pulsatile GnRH secretion in women with hypothalamic amenorrhea results in low levels of pituitary gonadotropin release that fail to stimulate or sustain progressive follicular development.

Occasionally, a *hypothalamic tumor* (craniopharyngioma, meningioma, hamartoma, chordoma) may distort the tuberoinfundibular tract or portal venous network, thereby interfering with effective delivery of GnRH stimulation, and result in decreased pituitary FSH and LH secretion. Alternatively, interference with hypothalamic dopamine delivery to pituitary lactotrophs may cause *hyperprolactinemia.* In either case, hypothalamic tumors may result in a secondary hypogonadotropic hypogonadism and amenorrhea. In other rare instances, GnRH deficiency is congenital and associated with midline craniofacial defects or with anosmia due to a failure of olfactory axonal and GnRH neuronal migration during embryogenesis *(Kallmann syndrome)*, resulting in primary amenorrhea and sexual infantilism.

EVALUATION OF AMENORRHEA

A detailed medical history and physical examination are always important. In the patient with amenorrhea, elements of particular interest include growth and secondary sexual development (breast and pubic hair), menstrual history (if any), previous surgery or trauma to the pelvis or central nervous system (CNS), family history of hereditary disorders, evidence of physical, psychological or emotional stress, symptoms and signs of hirsutism or galactorrhea, as well as reproductive tract anatomy.

Medical History

The age at which menarche should be expected varies but, in general, the first menses should occur within 2 to 3 years after the initiation of pubertal development. In most young girls (approximately 80%), the first sign of puberty is an acceleration of growth, followed by breast budding (thelarche), and the appearance of pubic hair (adrenarche). In the remainder, adrenarche precedes thelarche by a brief interval, but the two events typically are closely linked. Consequently, menarche should be expected as early as age 10 (when puberty begins at age 8), and rarely later than age 16 (when puberty begins at age 13). On average, in the United States, the mean ages for thelarche, adrenarche, and menarche in black girls are 6 to 12 months earlier than in white girls. When secondary sexual development fails to begin by age 14, or begins but fails to progress at the normally expected pace, evaluation is indicated. Once menstrual cycles have been established, amenorrhea for an interval equivalent to three previous cycles, or 6 months, warrants evaluation.

Questions relating to past medical history, general health, and lifestyle may identify a severe or chronic illness (diabetes, renal failure, inflammatory bowel disease), head trauma, or evidence of physical, psychological, or emotional stress. Weight loss or gain and the frequency and intensity of exercise may be revealing. Headaches, seizures, vomiting, behavioral changes, or visual symptoms may suggest a CNS disorder. Vaginal dryness or hot flushes are evidence of estrogen deficiency and suggest ovarian failure. Progressive hirsutism or virilization is evidence of hyperandrogenism that may result from PCOS, nonclassic (late-onset) congenital adrenal hyperplasia (CAH), or an androgen-producing tumor of the ovary or adrenal gland. Bilateral galactorrhea suggests hyperprolactinemia. Cyclic pelvic or lower abdominal pain or urinary complaints may be caused by developmental anomalies resulting in obstructed menstrual flow, including an imperforate hymen, transverse vaginal septum, or cervical atresia. A previous inguinal hernia repair or curettage suggests the possibility of a developmental anomaly or damage to the reproductive tract. The timing and duration of any treatment with progestational agents (oral contraceptive pills [OCP], depot-medroxyprogesterone acetate), GnRH agonists (leuprolide, goserelin, nafarelin), or other medications (phenothiazines, reserpine derivatives, amphetamines, opiates, benzodiazepines, antidepressants, dopamine antagonists) or drugs (opiates) may provide important diagnostic clues.

Physical Examination Body habitus often provides important clinical information. Height, weight, and body mass index (BMI) should be recorded. Short stature (less than 60 inches) is a hallmark of gonadal dysgenesis; sexual infantilism, webbing of the neck, low set ears and posterior hairline, widely spaced nipples, short fourth metacarpal, and a wide carrying angle of the arms (cubitus valgus) are among the classical stigmata of Turner syndrome. Low body weight is frequently associated with hypothalamic amenorrhea resulting from poor nutrition (eating disorders) or physical, psychological, or emotional stress. Obesity or an increased waist-to-hip ratio (>0.85) is often associated with insulin resistance and chronic anovulation. Examination of the skin may reveal a soft, moist texture as seen in hyperthyroidism; a rapid pulse and classic eye signs (exophthalmos, lid lag), a fine tremor, and hyperreflexia may provide further evidence to suggest a diagnosis of Graves disease. Conversely, dry, thick skin, a slow pulse, diminished reflexes, and thinning of the hair suggest hypothyroidism. Both hypothyroidism and hyperthyroidism may be associated with amenorrhea. Orange discoloration of the skin in the absence of scleral icterus may result from hypercarotinemia associated with excessive ingestion of low-calorie, carotene-containing fruits and vegetables in dieting women. Acanthosis nigricans, velvety hyperpigmented skin most commonly observed at the nape of the neck, in the axillae, and beneath the breasts, strongly suggests severe insulin resistance and the possibility of diabetes. Acne and hirsutism are indications of hyperandrogenism that may result from chronic anovulation (PCOS), nonclassic CAH, or ingestion of androgenic anabolic steroids. When accompanied by any sign of frank virilization (deepening of the voice, frontotemporal balding, decrease in breast size, increased muscle mass, clitoromegaly), the possibility of ovarian hyperthecosis or an ovarian or adrenal neoplasm must be considered. Breast development, as assessed by Tanner staging, is a reliable indicator of estrogen production or exposure to exogenous estrogens. Arrested breast development suggests a disruption of the hypothalamic–pituitary–ovarian (HPO) axis. When menarche has not followed adult breast development, a developmental anomaly of the reproductive tract should also be considered. The breast examination should include gentle compression, beginning at the base and moving toward the nipple. Microscopic examination of any expressed cloudy or white nipple secretions that demonstrate lipid droplets indicate true galactorrhea and suggest hyperprolactinemia. Abdominal examination may rarely reveal a mass as may result from hematometra or an ovarian neoplasm. Growth of hair from the pubic symphysis to the infraumbilical region suggests hyperandrogenism. Abdominal striae raise the possibility of Cushing syndrome, but much more often result from progressive obesity or previous pregnancy. As noted earlier, thelarche and adrenarche typically are closely linked events during puberty and, in general, breast development and growth of pubic hair progress in a symmetric manner. The Tanner stages of breast and pubic hair development should be consistent. Absent or scant growth of pubic hair is a classic sign of AIS when breast development is asymmetrically advanced. Attempts at office examination of the vagina in sexually infantile girls or those with a small hymeneal ring are often difficult and counterproductive, but whenever feasible, speculum examination should be performed. A patent vagina and visible cervix excludes müllerian/vaginal agenesis, AIS, and most obstructive causes of amenorrhea. In those with an absent or infantile vaginal orifice, rectal examination should be performed and may reveal a distended hematocolpos above the obstruction when the uterus is present and functional.

Diagnostic Evaluation A careful history and physical examination will always narrow the range of diagnostic possibilities that must then be differentiated. The subsequent laboratory investigation or imaging should be focused on that differential diagnosis and, with few exceptions a diagnosis can be quickly and easily established. Sexual ambiguity and virilization should be evaluated as separate disorders, mindful that amenorrhea is an important element of their presentation.

Abnormal Genital Tract Anatomy A history of primary amenorrhea accompanied by physical examination that reveals an absent or blind vagina indicates a developmental anomaly of the genital outflow tract. The list of diagnostic possibilities is short and includes an imperforate hymen, a transverse vaginal septum, cervical atresia, müllerian/vaginal agenesis, and androgen insensitivity syndrome (Fig. 34.1). Because each of these disorders has unique features, they generally are not difficult to distinguish.

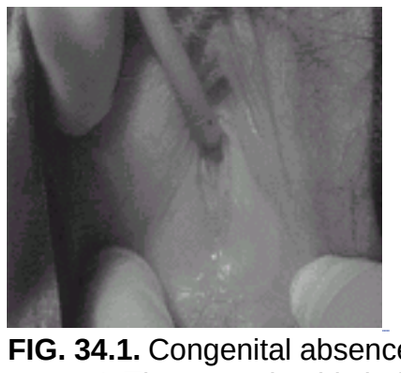

FIG. 34.1. Congenital absence of the vagina. The external genitalia are entirely normal in appearance without any evidence of ambiguity but there is simply no vagina present. The normal pubic hair indicates androgen responsiveness and eliminates the possibility of androgen insensitivity syndrome indicating that this is simply congenital absence of the müllerian duct system.

Patients with an imperforate hymen or transverse vaginal septum/cervical atresia typically present at the expected time of menarche with complaint of cyclic perineal, pelvic, or abdominal pressure or pain and exhibit normal secondary sexual development. In those with an imperforate hymen, genital examination reveals no obvious vaginal orifice, but a thin, often bulging, blue perineal membrane and a fluctuant mass, resulting from the accumulation of mucus and blood in the vagina. In those with a transverse vaginal septum or cervical atresia, examination typically reveals a normal vaginal orifice, a short blind vagina of varying length, and a fluctuant pelvic mass well above to the level of obstruction (hematocolpos, hematometra, hematosalpinx). Differentiation of imperforate hymen and transverse vaginal septum/cervical atresia generally requires no laboratory investigation. Whereas a *transabdominal* or *transperineal ultrasound* examination will reveal the level and volume of sequestered menses, an *abdominalpelvic MRI* provides greater anatomic detail and helps to define the nature of an anomaly (Fig. 34.2). In some instances, laparoscopy may be required to clearly identify the anatomy of a developmental anomaly.

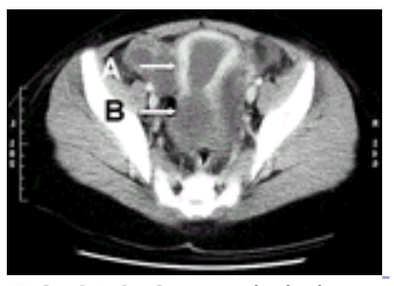

FIG. 34.2. Congenital absence of the lower one third of the vagina. Magnetic resonance imaging demonstrates that a uterus is present (**A**) as well as an upper vaginal pouch (**B**). The upper vagina has formed a hematocolpos which began soon after menarche and presented as a pelvic mass.

In contrast, patients with amenorrhea resulting from müllerian agenesis generally are otherwise entirely asymptomatic. They exhibit normal breast and pubic hair development, an absent vagina, and have no symptoms or signs of cryptomenorrhea because the uterus is altogether absent. The diagnosis is usually self-evident from physical examination alone. Further evaluation to exclude skeletal and urinary tract anomalies is indicated because approximately 12% to 15% of women with müllerian agenesis have skeletal abnormalities (vertebral anomalies are most common) and one third or more have urinary tract anomalies (ectopic kidney, renal agenesis, horseshoe kidney, abnormal collecting system). In girls who have not yet reached the age when menarche (and cryptomenorrhea) would be expected if a uterus was present, imaging must be interpreted cautiously because even abdominal/pelvic MRI can be misleading when the reproductive organs are immature. Remaining alert to the diagnostic possibilities, careful observation over time is preferable to invasive investigations that are otherwise unnecessary. Normal breast development, absent or sparse growth of pubic hair, and a short blind vagina clearly suggest AIS. Although the chromosomal sex is male (46,XY), the phenotype is female. The testes are undescended, often palpable in the inguinal canals (most commonly at the level of the external inguinal ring), and produce normal male levels of testosterone and müllerian inhibitory hormone (MIH). Whereas end-organ insensitivity to androgen action (due to abnormalities of the androgen receptor) prevents normal masculinization of the genitalia, MIH inhibits müllerian development in a normal fashion. Consequently, the external genitalia are those of a female (absent androgen action), the uterus is absent (normal MIH action), and the vagina is short and ends blindly (derived from the invaginating urogenital sinus, absent androgen action). The diagnosis may be suspected when other family members (e.g., aunt, sister) are affected with this X-linked disorder. Incomplete penetrance may result in growth of more pubic hair than might be expected and sometimes can be misleading. However, a serum *testosterone* concentration easily distinguishes androgen insensitivity syndrome (AIS; normal or modestly elevated above the range observed in normal males) from müllerian agenesis (normal range for a female). A *karyotype* firmly establishes the diagnosis. Cervical obstruction/stenosis and Asherman syndrome are abnormalities of genital tract anatomy, but physical examination of the genital tract most often is normal. When cervical stenosis causes symptoms, worsening dysmenorrhea or prolonged light staining or spotting after menses are the most common complaints; amenorrhea is a rare occurrence. In women with a history of previous conization or other cervical surgery or ablative therapy, *uterine sounding* may help to establish a diagnosis. Similarly, most women in whom previous infection or surgical trauma has resulted in intrauterine synechiae present with dysmenorrhea, hypomenorrhea, subfertility, or recurrent early pregnancy loss, rather than amenorrhea. In women whose history clearly suggests the possibility of intrauterine adhesions, *ultrasound* and *hysterosalpingography* can reveal their location and extent, but hysteroscopy is the definitive method for diagnosis.

Normal Genital Tract Anatomy When physical examination reveals normal genital tract anatomy, further evaluation is required to determine the cause of amenorrhea. The possibility of pregnancy should always be considered and excluded. When breast growth is absent or inconsistent with age and associated with primary amenorrhea, the cause of delayed puberty should be determined. The vast majority of these cases have no pathology. In the remainder, evaluation may reveal thyroid disease, chronic illness (malabsorption, renal disease, eating disorders, inflammatory bowel disease), ovarian failure (e.g., gonadal dysgenesis), a pituitary disorder (tumor, empty sella syndrome, hyperprolactinemia), or a hypothalamic cause (Kallmann syndrome; physical, emotional, or psychological stress; tumor). Wrist x-rays for *bone age* and a *GnRH stimulation test* are important components of the evaluation for delayed puberty in children and adolescents, but the diagnostic possibilities and scope of evaluation in adolescents and adults with either primary or secondary amenorrhea are otherwise very much the same.

Thyroid Function Tests Initial evaluation should include a measurement of serum *TSH*. The newest generation of ultrasensitive TSH assays in common use provides the means to detect both primary hypothyroidism (elevated TSH) and primary hyperthyroidism (low TSH). Either may result in chronic anovulation and amenorrhea. Any abnormal value should be confirmed and accompanied by measurement of serum *thyroxine* (tetraiodothyronine; T4) to better define the nature and extent of the

thyroid disorder. When TSH is elevated and the T4 concentration is normal, the diagnosis is subclinical hypothyroidism, best viewed as a compensated state wherein normal levels of T4 are maintained, but only under increased levels of pituitary stimulation. On rare occasions, both TSH and T4 levels may be low, suggesting hypothyroidism of pituitary origin that will require additional evaluation to include hypothalamic/pituitary imaging (MRI) and careful assessment to determine whether other pituitary functions also are affected.

Prolactin A serum *prolactin* determination is another component of the initial evaluation of amenorrhea. Hyperprolactinemia may be associated with a variety of menstrual disturbances—oligomenorrhea and amenorrhea being the most common. In general, prolactin concentrations are higher in amenorrheic than in oligomenorrheic hyperprolactinemic women. Hyperprolactinemia may occasionally result in delayed puberty and primary amenorrhea, if it arises before menarche, and is among the most common causes of secondary amenorrhea. Hyperprolactinemia inhibits pulsatile hypothalamic GnRH secretion, resulting in depressed levels of pituitary FSH and LH secretion. The end result is anovulation or more profound hypogonadotropic hypogonadism, depending on the extent to which gonadotropin secretion is suppressed. One cannot rely on the symptom or finding of galactorrhea to identify individuals whose amenorrhea may result from hyperprolactinemia. Only approximately one third of hyperprolactinemic women will exhibit galactorrhea, probably because breast milk production requires several other hormones, including GH, T4, cortisol, insulin, and most important, estrogen and progesterone. Serum prolactin determinations therefore should be obtained in all amenorrheic women. Hyperprolactinemia has many causes. Among these are:

- prolactin-secreting pituitary adenomas
- other pituitary or hypothalamic tumors that may distort the portal circulation and thereby prevent effective delivery of hypothalamic dopamine (the putative prolactin inhibitory factor or hormone)
- a variety of drugs that lower dopamine levels or inhibit dopamine action (amphetamines, benzodiazepines, butyrophenones, metoclopramide, methyldopa, opiates, phenothiazines, reserpine, and tricyclic antidepressants)
- breast or chest wall surgery, cervical spine lesions, or herpes zoster (activation of the afferent sensory neural pathway that stimulates prolactin secretion, in a manner similar to suckling)
- hypothyroidism (increased hypothalamic thyrotropin-releasing hormone stimulates pituitary prolactin secretion directly)
- pharmacologic estrogens (OCP)
- other rare, nonpituitary sources (lung and renal tumors) or causes of decreased prolactin clearance (renal failure).

All causes must be considered and systematically excluded; a careful history will eliminate many of the possibilities. When medications are the cause, prolactin concentrations are usually only moderately elevated and levels greater than 100 ng/mL generally are uncommon. Although medications may offer an obvious explanation, one cannot confidently assume they are the cause of hyperprolactinemia. If possible, a trial discontinuation or use of an alternative medication should be considered. When that is not possible and hypothyroidism has been excluded, further evaluation to exclude hypothalamic and pituitary tumors and other causes of hyperprolactinemia is appropriate. Imaging of the hypothalamic and pituitary regions to exclude mass lesions in hyperprolactinemic patients can be accomplished with head *CT* or *MRI*. MRI generally is regarded as the superior method because it is more accurate for identification of very small lesions or an empty sella and better defines tumor margins and relationships to surrounding structures. The indications for CT or MRI in the evaluation of hyperprolactinemia remain controversial. Those who advocate liberal use of imaging correctly emphasize that the likelihood of a pituitary tumor does not correlate with the prolactin concentration. Pituitary microadenomas (=10 mm) are very common (10%–30% prevalence in autopsy studies) and even macroadenomas (>10 mm) may be associated with only modest elevations (25–100 ng/mL) of prolactin because they are nonfunctional tumors or may have undergone necrosis. Moreover, imaging may reveal evidence of other hypothalamic disease that may be important (tumor, tuberculosis, sarcoidosis, aqueductal stenosis) and amenable to specific treatment. Those who prefer a more selective approach stress that imaging is costly and has a relatively low yield when performed routinely. They correctly emphasize that pituitary tumors rarely grow (even in pregnancy), are not a contraindication to hormone replacement or OCP, and that their natural course is unaffected by treatment with dopamine agonists (bromocriptine, pergolide, cabergoline). In this view, because diagnosis of a pituitary microadenoma generally has little or no impact on clinical management decisions, MRI should be limited to those with grossly elevated prolactin levels (>100 ng/mL) who are hypoestrogenic, in whom a macroadenoma of greater clinical significance is more likely, and to those with suspicious symptoms (visual disturbances, headaches) or findings (visual field defects, abnormal optic fundi). For asymptomatic patients with moderate hyperprolactinemia (20–100 ng/mL), some advocate a less costly *coned down lateral view of the sella turcica* and reserve MRI for those with an enlarged or abnormal sella (erosion of the sellar floor or clinoid processes) or hypothalamic calcifications that suggest a tumor (e.g., craniopharyngioma). The most prudent approach is to obtain an MRI whenever persistent hyperprolactinemia cannot be confidently attributed to medication or hypothyroidism.

FSH Initial evaluation of amenorrheic women with normal genital tract anatomy should include measurement of serum *FSH* to distinguish ovarian failure (elevated FSH) from hypothalamic/pituitary disease or dysfunction that yields inadequate or ineffective patterns of gonadotropin secretion (low or normal FSH). An elevated FSH level generally is a reliable indicator of ovarian failure, but must be interpreted in the context of the clinical presentation. During the perimenopause, regardless whether it occurs prematurely or at the usual age, FSH levels may rise well before menses have ceased entirely. Those follicles that remain also are relatively insensitive to FSH, but many can and will respond to rising levels of stimulation when the requisite threshold FSH concentration is achieved. Once follicular growth begins and estrogen levels rise, FSH concentrations decline, albeit transiently, before rising again to the levels necessary to stimulate new follicular growth. FSH levels therefore are dynamic, often fluctuate widely during the perimenopause, and must be interpreted cautiously. The FSH level is high in the enigmatic gonadotropin-resistant ovary syndrome that may result from inactivating mutations in the FSH or LH receptor. However, specific efforts to diagnose these rare conditions *(ovarian biopsy, genotyping)* are academic and have no practical clinical value because the prognosis for future fertility is extremely poor and treatment options are no different from those for women with true ovarian failure. Serum FSH concentrations also are elevated in individuals with 17a-hydroxylase or aromatase deficiencies and galactosemia, but these conditions are extremely rare and do not enter into clinical consideration. With few exceptions, a high serum FSH level is an indication of ovarian failure. A history of previous radiation or chemotherapy may provide an obvious explanation. Doses of radiation under approximately 100 rads generally have no significant effect, but risk of ovarian damage rises progressively with higher doses. Individuals treated when young may have only transient amenorrhea with a return of menstrual cycles months or years later, but also are more likely to develop POF. Those treated as adults are at greater risk for immediate and irreversible ovarian failure. Alkylating agents (e.g., cyclophosphamide), used in the treatment of malignancies and other diseases (systemic lupus erythematosus), are extremely toxic to gonadal tissues. As with radiation, the dose required to induce ovarian failure is inversely related to age at the time of treatment. Other chemotherapeutic agents have the potential for ovarian damage, but their effects are less clear; risk increases with the number of agents involved in combination therapies. When ovarian failure occurs before age 30 and cannot be confidently explained, a karyotype should be obtained. An abnormal karyotype may be observed in up to one-half of all women with primary amenorrhea. Classic Turner syndrome (45,X), structural abnormalities of the X chromosome (deletion, ring, iso-chromosome), and mosaicism (e.g., 45,X/46,XX) are the most common abnormalities found. A karyotype also will detect the presence of a Y chromosome that might not otherwise be suspected. The phenotype in Swyer syndrome (46,XY gonadal dysgenesis) and some with Turner mosaicism (45,X/46,XY) is female because the dysgenetic (streak) gonads fail to produce both MIH and androgens. Consequently, the uterus, fallopian tubes, cervix, and vagina develop normally but the genitalia do not masculinize. However, a peripheral leukocyte karyotype alone cannot exclude the presence of occult Y chromosomal material. Further analysis with *fluorescence in situ hybridization (FISH)* using one or more probes that are specific for segments of the Y chromosome is required and should be performed in any individual with a 45,X karyotype or 45,X mosaic cell line. An occult Y chromosome must be identified because affected individuals are at significant risk (approximately 25%) for developing a unique type of germ cell tumor (gonadoblastoma) that may contain malignant elements (dysgerminoma, embryonal cell carcinoma, choriocarcinoma). Virtually all such tumors arise early in life. Over the age of 30, therefore, karyotype is unnecessary and ovarian failure can be confidently regarded as premature menopause. Approximately 25% of patients with gonadal dysgenesis have a normal karyotype (46,XX). As gonadal dysgenesis with a normal karyotype is associated with neurosensory deafness, *audiometry* should be considered. In women with secondary amenorrhea and unexplained POF, further evaluation to exclude autoimmune disease is appropriate as up to 40% may have autoimmune disorders. POF develops in 10% to 60% of women with Addison disease (adrenal insufficiency) and also is more common in women with diabetes mellitus (type 1), myasthenia gravis, and parathyroid disease than in healthy women. However, only those with Addison disease are likely to have a demonstrable autoimmune lymphocytic oophoritis. Ovarian biopsy is not indicated in clinical practice, but because POF may be a component of a polyglandular syndrome, general screening for autoimmune disorders is reasonable. Thyroid abnormalities are the most common and can be identified by measuring *TSH, T4*, and *thyroid autoantibodies (antiperoxidase, antithyroglobulin).* Screening may also include *24-hour urinary free cortisol, fasting blood glucose, serum calcium and phosphorus*, and *antinuclear antibody*. More extensive or specific testing for autoimmune disorders is unnecessary in the absence of other clinical signs and symptoms of disease. Although autoimmune screening is logical and practical, no one or combination of serum markers can confirm a diagnosis of autoimmune ovarian failure. A low normal serum FSH concentration is an indication of hypothalamic or pituitary dysfunction and the most common result observed in clinical practice. PCOS and hypothalamic amenorrhea are the two main diagnostic possibilities and generally are easily distinguished by their clinical presentations.

POLYCYSTIC OVARY SYNDROME

Although there is no universally accepted definition of PCOS, diagnosis generally is based on three criteria—ovulatory dysfunction, clinical evidence of hyperandrogenism (hirsutism, acne, androgenic alopecia) or hyperandrogenemia, and exclusion of other disorders (hyperprolactinemia, thyroid abnormalities, nonclassic CAH). Women with PCOS more commonly exhibit oligomenorrhea (75%) than amenorrhea (25%); irregular and infrequent menses typically begin soon after menarche, but may emerge later, often in association with progressive weight gain. Signs of androgen excess generally do not become evident until years later and progress gradually. Transvaginal ultrasound examination typically reveals ovaries that are modestly enlarged and contain numerous small follicles aligned in the periphery (“string of pearls”), but such findings are not useful for diagnosis because in up to one-third of normal women between the ages of 18 and 25 years, the ovaries have a similar polycystic appearance. Women with PCOS are frequently insulin-resistant (insulin sensitivity is reduced by 30%–40%), exhibit compensatory hyperinsulinemia (up to 80%), and are predisposed to glucose intolerance. Approximately 30% have demonstrable impaired glucose intolerance by glucose tolerance testing; *fasting glucose* is elevated in less than 10%. A *fasting glucose/insulin ratio* less than 4.5 is a fairly specific but somewhat insensitive diagnostic criterion for insulin resistance. Obesity is a common feature of women with PCOS (50%–75%) and exacerbates insulin resistance and the hyperinsulinemia that is associated with elevated androgen levels. Prolactin levels are mildly elevated in 10% to 25% of women with PCOS. Although the ratio of serum LH/FSH is frequently increased (>2.0), measurement of the serum LH level generally is not useful or necessary. The diagnosis of PCOS is not based on findings of ovarian or hormonal abnormalities, but on a history of chronic anovulation and clinical findings of androgen excess or obesity.

When hirsutism is severe or perimenarchial in onset, the possibility of nonclassic CAH also must be considered. Most commonly, nonclassic CAH results from a deficiency of the enzyme 21-hydroxylase which mediates an essential step in cortisol synthesis. Affected individuals cannot efficiently convert 17-hydroxyprogesterone (17-OHP) to 11-deoxycorticosterone (DOC; an intermediate step in cortisol synthesis). A follicular phase 17-OHP level greater than 2 ng/mL merits further evaluation with an *ACTH stimulation test* (serum 17-OHP before and 30–60 minutes after intravenous injection of 250 g ACTH) to confirm the diagnosis (post-stimulation serum 17-OHP concentration >1,000 ng/dL).

Determination of Estrogen Status

Evaluation of estrogen levels would seem logical for differentiating PCOS from hypothalamic amenorrhea and other hypoestrogenic disorders. Unfortunately, available methods cannot easily and reliably define the level of ovarian estrogen production. One cannot rely on symptoms and signs of estrogen deficiency to identify hypogonadal women. Genitourinary atrophy develops only gradually and is uncommonly observed in young women, even when estrogen levels are extremely low, and vasomotor symptoms typically are absent in women with hypothalamic dysfunction. Other methods for assessing the level of ovarian estrogen production include immunoassay of the serum estrogen concentration and “bioassays” based on clinical observation of the amount and character of cervical mucus (“estrogenic” mucus being clear, watery, and relatively abundant) or results of a “progestin challenge test” (presence or absence of withdrawal bleeding after administration of an exogenous progestin). Each of these methods may be useful, but each clearly also has pitfalls.

A serum *estradiol* measurement is easy to perform and relatively inexpensive. One might reasonably expect low estrogen levels in women with hypothalamic amenorrhea and normal levels in women with PCOS. Unfortunately, estradiol concentrations fluctuate erratically and may be normal or low on any given day, and therefore can be misleading. Whereas observations of estrogenic cervical mucus clearly suggest a normal level of ovarian estrogen production, the absence of such findings cannot be confidently interpreted because many women exhibit such mucus only in the late follicular phase of the cycle when estrogen levels are relatively high, or not at all.

The *progestin challenge* is based on the observation that progestin treatment (e.g., medroxyprogesterone acetate 10 mg daily for 5–7 days or progesterone in oil 100 mg i.m.) will induce menses only in those with normal circulating estrogen concentrations. For this purpose, a pure progestational agent must be used; endogenous estrogen status cannot be inferred from the response to an OCP that contains both estrogen and progestin. A positive test (bleeding after completion of progestin treatment) implies normal levels of estrogen production and a negative test (no withdrawal menses) suggests frank hypogonadism. However, withdrawal bleeding correlates poorly with estrogen status; both false-positive (withdrawal bleeding despite generally low levels of estrogen production) and false-negative (absent bleeding despite significant estrogen production) results are common. Up to 20% of women with oligomenorrhea or amenorrhea in whom substantial estrogen is present do not exhibit withdrawal bleeding. Conversely, up to 40% of women whose amenorrhea relates to stress, exercise, weight loss, or hyperprolactinemia, in whom estrogen levels are generally low, exhibit withdrawal bleeding. A false-positive progestin challenge also has been frequently observed in women with POF.

Hypothalamic Amenorrhea

In the absence of obesity or evidence of hyperandrogenism characteristic of PCOS, the most likely cause of amenorrhea in women with a normal or low serum FSH level is a functional disorder of the hypothalamus or higher CNS centers. Women with such “hypothalamic amenorrhea” generally present with secondary amenorrhea that is frequently accompanied by history of emotional stress, weight loss (dieting), poor nutrition (eating disorders, chronic illness), or regular strenuous exercise (endurance training). In contrast to women with PCOS, they typically have normal or low body weight and are poorly estrogenized. In the context of low levels of estrogen production, a low or normal serum FSH has the same implication—a dysfunctional HPO axis—because if that axis were intact and fully functional, the classic negative feedback relationship between estrogen and FSH would stimulate a compensatory increase in FSH secretion and result in an elevated serum FSH concentration. A low or normal serum FSH therefore clearly suggests hypothalamic or pituitary disease or dysfunction. Most women with hypothalamic amenorrhea have a normal FSH concentration; extremely low or undetectable FSH levels are seldom seen except in women with large pituitary tumors or anorexia nervosa.

Amenorrhea associated with weight loss due to dieting is common; anorexia nervosa is fortunately much less common (15/100,000 women/year). In athletic women, the risk of amenorrhea is increased approximately three-fold over that in nonathletic women with the highest prevalence observed in endurance athletes (long-distance running). Chronic debilitating diseases (end-stage renal disease, malignancy, acquired immune deficiency syndrome, malabsorption) also may result in anovulation and amenorrhea. In such cases, hypothalamic amenorrhea represents a functional suppression of the reproductive system that may be viewed as a psychobiologic response to psychological, physical, or nutritional stress. One proposed unifying hypothesis emphasizes the concept of energy balance: When available energy is excessively diverted (exercise), or insufficient (dieting, malnutrition), reproduction is suspended in order to support essential metabolism for survival. The mechanism responsible may involve a stress-induced increase in hypothalamic corticotropin-releasing hormone (CRH) and endogenous opioid secretion that inhibits pituitary gonadotropin release directly, or inhibition of pulsatile hypothalamic GnRH secretion by increased dopamine or opioids.

Hypothalamic–Pituitary Imaging The diagnosis of hypothalamic amenorrhea cannot be established until organic disease of the CNS, hypothalamus, or pituitary gland is excluded with a CNS *MRI.* Imaging is prudent, even when emotional stress, weight loss, poor nutrition, or regular strenuous exercise appear to offer an explanation for hypothalamic dysfunction and amenorrhea. Imaging may reveal a pituitary tumor, an empty sella, or evidence of a hypothalamic tumor, anomaly, or other disease. The vast majority of pituitary tumors are prolactinomas or nonfunctioning adenomas, but other varieties are rarely encountered. Additional evaluation can help to define the nature of a tumor and the extent to which other pituitary functions may be compromised. Grossly elevated prolactin levels clearly suggest a prolactinoma; more modest prolactin elevations may be observed when large tumors infarct or a nonfunctioning adenoma distorts sellar anatomy and disrupts normal dopamine delivery to pituitary lactotrophs. When the clinical presentation suggests Cushing syndrome, screening *(24-hour urinary free cortisol, overnight dexamethasone suppression test)* is indicated; additional evaluation (serum *ACTH, adrenal CT or MRI*) is required when results are abnormal. Physical findings that suggest acromegaly are an indication to measure serum *insulin-like growth factor-1 (IGF-1; somatomedin-C)*; if elevated, an *oral glucose tolerance test with GH levels* should be performed (lack of suppression is diagnostic). Pituitary function testing (TSH, T4, prolactin, 24-hour urinary free cortisol, IGF-1) also is indicated when imaging reveals a macroadenoma or an empty sella to insure that the other trophic pituitary hormones are normal. Dynamic testing is unnecessary in otherwise asymptomatic women with a microadenoma or normal sella. The empty sella syndrome generally is a benign condition and not progressive. However, because of the possibility of an unrecognized coexisting tumor, periodic surveillance with a prolactin determination and MRI are indicated. Anatomic abnormalities of the hypothalamus are distinctly uncommon. Hypothalamic tumors (craniopharyngioma, hamartoma, meningioma) generally are rare and other mass lesions (tuberculosis, sarcoidosis) are even more so. Congenital hypogonadotropic hypogonadism associated with anosmia or hyposmia (Kallmann syndrome) is another rare inheritable disorder associated with a specific anatomic defect: Hypoplastic or absent olfactory sulci. The condition results from a failure of both olfactory axonal and GnRH neuronal migration during development and is genetic in origin (X-linked, autosomal dominant, or autosomal recessive). The most common form (X-linked) derives from mutations in a single gene (*KAL*) on the short arm of the X chromosome that encodes a protein (anosmin-1) necessary for normal neuronal migration. The clinical presentation (primary amenorrhea, sexual infantilism, hypogonadotropic hypogonadism, and anosmia) and common association with other anatomic (cleft lip and palate) and neurologic (hearing loss, cerebellar ataxia, color blindness) abnormalities is not difficult to recognize. Very often, imaging fails to reveal any anatomic abnormality of the pituitary or hypothalamus and in otherwise asymptomatic individuals, the diagnosis is, by exclusion, hypothalamic dysfunction.

TREATMENT OF AMENORRHEA

Treatment of amenorrhea is obviously focused on the specific etiology, when known, and always is tailored to the goals of the patient.

Genital Tract Abnormalities

In women with vaginal/müllerian agenesis, the primary goal of treatment—creation of a functional vagina—can be accomplished with a variety of methods when the time is appropriate. In most cases, progressive vaginal dilation will be successful in the motivated patient. The technique involves application of pressure to the point of moderate discomfort (approximately 20–30 min/d) using commercially available vaginal dilators, first in a posterior direction (to create a pouch), and then in the usual line of the vaginal axis (after about 2 weeks). After the desired depth is achieved, increasingly larger dilators will expand the vaginal diameter and create a functional vagina in approximately 3 to 6 months.

Operative treatment of women with vaginal/müllerian agenesis generally should be reserved for those who refuse or poorly tolerate vaginal dilation. Traditionally, a neovagina has been created by dissection of the rectovaginal space and placement of a skin graft, held in place with a soft mold until the graft was established (McIndoe procedure). Subsequent regular intercourse or vaginal dilation must be maintained to avoid risk of fibrosis and loss of function. More recently, an operation that employs a transabdominal traction device has been described that can create a functional vagina within 7 to 9 days. Where available and applicable, the technique would appear to offer significant advantages over the traditional vaginoplasty procedure. In the rare woman with vaginal/cervical agenesis with a well-formed uterine body, it may be technically possible to create a neovagina continuous with the uterus with the goal of preserving fertility, but the associated long-term infectious morbidity has led most to conclude that the uterus should be removed in most circumstances.

Reassurance and support are important elements of the management of vaginal/müllerian agenesis. Affected women should be counseled that although they are infertile, normal sexual function can be expected and that genetic offspring can be achieved by in vitro fertilization using oocytes retrieved from the normal ovaries and the sperm of the partner, with subsequent transfer of embryos to a gestational surrogate. A growing experience with these techniques has revealed no evidence to

indicate that congenital absence of the vagina and uterus is heritable in a dominant fashion.

AIS presents both similar and different treatment challenges. A functional vagina again can be created by any of the techniques described previously for women with vaginal/müllerian agenesis, but surgical treatment much less often is required as the vagina generally is short but otherwise normal rather than altogether absent. Genetic offspring, of course, are not possible because women with AIS do not have oocytes. They have testes, most commonly located in the inguinal canals at the level of the external inguinal ring but sometimes found within the abdomen. Like women with gonadal dysgenesis whose karyotype contains a Y chromosome (46,XY, 45,X/46,XY), individuals with AIS are at increased risk for development of tumors in their undescended testes. Therefore, the testes should be removed. However, the risk of neoplasia is lower (approximately 5%–10% vs. 25%), tumors are rarely encountered before puberty, and the secondary sexual development that accompanies puberty in women with AIS from the aromatization of testosterone is more natural than can be accomplished pharmacologically. Consequently, removal of the testes and hormone replacement are best delayed until pubertal maturation is complete, generally by age 16 to 18 years.

Initial treatment of women with an imperforate hymen, transverse vaginal septum, or cervical atresia centers on relief of symptoms related to accumulated menstrual fluid and debris. Surgical correction of imperforate hymen is straightforward, requiring only a cruciate incision in the hymen to the base of the hymeneal ring and excision of its central portion to allow drainage of sequestered menstrual fluid and subsequent normal menstruation. Surgical management of a transverse vaginal septum can be very challenging. In its simplest form, the procedure involves excision of the septum or dissection through the atretic segment to connect the margins of the lower and upper vaginal canals with split-thickness skin grafting occasionally required if the distance between the two precludes a primary junction without tension. In rare women with cervical atresia, as in those with vaginal agenesis who have a functional uterine body, the generally poor outcome and high postoperative morbidity associated with heroic efforts to preserve the uterus and fertility suggest that removal of the müllerian remnants is the safest management strategy.

Uterine sounding and gentle cervical dilation often are all that is required to correct a symptomatic cervical obstruction/stenosis. Operative hysteroscopy is the preferred method for treatment of intrauterine synechiae that may be lysed by blunt dissection, scissors, electrodissection, or with a laser; any of these methods achieves results superior to blind curettage. When adhesions are severe or extensive, an intrauterine balloon catheter (left in place for approximately 7–10 days) may be useful to maintain separation between the walls of the uterine cavity. Treatment with a broad-spectrum antibiotic and an inhibitor of prostaglandin synthesis (nonsteroidal antiinflammatory drugs) helps to minimize risk of infection and uterine cramping. High-dose exogenous estrogen treatment (2.5 mg conjugated equine estrogens/day or its equivalent for approximately 4 weeks) also generally is recommended to encourage rapid endometrial reepithelialization and proliferation. Repeated procedures may be required to restore a normal uterine cavity. Approximately 50% to 75% of affected women may be expected to achieve a successful pregnancy, although risks of preterm labor, placenta accreta, placenta previa, and postpartum hemorrhage are increased.

Ovarian Disorders

Women with gonadal dysgenesis and sexual infantilism should be offered growth and sex hormone replacement therapy to promote growth to maximum potential, normal bone density development, and secondary sexual maturation. Treatment with exogenous recombinant human GH (50g/kg/d) stimulates an acceleration of growth that generally can be sustained for 6 years or more and results in an adult height as much as 10 cm over initial predicted height. In those with short stature, sex hormone replacement should be postponed until the bone age reaches 12 or greater to avoid premature epiphyseal closure and allow a longer interval of time for long bone growth. Sex hormone replacement therapy should follow the normal sequence of sex hormone production observed during adolescence and begin with low doses of estrogen alone (0.3 mg conjugated equine estrogens or 0.5 mg micronized estradiol). Dosage should be increased gradually and after approximately 6 to 12 months or first evidence of vaginal bleeding, cyclic treatment with a progestin should be added. To achieve maximum bone and breast development, higher doses (1.25–2.5 mg conjugated equine estrogens or 2–3 mg micronized estradiol) often are required. Once secondary sexual development is completed, longer-term sex hormone replacement should continue to avoid the otherwise inevitable emergence of estrogen deficiency symptoms and bone mineral depletion. Alternatively, a low-dose OCP may be offered, for convenience.

Pregnancy may be achieved in women with gonadal dysgenesis through in vitro fertilization using oocytes provided by a genetically normal oocyte donor. However, pregnancy carries a unique risk for women with 45,X gonadal dysgenesis (Turner syndrome) as numerous cases of aortic dissection, aneurysm, and spontaneous rupture during pregnancy now have been reported. Preconceptional echocardiography may identify patients at risk for whom pregnancy is contraindicated, but catastrophic events may occur despite the absence of abnormal findings. Should they conceive spontaneously or by using donor oocytes, echocardiography should be performed at least once in each trimester, and the practitioner should remain alert to any evidence of progressive dilation of the ascending aorta. Women with 45,XY or 45,X/46,XY gonadal dysgenesis should have their gonads removed soon after diagnosis to avoid the substantial risk of gonadal tumors. Unlike those with AIS whose functional testes produce sex steroids that will promote normal secondary sexual maturation, women with gonadal dysgenesis have nonfunctional streak gonads. Consequently, there is no advantage to delay their removal.

The primary goals of treatment for women with POF that develops after secondary sexual maturation is complete generally are relief from symptoms of estrogen deficiency and prevention of premature bone mineral depletion. Standard regimens of cyclic or combined continuous estrogen/progestin hormone replacement therapy or a low-dose OCP will meet the need, and either is appropriate. In vitro fertilization with use of donor oocytes offers the possibility of pregnancy and the prognosis for success in most such women is excellent. Women in whom POF is diagnosed before age 30 and in whom karyotype reveals a mosaic 45,X cell line must be carefully evaluated and counseled on the potential risks of aortic dissection and rupture during pregnancy, as described earlier. Monitoring or treatment should be offered for any associated autoimmune disorders.

Pituitary Disorders The overwhelming majority of pituitary tumors are prolactin-secreting adenomas or nonfunctioning tumors. TSH-, ACTH-, or GH-secreting adenomas generally are rare. A pituitary tumor often will be discovered when imaging is performed in women with hyperprolactinemia and occasionally in euprolactinemic women with hypogonadotropic hypogonadism that cannot be confidently attributed to weight loss, eating disorders, or regular strenuous exercise (Fig. 34.3). It may be difficult to differentiate a prolactin-secreting adenoma from a nonfunctioning tumor that disrupts normal hypothalamic dopamine delivery, except perhaps when prolactin levels are markedly elevated. However, because treatment options in hyperprolactinemic amenorrheic women with small intrasellar tumors are the same in either case, a specific diagnosis is not critical. The nature of a tumor may become clear only after treatment with a dopamine agonist restores normal prolactin levels; the majority of prolactin-secreting adenomas shrink in size during treatment and those that do not are more likely to be nonfunctioning tumors. In euprolactinemic amenorrheic women, a pituitary tumor also may be only an incidental finding, having no clinical significance.

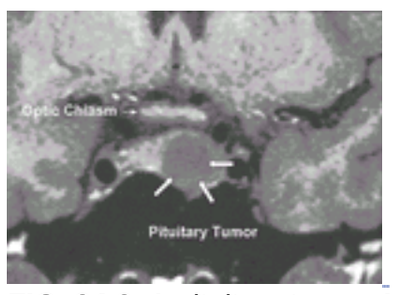

FIG. 34.3. A pituitary tumor. Magnetic resonance imaging of a prolactin-secreting pituitary tumor (*three large arrows*). Note the lateral location and elevation of the diaphragm sella. However, the tumor does not compress the optic chiasm (*single arrow*) and thus no visual disturbances would be anticipated.

Whereas transsphenoidal surgery was commonly performed in the past to remove pituitary tumors, it is now generally reserved for women with rare TSH-, ACTH-, or GH-secreting adenomas, those with large nonfunctioning tumors associated with complaints of headache or visual disturbances, and those in whom medical treatment (described subsequently) fails or is poorly tolerated. Surgery achieves immediate reduction of prolactin levels and restores cyclic menses in approximately 30% of women with prolactin-secreting macroadenomas and in up to 70% with microadenomas. However, residual or recurrent tumors and hyperprolactinemia are common and surgery may be complicated by cerebrospinal fluid leakage, meningitis, diabetes insipidus, or other trophic pituitary hormone deficiencies that require further treatment. Postoperative monitoring involves periodic serum prolactin determinations and repeated imaging. Radiation therapy for pituitary tumors is even less attractive because the response to radiation is slow and such treatment risks development of panhypopituitarism over time. As a result, radiation generally is reserved for postoperative recurrence of large tumors. Dopamine-agonist therapy is the mainstay of treatment for hyperprolactinemia, independent of whether a pituitary tumor is identified. Bromocriptine is highly efficacious but side effects (nausea, headache, orthostatic hypotension, dizziness, nasal congestion) are common. The dose should be titrated incrementally to normalize serum prolactin levels, beginning with a small dose (1.25–2.5 mg) at bedtime, with a second dose taken with breakfast or lunch when required; most patients will require 5.0 mg per day or less. Cabergoline may be an effective alternative when bromocriptine treatment cannot be tolerated, although its lower frequency of side effects and less frequent dosing (0.25–3.0 mg every 3–7 days) also make it an attractive initial therapeutic choice. Vaginal administration of bromocriptine or cabergoline is effective and may help to reduce side effects when oral treatment is poorly tolerated. Dopamine-agonist treatment restores menses and ovulatory function in up to 80% of amenorrheic hyperprolactinemic women, generally within approximately 6 to 8 weeks; reduction or cessation of galactorrhea typically requires somewhat longer-term treatment. Medical treatment with a dopamine agonist (bromocriptine, cabergoline) promotes shrinkage of pituitary macroadenomas in the majority of cases, usually within 6 to 12 weeks. Large tumors that fail to shrink despite effective suppression of excess prolactin secretion generally are nonfunctioning adenomas that cause hyperprolactinemia by interfering with delivery of dopamine from the hypothalamus and require surgery. Regardless of the treatment they receive, women with macroadenomas should be monitored with serum prolactin determinations and imaging every 6 to 12 months for at least 2 years, less often thereafter if tumor size and prolactin levels remain stable, and sooner if prolactin levels rise significantly or symptoms of headache or visual disturbances emerge or recur. Similar monitoring with serial prolactin determinations (every 6 to 12 months) and periodic imaging (annually for 2 years) is

recommended for those with microadenomas. Dopamine-agonist therapy is the best initial choice for persistent or recurrent tumor or hyperprolactinemia. For the few patients who may require radiation therapy, ongoing surveillance must be implemented to detect any evidence of developing panhypopituitarism. Pituitary tumors generally grow slowly or not at all, even during pregnancy. No more than approximately 5% of women with pituitary microadenomas will experience tumor growth during pregnancy, even fewer develop signs or symptoms as a result, and only a rare patient will require surgical intervention. The risk is greater but generally still modest for those with macroadenomas (approximately 15%). Routine serial visual field examinations and serum prolactin determinations therefore are unnecessary, but the patient and her physician must be alert to symptoms that may emerge in any trimester. Headaches generally precede visual disturbances and if either appears, monitoring with serum prolactin measurements, visual field examinations, and imaging should begin. With rare exceptions, dopamine-agonist therapy will arrest and reverse tumor expansion and eliminate associated symptoms and poses no significant risk to mother or fetus. Dopamine-agonist therapy clearly is the treatment of choice for anovulatory hyperprolactinemic women who desire pregnancy or have significant breast tenderness or troublesome galactorrhea, with or without a pituitary adenoma. In the absence of other coexisting causes of infertility, approximately 80% of anovulatory hyperprolactinemic women treated with dopamine agonists may be expected to conceive. In the few who cannot tolerate medical treatment with bromocriptine or cabergoline but desire pregnancy, ovulation induction with exogenous gonadotropins is an effective alternative as prolactin does not alter the effect of the gonadotropins on the ovarian follicles. Women not seeking pregnancy may be offered hormone replacement therapy or even a low-dose OCP that will restore menses and effectively eliminate or prevent the consequences of any associated estrogen deficiency. The uncommonly encountered empty sella syndrome generally is entirely benign and does not progress to pituitary failure. Treatment and subsequent surveillance are the same as in women with a pituitary adenoma. In the rare patient whose amenorrhea results from Sheehan syndrome and its related pituitary insufficiency, more than simple sex steroid replacement therapy may be required. Depending on the extent and scope of pituitary damage, such women also may require glucocorticoid and thyroid hormone replacement. For those affected women who desire a subsequent pregnancy, ovulation induction may be achieved, but only with exogenous gonadotropins.

Hypothalamic Disorders

Chronic anovulation resulting from abnormal patterns of pulsatile hypothalamic GnRH secretion is the cause of amenorrhea most commonly encountered in practice. A hypothalamic etiology can be established only after first excluding other peripheral, ovarian, and pituitary disorders (normal serum TSH and prolactin levels, low or normal serum FSH, negative imaging, where indicated). Most such women are estrogenized and can also be obese or androgenized (PCOS). Some have a more profound hypogonadism with grossly low levels of estrogen production (hypothalamic amenorrhea), often in association with history of emotional, nutritional, or physical stress.

Treatment of women with PCOS is based on whether pregnancy is an immediate goal. Those who desire pregnancy are candidates for ovulation induction. For those not seeking pregnancy, the goals of treatment are to establish regular menses and prevent the consequences of chronic unopposed estrogen stimulation on the endometrium (dysfunctional uterine bleeding, endometrial hyperplasia, endometrial adenocarcinoma), to prevent the emergence or progression of hirsutism, and to reduce the longer-term risks of diabetes and cardiovascular disease associated with the disorder.

The wide range of therapeutic options for ovulation induction in anovulatory women with PCOS who desire pregnancy is only summarized here. When obese, weight loss should always be encouraged and may be all that is required to restore menstrual cyclicity. Even if weight loss does not restore ovulatory function, it may be expected to improve the response to ovulation-inducing agents. The substantial costs, risks, and logistic demands of more aggressive forms of treatment might thus be avoided, but weight loss should never be a prerequisite for treatment.

Clomiphene citrate is the initial treatment of choice as it is safe, inexpensive, and has few serious side effects. Clomiphene is a competitive estrogen receptor antagonist that acts centrally to deplete hypothalamic estrogen receptors, thereby interfering with estrogen-negative feedback and resulting in a compensatory alteration in pulsatile GnRH secretion that stimulates increased pituitary gonadotropin release and, in turn, drives ovarian follicular activity. Treatment should begin with a low dose (50 mg/d cycle days 3–7 or 5–9 after a spontaneous or progestin-induced menses) and subsequently increase in increments (100 mg/d, 150 mg/d) as needed to achieve ovulation. Most women with PCOS will respond to clomiphene, but many prove resistant and ultimately require alternative treatment. Among clomiphene-resistant anovulatory women with PCOS, a significant majority have insulin resistance. Metformin (1,000–2,000 mg/d in divided doses) is an insulin-sensitizing agent that can restore spontaneous menses and cyclic ovulation in many amenorrheic women with PCOS. Consequently, metformin can be used as the first treatment option for ovulation induction, adding clomiphene in those who fail to respond or, as is more commonly done, metformin can be reserved for those who first prove resistant to clomiphene. In either case, many who fail to ovulate in response to either alone will respond when the two are used in combination. Although the safety of metformin treatment in pregnancy has not been established, preliminary evidence suggests that it may reduce the incidence of spontaneous abortion and gestational diabetes in the subset of women with PCOS and insulin resistance.

Those who prove resistant to clomiphene and metformin are candidates for treatment with exogenous gonadotropins. Because such women often are very sensitive to low doses of gonadotropins, unifollicular ovulation can be difficult to achieve and the risk for both multiple pregnancy and ovarian hyperstimulation syndrome is increased. Consequently, treatment must be carefully monitored and is best provided only by clinicians having the necessary training or experience.

Ovarian drilling is a contemporary version of the classic ovarian wedge resection and another treatment option for ovulation induction in clomiphene-resistant, hyperandrogenic, anovulatory women with PCOS (Fig. 34.4). The technique involves laparoscopic cautery, diathermy, or laser vaporization of the ovaries at multiple sites, the objective being to decrease circulating and intraovarian androgen levels by reducing the volume of ovarian stroma. However, the effects of treatment are temporary and postoperative adhesions that may compromise fertility are a distinct possibility. Drilling also has the potential to destroy oocytes and shorten the reproductive lifespan and therefore is best limited to those for whom all other alternatives have been exhausted.

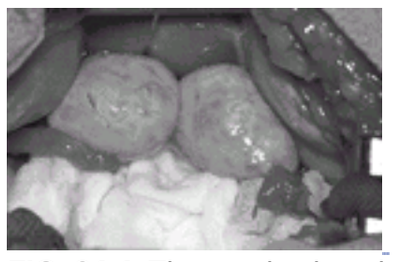

FIG. 34.4. The ovaries in polycystic ovary syndrome shown in a woman with polycystic ovary syndrome at laparotomy. Note the large size of the ovaries, relative to the uterus, with a smooth ovarian capsule without evidence of ovulatory events.

OCPs have long been the mainstay of treatment for amenorrheic women with PCOS who do not desire pregnancy because the combined actions of OCP offer a number of important benefits. Programmed cyclic OCP treatment restores regular, predictable menses, protects the endometrium from the adverse effects of otherwise unopposed estrogen stimulation, and provides effective contraception for the occasional spontaneous ovulation. OCPs decrease circulating androgens by suppressing typically increased serum LH levels that stimulate excess ovarian androgen production and further reduce levels of circulating free androgen by stimulating hepatic production of sex hormone binding globulin. Consequently, within 3 to 6 months after initiation of treatment hair typically grows more slowly, becomes both finer and lighter in color, and therefore is less noticeable and more easily managed.

For those with more severe hirsutism in whom treatment with OCP alone fails to achieve the desired effect, spironolactone can be added (100–200 mg/d in divided doses) to provide more effective control. In the dose range indicated, spironolactone acts as a competitive androgen receptor antagonist and blocks androgen action on the pilosebaceous unit (a hair follicle, sebaceous glands, and arrector pili muscle). The multiple actions of combined treatment with OCP and spironolactone (suppression of excess androgen production, increase in androgen binding, and blockade of androgen action) are complementary and generally quite effective for the management of hirsutism. In extreme cases, a more profound suppression of excess androgen production can be achieved by treatment with a GnRH agonist (e.g., leuprolide acetate) with superimposed cyclic or combined continuous hormone replacement with standard doses of estrogen and progestin to prevent the otherwise inevitable emergence of estrogen deficiency symptoms. Suppression of adrenal androgen production by chronic glucocorticoid treatment risks suppression of the adrenal response to stress, immunosuppression, and progressive bone mineral depletion, should therefore be reserved only for those with documented nonclassic CAH, and must be carefully monitored when offered.

Insulin resistance certainly contributes to the pathophysiology of PCOS by local amplification of ovarian androgen production in response to LH (directly or via IGF-1) and by reducing hepatic synthesis of sex hormone binding globulin (directly). Moreover, hyperandrogenism clearly is associated with an atherogenic lipid profile. There also is evidence that in individuals with glucose intolerance, metformin treatment can reduce the risk of progression to frank diabetes and, presumably, the increased risk of cardiovascular disease associated with that disease. However, these longer-term potential benefits of primary metformin therapy remain unproven. Moreover, the drug is relatively costly and often poorly tolerated (nausea, vomiting, diarrhea). Under such circumstances, whether primary metformin treatment offers sufficient benefits to justify its use as an alternative or complement to other already proven treatment strategies (weight loss, exercise, OCP, statin therapy) remains controversial. Based on the evidence available to date, primary metformin treatment cannot be recommended for all women with PCOS, but may merit serious

consideration in selected individuals.

In the absence of obesity, hirsutism, or other evidence of hyperandrogenism that is characteristic of PCOS, the most likely cause of amenorrhea in women with a normal or low-serum FSH level is a functional disorder of the hypothalamus or higher centers. As for women with PCOS, treatment for women with hypothalamic amenorrhea depends on whether pregnancy is an immediate goal. Those who desire pregnancy clearly are candidates for ovulation induction. For those not seeking pregnancy, the goals of treatment are to establish regular menses, if desired, and to prevent the consequences of chronic estrogen deficiency (genitourinary atrophy, progressive bone demineralization) as most, but not all women with hypothalamic amenorrhea exhibit frankly low levels of endogenous estrogen production.

The range of therapeutic options for ovulation induction for women with hypothalamic amenorrhea (Fig. 34.5) is somewhat narrower than for those with PCOS and again is only summarized here. In women with a low BMI, weight gain should be encouraged but weight gain, like weight loss, can be very difficult to achieve. Women with a low BMI should be educated on the relationship between weight and menstrual function and advised that weight gain may be all that is needed to restore menstrual cyclicity and ovulation. At the least, weight gain may be expected to increase the likelihood of response to more conservative ovulation induction strategies (clomiphene citrate) involving less cost and risk than otherwise may be required. Those in whom symptoms (fasting, purging) or physical findings suggest a potentially serious underlying eating disorder (bulimia, anorexia) should be offered psychiatric evaluation and care before attempting pregnancy as such disorders pose unique risks to both mother and fetus.

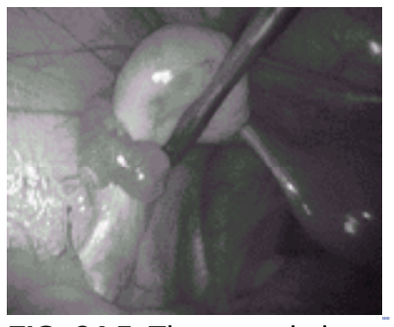

FIG. 34.5. The ovary in hypothalamic amenorrhea. Laparoscopy of the pelvis demonstrates a normal-appearing uterus with the left ovary having a smooth capsule without evidence of follicular activity. This is consistent with the lack of gonadotropin stimulation with a normal but unstimulated ovary.

Similarly, women whose hypothalamic amenorrhea is associated with a high level of regular strenuous exercise should be educated on the pathophysiology involved. Reduced physical activity may restore menstrual cyclicity and ovulation and, at the least, less exercise may improve the probability that conservative methods of ovulation induction will succeed. However, once again, reduced levels of exercise should not be a prerequisite for treatment. For many, high levels of exercise are intrinsic to lifestyle or represent the preferred method for relieving stress and may not be desirable or even feasible.

Ovulation induction should be offered to those who desire pregnancy. Because of its relatively low cost and risk, clomiphene citrate is again the initial drug of choice. However, unlike women with PCOS, those with hypothalamic amenorrhea often fail to respond to clomiphene treatment. Clomiphene response requires an intact and functional HPO axis, something that most women with hypothalamic amenorrhea do not have (as reflected by low or normal serum FSH levels despite frankly low estrogen production). Consequently, one of two alternative approaches to ovulation induction frequently is required. Exogenous synthetic GnRH, administered in a pulsatile fashion via a portable and programmable infusion pump can effectively restore normal levels of pituitary gonadotropin secretion and spontaneous ovulatory function. GnRH pump therapy requires relatively little monitoring once the effective dose has been established, allows ovulation to occur spontaneously, and is associated with only modest risk of a multiple pregnancy. However, many women object to having an indwelling intravenous catheter over an extended interval of time (approximately 3 weeks) and reject this option.

Most often, treatment with exogenous gonadotropins that directly stimulate ovarian follicular development is the preferred method for ovulation induction. Exogenous human chorionic gonadotropin is administered to trigger ovulation when follicular maturation is complete. Treatment requires careful monitoring with serial determination of serum estrogen concentrations and transvaginal ultrasound examinations to determine the size, number, and maturity of developing follicles and to minimize the risks of excessive follicular development, the ovarian hyperstimulation syndrome, and multifetal gestation.

Hormone replacement therapy is indicated for those women with hypothalamic amenorrhea who do not desire pregnancy and in whom weight gain or decreased exercise fails to restore menstrual function. In those who are simply anovulatory and not frankly hypoestrogenic or at risk for unwanted pregnancy, cyclic progestational therapy may be all that is required to restore predictable menses and to prevent the endometrial consequences of chronic unopposed estrogen stimulation. However, the level of estrogen production in such women often fluctuates unpredictably and is difficult to judge confidently on clinical or laboratory criteria. Consequently, treatment with cyclic or combined continuous hormone replacement or OCP is prudent to prevent any prolonged interval of hypoestrogenism and the depletion of bone mineral that may result. Given that spontaneous ovulation may occasionally occur, sexually active women with hypothalamic amenorrhea who do not desire pregnancy are best managed with OCP.

SUMMARY POINTS

- Amenorrhea is a common symptom resulting from an abnormality in the reproductive system that may be anatomic (developmental or acquired), organic, or endocrinologic in nature.
- Congenital anomalies of the müllerian duct system typically present with normal puberty and may be associated with abdominal pain if there is functional endometrium present.
- Gonadal dysgenesis represents the lack of any ovarian function prior to puberty leading to sexual infantilism.
- Premature ovarian failure presents as amenorrhea associated with an elevated FSH level and, if occurring prior to age 30, may be associated with the presence of a Y chromosome.
- Pituitary tumors are very common, with the majority secreting prolactin and associated with hypoestrogenic amenorrhea and galactorrhea.
- Hypothalamic amenorrhea is the general term used to describe hypoestrogenic amenorrhea when no anatomic abnormality is identified. It is commonly associated with weight loss or athletic stress.
- Polycystic ovarian syndrome is a very common clinical problem which may present with amenorrhea but is associated with excess androgen production. A significant majority of these women have insulin resistance.
- The most common cause of amenorrhea in women of reproductive age is pregnancy.

Management of Special Situations

This chapter presents a simplified diagnostic and therapeutic approach to the woman with abnormal uterine bleeding, discusses imaging studies that facilitate accurate diagnosis and management, and presents therapeutic plans for management of acute hemorrhage, menorrhagia, bleeding on oral contraceptives, and the dysfunctional bleeding associated with perimenopause. This chapter does not address abnormal bleeding in the postmenopausal woman either on or off hormone replacement.

This chapter is divided into three sections: the first is a simplified diagnostic approach with discussion about the differential diagnosis and therapeutic options for each condition. This is followed by section on imaging modalities available to aid in the diagnosis of abnormal uterine bleeding. Special emphasis is placed on the role of pelvic ultrasound, saline infusion sonogram, and magnetic resonance imaging (MRI). The third section presents a therapeutic approach in special clinical situations, including the patient presenting with acute hemorrhage, bleeding on oral contraceptives, menorrhagia, and perimenopause.

DIAGNOSIS

The differential diagnosis for all women presenting with abnormal uterine bleeding can be encompassed by the mnemonic PHIMIC (pregnancy, hormones, iatrogenic, mechanical, infection, and cancer) (Table 35.1). The use of this mnemonic simplifies the approach and allows the clinician to cover a vast array of possibilities in the most efficient and treatment focused manner. This category/group approach provides for patient safety by assuring that serious conditions such as pregnancy, cancer, or unrecognized infections are not overlooked.

P—Pregnancy
H—Hormones
I—Iatrogenic
M—Mechanical
I—Infection
C—Cancer

TABLE 35.1. *PHIMIC—differential diagnosis for abnormal uterine bleeding*

Before evaluating what is abnormal uterine bleeding, we must begin with a definition of what is normal uterine bleeding. Normal menstrual flow is the result of a withdrawal of an estrogen-primed endometrium. This should occur at regular intervals that vary by no more than 3 days from the woman's mean menstrual interval. Typically, normal ovulatory menses occur every 24 to 35 days with most women experiencing a predictable interval. Ovulatory women will set their own mean cycle length, which is defined as from the first day of bleeding, cycle day 1, to the next first day of bleeding in the subsequent cycle and will not vary more than 3 days. For example, if a woman's mean cycle interval is 26 days; her menstrual calendar should reflect menses varying from between 23 and 29 days. A variation greater than 3 days is suggestive of either oligoovulation or estrogenized anovulation and is classified as abnormal. The mean duration of normal menstrual flow is 3 to 7 days. Bleeding that persists longer than 7 days or decreases hemoglobin levels is considered, by definition, excessive. Unfortunately, there is no simple clinical way to quantitate the amount of blood lost during a menstrual period. Counting the number of sanitary protectives used in a menstrual cycle has proven to be inaccurate based on differences in personal hygiene and cultural backgrounds. When accurately quantitated, blood loss during an entire normal ovulatory menstrual cycle is approximately 60 to 80 mL. This amount of blood loss will not cause a decrease in hemoglobin in women consuming a normal balanced diet.

Traditionally, aberrations in menses have been classified as either *menorrhagia*, defined as an excessive amount of menstrual blood loss, *metrorrhagia*, defined as intermenstrual, irregular or otherwise noncyclic bleeding, or *menometrorrhagia*, which combines both menorrhagia and metrorrhagia leading to heavy irregular uterine bleeding (Table 35.2). While these terms are traditionally used they require that the clinician make a cognitive decision based on the patient's description of her symptomatology. This has the potential to alter the ability to make an accurate diagnosis, as the differential diagnosis of a woman with menorrhagia is different than that of metrorrhagia. Since menstrual histories are sometimes difficult to obtain due to the frequent miscommunication between the patient and her physician, limiting the description of the symptomatology to abnormal uterine bleeding without narrowing it to the more scientific term is encouraged. By approaching every woman, irrespective of whether she has menorrhagia, metrorrhagia, or menometrorrhagia with a generalized mnemonic such as PHIMIC, the clinician avoids narrowing the differential diagnosis too quickly, thus assuring that all possibilities are considered. Therefore, when a patient presents with abnormal uterine bleeding, its etiology will be found within one of six broad diagnostic categories: pregnancy, hormonal, iatrogenic, mechanical, infection, or cancer. This allows the same diagnostic approach for every woman, regardless of her age.

Menorrhagia—excessive blood loss at regular intervals
Metrorrhagia—irregular or frequent menses that are not excessive
Menometrorrhagia—excessive irregular bleeding
Polymenorrhea—menses more frequent than 21 days
Hypermenorrhea—excessive menstrual flow
Oligomenorrhea—menses greater than every 34 days

TABLE 35.2. *Definitions*

Pregnancy

Pregnancy should be considered in any woman who presents with abnormal uterine bleeding unless she has had a hysterectomy or is over the age of 60. Even women who have had tubal ligations as well as women who are in their 50s and have not menstruated in 1 to 2 years may have the occasional pregnancy. It is safe, on a clinical basis, to say that a physician will never regret ordering too many pregnancy tests, but may regret not ordering enough.

Screening for pregnancy is typically accomplished by using a highly accurate urinary pregnancy test. It is not necessary to do a serum quantitative human chorionic gonadotropin (hCG) evaluation on every woman who presents with abnormal uterine bleeding. Currently available urinary pregnancy tests are immunometric or “sandwich” assays that use antibodies directed to the intact hCG molecule. This makes the urine pregnancy test extremely sensitive and specific. It is important that every clinician know what the limits are in sensitivity of the pregnancy test and the reference preparation that their practice uses. The two reference preparations currently in use are the First and the Third International Reference preparations. The original reference preparation was the Second International Reference Preparation (2nd-IRP) which measured intact and free ß-hCG subunits. One unit of the 2nd-IRP is approximately equivalent to two units of the first or third IRP.

If the woman with abnormal uterine bleeding is found to have a positive urinary pregnancy test, a serum quantitative ß-hCG assay should be obtained. While this result is pending, it is appropriate to perform a pelvic sonogram to determine whether there is an identifiable intrauterine pregnancy, an adnexal mass, or a negative exam (no pregnancy within the uterus and no adnexal masses). If the ß-hCG returns above the discriminatory zone, then the finding of an empty uterus is suggestive of an ectopic pregnancy and management of ectopic pregnancy can be instituted. If the ß-hCG is below the discriminatory zone and the patient is asymptomatic and reliable, she can return in 48 hours for a repeat ß-hCG assay to determine the probability of a viable intrauterine pregnancy. Upon return, the patient can be rescanned if her ß-hCG is expected to be over the discriminatory zone or a repeat ultrasound can be scheduled based upon the projected time period interval when the level will be anticipated to exceed the discriminatory zone maximum. It is important to remember that 10% to 15% of all ectopic pregnancies have normal ß-hCG doubling times and that rupture of ectopic pregnancies has occurred with falling ß-hCG values. If the level has remained constant or is falling this is suggestive of a nonviable pregnancy, whether in the uterus or in an ectopic location, this can be followed for another 48 hours.

Many pregnancies are lost without being able to determine if it was an early intrauterine loss or a nonviable ectopic pregnancy which resolved without becoming clinically symptomatic.

Hormones

Hormonal disorders that can cause abnormal bleeding can be grouped under four broad categories: coagulation disorders, prolactin disorders, thyroid disorders, and chronic anovulation (Table 35.3). Coagulation disorders are relatively rare. Coagulation disorders are most commonly found in girls who are within 1 year of their first menstrual cycle and have a falling hemoglobin level. Von Willebrand disease needs to be excluded in every adolescent presenting with excessive menstruation (menorrhagia). Women with coagulopathies may present with acute hemorrhage and hypovolemic symptoms. These women almost invariably present with anemia or frank hemorrhage to the emergency department within a short interval after the onset of menstruation. They also need to be evaluated for conditions associated with abnormal bone marrow function or rapid turnover of platelets such as leukemia, idiopathic thrombocytopenic purpura, or aplastic anemia.

1. Coagulation—Von Willibrand, leukemia, idiopathic thrombocytopenic purpura, aplastic anemia
2. Hyperprolactinemia
3. Thyroid disorders
4. Chronic anovulation—hypothalamic, adrenal, polycystic ovarian syndrome (hyperandrogenic anovulation), perimenopause

TABLE 35.3. *Hormonal causes: disorders to consider*

While hyperprolactinemia is a significant cause of abnormal bleeding in women, the prolactin itself is not the direct cause of the abnormal bleeding. The high prolactin levels are the result of alterations in neurotransmitters within the hypothalamus and prolactin down-regulates gonadotropin-releasing hormone (GnRH) secretion resulting in altered gonadotropin release, ovarian dysfunction, and subsequent abnormal uterine bleeding. A prolactin-secreting pituitary adenoma is the most common pituitary tumor in women and should be the first concern of a health care provider when evaluating a patient with an elevated prolactin level. It is reasonable to perform an MRI of the sella turcica in all women with a prolactin level greater than 60 ng/mL. In general, prolactin excess should be treated with bromocriptine if pregnancy is desired. If pregnancy is not desired and the patient has enough endogenous estrogen to prevent osteoporosis, then the prolactin level can simply be followed. Whether or not the woman has enough estrogen to prevent osteoporosis can be determined by the patient's response to progestin administration. If the patient fails to menstruate in response to this progestin challenge then consideration of estrogen replacement or other drug for prevention of osteoporosis is necessary. However, the abnormal bleeding will not resolve unless the prolactin level is returned to normal by treatment with a dopamine agonist such as bromocriptine. Even after the prolactin level has returned to normal there may be enough hypothalamic dysfunction that ovulation induction by other means may be required in women desirous of pregnancy. If the patient has a small microadenoma and desires contraception then oral contraceptives are the treatment of choice. If the patient does not need or desire contraception, cyclic progestin therapy with medroxyprogesterone acetate 10 mg for 14 days every other month can be used.

A woman's lifetime risk of developing thyroid disease is approximately 15% and excess or a deficiency of thyroid hormone can affect a woman's menstrual cycle. The most common disorder is hypothyroidism and approximately two-thirds of women with hypothyroidism will develop an aberration of menses. Any woman who develops abnormal uterine bleeding, postpartum depression, premenstrual syndrome, or depression should be screened for thyroid disease (Table 35.4). The principal screening test for thyroid disease is a measurement of serum thyroid-stimulating hormone (TSH). No further testing is required if the TSH is within normal limits. If the TSH is low this suggests hyperthyroidism and measurement of free thyroxine (T4) and free triiodothyronine (T3) should be performed. If either one is elevated the diagnosis of hyperthyroidism is made. After diagnosing hyperthyroidism, a radioactive iodine uptake scan is performed. If the T4 and T3 are normal a diagnosis of subclinical hyperthyroidism may be entertained. If the TSH is high then a free T4 should be obtained. If the free T4 is low, replacement with synthetic thyroxine is begun. A dose of 25 µg per day of synthetic thyroxine is given and increased every 4 weeks by 25 µg per day until the patient's TSH normalizes and her clinical symptoms have resolved. Menstruation will usually return to normal 8 to 10 weeks after the patient has achieved a euthyroid state.

1. Abnormal uterine bleeding
2. Postpartum blues/depression
3. Premenstrual syndrome
4. Depression

TABLE 35.4. *Thyroid dysfunction: when to screen*

The most common hormonal disorder causing abnormal uterine bleeding is estrogenized anovulation (World Health Organization type II anovulation). Anovulatory bleeding in the past has been described as dysfunctional uterine bleeding. Dysfunctional uterine bleeding refers to bleeding unrelated to mechanical factors, iatrogenic causes, infectious agents, cancer, or pregnancy. There is no one particular pattern of bleeding that unequivocally defines dysfunctional uterine bleeding. A woman may present with anything from complete secondary amenorrhea to frank hemorrhage. Therefore, characterizing the menstrual flow is of no diagnostic advantage.

Syndromes of chronic anovulation can be grouped etiologically as either hypothalamic (central nervous system), adrenal (adrenal androgen production), ovarian (polycystic ovarian syndrome; PCOS), or perimenopausal in origin. None of these groups have a clear-cut laboratory profile and a precise classification often proves difficult. PCOS is one of the more confusing causes of chronic anovulation. The exact etiology of this syndrome remains elusive, although a large percentage of women with PCOS have been noted to have hyperinsulinemia secondary to insulin resistance. The National Institutes of Health (NIH) consensus conference has defined PCOS as amenorrhea or oligoovulation with clinical or biochemical evidence of hyperandrogenemia. While many authorities have frequently found insulin resistance in women with PCOS, there currently is no practical and reliable method to clinically diagnose insulin resistance. The use of insulin sensitizers in this group, despite being somewhat controversial, is enjoying widespread use, primarily for women desirous of pregnancy. Because of the controversy in the use of insulin sensitizers in the treatment of the abnormal uterine bleeding associated with PCOS, it is best to treat these patients with cyclic progestin, oral contraceptives, or clomiphene citrate if pregnancy is desired and reserve insulin sensitizers for those women in whom clomiphene citrate has failed and who want to become pregnant.

Another common hormonal cause of anovulatory uterine bleeding is the perimenopausal transition. Most women experience a 5- to 8-year transition from regular menstrual cycles to frank amenorrhea with an interval of abnormal uterine bleeding in between. This interval is marked by intervals of hypoestrogenism with symptoms such as hot flashes, irritability, and some vaginal atrophy, alternating with intervals of estrogenized anovulation. Usually the first sign of the perimenopausal transition is a shortening of the menstrual cycle accompanied by an increase in premenstrual symptomatology. Women over the age of 35 who present with a change in their mean menstrual cycle interval irrespective of other symptomatology who desire future childbearing should be screened for impending ovarian failure with a day 3 follicle-stimulating hormone (FSH) level. There are two therapeutic options for women with abnormal bleeding in the perimenopausal transition. The first is the cyclic administration of progestins. Typically, this is accomplished by the administration of 10 mg of medroxyprogesterone acetate for 14 days each month or every other

month. This therapy may be associated with intermenstrual bleeding and occasionally may precipitate premenstrual symptoms. There is no place for the use of injectable progestins in the management of perimenopausal bleeding. The best choice to control abnormal bleeding in the perimenopausal transition, if the patient is a healthy nonsmoking woman, is the use of continuous combined oral contraceptives. The use of oral contraceptives in perimenopause will ease the transition by enforcing regular menstrual shedding, decrease blood loss, reduce premenstrual symptoms, preserve bone mass, and reduce the lifetime risks of endometrial and ovarian cancers without increasing the risk of breast cancer. The use of hormone replacement therapy, as used in frankly menopausal women, is to be discouraged as this provides additional estrogen and progestin without suppressing the endogenous production and thus increases the total amount of sex steroid exposure to the uterus.

Iatrogenic

Iatrogenic causes of abnormal uterine bleeding appear to be increasing as many drugs used for cancer, renal disease, and transplantation either mimic or modify endogenous hormones and cause abnormal uterine bleeding. Every woman presenting with a change in her menstrual cycle requires that a careful history be taken with respect to her general health as well as use of any prescription or over-the-counter medications. The physician should inquire about drugs prescribed within the past 6 months even if the patient is not currently taking any medications (Table 35.5). Drugs that can effect the menstrual cycle include prednisone, tamoxifen, coumadin, heparin, and Depo-Provera.

1. Prednisone
2. Tamoxifen
3. Coumadin
4. Heparin
5. Depo-Provera

TABLE 35.5. *Drugs associated with abnormal uterine bleeding*

Mechanical

Uterine leiomyomata are one of the most common causes of abnormal uterine bleeding and one of the leading causes of hysterectomy in the United States. Approximately one fourth of all women have uterine leiomyomata, but fortunately only a small fraction of that number will be clinically symptomatic and come to medical attention. Submucous or intracavitary myomas most commonly cause abnormal uterine bleeding. Submucous myomas may cause bleeding by frank erosion and ulceration of the endometrial surface, and intracavitary myomas prevent the normal hemostatic mechanisms required to stop normal menstruation. An intramural myoma may cause bleeding by creating large venous lakes and preventing the uterus from appropriately constricting blood vessels supplying the endometrium at the time of menstruation (Fig. 35.1). Bleeding from a myoma can vary from frank hemorrhage to slight intermenstrual spotting. Uterine leiomyomata are estrogen-dependent. Therefore, any agent that blocks estrogen's biosynthesis or action could theoretically cause regression of myoma. Currently, there is no medical therapy that truly causes regression of leiomyomata. GnRH agonists block gonadotropin secretion resulting in hypoestrogenism and, hence, cause a reduction in the size of the estrogen-dependent muscle cells within the myoma. However, there is rapid return of myoma volume and symptomatology once the GnRH agonist is discontinued and estrogen production by the ovary resumes. RU-486 and other antiprogesterone drugs have been shown to shrink myomas in clinical trials. The long-term effect of these agents on leiomyomata however is unknown. Depo-Provera is often effective in reducing the amount of abnormal bleeding and may even cause some regression in myoma size. Oral contraceptive agents do not cause regression of the myoma but they may stabilize the endometrium enough to effectively control the abnormal bleeding associated with uterine myoma. It is very reasonable to make an attempt to control abnormal uterine bleeding with a trial of oral contraceptive agents in women with leiomyomata before attempting more expensive and hazardous therapies. Despite the use of oral contraceptives, the abnormal bleeding in many women will not be controlled or they may not want to take oral contraceptives on a continuous basis. It is reasonable to consider a hysterectomy or a uterus-sparing operation such as myomectomy when more conservative medical methods have proven unsuccessful. There is not enough outcome evidence in the literature to recommend one surgical approach over the other. Until more data are available, management of uterine leiomyomata will remain empirical.

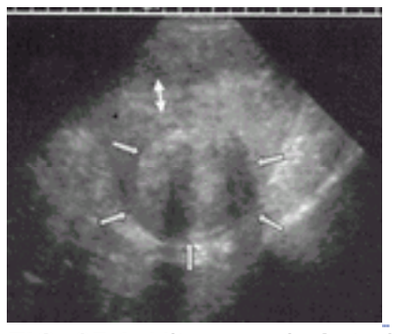

FIG. 35.1. Ultrasound of uterine leiomyoma. This is a transvaginal ultrasound in a woman who has an intramural myoma (*arrows*). The myoma clearly does not impinge on the endometrial cavity with intervening myometrium. The endometrial stripe is defined by a *double arrow.*

Endometrial polyps are found in up to 50% of women presenting with abnormal uterine bleeding. There is no precise etiology for the formation of these polyps but they clearly originate from the endometrium. Detecting polyps can often be difficult. Endometrial polyps are best diagnosed by either hysteroscopy (Fig. 35.2) or saline infusion sonogram (SIS). The SIS is extremely sensitive but may overdiagnose the polyps. It is not uncommon at the time of hysteroscopy and dilation and curettage (D&C) for removal of the polyps diagnosed by SIS to find none present. Additionally, many small polyps will regress spontaneously. Since small polyps are found in asymptomatic women, the role of small endometrial polyps in a woman complaining of abnormal uterine bleeding is unknown.

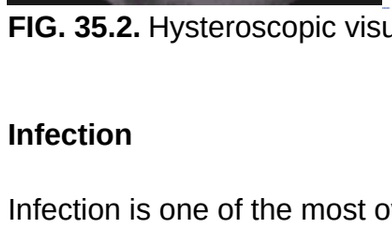

FIG. 35.2. Hysteroscopic visualization of an endometrial polyp. An endometrial polyp is present on the anterior fundal aspect of the endometrial cavity (*arrow*).

Infection

Infection is one of the most overlooked causes of abnormal uterine bleeding. Historically, endometritis has been considered a cause of abnormal uterine bleeding, despite a paucity of evidence in the literature. Endometritis is diagnosed by the finding of an increased number of plasma cells on endometrial biopsy. Culture of the endometrial cavity is not clinically useful and is complicated by the high rate of contamination by vaginal organisms. Studies have failed to show any significant endometrial infection associated with abnormal uterine bleeding. The absence of culture-positive studies and the subjective diagnostic criteria used casts doubt whether chronic endometritis truly causes abnormal uterine bleeding. However, endocervicitis is a known cause of abnormal bleeding, particularly intermenstrual and postcoital bleeding. It is appropriate for women with abnormal bleeding to have cultures or DNA probe tests performed for chlamydia and gonorrhea to rule out those organisms as a cause. Due to the false-negative rate of these diagnostic procedures it is often prudent to treat empirically for chlamydia, if no other cause is found.

Cancer

Endometrial and cervical cancers are uncommon yet important causes of abnormal uterine bleeding. Cervical cancer often presents with postcoital bleeding or irregular menstruation. Even if the patient has a normal Pap smear within the previous year it is prudent to repeat the smear, particularly if the patient has other risk factors for cervical cancer. Endometrial cancer remains a possibility in any woman presenting with abnormal uterine bleeding and endometrial biopsy should be performed in all

women over the age of 35, the age at which the incidence begins to rise. Therapy will depend upon the staging of the disease. Complex endometrial hyperplasia with atypia is usually managed by simple hysterectomy. Other forms of hyperplasia may be safely managed with cyclic or continuous high-dose progestin therapy. If cyclic progestin is chosen, the minimum effective dose is 10 mg of medroxyprogesterone acetate for 14 days each month. Continuous progestin therapy is usually 20 to 40 mg of medroxyprogesterone acetate daily for 90 days. The use of a test-of-cure endometrial biopsy or hysteroscopy with curettage is controversial. However, it is reassuring to the patient and physician to document regression and uncover the rare progesterone receptor–negative hyperplasia.

IMAGING AND SPECIAL STUDIES IN THE MANAGEMENT OF ABNORMAL UTERINE BLEEDING

A transvaginal sonogram (TVS) has become an integral component of the evaluation of women with abnormal uterine bleeding. This is true even if the patient has a normal pelvic exam as the sonogram is focusing on the internal architecture of the uterus not necessarily the overall size. The use of TVS identifies small myoma, adenomyosis, and excessive endometrial thickness. The presence of these factors requires further evaluation with either biopsy or SIS. While TVS is necessary even if the patient has a normal pelvic exam, the TVS does not replace the health care provider performing a thorough and careful pelvic exam.

TVS and SIS in the Evaluation of Abnormal Uterine Bleeding

Hysteroscopy and D&C are not often used as primary diagnostic and therapeutic modalities. While office hysteroscopy does not require anesthesia, the procedure is expensive and requires an experienced operator as compared to TVS and endometrial biopsy. TVS allows acoustic visualization of the endometrium, ovaries, and the myometrium, which is more information than obtained by hysteroscopy. TVS is very sensitive for identification of leiomyomata that are greater 2 cm in diameter. TVS also has the ability to identify adenomyosis and endometrial polyps but its sensitivity and specificity for these conditions is lower. TVS has a 60% sensitivity and a 93% specificity for identifying pathology within the endometrial cavity. Still, TVS should be the first- line diagnostic modality when evaluating disorders of the myometrium and endometrium because of its simplicity and lack of risk. The sensitivity and specificity of TVS can be enhanced with the infusion of saline creating an SIS. Many other names have been used for this procedure including hydrosonogram, sonohysterosalpingography, and saline hysterosonography. No consensus for the appropriate terminology has been reached, but “saline infusion sonography” appears to be gaining acceptance due to its acronym SIS, which avoids confusion with old acronyms of HSG for hysterosalpingogram.

The endometrial thickness in women of reproductive age varies greatly. Still, it should be measured to enhance the sensitivity of TVS in predicting intrauterine pathology. When the endometrial thickness is greater than 8 mm consideration should be given to SIS. The accuracy and precision of SIS can be further enhanced with the addition of an endometrial biopsy. One study has suggested the sensitivity and specificity for the detection of intrauterine pathology at 97% and 70%, respectively, and a positive and negative predictive value of 82% and 94% compared with hysteroscopy/D&C or hysterectomy. Therefore, the use of endometrial biopsy and SIS to identify intrauterine pathology has displaced hysteroscopy and D&C as the primary procedure in the evaluation of abnormal uterine bleeding. Even though surgical evaluation is now a second-line procedure, the health care provider must still remember that hysteoscopy with curettage is more accurate than the less invasive office-based procedures and still has a place in the diagnosis and management of the patient with abnormal uterine bleeding.

The Role of MRI in the Evaluation of Women with Abnormal Uterine Bleeding

With the development of new high-field strength magnets the evaluation of the uterus by MRI has become much quicker and accurate. MRI has the advantage over computed tomography (CT) by not being limited by the surrounding bony structures. Compared to TVS, the MRI is less dependent on operator experience, uterine position, and size. The uterus on MRI is best seen on the T2 weighted sequence. Three regions within the uterus are normally identified: a central bright area that corresponds to the endometrium, another area of intermediate signal intensity that corresponds to the myometrium, and a third layer between the endometrium and myometrium that is hormonally sensitive and termed the *junctional zone.* The thickness signal characteristics of these three areas are evaluated independently when looking for uterine pathology. The greatest advantage of MRI is its ability to distinguish between adenomyosis and uterine leiomyomata. While both of these conditions can cause pelvic pain, typically increasing dysmenorrhea as well as abnormal bleeding, there are patients who desire future fertility or for other reasons desire to preserve their uterus and the conservative operations are different for each condition. The MRI image has a sensitivity of 86% and a positive predictive value of 65% in detecting the presence of adenomyosis when junctional zone thickening is greater than 12 mm. The MRI can also be used to determine whether the adenomyosis is diffuse or superficial. If the adenomyosis is superficial it can successfully be treated with roller-ball endometrial ablation, whereas deep adenomyosis is best treated by hysterectomy. Additionally, the MRI has the ability to accurately define myoma less than 2 cm, the limit of TVS. This is important for women undergoing in vitro fertilization. MRI is becoming an efficient and cost-effective complementary tool and may soon supplant hysteroscopy as the second-line diagnostic modality in abnormal uterine bleeding.

MANAGEMENT OF SPECIAL SITUATIONS

Acute Hemorrhage

It is not uncommon for women with chronic anovulation or uterine leiomyomata to present to the emergency department with acute hemorrhage and symptoms of hypovolemia. These patients need rapid control of their hemorrhage and a clinical decision has to be made quickly as to whether to proceed to the operating room or to make an attempt at medical control. If the patient is hemodynamically unstable, a D&C is indicated as it will result in immediate cessation of the bleeding and allow time for transfusion and correction of the underlying pathology. If the patient is stable enough to attempt medical management, fluid resuscitation is begun. Blood products are then given as necessary and high-dose parenteral estrogen therapy initiated. The high dose of estrogen will initiate endometrial proliferation and increase fibrinogen as well as factors V and IX, but most important, it promotes platelet aggregation and clotting at the capillary level. It is appropriate to use i.v. estrogen even when the patient has uterine leiomyomata. Both i.v. and p.o. estrogen work equally as well but the parenteral route is usually chosen if the clinical situation requires rapid cessation of the blood loss. Intravenous conjugated estrogen is given 25 mg every 4 hours until the bleeding stops. The oral regimen is equally efficacious and consists of 2.5 mg conjugated estrogen or 2 mg of micronized estradiol every 4 hours for 24 hours followed by a single daily dose for 7 to 10 days. If the bleeding persists for more than 12 to 24 hours with either one of these regimens, a D&C is indicated. Whether the estrogen is given i.v. or p.o., a progestin should be started at the same time and continued for 5 to 7 days at which time the patient should expect a withdraw bleed. If the patient is not having acute hemorrhage but rather is having heavy menstrual flow and becoming anemic then the use of high-dose oral contraceptives may be considered. In these cases the patient is given 4 pills containing 30 to 35 µg of ethinyl estradiol for 4 days followed by 3 pills for 7 days followed by 2 pills for 11 days then 1 pill a day thereafter. Hysterectomy should be considered in women who have completed childbearing and when medical management has failed.

Menorrhagia

Menorrhagia affects approximately 15% to 20% of women presenting with abnormal uterine bleeding and causes significant social inconvenience as well as the potential for significant anemia. The first line of therapy for the treatment of women with menorrhagia is antiprostaglandin agents, the cyclooxygenase inhibitors or nonsteroidal antiinflammatory drugs (NSAIDs). Women with menorrhagia have significantly higher levels of prostaglandin E (PGE) when compared to prostaglandin F_{2a}. The antiprostaglandin agents affect the balance between PGE and thromboxane. Many prospective trials have shown use of NSAIDs beginning on the day of menstruation and continued throughout menses significantly decrease blood loss. The use of the cyclooxygenase-1 (COX-1) class of agents is contraindicated in women with peptic ulcer disease, asthma, and allergy to aspirin. Numerous regimens have been used all with similar efficacy: mefenamic acid 500 mg t.i.d., ibuprofen 400 mg t.i.d., and naproxen sodium 275 mg q6h after a loading dose of 550 mg. All these regimens have demonstrated a significant decrease in blood loss. The newer COX-2 inhibitors have markedly fewer problems and inhibit the same COX enzyme, but have not been tested in clinical trials. They may improve the overall success of this approach with fewer side effects.

Another strategy, using the levonorgestrel intrauterine device (IUD), has recently been introduced. Several controlled trials have shown that its use significantly decreases the amount of menstrual blood lost per cycle by causing an intense atrophy of the endometrium. The levonorgestrel IUD should be considered in any woman who needs contraception and who is experiencing menorrhagia. If these therapies fail to control the problem, oral contraceptives can also be considered. Surgical therapy should be considered when medical management has failed or is medically contraindicated. Surgical therapy consists of either endometrial ablation or hysterectomy. Endometrial ablation by any technique is reported to provide 90% to 95% patient satisfaction, with amenorrhea being achieved in approximately 50% of patients. Unfortunately, the long-term problems associated with endometrial ablation are not known. With regard to hormone therapy after menopause, the patient having endometrial ablation must be regarded as having fully responsive endometrium. There is a theoretical risk of concealed endometrial cancer, but this has not been reported to date. Hysterectomy results in amenorrhea 100% of the time and has a higher patient satisfaction rate than endometrial resection 2 years after the procedure.

Abnormal Bleeding on Oral Contraceptives

Abnormal bleeding on oral contraceptives is usually due to an insufficient amount of estrogen in a particular pill to stabilize the endometrium. Strategies to control the bleeding involve increasing the estrogen content of the pill, changing to a different birth control pill which increases the estrogen/progestin ratio, or giving supplemental estrogen. Since most noncompliance with oral contraceptives is related to the progestin content and if a patient is comfortable with the side effects in her particular pill, an attempt should be made to continue with that level of progestin and add supplemental estrogen, either 1.25 mg conjugated estrogen or 2 mg of estradiol starting at

the time the patient bleeds and continuing for 7 days. This regimen is repeated at the same time for two consecutive months whether or not the patient has spotting in the two subsequent cycles.

Alternatively, the patient can simply use a pill with a higher estrogen/progestin ratio or a higher-dose estrogen pill to determine if that will be sufficient to control the bleeding. If the patient fails to respond to these regimens then other factors need to be assessed. Abnormal bleeding on pills is significantly increased in women who smoke, due to enhanced estrogen clearance, and when taking antibiotics because of alterations in absorption. All efforts should be made to have the patient stop smoking. Additionally, cultures or DNA probe for chlamydia should be obtained as endocervicitis-related chlamydia is a significant cause of abnormal bleeding in women on birth control pills.

Abnormal Bleeding in Perimenopause

The most common cause of abnormal uterine bleeding in the perimenopausal woman is estrogenized anovulation. Still, every woman in this category needs a complete evaluation as detailed earlier in this chapter, particularly as they are now in the age range where the incidence of endometrial cancer is beginning to be significant. Attributing the abnormal uterine bleeding to the perimenopausal transition is a diagnosis of exclusion and can only be made after a through evaluation. Therapy with oral contraceptives should be initiated provided the patient has no contraindication to their use, primarily smoking. Oral contraceptives have been shown to decrease the amount of blood loss associated with menstruation providing cycle regulation and relief from menorrhagia. Additionally, oral contraceptive agents preserve bone mass during a time when occult bone loss may be occurring. Most significantly, oral contraceptive agents provide reduction in the risk of endometrial and ovarian cancer for 10 to 15 years following their discontinuation. Every effort should be made to encourage the use of oral contraceptives in all perimenopausal woman.

SUMMARY POINTS

- Use of the mnemonic PHIMIC (pregnancy, hormones, iatrogenic, mechanical, infection, and cancer) offers a simplified yet complete approach to the evaluation of abnormal uterine bleeding. Patients presenting with abnormal uterine bleeding should have a pregnancy test, luteinizing hormone, follicle-stimulating hormone, thyroid-stimulating hormone, prolactin, Pap smear, DNA probe for gonorrhea and chlamydia, and a transvaginal ultrasound.
- Estrogenized anovulation is the most common cause of abnormal uterine bleeding. Anovulation may be caused by a variety of conditions, including elevated prolactin, hyper- or hypothyroidism, adrenal disorders, and polycystic ovarian syndrome (hyperandrogenic anovulation).
- Von Willebrand disease should be considered in any young woman experiencing menorrhagia within 1 year of menarche.
- No therapeutic advantage of intravenous estrogen over oral estrogen in the control of acute hemorrhage is known.
- Saline infusion sonography and endometrial biopsy, when performed together, have a 97% sensitivity and 70% specificity in determining intrauterine pathology.
- MRI can reliably differentiate between deep and superficial adenomyosis. MRI can accurately identify leiomyomata less that 2 cm in size and determine their location.

Surgical Therapy

MOLIMINA, PREMENSTRUAL SYNDROME (PMS), AND PREMENSTRUAL DYSPHORIC DISORDER (PMDD)

During the reproductive years, up to 80% to 90% of menstruating women will experience symptoms (breast pain, bloating, acne, constipation) that forewarn them of impending menstruation, so-called *molimina*. Available data suggest that as many as 30% to 40% of these women are sufficiently bothered by such molimina that they would seek relief if it were readily accessible, simple, and safe. Since the term *premenstrual syndrome*, or *PMS*, has become so ingrained in lay culture most women describe the symptoms of molimina as PMS. However moliminal symptoms show a variable association with the more severe psychological symptoms typically required to meet research diagnostic criteria for PMS.

Researchers in the field have argued that the term *PMS* should be reserved for a more severe constellation of symptoms that affects closer to 5% of women during their reproductive years. To capture the true severity of PMS in this population, the definition describes not only the symptoms but also their functional impact. PMS has been defined as “the cyclic recurrence in the luteal phase of the menstrual cycle of a combination of distressing physical, psychological, and/or behavioral changes of sufficient severity to result in deterioration of interpersonal relationships and/or interference with normal activities.”

The American Psychiatric Association, following years of debate about whether to include PMS in their *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV)*, included as an appendix (meaning that the subject requires further study) a condition labeled *premenstrual dysphoric disorder (PMDD)* (Table 36.1). Such a designation was intended to alert physicians to a combination of specific severe symptoms (mostly psychiatric in nature) that could mimic other psychiatric disorders with the exception that the symptoms recurred in the premenstrual phase of the menstrual cycle.

1. Timing of symptoms
   Symptoms are present during the last week of the luteal phase, remit within the first few days of menses, and are absent during the week following menses. The symptoms occur during most, if not all, menstrual cycles.
2. Symptoms
   At least five symptoms are required, including at least one of the first four symptoms:
   - Markedly depressed mood
   - Marked anxiety
   - Marked affective lability
   - Persistent and marked anger
   - Decreased interest in usual activities
   - Lethargy
   - Marked change in appetite
   - Hypersomnia or insomnia
   - A sense of being overwhelmed or out of control
   - Physical symptoms
3. Severity
   The symptoms markedly interfere with work, school, social activities, and relationships with others.
4. Other disorders
   Rule out that the disorder is not merely an exacerbation of a major affective, panic dysthmic, or personality disorder, although PMDD can be superimposed upon any of these disorders.
5. Confirmation of the disorder
   The above criteria must be confirmed by prospective daily self ratings for two consecutive menstrual cycles.

TABLE 36.1. *Diagnostic criteria for premenstrual dysphoric disorder (PMDD)*

Diagnosis

History and Charting A typical woman suffering from PMS may describe herself as a well-adjusted person for most of the month who is productive at work and in other endeavors, and, if she has children, a good mother. However starting 7 to 10 days prior to menstruation she awakes in the morning with feelings of anger, anxiety, or sadness. At work she may have difficulty concentrating on the tasks at hand and she may overreact to otherwise typical actions of co-workers, friends, partner, or children. She feels depressed but she cannot understand why because she typically enjoys life and is happy with most of its aspects. Occasionally depression, anger and aggression, or anxiety may be extreme and result in concerns for the welfare of the affected woman or those around her. A “black and white” diagnostic cutoff for determining if someone suffers from PMS is not presently possible. Although many women report feeling bloated and irritable before menstruation, further questioning usually reveals that these symptoms have little substantive impact on their lives. In part, the distinction between troublesome premenstrual moliminal symptoms and PMS may have to do with the duration and severity of symptoms. Particularly in the first few years after symptoms appear, the severity of PMS may vary dramatically from month to month. The nature of symptoms and their functional impact is best established by self-report using a prospective calendar record. Any calendar used for this purpose must obtain information on four key areas: specific symptoms, severity, timing in relation to the menstrual cycle, and baseline level of symptoms in the follicular phase. Retrospective accounts about symptoms often fail to provide critical information on timing of symptoms or baseline level of symptoms during the follicular phase of the cycle. For example, many individuals with underlying psychiatric disease will experience premenstrual exacerbation of their symptoms. They will recall the severe symptoms prior to menstruation and may give a history that sounds typical for PMS. However when they complete a 2-month calendar record it usually becomes apparent that symptoms are present all the time and are at their worst premenstrually. This has been termed “premenstrual magnification” of an underlying psychiatric disorder. Typically PMS symptoms appear after ovulation, worsen progressively leading up to menstruation, and are relieved at varying rates after onset of menstruation. In some women there is almost immediate relief from psychiatric symptoms with the onset of bleeding while for others the return to normal is more gradual. The most severely affected women report symptoms beginning shortly after ovulation (2 weeks before menstruation) and resolving at the end of menstruation. Such individuals typically report having only one “good week” per month. If this pattern is longstanding then it becomes increasingly difficult for interpersonal relationships to rebound during the good week with the result that symptoms may start to take on the appearance of a chronic mood disorder. (Whenever charting leaves the diagnosis in doubt, a 3-month trial of medical ovarian suppression [discussed later in the chapter] will usually provide a definitive answer.) About 5% to 10% of women who suffer from PMS experience a brief burst of symptoms (coincident with the midcycle fall in estradiol that accompanies ovulation) with a return to normal until later in the luteal phase when symptoms recur (Fig. 36.1). The different patterns of PMS symptoms are shown in Figure 36.2.

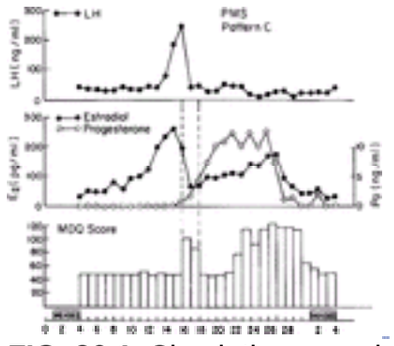

FIG. 36.1. Circulating gonadotropin, estradiol, and progesterone concentrations correlated to symptom severity in a woman with midcycle and premenstrual syndrome (PMS) symptoms—so-called pattern C PMS. (From Reid RL. Premenstrual syndrome. In: DeGroot L, ed. Female Reproductive Endocrinology. Available at: http://www.endotext.com/. Accessed January 16, 2003, with permission.)

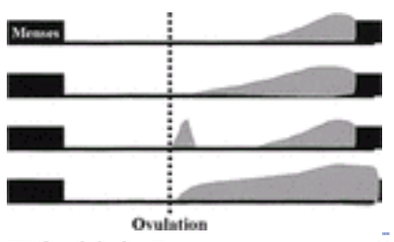

FIG. 36.2. Four common patterns of premenstrual syndrome symptomatology in relation to the menstrual cycle. Note that in every case symptoms commence after ovulation. (From Reid RL. Premenstrual syndrome. In: DeGroot L, ed. Endotext.com. Available at: http://www.endotext.com/. Accessed January 16, 2003, with permission.)

Information should be sought about stresses related to the woman's occupation and personal life as these may tend to exacerbate PMS. Past medical and psychiatric diagnoses may be relevant in that a variety of medical and psychiatric disorders may show premenstrual exacerbation. A prospective symptom record should usually be maintained for a minimum of two complete cycles prior to establishing a diagnosis since an unfavorable life event occurring during the follicular phase of a single month could give the erroneous impression that symptoms were continuously present. Key components of a prospective symptom record are listed in Table 36.2.

1. Daily listing of symptoms
2. Ratings of symptom severity throughout the month
3. Timing of symptoms in relation to menstruation
4. Rating of baseline symptom severity during the follicular phase

TABLE 36.2. *Key elements of a prospective symptom record used for the diagnosis of premenstrual syndrome*

One example of such a calendar record, the PRISM calendar (prospective record of the impact and severity of menstrual symptoms) (Fig. 36.3) allows rapid visual confirmation of the nature, timing, and severity of menstrual cycle–related symptomatology and at the same time provides information on life stressors and use of PMS therapies. Although symptoms are rated in severity on a scale from 1 to 3, the actual interpretation of the calendar requires no mathematical calculations. An arm's length assessment of the month-long calendar usually allows a rapid distinction to be made between PMS and other more chronic conditions (Fig. 36.4).

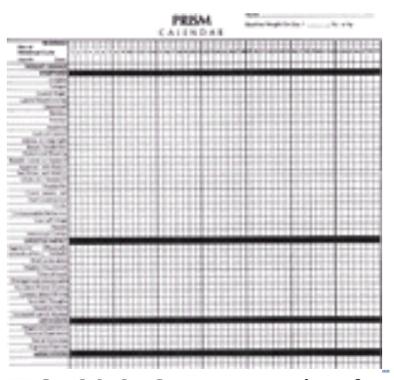

FIG. 36.3. One example of a prospective record of the impact and severity of menstrual symptoms—the PRISM calendar. (From Reid RL. Premenstrual syndrome. In: DeGroot L, ed. Endotext.com. Available at: http://www.endotext.com/. Accessed January 16, 2003, with permission.)

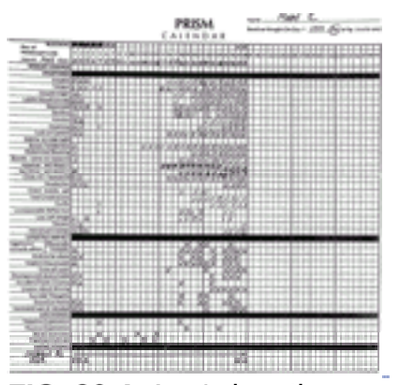

FIG. 36.4. Arm's length assessment of a completed PRISM (prospective record of the impact and severity of menstrual symptoms) calendar reveals a pattern of symptoms consistent with premenstrual syndrome. (From Reid RL. Premenstrual syndrome. In: DeGroot L, ed. Endotext.com. Available at: http://www.endotext.com/. Accessed January 16, 2003, with permission.)

Physical Findings History should usually be accompanied by physical and gynecologic exam since many women with apparent PMS may have coexisting medical conditions. The summation of premenstrual and menstrual symptoms often determines the overall experience of women who suffer from PMS and therapy directed at gynecologic disorders such as dysmenorrhea (associated with endometriosis) or heavy flow (associated with fibroids) can dramatically reduce the perceived severity of PMS. Organic causes of PMS-like symptoms must be ruled out. Marked fatigue may result from anemia, leukemia, hypothyroidism, or diuretic-induced potassium deficiency. Headaches may be due to intracranial lesions. Women attending PMS clinics have been found to have brain tumors, anemia, leukemia, thyroid dysfunction, gastrointestinal disorders, pelvic tumors including endometriosis, and other recurrent premenstrual phenomena such as arthritis, asthma, epilepsy, and pneumothorax. Efforts to rule out such causes for premenstrual distress are important before choosing any PMS therapy.
Blood Tests Contrary to some claims there is no blood test that will establish a diagnosis of PMS. Blood work is only helpful to rule out conditions such as anemia, leukemia, or thyroid dysfunction.

Etiology

Many theories have attempted to explain the diverse manifestations of PMS but until recently no single theory has received widespread acceptance. Many of the early theories lacked biologic plausibility and appeared to have emerged as a means to market specific therapeutic products (Table 36.3). More recently a theory that links gonadal steroid levels and central serotonergic activity has started to emerge.

TABLE 36.3. *List of proposed etiologies for premenstrual syndrome*

The current consensus seems to be that in some predisposed women normal fluctuations in the gonadal hormones estrogen and progesterone trigger central biochemical events related to PMS symptomatology. Of all the neurotransmitters studied to date, serotonin seems to be the most promising central target. It is likely that serotonin levels dip premenstrually in most women and that susceptible individuals will show varying degrees of psychiatric symptomatology. Many women report a menstrual or immediate postmenstrual state of mental well-being (sometimes bordering on euphoria) that may reflect a rebound surge of serotonin activity. The theoretic effects of gonadal hormones on serotonin activity (Fig. 36.5) form the basis for most of the current interventions for PMS and PMDD.

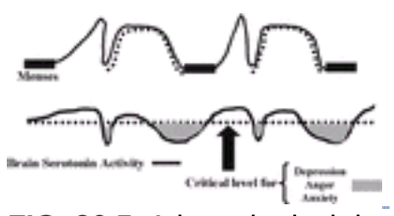

FIG. 36.5. A hypothetical depiction of the interrelationship between gonadal steroid fluctuations and central changes in serotonin activity to explain the timing of symptoms in premenstrual syndrome. When serotonin levels or activity fall below an arbitrary level (that may be influenced by stress, heredity, or other factors) symptoms of anger, anxiety, or depression may emerge. (From Reid RL. Premenstrual syndrome. Solid line, estrogen; dotted line, progesterone. In: DeGroot L, ed. Endotext.com. Available at: http://www.endotext.com/. Accessed January 16, 2003, with permission.)

Several lines of evidence from clinical medicine support this interrelationship between estrogen or lack of estrogen effect (perhaps mediated by progestin-induced depletion of estrogen receptors) and central serotonergic activity. The midcycle appearance of PMS symptoms in women with pattern C PMS coincides with the periovulatory fall in estradiol, whereas the reappearance and ever-increasing severity of symptoms in the late luteal phase may result from progesterone-induced depletion of central estrogen receptors coincident with the decline of estradiol leading up to menstruation (see Fig. 36.1). Estrogen has been shown to alleviate clinical depression in hypoestrogenic perimenopausal women in double-blind clinical trials. The addition of sequential progestin therapy to estrogen replacement triggers characteristic PMS-like mood disturbance in some susceptible postmenopausal women. Anti-estrogens given for ovulation induction may, at times, provoke profound mood disruption. Women with premenstrual syndrome show a surprisingly high frequency of premenstrual and menstrual hot flashes (85% of those with PMS vs. 15% of non-PMS controls) that are typical of those experienced by menopausal women. Selective serotonin reuptake inhibitors (SSRIs) have been shown to relieve hot flashes in breast cancer survivors made menopausal by chemotherapy. In each of these circumstances, a decrease in exposure to estrogen has been linked to mood disturbance and in each case a decrease in serotonin activity (inferred from the response to SSRIs) appears to be the proximate cause.

Therapy

Education and Counseling Women who present with severe premenstrual complaints often benefit from reassurance that they are not “losing their minds” and that PMS is a real condition that affects many women of reproductive age. Reassurance that, although we do not yet have all the answers about PMS, we have available a range of very effective therapies is equally important information. The prospective documentation of symptoms is as much a part of therapy as it is the key to diagnosis (see Table 36.1). The very use of a calendar record (listing the range of PMS symptoms) may provide much needed reassurance that other women experience similar symptoms. The completed chart may demonstrate to the patient for the first time the cyclicity of her symptoms supporting a clear link to hormonal shifts of the menstrual cycle. While it is useful for women with PMS to learn to anticipate times in the month when vulnerability to emotional upset and confrontation may be greatest, the strategy of making important decisions “only on the good days,” as espoused in some PMS clinics, falls apart if premenstrual symptoms last for more than just a few days per month. For some women premenstrual symptoms may last for a full 3 weeks and advising them to restrict their important activities to the remaining days of the month is neither helpful nor warranted. Interventions aimed at reducing symptoms are more appropriate in this circumstance.

Lifestyle Modification

Communication Strategies When an individual is suffering to a degree that requires more than simple counseling and reassurance, measures aimed at lifestyle modification should first be explored. Women with such symptoms should be encouraged to discuss the problem with those individuals who are central to their life including partner, other family members, or friends. Often confrontations can be avoided if an understanding partner or friend recognizes the cause for a woman's upset and defers discussion of the controversial subject until another time. Strategies for stress reduction can be helpful. Communication skills and assertiveness may be improved with counseling. Group counseling in a program supervised by a clinical psychologist may be invaluable.

Diet While there have been many books written describing specific “PMS diets” few of the recommendations contained therein are based on scientific fact. Several simple dietary measures may afford relief for women with PMS. Reduction of the intake of salt and refined carbohydrates may help prevent edema and swelling in some women. Although a link between methylxanthine intake and premenstrual breast pain has been suggested, available data are not convincing. Nevertheless, a reduction in the intake of caffeine may prove useful in women where tension, anxiety, and insomnia predominate. Anecdotal evidence suggests that small, more frequent meals may occasionally alleviate mood swings. Based on evidence that cellular uptake of glucose may be impaired premenstrually, there is, at least, some theoretic basis for this dietary recommendation. Several lines of evidence indicate that there is a tendency toward increased consumption of alcohol premenstrually and women should be cautioned that excessive use of alcohol is frequently an antecedent factor in relationship discord. Calcium supplementation to reduce symptoms has been shown to be marginally superior to placebo in a randomized placebo-controlled trial.

Exercise Exercise is reported to reduce premenstrual molimina in women running in excess of 50 km per cycle. The effects of exercise in women with well-characterized PMS have not been rigorously evaluated. As part of an overall program of lifestyle modification, exercise may reduce stress by providing a time away from the home and by providing a useful outlet for any anger or aggression. Some women who suffer from PMS report that exercise promotes relaxation and helps them sleep at night.

Medical Interventions

The primary factor directing the selection of therapy should be the intensity and impact of premenstrual symptoms. Symptoms that are causing major disruption to quality of life rarely respond to lifestyle modification alone and efforts to push this approach often do nothing more than delay effective therapy. Conversely, minor symptoms or symptoms that are short-lived each month seldom justify major medical interventions.

Attention should always initially be directed to symptoms for which simple, established treatments exist. For example, dysmenorrhea or menorrhagia may be satisfactorily relieved with prostaglandin synthetase inhibitors or oral contraceptives.

Mefenamic acid (500 mg t.i.d.) in the premenstrual and menstrual weeks has outperformed placebo for the treatment of PMS in some, but not all, clinical trials. It is likely that many of the end-stage mediators of PMS symptomatology are prostaglandins, which indicates this prostaglandin synthetase inhibitor may be working through a general inhibition of prostaglandin activity. Based on this, mefenamic acid is an ideal adjunct for any woman with coexisting dysmenorrhea and menorrhagia. In practice however, its effectiveness for premenstrual symptomatology, particularly psychological symptoms, seems quite variable. Mefenamic acid is contraindicated in women with known sensitivity to aspirin or those at risk for peptic ulcers.

Trials comparing oral contraceptive therapy to placebo have not shown a beneficial effect on mood in most circumstances. However, when contraception is required in a woman with PMS and coexisting dysmenorrhea or menorrhagia, the net effect of an oral contraceptive pill may be positive. Although oral contraceptives by no means guarantee relief from PMS they may afford sufficient relief from associated physical symptoms, so that for some women, the remaining premenstrual manifestations become tolerable. When an oral contraceptive user presents with PMS it is common to find that symptoms begin earlier in the cycle. This effect may result from exposure to progestin in the oral contraceptive 3 weeks before onset of menstruation rather than progesterone exposure 2 weeks before menses as occurs in natural cycles. In the woman presenting with distressing PMS while on an oral contraceptive, a switch to an alternate means of contraception is often attended by a substantial reduction in symptoms.

Published data in regard to the efficacy of pyridoxine (vitamin B_6) have been contradictory, however, this medication in proper doses (100 mg daily) is, at worst, a safe placebo that becomes one part of an overall management plan for women with distressing molimina that should include lifestyle modification and changes in diet. Patients should be cautioned that these medications do not work for all women and that increasing the dose of pyridoxine in an effort to achieve complete relief of symptoms may lead to peripheral neuropathy. Pyridoxine should be discontinued if there is evidence of tingling or numbness of the extremities.

Neither progestin therapy nor oil of evening primrose has been shown to be efficacious for PMS in controlled clinical trials.

Premenstrual mastalgia which affects up to 10% of women in reproductive age may occur in isolation from other PMS symptoms and, as such, should be considered a moliminal symptom. Low-dose danazol (100 mg OD) or luteal phase–only danazol (200 mg OD) can bring about dramatic relief of mastalgia in most women, however higher doses (400 mg OD) may be required to relieve other PMS symptoms. Mastalgia may also respond to tamoxifen (10 mg daily), but has not been shown to

respond to diuretics, medroxyprogesterone acetate, or pyridoxine.

The routine use of diuretics in the treatment of PMS should be abandoned. Most women show only random weight fluctuations during the menstrual cycle despite the common sensation of bloating. In the absence of demonstrable weight gain it is likely that this symptom may result from constipation or bowel wall edema rather than from an overall fluid accumulation. In rare cases, ingestion of salt and refined carbohydrates has been shown to result in true fluid retention. In cases where a consistent increase in weight can be documented or where edema is demonstrable, limitation of salt and refined carbohydrate intake should be attempted first. If such dietary restrictions fail to relieve premenstrual fluid accumulation, use of a potassium-sparing diuretic, such as spironolactone, may be considered. Continued use of a diuretic activates the renin–angiotensin–aldosterone system resulting in rapid rebound fluid accumulation as soon as the diuretic is discontinued. Weight takes approximately 2 to 3 weeks to return to normal after discontinuation of a diuretic in some people. Unfortunately this leaves the affected woman with the impression that she has to have a diuretic to maintain normal fluid balance.

Some women report overriding symptoms of anxiety, tension, and insomnia in the premenstrual week. New short-acting anxiolytics or hypnotics such as alprazolam or triazolam, respectively, may be prescribed sparingly for such individuals. Buspirone has also proven useful in preliminary trials.

Estrogen withdrawal has been implicated in menstrually-related migraines and evidence indicates that estrogen supplementation commencing in the late luteal phase and continued through menstruation may alleviate headaches in some women. As discussed subsequently, if headaches are severe and are unrelieved by short-term estrogen supplementation they can often be controlled by intramuscular or oral sumatriptan therapy or by medical ovarian suppression with gonadotropin-releasing hormone (GnRH) agonists and continuous combined hormone replacement therapy.

Antidepressant Therapy A range of newer antidepressant medications that augment central serotonin activity (SSRIs or selective serotonin and norepinephrine reuptake inhibitors [SNRIs]) have been shown to alleviate severe premenstrual syndrome. The theoretic effect of these agents on serotonin levels throughout the menstrual cycle is depicted in schematic fashion in Figure 36.6. Since these agents will also relieve endogenous depression, a pretreatment diagnosis, achieved by prospective charting, is very important. Practically speaking, many women who attend a gynecology clinic to seek relief from premenstrual symptoms express reservations about taking an antidepressant, particularly if a short-term end point (3–6 months away) is not likely. Long-term therapy may be required to control symptoms of PMS for women in their 30s until menopause. Rapid reappearance of PMS has been reported after cessation of SSRI therapy by premenopausal women.

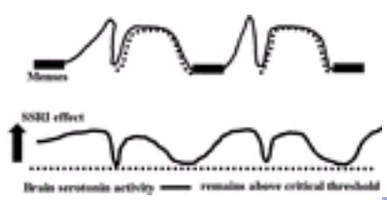

FIG. 36.6. Hypothetical depiction of how drugs that elevate serotonin activity can alleviate premenstrual syndrome. Solid line, estrogen; dotted line, progesterone. (From Reid RL. Premenstrual syndrome. In: DeGroot L, ed. Endotext.com. Available at: http://www.endotext.com/. Accessed January 16, 2003, with permission.)

For patients in whom PMS psychiatric symptoms predominate, antidepressant therapy may provide excellent results. SSRIs, such as fluoxetine, sertraline, paroxetine, fluvoxamine, and velafaxine (an SNRI) have all been successfully employed. Symptom profiles may help in selecting the most appropriate agent (i.e., fluoxetine in patients where fatigue and depression predominate; sertraline if insomnia, irritability, and anxiety are paramount). SSRIs have been associated with loss of libido and anorgasmia, which are particularly distressing to this patient population. Appropriate pretreatment counseling is essential. Tricyclic antidepressants (TCAs) have not generally been effective with the exception of clomipramine, a TCA with strong serotonergic activity. Intolerance to the side effects of TCAs is common. Most women who suffer from PMS would prefer to medicate themselves only during the symptomatic phase of the menstrual cycle. Studies have demonstrated that luteal phase therapy may be effective for many women with PMS. Practically speaking, a trial of SSRI therapy should be commenced with continuous use. After a woman has determined the optimal dosage to achieve the desired response it is reasonable to test luteal phase–only therapy to determine if the benefit is maintained.
Medical Ovarian Suppression Suppression of cyclic ovarian function may afford dramatic relief for the woman with severe and long-lasting symptoms (Fig. 36.7). In each case therapy should be directed to the suppression of cyclic ovarian activity while ensuring a constant low level of estrogen sufficient to prevent menopausal symptomatology and side effects.

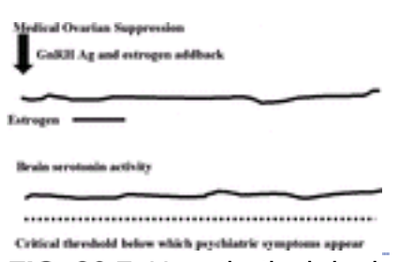

FIG. 36.7. Hypothetical depiction of how medical or surgical elimination of ovarian steroid fluctuations can stabilize central serotonin activity and eliminate premenstrual syndrome. (From Reid RL. Premenstrual syndrome. In: DeGroot L, ed. Endotext.com. Available at: http://www.endotext.com/. Accessed January 16, 2003, with permission.)

As a rule, although oral contraceptives suppress ovulation they seldom relieve the psychiatric symptoms of PMS, perhaps because ovarian steroidogenesis is replaced by exogenous synthetic steroids. Danazol 200 mg b.i.d. will effect ovarian suppression in approximately 80% of women with prompt relief from symptoms. Higher doses up to 200 mg q.i.d. may be required in the remaining women in order to achieve complete menstrual suppression. Danazol, at a dose of 200 mg b.i.d., has relatively few side effects; these may include hot flashes, muscle cramps, and occasional cases of epigastric pain, fine tremor, or insomnia. In the woman without preexisting hair growth, hirsutism is rarely a problem at these dosages when treatment is limited to 1 year or less. In the individual with preexisting acne or increased body hair, alternative interventions should be considered. The use of danazol causes a shift to a more unfavorable lipid profile which is likely to have little impact when danazol is used on a short-term basis. In the patient who tolerates danazol well, and in whom symptomatic relief is dramatic, this effect is the primary concern that will influence decision making about long-term treatment. GnRH agonists effect rapid medical ovarian suppression thereby inducing a pseudomenopause and affording relief from PMS. This approach is unsatisfactory in the long term not only because of the troublesome menopausal symptoms it evokes but also because if creates an increased risk for osteoporosis and ischemic heart disease. When combined with continuous combined hormone replacement therapy, GnRH agonists afford excellent relief from premenstrual symptomatology without the attendant risks and symptoms resulting from hypoestrogenism. The major drawback to this therapeutic approach is the expense of medication and the need for the patient to take multiple medications on a long-term basis. A simpler and less expensive approach involves the use of depo-medroxyprogesterone acetate (DMPA). This approach results in rapid suppression of cyclic ovarian function without attendant menopausal symptomatology. The major drawback to this approach is that a substantial percentage of women will experience irregular bleeding and gradual weight gain. The ideal situation, in which DMPA induces amenorrhea, may be problematic for the woman who wishes future fertility. Patients should always be counseled about the potential for protracted anovulation following use of this medication.
Surgical Therapy The fact that medical approaches to PMS should be exhausted prior to considering surgery (hysterectomy and oophorectomy) for debilitating PMS has been emphasized in an American College of Obstetricians and Gynecologists' committee opinion on premenstrual syndrome (No. 155, April 1995). Clinical trials, however, have clearly shown this therapy to be effective. For the woman in whom there is unequivocal documentation that premenstrual symptoms are severe and disruptive to lifestyle and relationships, and in whom conservative medical therapies have failed (either due to lack of response, intolerable side effects, or prohibitive cost), the effect of medical ovarian suppression should be tested. At times this therapeutic approach (a GnRH agonist and continuous combined hormone replacement therapy) can be maintained until menopause with satisfactory symptom control. Some women, despite complete relief of symptoms, cannot afford or choose not to take this combination of medications for prolonged intervals (as long as 10–15 years from diagnosis until menopause in some cases). In these specific circumstances a surgical option may be considered. In the circumstance where family is complete and permanent contraception is desired, the pros and cons of oophorectomy for lasting relief from premenstrual symptomatology should be discussed with the patient. In many women the progestin component of hormone replacement therapy, when given sequentially, may induce an apparent recrudescence of PMS-like symptoms and, when given continuously, may result in unwanted irregular bleeding. Accordingly, hysterectomy at the time of oophorectomy is a consideration that allows subsequent hormone replacement with low-dose estrogen alone.

Treatment of Androgen Excess

Androgen excess (i.e., hyperandrogenism) is a common, albeit heterogeneous, endocrine disorder of women. The clinical presentation of androgen excess may range from mild hirsutism, acne, or subtle ovulatory dysfunction, to the rare patient with frank virilization and masculinization. Androgen excess disorders include the polycystic ovary syndrome (PCOS), nonclassic adrenal hyperplasia (NCAH), the hyperandrogenic–insulin resistant–acanthosis nigricans (HAIRAN) syndrome, and androgen-secreting neoplasms. Although the most recognizable clinical feature of androgen excess is hirsutism, it should be noted that not all patients with hirsutism have evidence of androgen excess, as in the patient with idiopathic hirsutism (IH). Likewise, not all patients with an androgen excess disorder have clinically evident hirsutism, as in the Asian patient with PCOS. Because of its frequent association with PCOS, clinically evident androgen excess (e.g., hirsutism) is a useful marker for the presence of metabolic abnormalities in these women, including insulin resistance and glucose intolerance resulting in an increased risk for type 2 diabetes mellitus (DM) and cardiovascular disease (CVD). With these new insights, the burden of care for the treating physician has increased beyond that of solely treating the presenting complaint to include the detection and, if possible, prevention of these metabolic consequences.

NORMAL ANDROGEN PRODUCTION AND METABOLISM

Androgen Production and Action

Androgens are C19 steroids (that is they contain 19 carbons) produced from circulating low-density lipoprotein (LDL) cholesterol (a C27 molecule). As in most metabolic pathways, the first step is rate limiting (i.e., the conversion of cholesterol to the weak progestogen pregnenolone, a C21 steroid) by cytochrome P450scc (Fig. 37.1). The zona reticularis of the adrenal cortex, and the theca and stroma of the ovaries, secrete androgens produced through de novo synthesis from cholesterol. In addition, circulating steroid precursors can be metabolized further in these organs or in peripheral tissues, including the liver, adipose tissue stroma, and the pilosebaceous unit (PSU) in skin, to more potent androgens (e.g., the conversion of testosterone to dihydrotestosterone [DHT]), to estrogens via the action of aromatase, or they can be inactivated and readied for excretion (Fig. 37.2). The origins of the principal circulating plasma androgens in pre- and postmenopausal women are summarized in Table 37.1. Androstenedione is the most important precursor of testosterone and DHT, while dehydroepiandrosterone (DHEA) accounts for only 5% to 13% of circulating testosterone in normal women.

FIG. 37.1. Pathways of androgen synthesis. The ovary, the testis, and the adrenal gland produce six common core steroids. The core d5 steroids are pregnenolone, 17-hydroxypregnenolone, and dehydroepiandrosterone. The core d4 steroids are progesterone, 17-hydroxyprogesterone, and androstenedione (androstene-3,17-dione). The core steroids are important precursors for the production of sex steroids, glucocorticoids, and mineralocorticoids.

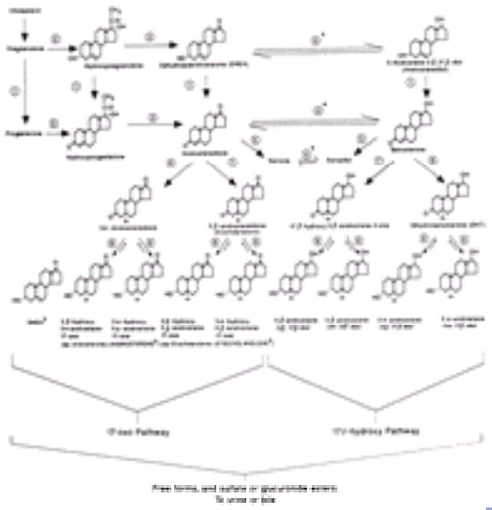

FIG. 37.2. Principal pathways of androgen metabolism. Enzymes: *1*, 3ß-hydroxysteroid dehydrogenase; *2*, 17ß-hydroxylase; *3*, 17,20-lyase (17,20-desmolase); *4*, 17ß-hydroxysteroid dehydrogenase (17-keto reductase); *5*, aromatase; *6*, 5a-reductase; *7*, 5ß-reductase; *8*, 3ß-oxoreductase; and *9*, 3a-oxoreductase. **a:** In the gonads the 17ß-hydroxysteroid dehydrogenase reaction predominantly produces 17ß-dehydrogenated products (androstenediol and testosterone), while the reverse is true in peripheral tissues. **b:** Aldosterone, etiocholanolone, and dehydroepiandrosterone are the principal urinary metabolites of androgens. (From Azziz R. Reproductive endocrinologic alterations in female asymptomatic obesity. *Fertil Steril* 1989;52:703–725, with permission.)

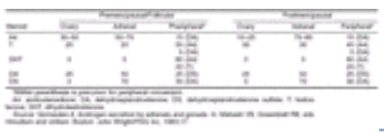

TABLE 37.1. *Percent origin of androgens in women*

Androgens, either directly or through metabolites, can act systemically in a classic endocrine fashion, or locally in a paracrine and intracrine fashion (e.g., in the PSU). Androgens exert their genomic effects through interaction with the androgen receptor, a member of the nuclear receptor superfamily. The unbound androgen receptor is a cytoplasmic protein and, upon ligand binding, it translocates into the nucleus. In the nucleus it influences the transcription of target genes through a complex process which includes interactions with other transcription factors and coactivators. As noted, androgens can also exert their effects indirectly, though metabolites such as the aromatization to estrogens.

Androgen Clearance

The clearance of androgens is accomplished by hepatic extraction and peripheral metabolism, which are highly dependent on the unbound portion of circulating steroid. Approximately 10% of testosterone and 50% of androstenedione are metabolized peripherally in women. Clearance of androgens by the hepatic splanchnic circulation involves mainly catabolism via 5a- and 5ß-reductase. Androgen metabolites are further conjugated by the liver (95% glucuronic and 5% sulfuric), facilitating their urinary excretion (see Fig. 37.2). Some 15% of androgen sulfates are excreted in bile, of which 80% are reabsorbed in the gut. Peripheral metabolism of androgens also occurs in the various target tissues including skin, muscle, brain, and adipose tissue. A-ring (aromatization), 17ß-hydroxysteroid dehydrogenization, 5a- and 5ß- A-ring reduction, and 3a- and 3ß-oxo-reduction give rise to potent androgens such as DHT, or to weaker metabolites such as 5a-androstane-3a,17ß-diol, androsterone, and etiocholanolone. These are subsequently conjugated by the liver and excreted in the urine and bile. Measurement of these metabolites (e.g., 3a-androstanediol glucuronide) was proposed as a circulating marker of peripheral androgen excess, but its clinical use currently is negligible.

Bioavailability of Androgens

Androgens circulate in the body bound by a variety of proteins, including albumin, cortisol-binding globulin, acid a2-glycoprotein and, most important, sex hormone binding globulin (SHBG, formerly known as testosterone or testosterone-estradiol binding globulin [TeBG]). Because of its much higher concentration and total amount, albumin has a much greater overall binding capacity for androgens than SHBG, but the affinity of androgens for SHBG is several orders of magnitude higher, thus binding the largest portion of circulating testosterone. Androgens bound to SHBG are essentially not bioavailable, although those complexed with albumin are more readily available for tissue interaction due to the much lower affinity of this protein for these steroids. The liver produces SHBG, and production is stimulated by estrogen, particularly oral forms; and inhibited by androgens, and most importantly, insulin. These factors lead to lower levels of SHBG and higher bioavailable androgens in men and in women with androgen excess disorders compared to healthy women.

As noted in the following sections, the production, metabolism, and circulating levels of androgens are affected by age, menopausal status, and the presence of obesity, among other factors.

Androgens, Age, and Menopause

Androgen metabolism and circulating levels can be significantly altered by age. Most notably, adrenal androgen production clearly decreases with age in premenopausal and postmenopausal women. Serum dehydroepiandrosterone sulfate (DHEA-S) concentrations decrease linearly with age beginning at about 20 years, independent of menopause. An impaired secretion of 17 a-hydroxyprogesterone, 17 a-hydroxypregnenolone, DHEA, and androstenedione has also been observed in postmenopausal women following acute adrenal stimulation. In normal postmenopausal women plasma concentrations of androstenedione are about half that observed in premenopausal women, although there is no observable difference in the clearance rate of this steroid between premenopausal and postmenopausal women. After menopause androstenedione levels continue to gradually decrease with age. Testosterone levels are less affected by age and menopause, and it is clear that the ovary continues to produce a significant amount of testosterone in postmenopause. Most of the decrease in circulating testosterone with age and menopause is explained by the lower androstenedione levels.

Androgens and Obesity

In eumenorrheic obesity the production rate and metabolic clearance rate (MCR) of ovarian and adrenal-secreted androgens are increased while circulating levels remain normal. The increased MCR may be due to an obesity-related decrease in the plasma concentration of the carrier protein SHBG. Steroid sequestration by fat may also increase steroid clearance, leading to an extremely large pool of sex hormones in obese individuals. Adipose tissue metabolism of steroids, including aromatization and 17ß-hydroxysteroid dehydrogenation, also contributes to the increased MCR of androgens while alterations in hepatic conjugation and extraction can also be a contributing factor. The increased ovarian and adrenal production noted in obesity may reflect changes in the intraglandular or circulating concentration of androgens, estrogens, prolactin, growth hormone and other growth factors, and most importantly, insulin. Although weight reduction corrects any abnormality noted in steroid levels, it is not known whether the elevated production and MCRs of androgens also normalize following weight reduction.

The degree of androgen excess that can result in the appearance of clinical features most commonly has its source in the increased production (or intake) of androgens, which can be altered by age and degree of obesity. However, other factors such as the potency of the androgen produced (DHT>testosterone>androstenedione>DHEA), the amount of androgen that is free or weakly bound in serum (i.e., the amount bioavailable), and the degree and type of central and peripheral metabolism also play a role in determining and modifying the phenotype of androgen excess.

SIGNS AND SYMPTOMS OF ANDROGEN EXCESS

Androgen excess results in various clinical signs and symptoms, including abnormalities of the PSU (hirsutism, acne, and androgenic alopecia), the hypothalamic–pituitary–ovarian axis (i.e., ovulatory and menstrual dysfunction), and the hypothalamic–pituitary–adrenal axis (adrenal androgen excess). If the androgen excess is very severe, virilization or masculinization can also be apparent.

Androgen Excess and the Pilosebaceous Unit

The pilosebaceous unit (PSU) is the common skin structure that gives rise to both hair follicles and sebaceous glands, which are found everywhere on the body except

the palms, soles, and lips. The density is greatest on the face and scalp (400–800 glands/cm ^{2}) and lowest on the extremities (50 glands/cm ^{2}). The number of PSUs does not increase after birth (about 5 million), but they can become more prominent through activation and differentiation. Generally, three phases of the hair growth cycle can be considered. The period of active growth is termed anagen, after which the hair follicle enters a resting or catagen phase of varying length of time (Fig. 37.3). During this transition the hair shaft separates from the dermal papillae at the base. The separated hair is then shed during the telogen phase. The period of anagen varies from 3 years on the scalp to 4 months on the face. For corresponding parts of the skin, men have longer anagen phases than women do, which may be partially due to their higher circulating androgen levels.

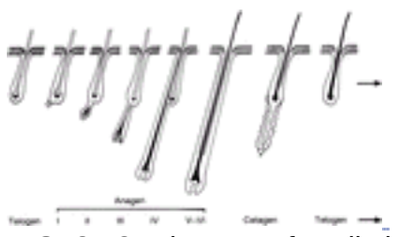

FIG. 37.3. Diagram of cyclic hair follicles, a club hair (white) in old telogen and early anagen (I–IV) follicles, and a new hair (black) in new anagen (V–VI) follicles. (From: Uno H. *Seminars in reproductive endocrinology.* Vol 4. New York: Thieme, 1986, with permission.)

The effects of androgens are most visible on the PSU. Androgens stimulate the transformation of fine, unpigmented vellus hairs to coarse, pigmented, thickened terminal hairs, a process known as *terminalization*, in skin areas sensitive to the effects of androgens. The peripheral effects of androgens are determined primarily by the intracellular actions of the enzymes 17ß-ketosteroid reductase (converting androstenedione to testosterone) and 5a-reductase (converting testosterone to the more potent androgen, DHT), and the androgen receptor content. Before puberty body hair is primarily composed of fine, short unpigmented vellus hairs. The increase in androgen production observed with pubertal development transforms some of these, mainly in androgen-sensitive areas of skin such as the axilla and the genital triangle, into the coarser, longer, pigmented terminal hairs. It should be noted that not all skin areas are androgen-sensitive. For example, the development of terminal hairs in body areas such as the eyebrows, eyelashes, and the temporal and occipital scalp is relatively androgen-independent.

Excess androgen-dependent hair growth present in women can result in clinically evident hirsutism (see the following section). Paradoxically, androgens can exert opposite effects on the hair follicles of the scalp, causing conversion of terminal follicles to vellus-like follicles, a process termed *miniaturization.* This effect may lead to the development of androgenic alopecia in women (see " Androgenic Alopecia") or male-pattern baldness characterized by frontal and sagittal scalp hair loss. Androgens can also cause increased sebum production and abnormal keratinization of the PSU, contributing to the development of seborrhea and acne evident at puberty and in women with androgen excess. Ethnic and genetic differences can modify the effects of androgens on skin, as demonstrated by the lesser degree of hirsutism present in Asian women with PCOS (Fig. 37.4).

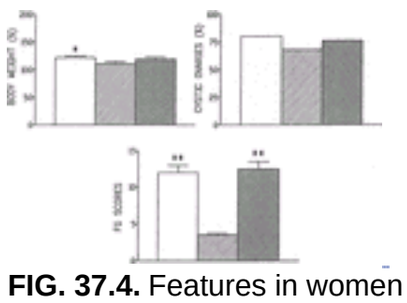

FIG. 37.4. Features in women with polycystic ovary syndrome (75 women, 25 each from the United States, Italy, and Japan). Note the much lower prevalence of hirsutism among Japanese women. (From Carmina et al, *Am J Obstet Gynecol* 1992;167:1807–1812, with permission.)

Hirsutism Hirsutism is the presence of terminal (coarse) hairs in females in a male-like pattern. Excessive growth of coarse hairs of the lower forearms and lower legs alone does not constitute hirsutism, although women suffering from hirsutism may note an increase in the pigmentation and growth rate of hairs on these body areas. Hirsutism should be viewed much as polycystic ovaries, as a sign rather than a diagnosis. Most commonly hirsutism is associated with androgen excess. Although the term "idiopathic hirsutism" was coined to identify the presence of hirsutism without other identifiable cause or abnormality, this may actually reflect our limited ability to assess androgen action in the peripheral compartment or even in the circulation (see Evaluation of Androgen Excess).
Acne The PSU, in addition to the hair follicle, also contains a sebaceous gland that produces an oily protective secretion, sebum. The excessive production of sebum, in response to androgen action, may lead to oily skin, clogged hair follicles, folliculitis, and the development of acne. Elevations in serum androgen levels have been noted in patients with acne, particularly in those with concurrent hirsutism, although not all investigators agree. Although the persistence or appearance of acne in adulthood has been suggested to be more frequently associated with androgen excess, we observed evidence of hyperandrogenemia in the majority of 30 consecutive nonhirsute, acneic patients regardless of age. Some investigators have observed that while serum androgen levels may be relatively normal in acneic patients, the conversion of androgens to DHT via 5a-reductase was increased in the affected skin. These data suggest that androgen suppression may be useful in treating acne in many of these patients, and it is clear that acne frequently improves following treatment with antiandrogens, oral contraceptives, or glucocorticoid suppression. Thus, empirical treatment with oral contraceptives, or even glucocorticoids, may be justified in acneic patients without other evidence of overt androgen excess.
Androgenic Alopecia Scalp hair loss as a consequence of androgen excess can take two forms. In severe cases, where massive androgen excess and virilization/masculinization are present, patients can demonstrate the typical pattern of balding found in men (i.e., premature male-pattern balding). More common, however, is the so-called androgenic (also termed *androgenetic*, as an inherited etiology is often suspected) alopecia of women (i.e., female-pattern balding). In female androgenic alopecia a diffuse thinning of hair throughout the sagittal scalp is primarily noted and approximately 40% of women with androgenic alopecia have some form of hyperandrogenemia. However, if only nonhirsute women with androgenic alopecia are considered, then only 20% of these patients are found to be hyperandrogenemic.

Androgens and Hypothalamic–Pituitary–Ovarian Axis Dysfunction

Androgens, indirectly, through conversion to estrogens, and directly may alter the secretion of gonadotropins in women. However in most patients without severe forms of androgen excess, the direct effect of androgens on the hypothalamic–pituitary–ovarian axis, independent of their aromatization to estrogens, appears to be limited. Excessive androgen levels may also directly inhibit follicular development at the ovarian level, which may result in the accumulation of multiple small cysts within the ovarian cortex, the so-called "polycystic" ovary.

Androgens and Hypothalamic–Pituitary–Adrenal Axis Dysfunction

Adrenal androgen excess (i.e., elevated levels of DHEA and DHEA-S, and of the adrenal fraction of androstenedione) is a concomitant finding in many women with androgen excess. However, it is also possible that extraadrenal androgens (e.g., ovarian) may alter adrenocortical steroidogenesis and androgen secretion. For example, a 20% to 25% decrease in mean DHEA-S levels follows long-acting gonadotropin-releasing hormone-a (GnRH-a) suppression in women with PCOS with elevated levels of this adrenal androgen, although elevated adrenal androgen levels in these women rarely normalize with GnRH-a suppression. Thus, it appears that the secretion of adrenal androgen can be increased by extraadrenal hyperandrogenemia, although the clinical relevance of such an effect is unclear.

Virilization and Masculinization

Virilization includes the appearance of sagittal and frontal balding, clitoromegaly, and severe hirsutism. Furthermore, if androgen levels are extremely elevated for a substantial period of time the features of virilization may be accompanied by masculinization of the body habitus, with atrophy of the breasts, an increase in muscle mass, a redistribution of body fat, and a deepening of the voice. Premenopausal patients with virilization or masculinization are almost always amenorrheic. In general, virilization or masculinization should raise the suspicion of an androgen-secreting neoplasm or classic (but not nonclassic, as discussed later) adrenal hyperplasia. Occasionally girls suffering from severe insulin-resistance syndrome (discussed later in the chapter) may exhibit a moderate degree of virilization.

THE POLYCYSTIC OVARY SYNDROME

By far the most common, although the least understood, cause of androgen excess is polycystic ovary syndrome (PCOS), accounting for a vast majority of patients seen. PCOS affects 4% to 6% of women in the developed world. There is no firm consensus as to the definition of PCOS; criteria arising from a 1990 National

Institutes of Health conference on the subject have proven clinically and investigationally useful. These criteria note that PCOS should include the presence of:

- clinical or biochemical evidence of hyperandrogenism
- ovulatory dysfunction
- the exclusion of other causes of androgen excess or ovulatory dysfunction, such as including adrenal hyperplasia, hyperprolactinemia, thyroid dysfunction, and androgen-secreting neoplasms.

Thus, PCOS represents unexplained functional hyperandrogenic chronic anovulation and is a diagnosis of exclusion.

Other diagnostic criteria for PCOS have been proposed, including the finding of a polycystic ovary morphology on ultrasound, with multiple 2-to 8-mm subcapsular preantral follicles forming a “black pearl necklace” sign (Fig. 37.5). However, it should be noted that “polycystic ovaries” on sonography or at pathology are simply a sign of androgen excess and possibly PCOS. For example, this ovarian morphology is frequently seen in patients with adrenal hyperplasia (Table 37.2), and up to 25% of unselected women have polycystic ovaries on ultrasound, many of which are normoandrogenic with regular menstrual cycles. Hence, we consider the appearance of polycystic ovaries, particularly on sonographic exam, to be a sign, albeit nondiagnostic, of androgen excess and PCOS.

FIG. 37.5. Transvaginal ultrasound visualization of a polycystic ovary. Note the string of subcapsular follicles measuring 2 to 8 mm in diameter, with increased central stromal mass.

Hyperandrogenism without insulin resistance
Steroidogenic enzyme deficiencies
Congenital adrenal hyperplasia
Aromatase deficiency
Androgen-secreting tumors
Ovarian
Adrenal
Exogenous androgens
Anabolic steroids
Transsexual hormone replacement
Other
Acne
Idiopathic hirsutism
Hyperandrogenism and insulin resistance
Congenital
Type A syndrome
Type B syndrome
Leprechaunism
Lipoatrophic diabetes
Rabson-Mendenall syndrome
Polycystic ovary syndrome
Acquired
Cushing’s syndrome
Insulin resistance
Glycogen storage diseases
Type 2 diabetes
Other
Central nervous system
Trauma/lesions
Hyperprolactinemia
Nonhormonal medications
Valproate
Hereditary angioedema
Bulimia
Idiopathic (includes normoandrogenic women with cyclic menses)

TABLE 37.2. *Syndromes or diseases entities associated with polycystic ovaries*

Clinical, Biochemical, and Metabolic Features of PCOS

Approximately 70% to 80% of women with PCOS demonstrate frank elevations in circulating androgens, particularly free testosterone, and 25% to 50% will have elevated levels of the adrenal androgen metabolite, DHEA-S. Prolactin levels are usually normal, although they may be slightly elevated (generally <40 ng/mL) in a small fraction of patients. The luteinizing hormone/follicle-stimulating hormone (LH/FSH) ratio is greater than 2 or 3 to 1 in approximately 60% of these patients. As noted, the ovaries of about 70% of patients with PCOS usually contain intermediate and atretic follicles measuring 2 to 8 mm in diameter, resulting in a “polycystic appearance” at sonography (see Fig. 37.4, Fig. 37.5). About 60% of patients with PCOS are obese, although significant fractions are nonobese.

While not part of the diagnostic criterion, many women with PCOS appear to be uniquely insulin-resistant. Approximately 50% to 70% of patients with PCOS demonstrate profound insulin resistance and secondary hyperinsulinemia, independent of body weight. In PCOS, insulin resistance usually refers to the impaired action of insulin in stimulating glucose transport and in inhibiting lipolysis in adipocytes. Insulin resistance in PCOS appears to be due to an intracellular defect of insulin signaling.

The compensatory hyperinsulinemia, resulting from the underlying insulin resistance, augments the stimulatory action of LH on the growth and androgen secretion of ovarian thecal cells, while inhibiting the hepatic production of SHBG. Treatment of patients with PCOS with insulin sensitizers may result in lower circulating levels of LH suggesting that insulin resistance, or more likely hyperinsulinemia, is in part responsible for the gonadotropic abnormalities observed in many women with PCOS. Since insulin is also a mitogenic hormone, the extremely elevated insulin levels may lead to hyperplasia of the basal layers of the epidermis, resulting in the development of acanthosis nigricans (a velvety, hyperpigmented change of the crease areas of the skin) (Fig. 37.6), and acrochordons. Overall, insulin resistance and secondary hyperinsulinemia affects a large fraction of patients with PCOS, and may cause or augment the androgen excess of these patients.

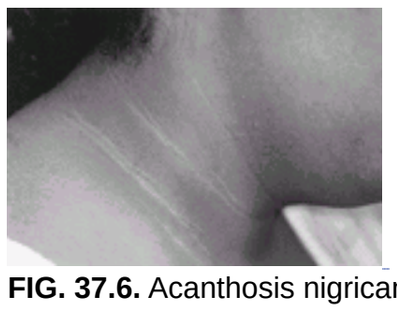

FIG. 37.6. Acanthosis nigricans on the nape of the neck: a sign of hyperinsulinemia.

Sequelae of PCOS

Clinically evident PCOS tends to develop shortly after menarche and persists through most of the reproductive life. Nonetheless, some patients may present initially in the prepuberty with premature adrenarche, with affected girls displaying hyperinsulinemia, elevated DHEA-S levels, and postmenarche oligomenorrhea. At the other end of the reproductive spectrum, both menstrual irregularity and hyperandrogenemia appear to normalize as women with PCOS approach perimenopause. Although the endocrine and reproductive features of the disorder may improve with age, the associated metabolic abnormalities, particularly glucose intolerance, may actually worsen with age.

Infertility-Chronic Anovulation One of the most common reasons that women with PCOS present to the gynecologist is due to infertility secondary to chronic anovulation. These women are not sterile, but subfertile due to the infrequency and unpredictability of their ovulation. As a general rule, women with PCOS represent one of the most difficult groups in which to safely induce ovulation. Many women with PCOS are unresponsive or resistant to ovulation induction with clomiphene citrate and may have an inappropriate or exaggerated response to the administration of human menopausal gonadotropins (menotropins). In part, the abnormal response to

ovulatory agents of patients with PCOS relates to their degree of hyperinsulinemia and obesity, and to abnormalities of the intraovarian hormonal milieu and the increased number of preantral follicles. Women with PCOS are especially at increased risk for multiple gestation and developing the hyperstimulation syndrome—a syndrome of massive enlargement of the ovaries, development of rapid and symptomatic ascites, intravascular contraction, hypercoagulability, and systemic organ dysfunction. These complications generally occur following treatment with gonadootropins, although ovarian hyperstimulation has even been reported in women with PCOS conceiving a singleton pregnancy spontaneously, or after clomiphene citrate or pulsatile GnRH use.

Gynecologic Cancers Many gynecologic cancers have been reported to be more common in women with PCOS including ovarian, breast, and endometrial carcinomas. However, the best case of an association between PCOS and cancer can be made for endometrial cancer, as many risk factors for this cancer, including obesity, chronic anovulation, and hyperinsulinemia, are present in the patient with PCOS. Patients with endometrial cancer have significantly higher body mass index (BMI) and frequency of diabetes hypertension, hirsutism, nulliparity, and infertility than controls.

Type II Diabetes Mellitus The inherent insulin resistance present in many with PCOS, aggravated by the high prevalence of obesity in these individuals, places these women at increased risk for impaired glucose tolerance and type 2 DM. About 30% to 40% of obese women of reproductive age with PCOS have been found to have impaired glucose tolerance (IGT), and about 10% have frank type 2 DM based on a 2-hour glucose level greater than 200 mg/dL. Of note is that only a small fraction of women with PCOS with either IGT or type 2 DM display fasting hyperglycemia consistent with diabetes by the 1997 American Diabetes Association criterion (fasting glucose =126 mg/dL) (Fig. 37.7). The conversion rate to glucose intolerance over time is unknown, which makes recommendations for frequency of screening for glucose intolerance difficult. However, the level of insulin resistance found in women with PCOS based on dynamic measures of insulin action has in other populations (i.e., children of parents with diabetes) been associated with a marked increased risk of developing type 2 DM.

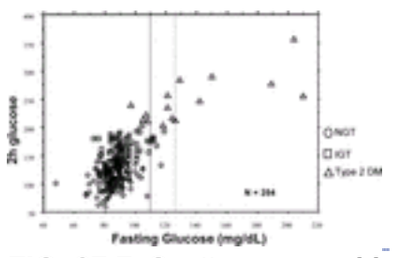

FIG. 37.7. Scatterogram of fasting blood glucose levels versus 2-hour postchallenge glucose levels in 254 women with polycystic ovary syndrome (PCOS). Points on the graph are coded to reflect the World Health Organization status based on postchallenge glucose levels. *A*, 140 to 199 mg/dL = impaired glucose tolerance. The *dashed vertical line* is the threshold (110 mg/dL) for the diagnosis of impaired fasting glucose according to the 1997 American Diabetes Association criteria. The *solid vertical line* (126 mg/dL) is the threshold for the diagnosis of type 2 diabetes mellitus by the same criteria. (From Legro RS, Kunselman AR, Dodson WC, et al. Prevalence and predictors of risk for type 2 diabetes mellitus and impaired glucose tolerance in polycystic ovary syndrome: a prospective, controlled study in 254 affected women. J Clin Endocrinol Metab 1999;84:165–169, with permission.)

Cardiovascular Disease Many women with PCOS appear to form a subset of the metabolic syndrome first described by Reaven (i.e., syndrome X or insulin-resistance syndrome) consisting of insulin resistance, hypertension, dyslipidemia, glucose intolerance, and CVD. The mechanisms underlying the relationship between the insulin resistance/hyperinsulinemia and hypertension are unclear, but may include sodium retention, overactivity of the sympathetic nervous system, impairment of membrane transport, and stimulation of vascular smooth muscle cells. Other effects of hyperinsulinemia and insulin resistance include the development of an atherogenic plasma lipid profile due to insulin enhancement of synthesis of very-low-density lipoproteins and hypertriglyceridemia. Insulin also causes the proliferation of smooth muscle cells and stimulation of collagen synthesis in small arterioles. These effects, in combination with insulin-induced growth factor elaboration and inhibition of regression of lipid plaques, contribute to the development of atherosclerosis and the resultant CVD. Many women with PCOS have significant dyslipidemia, with lower high-density lipoprotein (HDL), and higher triglyceride and low-density lipoprotein (LDL) levels than age, sex, and weight-matched controls. Studies have documented other interim risk factors, such as increased carotid artery intimal thickness, to suggest that these women have evidence of atherosclerotic disease earlier and at a more advanced stage than control women. However, an increase in actual cardiovascular events in women with PCOS, such as myocardial infarction, has not been observed, although a higher number of nonfatal cerebrovascular disease events have been noted. We should note that there are a number of features of PCOS that do not fully fit the definition of the metabolic syndrome. For example, although dyslipidemia is part of the metabolic syndrome, the elevation in LDL levels noted in PCOS is not one of the characteristic findings. Additionally, although the risk of developing hypertension later in life appears to be higher in patients with PCOS, hypertension has not been associated with PCOS in women of reproductive age.

OTHER ANDROGEN EXCESS DISORDERS

Other major androgen excess disorders include the HAIRAN syndrome, 21-hydroxylase (21-OH) deficient NCAH, and very rarely, ovarian or adrenal androgen-secreting neoplasms.

The HAIRAN Syndrome

The HAIRAN (hyperandrogenic-insulin resistant-acanthosis nigricans) syndrome is an inherited disorder of severe insulin resistance, distinct from PCOS, and which actually includes many different genetic syndromes. Although single-point mutations of the insulin receptor are rare among these patients, some patients with this syndrome may actually suffer from a form of the familial lipodystrophy syndrome. Approximately 3% of hyperandrogenic women suffer from these disorders. These patients are diagnosed by having extremely high circulating levels of basal (>80 µU/mL) or glucose-stimulated (>300–500 µU/mL) insulin levels, although exact diagnostic criteria are lacking, in part due to the heterogeneity of the syndrome. Patients can be severely hyperandrogenemic, with testosterone levels reminiscent of patients with androgen-secreting neoplasms, resulting in the development of severe hirsutism and even virilization. In addition to significant hirsutism, patients also develop the characteristic dermatologic finding of acanthosis nigricans (see Fig. 37.6). Because of their high androgen levels, gonadotropin levels in these patients may be somewhat suppressed resulting in persistent endometrial atrophy and amenorrhea in spite of the administration of a cyclic progestogen or an oral contraceptive.

Because of the mitogenic effect of insulin on ovarian theca cells, the ovaries of many patients with the HAIRAN syndrome will become hyperthecotic. On ultrasound and histology the ovaries morphologically have a paucity of cortical cysts, and demonstrate a thickened and enlarged theca/stroma compartment. In addition, these patients are at significant risk for dyslipidemia, type 2 DM, hypertension, and CVD. These patients can be particularly difficult to treat although the selected use of long-acting GnRH analogs has been promising. Some patients may necessitate surgery, either ovarian wedge resection or oophorectomy.

Nonclassic Adrenal Hyperplasia

Nonclassic adrenal hyperplasia (NCAH), also referred to as late-onset congenital adrenal hyperplasia, is a homozygous recessive disorder due to mutations in the *CYP21* gene which results in an abnormal (or absent) cytochrome P450c21 with relatively deficient 21-OH activity. Overall, between 1% and 8% of women with androgen excess have 21-OH–deficient NCAH depending on ethnicity, with the highest rates reported among Ashkenazi Jews. Due to the lack of 21-hydroxylation the progestogenic precursors to cortisol, 17 a-hydroxyprogesterone (17 a-HP) and to a certain degree 17 a-hydroxypregnenolone, accumulate in excess. These steroids are then metabolized to C19 products, principally androstenedione and testosterone (see Fig. 37.1, Fig. 37.2). However, clinically and biochemically these patients are very difficult to distinguish from other hyperandrogenic patients, particularly patients with PCOS. Patients with NCAH may present only with persistent acne or may have moderate degrees of hirsutism and oligoamenorrhea. Frank virilization or even severe hirsutism is relatively rare. The levels of the exclusive adrenal androgen metabolite DHEA-S are not any higher than that of other hyperandrogenic women.

Although the frequency is relatively low, all patients with unexplained androgen excess should be screened for NCAH due to *CYP21* mutations, as this diagnosis has a different prognosis, a different treatment regimen, and requires genetic counseling regarding the risks of congenital transmission. The measurement of a basal 17 a-HP in the follicular phase and in the morning can be used to screen for this disorder. In addition, these patients can be treated with corticosteroid replacement, although many of the patients who are diagnosed in adulthood tend to also demonstrate a PCOS-like pattern requiring additional ovarian suppression.

While it is theoretically possible that NCAH may be due to mutations in other genes determining steroidogenic enzymes, such CYP11B1 (encoding for P450c11a and 11ß-hydroxylase (CYP11B1) or HSD3B (for 3ß-hydroxysteroid dehydrogenase), mutations in the genes coding for these enzymes are rarely noted in adult women presenting with androgen excess.

Androgen-Secreting Tumors

Androgen-secreting neoplasms are relatively rare, affecting between 1 of 300 and 1 of 1,000 hirsute patients. These tumors usually originate in the ovary, and rarely the adrenal cortex. The most common androgen-producing tumor in a premenopausal woman is a Sertoli-Leydig cell tumor, with thecomas and hilus cell tumors being less frequent. Hilus cell tumors are often small, and can be less than 1 cm in diameter, theoretically below the range of ultrasound visualization. Another rare neoplasm may be a granulosa cell tumor, 10% of which primarily secrete androgens instead of estrogens. Also, any large tumor within the body of the ovary (i.e., benign cystic teratomas, dysgerminomas, epithelial tumors) can produce androgens indirectly by causing hyperplasia of the surrounding normal stroma. Fortunately, the vast majority of ovarian androgen-secreting neoplasms are benign.

Alternatively, adrenal androgen-secreting tumors are generally malignant (i.e., adrenocortical carcinoma) and associated with a high mortality rate, although androgen-secreting adrenal adenomas have also been reported. Fortunately, adrenal androgen-secreting neoplasms are rare with an estimated incidence of two cases per one million persons per year. The age of onset in adults peaks in the fifth decade. Virilization can accompany both tumors primarily producing androgens and tumors primarily producing cortisol (Cushing syndrome). A long history of symptoms, as in the case with an ovarian tumor does not exclude the presence of an adrenocortical neoplasm.

The presence of androgen-secreting neoplasms should be suspected when the onset of androgenic symptoms is rapid and sudden, when androgen excess initially presents in late life, when they lead to virilization and masculinization, or are associated with cushingoid features. Nonetheless, it should be remembered that some of younger patients with virilization suspected of having an androgen-secreting neoplasm actually suffer from the HAIRAN syndrome (discussed earlier). Suppression and stimulation tests can be misleading and are not encouraged for the diagnosis of these neoplasias. Overall, the single best predictor of an androgen-producing tumor is clinical presentation, and not biochemical markers. For example, in one study we noted that the positive predictive value of a repeat total testosterone above 250 ng/dL was only 9%, as most women with total testosterone levels above this cutoff have other abnormalities, such as the HAIRAN syndrome or PCOS.

Rare Causes of Androgen Excess

Clinical signs of androgen excess may also result from the presence a corticotropin-secreting tumor, due to either a pituitary adenoma (i.e., Cushing's disease) or an extrapituitary (ectopic) source, although patients are usually also cushingoid. In one study of young women with Cushing's syndrome all had stigmata of hyperandrogenism (hirsutism, acne, or balding), but only 70% had oligomenorrhea. However, as Cushing's syndrome has an extremely low prevalence in the population (1 in a million) and screening tests do not have 100% sensitivity/specificity, routine screening of all women with androgen excess for Cushing's syndrome is not indicated. Nonetheless, clinical signs more commonly found in Cushing's syndrome, such as ecchymoses, proximal muscle weakness, centripetal reddened striae, facial rubor and swelling, and perhaps hypertension and glucose intolerance should signal screening tests. Screening for cortisol excess can be conducted with a 24-hour urine collection for free cortisol.

The use of exogenous androgens, often found among body builders, or the excessive use of androgens among postmenopausal women should also figure in the differential diagnosis. Severe hirsutism, and even virilization, that begins during pregnancy has its own unique differential including benign ovarian sources such as hyperreactio luteinalis (i.e., gestational ovarian theca–lutein cysts) or luteomas, and extremely rare fetoplacental sources, such as aromatase deficiency resulting in androgen excess due to the placental inability to convert precursor androgens into estrogens. Finally, gonadal dysgenesis associated with an abnormal Y chromosome can initially present as peripubertal androgenization.

IDIOPATHIC HIRSUTISM

Although idiopathic hirsutism (IH) is not actually an androgen excess disorder, it is included among them and should be considered in the differential diagnosis of androgen excess. Overall, approximately 5% to 15% of hirsute women will have the diagnosis of “idiopathic” hirsutism. The diagnosis of IH is, by exclusion, made in a patient who is obviously hirsute, but in whom the circulating androgens and ovulatory function appear to be normal, and no other disorders can be identified. While some clinicians use regular menses as diagnostic of normal ovulatory function, we should note that approximately 40% of eumenorrheic hirsute women are actually anovulatory, and hence do not suffer from IH. Although biochemically these patients do not have an obvious elevation in circulating androgen levels, it also is likely that many of these patients simply demonstrate degrees of hyperandrogenemia that may not be detectable with routine clinical androgen assays. Nonetheless, in some of these women the 5a-reductase activity in the skin and hair follicles is probably overactive and leads to hirsutism in spite of normal circulating androgen levels.

EVALUATION OF ANDROGEN EXCESS

The history and physical examination are essential to making a diagnosis of the underlying cause of androgen excess. History taking should focus on the onset and duration of the various stigmata of androgen excess, should include a thorough menstrual history, and a discussion of concomitant medications. The physical examination should carefully assess the patient for cushingoid features, acanthosis nigricans, balding, acne, and degree and type of body hair distribution. One commonly used scale to score the degree of excess hair growth is based on a modification of the Ferriman-Gallwey scale (Fig. 37.8). Signs of virilization and masculinization should be sought, although their recognition is usually obvious. Clitoromegaly is usually defined as a clitoral index greater than 35 mm^2, where the clitoral index is the product of the sagittal and transverse diameters of the glans of the clitoris in millimeters. In normal women these diameters are in the range of 5 mm.

FIG. 37.8. Modified Ferriman-Gallwey scale for assessing hirsutism. (Modified from Hatch, et al. Hirsutism: implications, etiology, and management. *Am J Obstet Gynecol* 1981;140:815–830.)

Evidence and risk factors for insulin resistance should be sought out as they are critical to the long-term health of the women affected. Family history of diabetes and CVD, especially of first-degree relatives with premature-onset heart disease (males <55 years and females <65 years), is an important part of the assessment. Lifestyle factors such as smoking, alcohol consumption, and diet and exercise histories should be recorded. Signs of insulin resistance on physical exam such as obesity, particularly with a centripetal fat distribution, and the presence of acanthosis nigricans and acrochordons should be recorded. Acanthosis nigricans is principally noted in most crural areas of the body, including the back of the neck, the axilla, underneath the breasts, and even on the vulva.

Weight should be corrected for height by using the BMI (divide weight in kilograms by the square of the height in meters, i.e., kg/m^2). However, the pattern of fat distribution rather than BMI seems to be most predictive of morbidity and mortality. In women a central or abdominal distribution of adiposity fat (the so-called apple-shaped or android obesity) has been associated with an increased risk for CVD and with an increased index of death from all causes. Fat distribution is most easily assessed using the waist-to-hip ratio (WHR), obtained by measuring the circumferences at the narrowest point of the abdomen (i.e., the abdominal measure), generally immediately above the umbilicus, and the widest part of the hips (i.e., the hip measures). Values greater than 0.72 (primarily android fat distribution) are considered abnormal but increased morbidity and mortality becomes more noticeable at values greater than 1.0. In women, the android pattern of obesity has been associated with abnormal lipid profiles and increased insulin resistance compared to the gynecoid pattern.

The laboratory evaluation should have the objective of excluding related and specific disorders and, if necessary, providing confirmation of androgen excess. As well, the presence of metabolic abnormalities, particularly in patients with PCOS or the HAIRAN syndrome, should be sought out.

Laboratory Evaluation of Androgen Excess

Specific related disorders that should be excluded prior to diagnosis of androgen excess are thyroid dysfunction, hyperprolactinemia, NCAH, the HAIRAN syndrome, and androgen-secreting tumors. Thyroid dysfunction and NCAH are ruled out by measuring a third generation thyroid-stimulating hormone (TSH) and a basal 17- aHP level, the latter measured in the follicular phase of the menstrual cycle. If the 17-HP level is greater than 2 ng/mL, the patient should undergo an acute adrenal stimulation test to exclude 21-hydroxylase deficient NCAH. If the 17-HP level 60 minutes following corticotropin administration is greater than 10 ng/mL, the diagnosis of 21-OH–deficient NCAH is established.

As noted previously, hirsute women claiming to have regular menstrual cycles should be evaluated for ovulatory dysfunction, most simply by obtaining a basal body temperature chart and a serum progesterone in the luteal phase (days 20–24) of the menstrual cycle. If the patient has ovulatory dysfunction, as evidenced by either a luteal progesterone level less than 4 ng/mL in a eumenorrheic patient, or because she has overt menstrual abnormalities, the diagnosis of PCOS should be entertained. In women with ovulatory dysfunction, serum prolactin and fasting insulin levels should also be obtained to exclude hyperprolactinemia and the HAIRAN syndrome, respectively. Androgen-secreting neoplasms are generally excluded by the history and physical exam. Rarely, a 24-hour urine free cortisol is required in a

patient with features suggestive of Cushing's syndrome.

The measurement of circulating androgen levels, including total and free testosterone, and DHEA-S is useful, primarily in the minimally or nonhirsute oligoovulatory patient, to exclude the presence of androgen excess as the cause of the ovulatory dysfunction. However, these measurements have limited diagnostic use in the patient who is frankly hirsute, and have a low positive predictive value for adrenal or ovarian androgen-secreting neoplasms.

Inappropriate gonadotropin secretion has been one of the characteristic signs of PCOS, and many clinicians have used elevated LH/FSH ratios of 2:1 or 3:1 as diagnostic criteria for PCOS. Nonetheless, because up to 50% of patients with PCOS may have a normal ratio, the LH and FSH are episodically secreted, and the LH/FSH ratios tend to normalize with increasing BMI, or alternatively with insulin-sensitizer therapy. Measuring gonadotropins is an insensitive marker of PCOS.

Laboratory Assessment for Metabolic Abnormalities

Metabolic abnormalities are common among women with PCOS, and occur in all patients with the HAIRAN syndrome. In patients with the HAIRAN syndrome the presence of insulin resistance is obvious, although this may not be the case in women with PCOS. Unfortunately, there are no accurate, inexpensive, or reproducible tests for clinically assessing insulin sensitivity. The standards are dynamic tests such as the euglycemic clamp and the frequently sampled intravenous glucose tolerance test (FSIVGTT). These assessments primarily determine insulin-mediated glucose uptake in the skeletal muscle, the primary tissue using circulating insulin. Insulin-mediated glucose uptake, however, is just one aspect of insulin's protean actions. While these methods are the most accurate for determining decreased sensitivity to insulin (or insulin resistance), they are too laborious and expensive to use for the routine clinical evaluation of insulin resistance.

A fasting glucose-to-insulin ratio of less than 4.5 may be a good marker of insulin resistance in obese women with PCOS. Although a fasting insulin level alone is often clinically useful in other non-PCOS populations, insulin levels, either fasting or postprandial, have only a moderate correlation with more detailed studies of insulin action, and are less useful in patients with impaired glucose tolerance or frank diabetes, due to deficiencies in insulin secretion. Most important, it is key to understand that there is a wide range of insulin sensitivities in normal populations, and that substantial overlap of even the most precise measure of insulin action between insulin-resistant and control populations is always present. As such, about 50% of obese women with PCOS may not have clinically recognizable insulin resistance on the basis of either fasting values or more dynamic test results. On an individual basis, therefore, it is often not possible to diagnose insulin resistance and a diagnostic trial with an insulin sensitizer should be considered.

Given the high prevalence of abnormalities in glucose tolerance, patients with PCOS or HAIRAN syndrome should be screened for IGT or frank diabetes with an oral glucose tolerance test (oGTT) using a 75-g glucose load. Considering the World Health Organization criteria, IGT is diagnosed by a 2-hour glucose of between 140 mg/dL and 199 mg/dL, while frank diabetes is diagnosed by 2-hour glucose during the oGTT =200 mg/dL. Abnormal oGTT results need to be repeated for confirmation. The development of glucose intolerance heralds ß-cell dysfunction with inadequate insulin secretion for the degree of reduced peripheral insulin sensitivity. The development of IGT is a clear risk factor for developing type 2 DM and may also be an independent risk factor for CVD, such as myocardial infarction and stroke.

Although no firm guidelines exist, obtaining a plasma lipid profile in patients with PCOS or the HAIRAN syndrome should be considered, particularly in women over the age of 35, those with a strong family history of diabetes or CVD, and those with significant insulin resistance.

Radiologic Imaging in the Evaluation of the Patient with Androgen Excess

Routine ultrasound of the pelvis in patients with androgen excess is probably not indicated. Polycystic ovaries can be noted with many of the androgen excess disorders and remain nonspecific (see Fig. 37.8). Nonetheless, the appearance of polycystic ovaries may be useful as a potential predictor for the development of ovarian hyperstimulation syndrome during ovulation induction. Furthermore, a transvaginal sonogram in obese individuals to properly examine the ovaries for pathologic masses may be appropriate. In cases where an androgen-secreting tumor is suspected, a computed tomography (CT) scan or magnetic resonance imaging (MRI) of the adrenals should be considered to exclude adrenal masses as small as 5 mm in diameter and detect bilateral adrenal hyperplasia in the event of a corticotropin-secreting tumor. However, about 2% of the population harbor a clinically insignificant adrenal adenoma (i.e., incidentaloma) making the finding of such an adrenal mass not diagnostic for an androgen-secreting adrenal tumor. Functional radiologic techniques such as selective venous catheterization or scintigraphy with iodomethyl-norcholesterol are rarely used for the localization of such tumors.

TREATMENT OF ANDROGEN EXCESS

Treatment of androgen excess tends to be symptom-based. In general, we can consider four different reasons for treatment including:

1. regulation of uterine bleeding, reducing the risk of endometrial hyperplasia and cancer, dysfunctional uterine bleeding (DUB), and secondary anemia
2. improvement of dermatologic abnormalities such as hirsutism, acne, or alopecia
3. amelioration and prevention of associated metabolic abnormalities, particularly insulin resistance and hyperinsulinemia
4. treatment of the associated anovulatory infertility.

Overall, avenues of treatment include the suppression of androgen production, the blockade of peripheral androgen action, the improvement of any associated insulin resistance and dyslipidemia, and topical, mechanical, or cosmetic measures for improving the dermatologic manifestations of these disorders (Fig. 37.9). The vast majority of patients with androgen excess will require, and benefit the most from, combination therapy.

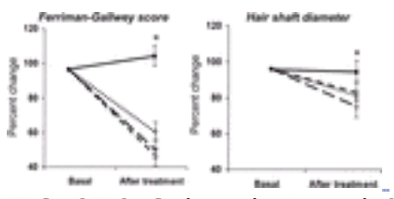

FIG. 37.9. Spironolactone (100 mg/d), flutamide (250 mg/d), and finasteride (5 mg/d) were compared for the treatment of hirsutism in a randomized, double-blind, placebo-controlled trial including 40 affected women. (Modified from Moghetti P, Tosi F, Tosti A, et al. Comparison of spironolactone, flutamide, and finasteride efficacy in the treatment of hirsutism: a randomized, double blind, placebo-controlled trial. *J Clin Endocrinol Metab* 2000;85:89–94, with permission.)

Regulation of Uterine Bleeding

In general, the regulation of uterine bleeding can be achieved with oral contraceptives, cyclic or continuous progestogens, and in some patients with PCOS, with insulin-sensitizing agents, and rarely surgery.

Oral Contraceptives Oral contraceptive medications generally act by suppressing circulating LH and FSH leading to a decrease in ovarian androgen production. In addition, the estrogen in the birth control pill increases SHBG, decreasing free testosterone levels. Furthermore, the progestin in the birth control pill can lead to a beneficial antagonism of 5a-reductase activity and androgen binding to the androgen receptor. Finally, these medications may also decrease adrenal androgen production by a mechanism not yet clear. Oral contraceptives are very effective at regulating uterine bleeding and decreasing the associated risk of endometrial hyperplasia or carcinoma in the hyperandrogenic patient, regardless of etiology. It is preferable, although not critical, to select a pill containing a progestin with low androgenic activity (e.g., norethindrone acetate, ethynodiol diacetate, desogesterol, gestodene, or norgestimate). There is some evidence that oral contraceptives can worsen insulin resistance and glucose tolerance in women with PCOS. However, there is no evidence that these effects of the oral contraceptive pill on glucose metabolism result in an increased risk for developing type 2 DM in the general population, and their use in patients with androgen excess patients not be limited by this concern.

Cyclic or Continuous Progestogens Cyclic progestogen administration is also useful to regulate uterine bleeding in patients with androgen excess, particularly in amenorrheic women. It is not known how many progestin-induced withdrawal bleeds per year are necessary to adequately prevent the development of endometrial cancer in women with PCOS, although extrapolating from the postmenopausal hormone replacement literature, monthly treatment for a minimum of 12 days or longer is optimal. Because progestogen administration can occasionally stimulate an ovulatory event, and because not all these patients are completely anovulatory, it may be preferable to treat sexually active at risk for pregnancy women with continuous oral micronized progesterone, 100 to 200 mg twice daily.

Glucocorticoids Glucocorticoid therapy may be beneficial in regulating menstrual bleeding in the patient with NCAH. However, we have found that NCAH monotherapy is effective primarily in those women whose treatment is initiated in adolescence and that many older patients will require combination therapy. The lowest effective dose of glucocorticoids should be used (e.g., dexamethasone 0.25 mg daily or every other day). Glucocorticoids should be administered with caution

as they have the potential of producing weight gain and cushingoid features, and worsening existing insulin resistance.
Insulin-Sensitizing Agents Drugs developed initially to treat type 2 DM have now also been used to treat PCOS. These include metformin and thiazolidinediones. Other drugs such as acarbose have also been studied in PCOS, and beneficial effects have been reported. However, we should note that none of these agents are currently approved by the Food and Drug Administration (FDA) for the treatment of PCOS or for related symptoms such as anovulation, hirsutism, or acne.
Metformin Metformin was approved for the treatment of type 2 DM by the FDA in 1994, but was used clinically for close to 20 years before that in other parts of the world. Metformin is a biguanide that works primarily by suppressing hepatic gluconeogenesis, but it also improves insulin sensitivity peripherally. Gastrointestinal symptoms (diarrhea, nausea, vomiting, abdominal bloating, flatulence, and anorexia) are the most common reactions to metformin, occurring in about 30% of treated women. There is a small risk of lactic acidosis among women taking this medication, which may be triggered by exposure to intravenous iodinated radiocontrast agents in susceptible individuals, although this adverse effect occurs primarily in patients with poorly controlled diabetes and impaired renal function. Metformin therapy has also been found to improve uterine bleeding and menstrual function.
Thiazolidinediones Thiazolidinediones are peroxisome proliferator activating receptor ?-agonists, and are thought to improve insulin sensitivity through a postreceptor mechanism. In a large multicenter trial, troglitazone has been shown to have a dose-response effect in improving ovulation and menstrual dysfunction in women with PCOS. This appears to be mediated through decreases in hyperinsulinemia and decreases in free testosterone levels. Troglitazone has subsequently been removed from the worldwide market due to its potential for inducing hepatotoxicity. Newer thiazolidinediones such as rosiglitazone and pioglitazone appear to be safer in terms of hepatotoxicity, but have also been associated with embryotoxicity in animal studies (both are pregnancy category C). Furthermore, there are limited studies on their effectiveness in PCOS. When using these drugs, liver function tests should be monitored on a regular basis. Combination treatment with other insulin sensitizers, primarily metformin, has been shown to further improve insulin sensitivity and glycemic control in type 2 DM, although the effect of such combination therapy in women with PCOS is not yet clearly delineated.
Surgery In patients with intractable uterine bleeding who have completed their childbearing, consideration may be given to a hysterectomy and bilateral salpingo-oophorectomy. In addition, ovulatory function may also improve following ovarian wedge or laparoscopic ovarian drilling procedures, although the long-term effect of these therapies on menstrual function is unclear.
Weight Loss Multiple studies in hyperandrogenic or women with PCOS have shown that weight loss can lower circulating androgen levels and cause spontaneous resumption of menses. These changes have been reported with a weight loss as small as 5% of the initial weight. In patients with massive obesity, consideration may be given to surgical means of inducing weight loss, such as laparoscopic gastric bypass.

Treatment of Hirsutism, or Androgen Excess-Associated Acne or Alopecia

The treatment of hirsutism can be complex, and has recently been reviewed. Optimum therapy usually requires a combination of approaches, including suppression of circulating androgens (with oral contraceptives, insulin sensitizers, or even long-acting GnRH analogs or glucocorticoids), peripheral androgen blockade (with spironolactone, flutamide, cyproterone acetate, or finasteride); and the use of a topical hair growth inhibitor (eflornithine hydrochloride) or mechanical methods of hair reduction or destruction (electrology or lasers), and appropriate cosmetic measures (bleaching or chemical depilating). Acne in patients with androgen excess can usually be treated with oral contraceptives, accompanied by topical or antibiotic therapies. The treatment of androgenic alopecia may require the use of androgen suppression in combination with androgen blockade and topical means of stimulating hair regrowth (e.g., minoxidil).

Most medical methods alone, while improving hirsutism do not produce the dramatic results that many patients desire. In general, combination therapies appear to produce better results than single agent approaches. Response with medical therapies often take 3 to 6 months to notice improvement, and adjunctive mechanical removal methods are often necessary. However, the majority of women appear to experience improvement in their hirsutism. Unfortunately, there are no universally accepted techniques for assessing the response of hirsutism to treatment. Some of the depilatory treatments used by patients are so effective that it is difficult to ever determine baseline hirsutism and response to treatment such that the patient's subjective assessment guides therapy.

Androgen Suppression Women with documented hyperandrogenemia would theoretically benefit most from androgen-suppression therapy, although in actual practice, the clinical response to this type of therapy does not correlate with androgen levels. Suppression of ovarian androgen secretion has been achieved with oral contraceptives, progestins, or GnRH analog treatment. Oral contraceptives improve hirsutism, although the response of hirsutism to this therapy alone is generally modest. Treatment with a long-acting GnRH agonist may result in a greater lowering of circulating androgens, and theoretically a greater degree of hair growth suppression, although comparative trials against other agents and combined agent trials have yielded mixed results. It should be noted that a long-acting GnRH agonist given alone results in unacceptable bone loss. Glucocorticoid suppression of the adrenal glands also offers theoretical benefits, but deterioration in glucose tolerance is problematic for women with PCOS, and long-term effects such as osteoporosis are a significant concern. Furthermore, glucocorticoid suppression produces only minimal improvements in hair growth in hirsute women.
Androgen Receptor Antagonists Androgen receptor antagonists antagonize the binding of testosterone and other androgens to the androgen receptor. As a class therefore, they are teratogenic, and pose risk of feminization of the external genitalia in a male fetus, should the patient conceive. Spironolactone, a diuretic and aldosterone antagonist, binds to the androgen receptor with 67% of the affinity of DHT. It has other mechanisms of action, including inhibition of ovarian and adrenal steroidogenesis, and direct inhibition of 5-a-reductase activity. Hirsutism and acne have been successfully treated with spironolactone. The usual dose for the treatment of hirsutism is 25 to 100 mg twice a day, and the dose should be titrated to minimize the potential for side effects. About 20% of women given spironolactone will experience increased menstrual frequency, a reason for combining this therapy with oral contraceptive. Other side effects include polyuria, orthostatic hypotension, nausea, dyspepsia, and fatigue. Because spironolactone can cause and exacerbate hyperkalemia, it should be used cautiously in patients with renal impairment, and should not be combined with other potassium-sparing diuretics. The medication also has potential teratogenicity as an anti-androgen, although exposure has rarely resulted in ambiguous genitalia in male infants. Flutamide is another nonsteroidal anti-androgen that has been shown to be effective against hirsutism. The most common side effect is dry skin, but its use has rarely been associated with hepatitis. A dose of 250 mg per day is generally used. Because there is greater risk of teratogenicity with this compound, contraception should be used.
5a-Reductase Inhibitors There are two forms of the enzyme 5a-reductase: type 1, predominantly found in the skin and type II, predominantly found in the prostate and reproductive tissues. However, both forms are found in the pilosebaceous unit (PSU) and may contribute to the development of hirsutism, acne, and alopecia. Finasteride inhibits both forms of 5a-reductase, and is available as a 5-mg tablet for the treatment of prostate cancer and a 1-mg tablet for the treatment of male alopecia. It has been found to be effective for the treatment of hirsutism in women. Finasteride is better tolerated than other antiandrogens, but has the highest and clearest risk for teratogenicity in a male fetus and adequate contraception must be used. Overall, randomized trials have found that spironolactone, flutamide, and finasteride have similar efficacy in improving hirsutism (see Fig. 37.9).
Insulin-Sensitizing Agents and Lifestyle Modification It is difficult to separate the effects of an improvement in insulin sensitivity from that of androgen suppression, as any improvement in insulin sensitivity can raise SHBG and thus lower bioavailable androgen. Given the long onset of action for improving hirsutism and acne, longer periods of observation are needed. In the largest and longest randomized trial to date of these agents, troglitazone, in a dose-response fashion, was found to significantly improve hirsutism in women with PCOS without lowering total testosterone, a benefit presumably achieved through the decrease in free testosterone. Weight loss in the obese patient may also benefit hirsutism and acne, albeit modestly. Increases in SHBG through improved insulin sensitivity from weight loss may lower bioavailable androgen levels. About 50% of the women who lose weight experience an improvement in their hirsutism.
Topical Hair Growth Suppression—Ornithine Decarboxylase Inhibitors Ornithine decarboxylase is necessary for the production of polyamines, and is also a sensitive and specific marker of androgen action in the prostate. Inhibition of this enzyme limits cell division and function, including that of the PSU. A potent inhibitor of this enzyme, eflornithine, has been found to be effective as a facial cream for the treatment of unwanted facial hair. It is available as a 13.9% cream of eflornithine hydrochloride, and is applied to affected areas twice daily. In clinical trials, 32% of patients had marked improvement after 24 weeks compared to 8% of women given placebo, and the benefit was first noted at 8 weeks. It is pregnancy category C. The cream appears to be well tolerated, with only about 2% of patients developing skin irritation or other adverse reactions.
Mechanical and Cosmetic Means of Hair Reduction and Destruction Mechanical hair removal methods (shaving, plucking, waxing, depilatory creams, electrolysis, and laser vaporization) can assist in controlling hirsutism, and often are the front line of treatment used by women. Shaving, bleaching, or chemical depilation may be useful temporary treatments for unwanted hairs. Although shaving can lead to a blunt hair end that may feel “stubble-like,” it does not lead to a worsening of hirsutism. Depilating agents, while useful, can result in chronic skin irritation and worsening of hirsutism if used excessively or indiscriminately. The use of plucking or waxing in androgenized skin areas should be discouraged since these techniques not only do not kill the hair follicles, but also can induce folliculitis and trauma to the hair shaft with subsequent development of ingrown hairs and further skin damage. Electrolysis (i.e., electroepilation) results in long-term hair destruction, but this therapy is time consuming. Side effects may include temporary skin irritation, and rarely burning and scarring of the skin. Hair reduction via lasers can also be useful for selected patients. The main objective of laser therapy for hair removal is to selectively cause thermal damage of the hair follicle without destroying adjacent tissues, a process termed *selective photothermolysis.* Selective photothermolysis relies on the selective absorption of a brief radiation pulse to generate and confine heat at specific pigmented targets. Lasers useful in hair removal may be grouped into three categories based on the type of laser or light source each employs:

1. red light systems (694 nm ruby)
2. infrared light systems (755 nm alexandrite, 800 nm semiconductor diode, or 1,064 nm neodymium: yttrium-aluminum-garnet [Nd:YAG])
3. intense pulsed light (IPL) sources (590–1200 nm).

In general, laser hair removal is most successful in patients with fairer skin, who have dark color hairs. However, repeated therapies are necessary, and complete alopecia is rarely achieved. In general, treatment with the ruby, alexandrite, or diode lasers, or the IPL results in similar success rates, although it appears to be somewhat lower for the Nd:YAG laser. After laser-assisted hair removal, most patients experience erythema and edema lasting no more than 48 hours. Blistering or crusting may occur in 10% to 15% of patients. Temporary hyperpigmentation occurs in 14% to 25% of patients and hypopigmentation occurs in 10% to 17% of patients. Dyspigmentation is less common with the use of longer wavelengths, as in the alexandrite or diode lasers, and longer pulse durations. Overall, laser hair removal is a promising technique for the treatment of the hirsute patient. Nonetheless, we should note that most studies have been uncontrolled and included fewer than 50

patients, none have been blinded, and all have used a variety of treatment protocols, equipment, skin types, and hair colors studied.

Treatment of Associated Metabolic Abnormalities

The treatment of any associated metabolic abnormalities includes lifestyle alterations and weight reduction, and the use of insulin sensitizers and possibly lipid-lowering agents. Multiple studies have shown that improving insulin sensitivity, through lifestyle modifications or by pharmacologic intervention, can result in lowered circulating androgens (primarily mediated through a reduction in bioavailable androgen), and an increase in the spontaneous ovulation and pregnancy rates. In addition, it is possible that a decrease in insulin resistance may decrease the risk that patients with PCOS will develop type 2 DM. In support of this, data from the Diabetes Prevention Program, which enrolled men and women at risk for diabetes, demonstrate that lifestyle interventions have a more profound effect on preventing the development of subsequent type 2 DM than does the sole use of metformin, although both interventions were superior to placebo. However, long-term studies documenting a decrease in such sequelae as endometrial cancer, type 2 DM, or CVD with improvements in insulin sensitivity are still lacking among women with PCOS.

The gold standard for improving insulin sensitivity in obese women with PCOS should be weight loss, diet, and exercise. Obesity has become epidemic in our society and contributes substantially to reproductive and metabolic abnormalities in PCOS. Unfortunately there are no effective treatments that result in permanent weight loss, and it is estimated that 90% to 95% of patients who experience a weight decrease will relapse. In addition to improving the endocrine aspects of PCOS, weight loss can decrease circulating insulin levels. Unfortunately there have been few studies on the effect of exercise alone on insulin action in women with PCOS, although it is reasonable to assume that exercise would have the same beneficial effects in women with PCOS as women with type 2 DM.

Treatment of Hyperandrogenic Oligoovulatory Infertility

A full discussion of the treatment of oligoovulatory infertility is beyond the scope of this chapter. In brief, ovulation induction for the treatment of androgen-excess–related infertility typically includes the use of clomiphene citrate and human gonadotropins. In women with PCOS there are a variety of methods available to improve ovulatory function that act through a different mechanism (Fig. 37.10). For example, in patients with PCOS, insulin-sensitizer therapy, either alone or in combination, may be useful for improving ovulatory function and pregnancy rate. One of the more commonly used drugs for this purpose is metformin.

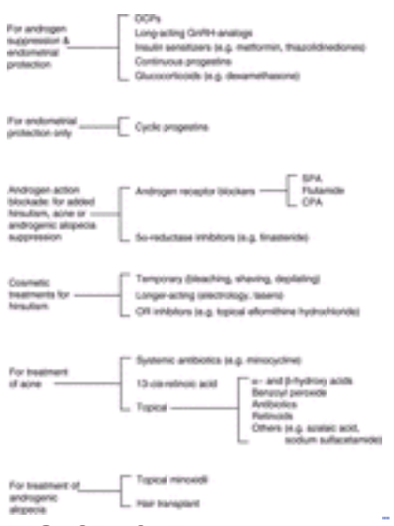

FIG. 37.10. Treatment strategies in the patient with androgen excess.

SUMMARY POINTS

- Androgen excess (i.e., hyperandrogenism) is one of the most frequent, albeit heterogeneous, endocrine disorders of women; the most common etiology of androgen excess, polycystic ovary syndrome (PCOS), affects 4% to 6% of unselected women of reproductive age.
- Androgen excess results in various clinical signs and symptoms including abnormalities of the pilosebaceous unit (hirsutism, acne, and androgenic alopecia), the hypothalamic–pituitary–ovarian axis (i.e., ovulatory and menstrual dysfunction), and the hypothalamic–pituitary–adrenal axis (adrenal androgen excess). If the androgen excess is very severe, virilization or masculinization can also be apparent.
- Common signs of androgen excess are hirsutism and acne, although in up to 15% of such patients, no obvious ovulatory or endocrine abnormality may be observed (i.e., idiopathic hirsutism). Alternatively, not all women with androgen excess will have hirsutism or acne.
- The vast majority of androgen excess is due to PCOS, with 21-OH–deficient nonclassic adrenal hyperplasia (NCAH), the hyperandrogenic-insulin resistant-acanthosis nigricans (HAIRAN) syndrome, androgen-secreting tumors, and drug-induced hyperandrogenism generally accounting for less than 10% of such patients.
- PCOS is a diagnosis by exclusion, basically defined as the presence of androgen excess (hyperandrogenemia or clinical evidence of androgen excess) combined with chronic oligoanovulation, after the exclusion of related disorders (e.g., 21-OH–deficient NCAH, thyroid dysfunction, hyperprolactinemia). Polycystic-appearing ovaries alone are insufficient for the diagnosis of PCOS, and their absence is not exclusionary.
- Approximately 50% to 60% of patients with PCOS suffer from insulin resistance and hyperinsulinism, and are at higher risk for the development of endometrial cancer, glucose intolerance, and type 2 diabetes mellitus. They also have an adverse cardiovascular risk profile.
- The history and physical examination are essential to making a diagnosis of the underlying cause of androgen excess. The laboratory evaluation should have the objective of excluding related and specific disorders and, if necessary, providing confirmation of androgen excess. As well, the presence of metabolic abnormalities, particularly in patients with PCOS or the HAIRAN syndrome, should be sought out.
- Treatment of androgen excess tends to be symptom-based, with reasons for treatment including: (a) regulation of uterine bleeding and reducing the risk of endometrial hyperplasia and cancer, dysfunctional uterine bleeding, and secondary anemia; (b) improvement of dermatologic abnormalities such as hirsutism, acne, or alopecia; (c) amelioration and prevention of associated metabolic abnormalities, particularly insulin resistance and hyperinsulinemia; and (d) treatment of anovulatory infertility.
- Overall, avenues of treatment of androgen excess include the suppression of androgen production, the blockade of peripheral androgen action, the improvement of any associated insulin resistance and dyslipidemia, and topical, mechanical, or cosmetic measures for improving the dermatologic manifestations of these disorders. The vast majority of patients with androgen excess will require and benefit the most from combination therapy.

SUMMARY POINTS

SUGGESTED READINGS
- Evaluation: Testing
- Evaluation: Advanced
- Treatment

Infertility affects approximately 14% of couples and is a medical concern for 2.7 million women of reproductive age in the United States. Over the past decade, successful treatments for virtually all causes of infertility have been developed, offering hope for couples with this medical condition. Unfortunately, many states continue to offer limited insurance coverage for infertility minimizing effective diagnosis and treatment despite evidence that providing infertility care does not increase insurance costs. It is the goal of this chapter to identify the basic diagnostic testing for couples with infertility that can allow the couple to rapidly move on to proven therapeutic options. Prompt diagnosis and effective treatment will maximize the opportunity for conception while minimizing the cost of infertility care.

Infertility is defined as 1 year of unprotected intercourse without conception. Fecundability is the chance of conception in one menstrual cycle, and per cycle fecundity is commonly used to identify the success rate of an infertility treatment. It is expected that approximately 25% of healthy young couples will conceive in a single cycle, although clearly the chance of conception drops throughout the first year without contraception. The per cycle fecundity falls below 10% after 7 cycles and only 3% of couples conceive during the 12th cycle. Although it is reasonable to wait 1 year to begin the infertility evaluation for young couples with no history suggestive of reproductive disorders, it is reasonable to begin the workup sooner in couples with a positive history for a fertility-lowering disease or advancing age. Decreased fecundity begins for women in the mid-30s, making it reasonable to begin the diagnosis and treatment of infertility for this age group following 6 months of unsuccessful attempts at pregnancy. When one or both members of the couple have a history suggestive of a disorder potentially altering reproduction, the diagnostic testing of infertility should begin immediately. Thus, it is critical for the obstetrician-gynecologist to consider both the history and physical examination of both members of the couple as well as advanced maternal age when deciding when to begin the infertility evaluation.

The increased diagnostic techniques and available treatments for infertility have raised the concern that infertility is a new disorder, increased by the exposure of men and women to environmental factors or high-risk behavior. Although the advancing age of the first pregnancy in our society does increase the risk of infertility, the primary explanation for advancing infertility treatment is the increased awareness of this disorder by patients. It is now socially acceptable for men as well as women to seek treatment for infertility. As patients continue to increase their knowledge of this disorder and learn of successful therapies, providers will increasingly be asked to provide prompt diagnosis and effective treatment.

EVALUATION: INITIAL ASSESSMENT

As with all medical problems, the first step in the evaluation of infertility is a thorough medical history and physical examination. Figure 38.1 demonstrates the history form used by the Reproductive Endocrinology and Infertility Division at the University of Vermont. Ovulation dysfunction, tubal risk factors, uterine and cervical abnormalities, peritoneal factors, and male factors are often identified at the initial visit. It is important for both members of the couple to be interviewed at this first meeting with the health care provider.

FIG. 38.1. Infertility history form.

The known causes of infertility and their incidences are listed in Table 38.1. The history should explore for ovulatory dysfunction by examining the age of menarche, cycle length, history of increased or decreased intervals between cycles, and physical symptoms of ovulation and hormone production such as mittelschmerz and premenstrual molimina. If ovulatory dysfunction is identified, an endocrine review of systems is valuable to determine the etiology of the irregular menses. Information regarding thyroid symptoms, androgen excess, marked weight changes, and galactorrhea should be obtained. Signs of decreased ovarian function, such as shortened menstrual cycle length, new onset of irregular cycles, or hot flashes can indicate a contributing factor to infertility. The menstrual history may also point to other causes of infertility. Worsening dysmenorrhea, intermenstrual bleeding, and menorrhagia may point to diseases in the pelvic peritoneum or uterus.

Main causes
Sperm defects or dysfunction, 30% (including spermatogenic failure [i.e., complete or virtually complete failure leading to azoospermia] in 1%–2%, seminal sperm antibodies in 5%, and varicocele in 1%–2%).
Ovulation failure (amenorrhea or oligomenorrhea), 25% (including primary ovarian failure in 1%–2%).
Tubal infective damage, 20%
Unexplained infertility, 25%
Other causes
Endometriosis (causing tubal or ovarian structural damage), 5%
Coital failure or infrequency, 5%
Cervical mucus defects or dysfunction, 3%
Uterine abnormalities (e.g., fibroids), rare as a true cause
Genital tuberculosis, rare in developed countries
General debilitating illnesses, rare

TABLE 38.1. *Causes of infertility and their approximate frequencies*

Risk factors for tubal factor infertility have been shown to be excellent predictors of tubal damage. A history of sexually transmitted diseases (STDs), pelvic inflammatory disease, pelvic surgery, ruptured appendix, septic abortion, endometriosis, and ectopic pregnancy can point to a heightened risk of tubal factor infertility. A history of uterine leiomyoma or uterine and cervical surgery may also affect fertility. The abdominal and pelvic exam can identify pelvic masses, cul-de-sac nodularity, irregular uterine contour, and fixed pelvic structures, suggestive of tubal damage or peritoneal disease.

The history from the male partner is crucial, as sperm abnormalities account for 30% to 40% of infertility. STDs and other genitourinary infections, chemotherapy or radiation therapy, mumps during adolescence, testicular surgery or injury, and decreased ejaculatory function suggest reasons for infertility. Chronic exposure to extreme heat may alter sperm motility and exposure to gametotoxic chemicals, such as the nematocide dibromocloropropane, may affect sperm production. Certain medications, such as cimetidine and sulfasalazine, are associated with decreased sperm production. Cystic fibrosis is associated with bilateral absence of the vas deferens. An examination of the male partner, either by the obstetrician-gynecologist or a medical colleague, is critical. Abnormal body habitus, lack of testicular descent, penile abnormalities, diminished size and consistency of the testes, and the presence of a varicocele may offer explanations for infertility.

Medical histories and family histories from the couple are important to identify factors that may complicate pregnancy. Preconceptual counseling is typically recommended for women with a history of diabetes, hypertension, heart disease, autoimmune diseases, severe pulmonary disease, breast or gynecologic cancer, and infectious diseases such as human immunodeficiency virus (HIV) and hepatitis. The use of medications, particularly those associated with fetal malformations such as isotretinoin for severe cystic acne, should be considered. Carrier screening can be offered for inherited disorders, such as cystic fibrosis, Tay-Sachs, thalassemia, and sickle cell anemia, based on the risk profile for each couple. A family history of genetic disorders such as fragile X and Down syndrome (trisomy 21) may lead to a need for genetic counseling. Women anticipated to be over the age of 35 at delivery should receive information about diagnostic testing during pregnancy by chorionic villus sampling and amniocentesis. The American College of Obstetricians and Gynecologists (ACOG) technical bulletin on preconceptional care is a valuable tool for all providers evaluating couples with infertility.

The social and lifestyle history is also very important for the infertile couple. Smoking, alcohol abuse, and drug abuse have an adverse effect of fertility in both men and women. Smoking is particularly harmful as it is associated with oocyte toxicity and an earlier age of menopause. Excessive exercise and anorexia may adversely affect both ovulation and sperm production. Exposure to potential teratogens, such as lead, should be excluded by the history. Although alterations in the usual dietary intake do not benefit the infertile couple, it is critical for women to begin taking at least 400 µg of folic acid and avoid alcohol intake once they conceive. Victims of sexual and physical abuse may be markedly affected by the intensive testing and treatment required for infertility. It is important to identify these potential emotional barriers prior to beginning the evaluation. Finally, infertility is remarkably stressful and can lead to dysfunction or even dissolution of the couple's relationship. One of the key members of any infertility team is the counselor or psychologist who is experienced in helping couples deal with the stresses involved in testing and treatment for infertility. Appropriate referrals to this individual will be discussed in the “ Treatment” section of this chapter, but often it is best to involve this member of team from the start of the evaluation.

EVALUATION: TESTING

The amount of testing for most medical conditions has increased markedly over the past decade. By contrast, as our understanding of infertility increases, the testing has simplified. Some tests have been eliminated as they are now known to be of limited value or do not alter the treatment decisions. The basic evaluation now includes only three tests—semen analysis, ovulation monitoring, and uterine/tubal evaluation—that can be completed in 1 to 2 months. Although additional testing may be indicated, for most couples the cause of infertility is identified and they may proceed rapidly to the appropriate treatment. This lessens the stress of the workup and minimizes the cost. Studies suggest that the majority of reproductive endocrinology and infertility subspecialists have minimized their infertility evaluation and authors have noted that a “targeted” evaluation is cost-effective and limits stresses for the couple. This section will examine the basic evaluation, the indications for expanded evaluation, and the justification for the elimination of previous testing methods.

The semen analysis remains the primary method for evaluation of the male partner. This test clearly identifies subfertile men. The World Health Organization criteria in Table 38.2 are well established and were republished in 1999. Alternatives in the basic criteria may occur at some centers; the use of Kruger's strict morphology has been associated as an improved predictor of sperm function during in vitro fertilization (IVF) cycles. Some centers use a computer-assisted semen analysis (CASA). It is important that your laboratory is experienced in the assessment of sperm, but the basic semen analysis is satisfactory for clinical care. If the initial semen analysis is abnormal, it is important to be certain that the specimen was fully collected, without undue stress, not exposed to excessive heat, not contaminated by lubricants or soaps, and that the patient did not have a recent severe illness within the past 3 months that might adversely impact sperm production. Repeat semen analysis is typically obtained to confirm male infertility. Although it is ideal to wait 90 to 108 days to allow new production of sperm, this delay in the workup is not generally recommended, and collection within a month is acceptable.

Parameter	Value
Ejaculate volume	≥ 2.0 mL
pH	7.2–7.8
Sperm density	≥ 20 million/mL
Total sperm count	≥ 40 million
Motility	≥ 50%
Forward progression	
Morphology	> 30% normal forms
No significant sperm agglutination	
No significant pyospermia	
No hyperviscosity	

TABLE 38.2. *Semen analysis: minimal standards of World Health Organization (WHO) criteria for normal semen values*

Although ovulation can be assumed in women with regular menses and premenstrual moliminal symptoms, ovulation should be confirmed. Only 1 month of documented ovulation is required; there is no value and significant frustration with many months of ovulation testing. There are three methods to evaluate ovulation. The classic method is a basal body temperature chart. This method is low cost, fairly reliable, and informs the patient of her timing of ovulation. It is important for the provider to evaluate this form with the patient, as it is notoriously difficult for patients to interpret. A simpler, but more costly method is the luteinizing hormone (LH) or ovulation predictor kit. Unlike the temperature chart, this method identifies the timing of ovulation 24 to 36 hours prior to release of the oocyte. This may be of value to patients whose lifestyles limit midcycle coitus. Finally, a serum progesterone greater than 3 ng/mL indicates ovulation is occurring. Although the timing of ovulation and the length of the follicular and luteal phase are not identified, this simple test unequivocally documents ovulation. Ultrasound, cervical mucus examination, and endometrial biopsy can also suggest or confirm ovulation, though these tests are less frequently used because of consideration of reliability and cost.

For women over the age of 30, testing for decreased ovarian function should be added to the assessment of ovulation. The effect of advancing maternal age on fertility will be fully discussed later in the chapter, but there is no doubt that fertility begins to decrease in the mid-30s. Although the method of testing may improve as our understanding of the menopausal transition increases, the classic test is a day 3 follicle-stimulating hormone (FSH) level. Normal values for day 3 FSH vary between laboratories with the current assays identifying decreased ovarian function with a level greater than 10 to 15 IU/L. Although pregnancy can occur in women with elevated day 3 FSH levels, the chance of pregnancy is markedly reduced with IVF. Alternatively, a low day 3 FSH should not falsely reassure women of the success of infertility treatment. This test primarily reassures the number of oocytes remaining (i.e., ovarian reserve), not oocyte quality. The chance of pregnancy in the late 30s and 40s is reduced, compared to younger women, even with a normal day 3 FSH level. This test cannot be used to offer hope for women with advanced maternal age. Other forms of ovarian reserve testing: the clomiphene citrate challenge test and a day 3 inhibin B level, have been used by some infertility specialists but are not of general applicability. The clomiphene challenge test measures a day 3 FSH and estradiol level, followed by 100 mg per day of clomiphene citrate on cycle days 5 to 9 and a day 10 FSH. Studies have suggested that the clomiphene challenge test may be a better predictor of decreased ovarian reserve for older women and those with unexplained infertility.

Following the semen analysis and ovulation monitoring, the basic investigation is completed by an evaluation of the uterus and fallopian tubes. As with ovulation monitoring, there are several options for testing, but the primary method is the hysterosalpingogram (HSG). This test, although mildly uncomfortable and having a 1% risk of postprocedure infection, offers the benefit of visualization of both the uterine cavity and the fallopian tubes. The test is performed in the early to mid-follicular phase to avoid interfering with tubal function following ovulation. Slow introduction of dye into the cervical canal below the internal os by someone skilled in the technique allows the best visualization of the uterine cavity and minimizes discomfort during the procedure. If any abnormality of tubal architecture is identified, antibiotics, usually doxycycline 100 mg b.i.d. for 5 days, are typically advised. Oil-based dye has been associated with increased pregnancy rates for a few months following the HSG, but its persistence in obstructed tubes is problematic. Water-based dye can be used initially to assure tubal patency, followed by oil-based dye as a therapeutic measure. If tubal patency does not need to be assessed, the woman can undergo uterine evaluation using ultrasound with saline injection sonohysterography, or office hysteroscopy. For women with known or strongly suspected tubal damage, moving promptly to operative laparoscopy and diagnostic hysteroscopy avoids the need for the HSG. A strong argument can be made for screening for tubal damage secondary to sexually transmitted diseases by testing for antichlamydial antibodies, and proceeding directly to surgery if the testing is positive. For women with no apparent risk factors for tubal factor infertility, however, the

HSG offers valuable information and results in increased fertility.

Following the basic workup, the couple will benefit from consultation with the provider. If additional testing is required to fully define the cause of male factor, ovulatory factor, or tubal/uterine factor infertility, this advanced evaluation and potential treatment options can be discussed and planned with the couple. If infertility remains unexplained, the provider may advise moving directly to treatment. In the past, all couples underwent advanced male factor testing, postcoital testing, timed endometrial biopsies, and laparoscopy/hysteroscopy before the infertility evaluation was considered complete. Although advanced testing may still be advised in selected cases, most couples benefit from rapid completion of testing and prompt initiation of effective therapy. The value of advanced testing for selected patients will be considered, but the basic workup is adequate to determine effective treatment options for most couples. Figure 38.2 demonstrates the basic infertility workup followed by more advanced evaluation.

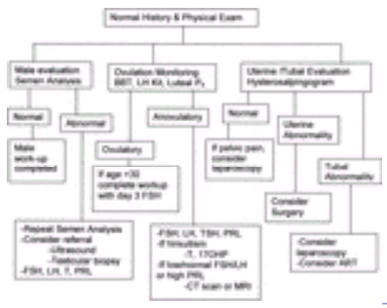

FIG. 38.2. Basic workup for couple with infertility.

EVALUATION: ADVANCED

Male Factor

If an abnormal semen analysis is identified, further workup may be indicated prior to moving on to treatment. If a history and physical exam have not yet been done, this may identify the cause of the abnormal test. Although controlled trials have not demonstrated efficacy, surgical ligation of a varicocele increases sperm motility, and finding a varicocele may lead to potential therapy. Hormonal testing—testosterone, FSH, LH, and prolactin—is of value for identifying a hypothalamic, pituitary, or testicular etiology for oligospermia or azoospermia, particularly when low male libido is noted. A fructose level and possible testicular biopsy can differentiate obstruction from testicular failure in men with azoospermia. If leukocytes are present in semen, bacterial cultures and antibiotic treatment are indicated. Unfortunately, most men with an abnormal semen analysis have idiopathic oligoasthenospermia. Although this is frustrating for the patient, very effective treatment options are available for unexplained male factor infertility.

The value of additional sperm testing in men with normal examination and hormonal testing, prior to proceeding with therapy, is debated. Abnormalities in seminal fluid have also been evaluated by antisperm antibody testing. Although studies suggest decreased fertility with the presence of antisperm antibodies, this finding does not affect the therapeutic choices of intrauterine insemination (IUI) or IVF. As a result, the value of this test remains unproven. The value of sperm function testing is also controversial. Many assays have been developed to evaluate sperm function—in vitro sperm penetration of hamster oocytes, hypoosmotic swelling, viability staining, sperm capacitation, acrosomal reaction bovine cervical mucus, sperm penetration, and human zona binding. Unfortunately, these tests have limited prognostic value and cannot consistently predict the effectiveness of selected treatments. Currently, these tests are limited to experimental use.

Inherited and medical problems can adversely affect fertility. Retrograde ejaculation can occur with diabetes, certain neurologic disorders, and pelvic surgery. The presence of sperm in the bladder can be determined by examining a post-ejaculation urine sample. Klinefelter syndrome can result in azoospermia and men with cystic fibrosis may have bilateral congenital absence of the vas deferens. Microdeletions of the Y chromosome have been associated with oligospermia. Testing for microdeletions of the Y chromosome is not yet standard practice, but it is important to inform men of the possibility of an inherited condition being passed to male children as a result of newer treatment techniques. Genetic screening can be offered to all men with nonobstructive severe oligospermia and azoospermia.

Ovulation Dysfunction

Women with oligomenorrhea and amenorrhea should be evaluated for the hypothalamic, pituitary, ovarian, or adrenal etiology of their condition. Often the history and physical examination will point to the cause of her irregular menses; there is limited value in obtaining a basal body temperature chart of LH predictor kit for women with markedly irregular menses. The most common causes of hypothalamic amenorrhea are due to weight loss (eating disorders) and excessive exercise. Rare causes include Kallmann syndrome and hypothalamic lesions. Pituitary disorders include hyperprolactinemia, thyroid disease, Cushing disease, and Sheehan syndrome. Women with significant hyperprolactinemia or unexplained hypothalamic hypogonadism should undergo a computed tomography (CT) scan or magnetic resonance imaging (MRI) to determine if a hypothalamic lesion or pituitary adenoma is present. Ovarian dysfunction is most commonly due to anovulation (World Health Organization [WHO] type II or polycystic ovarian syndrome accounting for the majority of cases). A less common etiology is premature ovarian failure, although decreased ovarian function occurs many years before menopause. The classic laboratory testing for women with oligoamenorrhea is a fasting prolactin, thyroid-stimulating hormone (TSH), FSH, and LH. Women with hirsutism should also have testosterone and 17-hydroxyprogesterone levels drawn to rule out ovarian neoplasm or late-onset adrenal hyperplasia. Women with suspected polycystic ovary syndrome (PCOS) are known to be at increased risk for hyperlipidemia, insulin resistance, and adult-onset diabetes (type II); a lipid profile and fasting glucose are recommended. The classic progestin challenge test, 10 mg of medroxyprogesterone acetate for 10 days, may be of some value, as women with hypoestrogenism will typically not have withdrawal bleeding due to progestins. Chapter 34 and Chapter 37 further discuss the evaluation of women with ovulatory dysfunction.

The use of the timed, luteal phase endometrial biopsy to assess for a minor ovulatory disturbance is now in question. There is a false-positive rate of 30% to 40% with a single endometrial biopsy. The rate of luteal phase defect when two biopsies are performed is estimated to be 7%. Luteal phase defects appear to be a rare cause of infertility and extensive testing is required to identify this problem. Additionally, the medications used for the treatment of unexplained infertility are also used to correct luteal phase defects, making a precise diagnosis less important. Women with a markedly shortened luteal phase by basal body temperature chart and normal hormonal workup may be treated empirically with medication, such as progesterone, clomiphene citrate, and gonadotropins for correction of a presumed luteal phase defect or unexplained infertility.

Uterine/Tubal Factor

Women with a history of tubal disease or significant risk factors for pelvic adhesions, such as extensive pelvic surgery, a ruptured appendix, or pelvic inflammatory disease, may elect to avoid the hysterosalpingogram and proceed directly to laparoscopic surgery. The risk of postprocedure infection is increased in these women and some authors have recommended preprocedure antibiotic therapy (100 mg doxycycline p.o. b.i.d. × 5 to 7 days). For most women, however, the HSG remains a reasonable test for uterine and tubal disorders. To evaluate the uterus alone, or in women with iodine allergies, sonohysterography or hysteroscopy can identify leiomyoma, polyps, and müllerian anomalies, and can replace the HSG.

The use of routine diagnostic laparoscopy following a normal HSG is no longer the standard infertility workup. Extensive peritubal adhesions in women with a negative history and normal HSG is rare. The most common finding at laparoscopy for women with otherwise unexplained infertility is endometriosis. The effect of severe endometriosis on fertility is not questioned, but the link between mild to moderate endometriosis and infertility remains an enigma. Research does suggest decreased fertility in women with endometriosis undergoing donor insemination. One study demonstrated an increase in fertility following laparoscopic laser ablation of mild endometriosis, but the value of surgical therapy requires further evaluation. Women with debilitating pain related to possible endometriosis, such as dysmenorrhea and dyspareunia, may benefit from laparoscopic treatment. The delay in conception required by medical therapy for pain argues for surgical treatment when symptomatic endometriosis is suspected. However, routine diagnostic laparoscopy for the identification and treatment of possible endometriosis must be compared to the benefit of proceeding with other treatment options. As will be discussed, the successful treatment of unexplained and endometriosis-related infertility argues for the selected use of laparoscopy surgery for the infertile woman.

Evaluation of cervical mucus was previously a routine part of the evaluation for infertility. Although women with a history of cervical surgery such as conization or loop electroexcision may benefit from treatment that bypasses the cervix, the postcoital test was shown to have limited predictive value of future fertility. The primary limitation of this test is its inability to predict fertility based on the number of motile sperm. It is clear that the postcoital test cannot replace the semen analysis as a test for male factor infertility. An argument can be made for an evaluation of preovulatory cervical mucus without a postcoital evaluation of sperm in the mucus. The woman herself can assess her spinnbarkeit, or mucus stretchability to 8 to 10 cm, prior to ovulation. If she has a history of cervical surgery and poor mucus production, a

cervical factor can be presumed and treated appropriately.

The evaluation for infertility is now simplified in couples with negative histories and normal physical examinations. Although hormonal testing may be indicated for both men and women, and laparoscopy or hysteroscopy has a role in the evaluation of selected women, the basic workup should be limited to semen analysis, ovulation monitoring, and uterine/tubal evaluation. The value of advanced male testing, endometrial biopsy, and postcoital test is limited. Until research can confirm that these tests are consistent and have predictive value, they can be removed from the basic infertility evaluation.

TREATMENT

Once the cause of infertility is determined to the extent possible by current techniques, the health care provider can advise the couple regarding treatment choices. Advances in infertility treatment offer virtually all couples a reasonable opportunity for pregnancy. Before moving onto treatment, it is critical for the provider to recognize the stress of infertility therapy and actively involve a counselor or psychologist in the care of couples with infertility. There are limited data that suggest increased pregnancy rates with stress reduction, but the primary benefit is to maintain the well-being of couples seeking to achieve their family. RESOLVE, the national support organization for couples with infertility, is an excellent source of information and support for infertile men and women. It is also important for providers to encourage and support a couple's decision to pursue adoption or remain child-free. The program at the University of Vermont College of Medicine offers free exams for adoption physicals for the couple as a symbol of our support for these alternative decisions.

The remainder of this section highlights the treatment options for male factor, ovulatory disorders, uterine/tubal factor, unexplained infertility, and advanced maternal age.

Male Factor

The basic treatments for male factor infertility have improved over the past decade. Although donor sperm continues to be a viable option for many couples, IUI (intrauterine insemination) and IVF (in vitro fertilization) with intracytoplasmic sperm injection (ICSI) now offer an excellent opportunity for many couples. Surgery remains the primary treatment for obstructive azoospermia secondary to previous vasectomy or injury. Additionally, surgical ligation of a varicocele improves sperm motility, although controlled trials demonstrating an improvement in fertility are lacking. Medical therapy for male factor infertility, with the exception of treatment for hypothalamic hypogonadism, has not been shown to be effective.

When there is a relatively mild oligoasthenospermia, IUI with the male partner's sperm offers a reasonable chance for pregnancy. Successful treatment with less than 1 million motile sperm is low, but most studies have shown improved pregnancy rates with higher levels of motile sperm. Whole semen cannot be used for IUI due to the reactions to the prostaglandins and bacteria in the semen. The IUI sample uses sperm washed in culture medium, often using a swim up procedure to isolate motile sperm. The IUI is often combined with ovarian stimulation and timed ovulation, although it can be timed using an ovulation predictor kit.

With more severe oligoasthenospermia, or as a primary treatment for less severe male factor infertility, IVF offers the highest per cycle fecundity of any therapy. ICSI has increased the ability of sperm to fertilize oocyte in vitro, even with very low numbers of motile sperm. ICSI is typically recommended with severe oligospermia ($<2–10 \times 10^{6}$ sperm/mL), severe asthenospermia (<5%–10% motile sperm), or poor morphology (<4% normal forms by strict criteria). Fertilization rates match those seen with traditional IVF procedures. Microsurgical epididymal sperm aspiration (MESA) or percutaneous epididymal sperm aspiration (PESA) obtain epididymal sperm for the treatment of obstructive azoospermia. Cases such as failed vasectomy reversal, postinflammatory obstruction, and congenital obstruction can be treated with MESA or PESA. Testicular sperm extraction (TESE) can be used to obtain sperm with nonobstructive or severe obstructive azoospermia. Even men with Sertoli-cell-only syndrome (up to 40%) have successful sperm retrieval with TESE.

Concerns about the risks associated with IVF and ICSI continue to be raised. Most studies to date have not shown an increase in congenital anomalies in children born by ICSI as compared to standard IVF. However, when a Y chromosome deletion is present, the defect will be passed to any male offspring. Data from the Society for Assisted Reproductive Technology and the Centers for Disease Control and Prevention have shown the risk of serious malformations to be 2%, which is the same rate as found with spontaneous pregnancies. Studies have suggested a possible increased risk of sex chromosome aneuploidy, particularly monosomy X and the presence of an extra X or Y chromosome. There is no increased risk of chromosomal structural defects with intracytoplasmic sperm injection.

Ovulatory Dysfunction

Excellent treatment options are available for all causes of amenorrhea and anovulation. The ACOG Practice Bulletin on the management of infertility caused by ovulation dysfunction offers a well-written overview of these therapies. Hypothalamic hypogonadism due to weight loss or excessive exercise may be treated by a change in lifestyle, although this does not always result in correction of menstrual cyclicity. Ovulation can be accomplished with either pulsatile gonadotropin-releasing hormone (GnRH) administration or injectable gonadotropins in women with ongoing amenorrhea or Kallmann syndrome. The GnRH pump delivers 50 to 75 ng per kg every 60 to 90 minutes; ovulation typically occurs in 10 to 20 days. Although side effects are minimal and the risk of multiple gestations is not increased over the general population, this method is labor-intensive for patients and health care providers, requiring continuous use of the pump for up to 3 weeks. Injectable human gonadotropins are now available as human menopausal gonadotropins, purified urinary FSH, and recombinant FSH, and can be given intramuscularly and subcutaneously. The use of any of these products requires close monitoring, including ultrasound and estradiol levels to lower the risk of multiple gestation and ovarian hyperstimulation. Human chorionic gonadotropin (hCG) is typically given when the follicle diameter reaches 15 to 18 mm. The risk of these medications will be further discussed in the section on “ Unexplained Infertility” later in the chapter.

Women with hyperprolactinemia can be treated with dopamine-agonist therapy. Bromocriptine mesylate and cabergoline are oral agents that successfully lower prolactin levels and routinely restore ovulation. Side effects, including headache, nausea, orthostatic hypotension, and dizziness, can be severe. Starting with a low dose and a slow, steady increase in the medication will minimize side effects. With bromocriptine we typically start with one-half tablet, 1.25 mg, at bedtime, increasing weekly to a maximum of 2.5 mg twice daily. Often one tablet at bedtime is sufficient to lower prolactin levels and restore ovulation. Cabergoline is taken only once or twice weekly at doses of 0.5 to 3 mg per week. Side effects are reported to be lower with this dopamine agonist, although it is still important to gradually increase the dose of the medication. Once women achieve pregnancy the medication is stopped, although there are no reports of harmful effects on the fetus. There is no restriction to breast-feeding in women with hyperprolactinemia, assuming there is no worsening of symptoms after pregnancy.

Our understanding of the etiology of PCOS has undergone a rapid expansion over the past decade. The methods of inducing ovulation have expanded, although the standard treatments remain effective for many women. For some women weight loss will allow them to ovulate and achieve pregnancy. Although long periods of time cannot be spent on unsuccessful attempts at weight loss, it is reasonable to start with this treatment option for obese women with PCOS. For slender women with PCOS or those who are not successful with weight loss, many other options are available. The classic medication is clomiphene citrate. The usual dose starts with 50 mg, or one tablet, daily on cycle days 5 to 9 following spontaneous or progestin-induced menses. Ovulation should be confirmed using temperature charts, ultrasound, or luteal progesterone levels. The maximal dose is typically 150 mg for 5 days, although higher doses (to 250 mg) for a longer period (to 8 days) are occasionally successful. In general, the higher the dose required for ovulation, the lower the pregnancy rate. Adding 0.5 mg of dexamethasone to clomiphene may increase the response in women with high adrenal androgen levels. Eight-five percent of women with PCOS will ovulate after taking clomiphene citrate. Side effects include hot flashes, headache, visual changes, breast tenderness, and bloating. Serious side effects are rare. A 10% chance of twins is the greatest risk, and the risk of higher order multiple gestations is less than 1%. It is important for women to realize that not all women conceive with clomiphene citrate; typically do not administer this medication beyond six ovulatory cycles.

Three additional options for women with PCOS include surgical treatment, injectable human gonadotropins, and insulin-sensitizing agents. The classic ovarian wedge resection for the treatment of PCOS fell into disrepute due to a high incidence of postoperative adhesions. Laparoscopic cautery, diathermy, and laser treatment have been used to allow spontaneous ovulation. The theory is that a reduction in the ovarian cortex by the surgical injury will allow ovulation to occur. Fifteen to twenty sites on each ovary are removed and 70% to 80% of women ovulate following surgery. Studies are currently limited and the advantages of surgical therapy versus medical therapy are limited as well. A significant advantage is a decrease in the risk of multiple gestations. Injectable gonadotropins affectively induce ovulation in women with PCOS. The need for close monitoring, to minimize the risk of multiple gestation and ovarian hyperstimulation, is greatest for women with PCOS. For women who do not ovulate with clomiphene, injectable gonadotropins are usually successful at inducing ovulation.

Studies suggest that a large percentage of women with PCOS are insulin-resistant and the use of insulin-sensitizing medications will restore ovulatory menstrual cycles. It is clear that women with PCOS are at increased risk for adult-onset diabetes and often have elevated fasting insulin levels despite a normal fasting glucose. The impact of insulin resistance and chronically elevated insulin levels on ovarian function has been studied and treatment with insulin-sensitizing agents—biguanide and thiazolidinediones—may induce ovulation in women with PCOS. Indeed, in comparison to low-dose clomiphene citrate alone, metformin increases ovulation rate in limited studies. Although the side effects with these medications are common, primarily nausea and diarrhea, they offer a potential treatment option for women with PCOS. This is not a Food and Drug Administration–approved use of these medications, and insulin-sensitizing agents may be less effective in slender women and those with normal fasting insulin levels. Future research on the use insulin-sensitizing agents to control obesity, hirsutism, and anovulation in women with PCOS will be

of great interest to patients and providers alike.

Limited treatment options are available for women with premature ovarian failure. Women with hypergonadotropic hypogonadism, secondary to a chromosomal abnormality, chemotherapy or radiation therapy, autoimmune disorder, or idiopathic loss of ovarian function, do not respond to gonadotropins, as there are simply no functional follicles remaining. Although pregnancies are reported with ovulation-induction agents after use of hormone replacement therapy, these are rare cases and do not justify the use of fertility medications with these women. Hormone replacement, to prevent osteoporosis and minimize hypoestrogenic symptoms, is the standard of care. Fortunately, donor oocytes can be offered as an option for these women. The generous contribution of oocytes by a donor undergoing gonadotropin stimulation and oocyte retrieval, offers women with premature ovarian failure an opportunity for pregnancy. As with women of decreased ovarian reserve and advanced maternal age, donor oocyte is a reasonable option for women with premature ovarian failure. The choice to pursue adoption or the decision to remain child-free should also be discussed with these couples in a nonjudgmental fashion.

Uterine/Tubal Factor

Limited studies are available to determine the value of surgical treatment of uterine abnormalities in women seeking fertility. Some studies demonstrate increased pregnancy rates in women undergoing hysteroscopic polypectomy or myomectomy, suggesting the value of this surgery. It is presumed that submucosal lesions, leiomyoma or endometrial polyps, should be removed prior to attempting pregnancy. Hysteroscopic surgery is recommended for women with intrauterine adhesions, or Asherman syndrome, and for removal of a uterine septum. The benefit of abdominal surgery—laparotomy or laparoscopy—for the removal of intramural and subserosal leiomyoma is less clear. An increase in pregnancy rate of 40% to 60% following abdominal leiomyoma was reported, but this surgery increases the risk of peritubal and periovarian adhesions. The risk of recurrence following surgery of leiomyoma is at least 30% and increases with time.

The treatment of known tubal factor infertility depends on the severity of the disease. Proximal tubal blockage can be treated hysteroscopically, radiographically, or by microsurgical reanastomosis. A meta-analysis documented an intrauterine pregnancy rate of 50% in women undergoing surgery for proximal tubal blockage, with the highest success rates achieved with selective salpingography and transcervical cannulation. Laparoscopic removal of thin, avascular adhesions involving the tube and ovaries offers a reasonable chance for pregnancy, with a success rate up to 70% but with an ectopic pregnancy rate of 20%.

Women with significant symptoms, such as pelvic pain, secondary to adhesions or endometriosis, also benefit from laparoscopic surgery. Removal of severe tubal adhesions and treatment of hydrosalpinges by neosalpingostomy offers a less predictable pregnancy rate. The per cycle fecundity following extensive tubal surgery is only 2% to 4%. Repair of bilateral tubal damage—proximal and distal tubal adhesions—has the lowest chance of an intrauterine pregnancy and is not recommended. The success of IVF, as will be discussed in Chapter 39, suggests this is a superior treatment for women with severe tubal factor infertility. IVF offers a reasonable chance for pregnancy, lowers the risk of ectopic pregnancy, and avoids the prolonged delay required to determine the success of treatment. Studies suggest an increased pregnancy rate if large hydrosalpinges are removed laparoscopically prior to IVF. Thus tubal surgery, with removal of the damaged fallopian tubes prior to IVF, increases the chance for successful infertility treatment.

Cervical factor infertility, although difficult to identify with standard testing, can be treated effectively with IUI. Limited studies have suggested a benefit of low-dose oral estrogen 1 week prior to ovulation for women with decreased cervical mucus; this treatment can be attempted for women with a history of cervical trauma, surgery, or diethylstilbestrol exposure. The standard therapy for these women is timed IUI, using washed sperm placed in the uterus the day following the LH surge or using ovarian hyperstimulation for timing ovulation.

Unexplained Infertility

Unexplained infertility is determined in 15% to 25% of infertile couples. This diagnosis often leads to significant distress, as the cause of infertility remains unknown. The good news is that treatment options for these couples allow a significant chance for pregnancy. One option, for a young couple, may be no therapy. Approximately one-half of couples who do not conceive in 1 year will do so within 2 years; up to 70% to 80% will conceive in 5 years. The primary benefit of treating unexplained infertility is to shorten the time to conception, a treatment of particular interest to couples in which the woman is over 30. The three primary treatment options are clomiphene with IUI, injectable gonadotropins with IUI, and IVF. IUI alone may also significantly increase per cycle fecundity from 1% to 3%, to 7%. Adding clomiphene citrate to the IUI, 50 to 100 mg daily on cycle days 5 to 9, increases the per cycle fecundity to 7% to 9% per cycle. A large group study demonstrated a two- to three-fold increase in pregnancy rate when controlled ovarian hyperstimulation occurred with gonadotropin and IUI compared to insemination alone. Studies have reported a per cycle fecundity rate of 10% to 18% with injectable gonadotropins and IUI; meta-analysis reports a 33% pregnancy rate with three cycles of gonadotropins and IUI. The pregnancy rate is increased with injectable gonadotropins alone, but the chance for pregnancy is increased with the addition of an IUI. The highest per cycle fecundity is accomplished with IVF. The 1998 data collected by the Society for Assisted Reproductive Technology reported a delivery rate per retrieval of 29.1% per IVF cycle. Gamete interfallopian transfer and zygote intrafallopian transfer also offer an excellent per cycle fecundity of 27.4% and 29.6%. The cost and invasive nature of these procedures however has limited their use. IVF, compared to clomiphene or citrate gonadotropin use, requires the greatest commitment of time, effort, and financial resources. But as is the case for couples with male factor or tubal factor infertility, IVF provides the highest per cycle fecundity for couples with unexplained infertility.

Women with endometriosis are often placed in the unexplained infertility category. Debate continues regarding the effect of mild endometriosis on fertility. If a woman is asymptomatic and has completed the evaluation, laparoscopy can be bypassed allowing the couple to move on to treatment for unexplained infertility. If laparoscopy is elected, and mild endometriosis is identified and removed, the treatment options are the same. As with unexplained infertility, the young couple with treated endometriosis may elect to have no infertility therapy.

Advanced Maternal Age

The American Society for Reproductive Medicine began a campaign in 2001 designed to alert women to the causes of infertility. Included in this campaign was information regarding the effect of advanced maternal age on fertility. Indeed, the age of first pregnancy has increased over the past several decades. In 1975 less than 20% of women attempted their first pregnancy between the ages of 35 to 39; in 1995, 44% of first pregnancies were attempted among this age group.

The Hutterites study published in the 1950s demonstrated the effect of age on fertility. In this population the overall rate of infertility was 2.4%; after age 34 it rose to 11%, after age 40 to 33%, and after age 45 to 87%. The average woman did not conceive after age 40. Donor insemination studies in France and the U.S. confirm this pattern. Cycle fecundity clearly increases with advancing age, likely beginning in the mid-30s. The risk of infertility increases at least 10 to 15 years prior to menopause, as does the risk of spontaneous abortion and chromosomal anomalies of ongoing pregnancies. Unfortunately, many women expect normal fertility until shortly before menopause and are surprised by the realization that natural infertility begins many years before their last menstrual period.

What can health care providers do to prevent this health issue from affecting their patients? Discussing the effect of aging on natural fertility with patients seeking contraceptive care provides them with useful information with which to make personal decisions. Although many women and couples do not pursue pregnancy until their lifestyle allows them to support and care for a child, awareness of age-related infertility is of great value. An active decision to remain child-free is better for women than an unexpected outcome due to simply delaying conception based on misinformation. Once a woman of advanced maternal age decides to pursue pregnancy, information about the timing of intercourse during the cycle is of value. If history or exam suggests a potential cause of infertility, for example irregular menses or history of STD, the workup can begin immediately. The new basic workup can be accomplished in 1 to 2 months, allowing rapid diagnosis of the cause of infertility once a couple does not conceive within a year or earlier, if the woman is over 35. Providing patients with information and rapid evaluation and treatment maximizes the chance that they will achieve their desired family.

It is now easier and faster for couples to determine the cause of infertility. The limited basic workup includes a semen analysis, ovulation monitoring, and uterine/tubal evaluation. For women over 30, a day 3 FSH or clomiphene challenge test is recommended to screen for decreased ovarian reserve. For selected couples, further male factor evaluation, hormonal testing, postcoital testing, endometrial biopsy, and laparoscopy can be considered. Treatment options for infertility now offer a variety of highly successful options for male factor infertility, ovulation dysfunction, uterine/tubal factor, and unexplained infertility.

SUMMARY POINTS

- Infertility is a common problem in the United States, occurring in approximately 14% of couples.
- The basic workup for infertility should begin 1 year after discontinuance of contraception. The workup includes a semen analysis, documentation of ovulation, and uterine/tubal evaluation with a hysterosalpingogram.
- A thorough history and physical examination of both the man and woman may identify the etiology of infertility and direct further testing to the most likely cause of infertility.
- Treatment for male factor infertility includes donor insemination, surgery, IUI, and IVF. Intracytoplasmic sperm injection and testicular sperm extraction, despite severe oligoasthenospermia or azoospermia, allow couples to conceive.
- Treatment of hypothalamic dysfunction includes the GnRH pump and injectable gonadotropins. Hyperprolactinemia is successfully treated with dopamine agonists. Polycystic ovarian syndrome can be treated with clomiphene citrate, surgery, injectable gonadotropins, and insulin-sensitizing medications. Premature ovarian failure can be treated with donor oocytes.
- Uterine and tubal factor infertility may be treated surgically. Severe tubal factor infertility is most successfully treated with IVF.
- Unexplained infertility can be treated with clomiphene citrate/intrauterine insemination, injectable gonadotropin/intrauterine insemination, or IVF.
- Women with advanced maternal age are best served by rapid workup and treatment.

On July 25, 1978, the field of reproductive medicine and infertility changed forever with the birth of Louise Brown in England by in vitro fertilization (IVF). Her birth gave hope to many couples not able to conceive conventionally. The initial indication for IVF was tubal factor or pelvic adhesive disease as IVF bypasses the fallopian tubes by using controlled ovarian hyperstimulation (COH), egg retrieval, and insemination with ultimate embryo transfer. COH produces large numbers of mature eggs for insemination extracorporally. Intracytoplasmic sperm injection (ICSI) injects a single sperm into the cytoplasm of an egg. It has revolutionized the treatment of men with oligospermia or azoospermia in whom intratesticular sperm are present. The uccess rate of IVF with ICSI approaches the pregnancy rate with conventional IVF for nonmale factor etiologies. Women with premature ovarian failure, decreased ovarian reserve, or age factor infertility, can chose to undergo an IVF cycle with donor oocytes and enjoy excellent pregnancy rates.

INITIAL EVALUATION FOR IVF

The initial evaluation includes a review of the couples' medical, surgical, and infertility history and informed consent process is obtained. Topics of discussion should include:

- genetic screening, testing, and counseling
- COH and retrieval techniques and risk factors
- fresh and frozen embryo transfer procedures
- a discussion of nonselective reduction
- ICSI and its indications
- an estimate of the number of embryos to be transferred
- an estimate of the individual couple's pregnancy rate with IVF
- potential adverse events such as cancellation of cycles, gamete/fertilization problems, and pregnancy risks (multiple gestation, spontaneous abortion, and ectopic pregnancy).

The couple should have access to a referral for psychological testing, particularly in cases of donor egg.

Gamete intrafallopian transfer (GIFT) and zygote intrafallopian transfer (ZIFT) are alternatives to conventional IVF. GIFT places retrieved oocytes and sperm into the fallopian tube via laparoscopy or laparotomy where fertilization takes place, while ZIFT places zygotes created by IVF, at the stage prior to cleavage, into the fallopian tube. ZIFT and GIFT require at least one normal fallopian tube. ZIFT allows evaluation of the rate of fertilization while GIFT does not. Initially, pregnancy rates with GIFT and ZIFT were higher than conventional IVF, but this occurred at a time when IVF success rates were relatively low. For religious reasons, some couples prefer GIFT because fertilization occurs in the fallopian tube and not in the laboratory. Both GIFT and ZIFT require an additional procedure—a mini-laparotomy or laparoscopy, for placement of the gametes or zygotes. This additional procedure carries an inherent surgical risk and added cost, which makes IVF the choice of virtually all couples. Pregnancy rates with IVF have improved sufficiently so that that the added surgical risk of GIFT and ZIFT is simply not warranted. With the advent of ICSI, assisted hatching, and advanced laboratory techniques (i.e., culture media and embryo day 3 or 5 transfers), IVF success rates rival and exceed ZIFT/GIFT rates and very few of these procedures are performed.

PATIENT SELECTION FOR IVF

Although tubal factor infertility was the original indication for IVF, the indications for IVF have now been expanded to make this the final step in virtually all infertile couples. Tubal factor infertility can arise from various etiologies, including pelvic inflammatory disease, endometriosis, prior abdominopelvic surgery (including tubal ligations), ectopic pregnancy, or a ruptured appendix. This diagnosis is made by hysterosalpingogram (HSG) or laparoscopy. Although surgical therapy may be a very reasonable option in some patients, IVF may be the best option, especially for women with significant tubal damage, older women, or those with multiple factor

infertility. Because of the poor prognosis for repeat tuboplasty, IVF is the treatment of choice.

The treatment of male factor infertility has been drastically advanced by IVF and ICSI. Men who have a motile sperm count below 10×10^6 with poor morphology have a significant reduction in pregnancy rates. ICSI has been used to treat severe male factor infertility, with pregnancy and fertilization rates similar to couples with normal semen parameters who are undergoing conventional IVF. Oligospermic and selected azoospermic males, who have intratesticular sperm, have high fertilization and pregnancy rates with ICSI, regardless of motility, morphology, or sperm concentrations.

Reduced fertility with advancing maternal age seems to be more common as women delay childbearing. In noncontracepting populations, fertility starts to decrease at age 30 with a severe decrease in fertility after age 40. This decline is manifested as an age-related decrease in ovarian follicles and a decline in oocyte quality. Women over 35 have a significantly decreased chance of pregnancy, compared to younger patients. Data from women of all ages, who have received an oocyte from a young donor, reveal that pregnancy rates are excellent, and independent of the recipient's age, implying that the uterus does not age. At present there are provocative tests that evaluate a patient's fecundity.

Women with diminished ovarian reserve (DOR), regardless of their age, have significantly lower pregnancy rates with any modality. They also have an increased risk of aneuploid pregnancy and spontaneous miscarriage compared to patients with normal ovarian reserve. Day 3 or basal follicle-stimulating hormone (FSH) and the clomiphene challenge test (CCT), correlate best with conception using assisted reproductive technologies (ARTs), and are also applicable to an infertility population. Typically, an abnormal day 3 FSH is =12.6 IU/L. These values are dependent on the particular assay used and are patient population–dependent. Infertile patients who are older than 43 years or have an elevated FSH, have a less than 5% pregnancy rate per cycle, and are encouraged to pursue donor egg or adoption.

Endometriosis affects 30% to 40% of infertile women. Endometriosis involving the ovaries, fallopian tubes, and pelvis may cause anatomic distortion and adhesions of the tubes and ovaries hampering ovum pickup. Patients with moderate to severe endometriosis (stages III and IV) are encouraged to attempt IVF, especially those with severe adhesive disease. Many of these patients have had one or more conservative surgeries and have not achieved pregnancy despite optimal debulking of their disease. Surgery prior to IVF to improve pregnancy rates is not recommended. Surgical excision of endometriomas prior to stimulation improves the stimulation and oocyte retrieval.

Many couples who fail clomiphene citrate (CC) and gonadotropin therapy eventually require IVF. Patients under 36 years of age, World Health Organization (WHO) group I and II, frequently try three to four cycles of CC or gonadotropins with intrauterine insemination (IUI). Of patients who become pregnant with CC and IUI, over 85% become pregnant within the first four cycles of treatment.

Patients with unexplained infertility are by definition ovulatory, with normal fallopian tubes and uterine cavity or stage I or II treated endometriosis, and a normal semen analyses by WHO criteria. The majority of these patients have already attempted other therapeutic strategies such as timed intercourse, CC, or gonadotropins with IUI. Women with unexplained infertility have a combined per cycle IVF pregnancy rate of approximately 20% compared to 8% and 17% for CC with IUI and gonadotropin with IUI, respectively. In 2000, IVF pregnancy rates for unexplained infertility were appreciably higher indicating this technique should be more rapidly offered.

Premature ovarian failure (POF) is defined as hypergonadotropic hypogonadism prior to the age of 40. Causes of premature oocyte loss include gonadal dysgenesis (Turner syndrome), failure of germ cell migration in fetal life, and postnatal germ cell loss (castration, autoimmune disease, infections). Iatrogenic oocyte depletion occurs with chemotherapy, radiotherapy, and ovarian surgery for benign disease. Patients with POF have excellent success when receiving donor oocytes with a delivery rate/cycle of approximately 30% and a cumulative delivery rate after four cycles approaching 86%. There is no decrease in pregnancy or delivery rates with increasing age or diagnosis of the recipient (i.e., POF, surgical castration, previous IVF failure, menopause, DOR). Thus, endometrial receptivity does not appear to be altered by recipient age or diagnosis. Using young oocyte donors optimizes success rates by having a greater chance of transferring healthy embryos.

TESTING PRIOR TO ASSISTED REPRODUCTION

Previous IVF cycles should be reviewed in detail focusing on the number and quality of embryos, the method of insemination (conventional vs. ICSI), follicular and endometrial development, estradiol levels throughout the stimulation, length of the stimulation, and the pregnancy outcome. In addition we review the method and number of embryos transferred. Frozen embryo transfer cycles are also assessed, noting the endometrial stimulation and embryo quantity and quality after thawing.

Evaluation should also consider thyroid disease (thyroid-stimulating hormone), hyperprolactinemia (prolactin), an insulin and glucose test to screen for hyperinsulinemia (if indicated), and a blood type and Rh. An infectious disease panel will consist of hepatitis B and C, syphilis, human immunodeficiency virus (HIV), and rubella titer. Initial selected genetic tests for carrier status are offered and include Tay-Sachs disease (Ashkenazi Jews), sickle cell anemia (African descent), ß-thalassemia (Mediterranean/Chinese), a-thalassemia (Southeast Asians), and cystic fibrosis (Caucasians). A day 3 or basal FSH and estradiol may be useful in selected patients.

Ovarian Reserve Testing

Testing ovarian reserve can be useful for all IVF patients regardless of age. These tests are inexpensive, noninvasive, and highly predictive of ultimate outcome with ARTs. Most IVF programs routinely check all patients 35 years or older or those at risk, including patients with multiple surgeries, stage III or IV endometriosis, severe adhesive disease, and cigarette smokers. A day 3 basal FSH is obtained during a natural cycle. Based on our laboratory assay, a day 3 FSH greater than 12.6 mIU/mL predicts a less than 5% chance of achieving a pregnancy per IVF cycle, regardless of age. In order to counsel patients effectively, each institution and laboratory must establish their own critical cutoff point, above which, a pregnancy becomes highly unlikely. In a large study, both FSH and estradiol were shown to be excellent predictors of IVF performance. As a “single predictor,” basal FSH was better than age at predicting a successful pregnancy. Regardless of age or fertility history, women with diminished ovarian reserve as manifested by an elevated day 3 FSH, ultimately conceived with a high rate of first trimester pregnancy loss. The live-birth rate in patients with DOR was less than 1%.

Significant intercycle variability can be found among basal FSH values, especially in patients with widely fluctuating FSH levels. This variability reflects the physiologic inability of the follicle cohort to suppress FSH as a result of declining follicular health. FSH levels rise as granulosa cell production of inhibin-B decreases. Inhibin exerts negative control on the pituitary. Studies have shown that patients with intermittently elevated basal FSH levels stimulate poorly, need more medication for stimulation, have fewer aspirated follicles, and lower peak estradiol levels compared to patients with minimal intercycle variability. Once a patient has an isolated elevated day 3 FSH, even among normal cycles, her chance for IVF pregnancy is poor.

Due to the intercycle variability of day 3 FSH values, a normal value has limitations. The CCT uses the day 3 FSH value, and a provoked day 10 response to 100 mg of clomiphene citrate, administered cycle days 5 through 9. The CCT specifically evaluates the day 10 FSH. An abnormal day 10 FSH carries the same poor prognosis as an abnormal day 3 FSH. A poor CCT response predicts a decreased pregnancy rate for an infertile population as well as for IVF patients. Unexplained infertility comprises 52% of the patients with an abnormal CCT.

A CCT should be performed on all patients over the age of 37, or in women who have a borderline day 3 FSH. Patients may be tested earlier if they have had ovarian surgery, are diagnosed with stage III or IV endometriosis, or have severe adhesive disease. The results of these tests help direct patient counseling. An elevated day 3 basal FSH value, or an abnormal CCT, predicts a less than 5% chance of pregnancy with ART.

Evaluation of the Uterus and Fallopian Tubes

An HSG, sonohysterogram, or office hysteroscopy should be done before starting IVF. An HSG aids in the diagnosis of hydrosalpinges or an intrauterine filling defect, both of which decrease IVF pregnancy rates. Since patients can develop uterine or tubal pathology in intervening years, a repeat study should be considered if the previous uterine evaluation is more than 1 year old. A complete pelvic ultrasound, a trial embryo transfer, vaginal cultures, and a Pap smear are done on all patients. During the ultrasound, the adnexae are evaluated for ovarian cysts, endometriomas, and hydrosalpinges, while any leiomyomas or polyps are noted in the uterus. Sonohysterography is almost as accurate as hysteroscopy, and more sensitive and specific than transvaginal ultrasound or HSG in diagnosing intrauterine pathology. Additionally, sonohysterography is less invasive, relatively inexpensive, and does not require the use of contrast dyes.

Hydrosalpinges and IVF

Tubal disease is one of the main indications for IVF with hydrosalpinges accounting for 10% to 30% of tubal factor infertility. Compared to other types of tubal pathology, women with hydrosalpinges (including surrogate carriers) have reduced IVF success. Hydrosalpinges decrease IVF implantation, pregnancy, and delivery rates while increasing early pregnancy loss. This has been confirmed by large meta-analyses as well as numerous retrospective studies.

Only two randomized, prospective studies have evaluated whether prophylactic salpingectomy of hydrosalpinges prior to IVF improves pregnancy rates. Pregnancy rates after a single IVF cycle are approximately 37% in women after salpingectomies and 24% when the hydrosalpinges were not removed. Subgroup evaluation of

these patients revealed that women with bilateral hydrosalpinges, visible on ultrasound, had a significant increase in implantation and delivery rates after salpingectomy compared to the nonintervention group. Ultimate delivery rates more than double in patients with ultrasound visible hydrosalpinges after salpingectomy.

Many mechanisms have been proposed to explain the adverse effects hydrosalpinges have on IVF success rates. Fluid that accumulates in the hydrosalpinx can move retrograde into the uterine cavity. Endometrial receptivity marker molecules have been shown to be decreased in patients with hydrosalpinges, while inflammatory cytokines within the fluid may act as inhibitors. Salpingectomy is recommended when the fallopian tubes have visible fluid within the tube on sonogram. Polyps, müllerian anomalies, intrauterine synechiae, and leiomyoma are all associated with reproductive loss or failure. In women undergoing IVF, a midfollicular office sonohysterogram (intrauterine saline infusion) can further delineate the nature of the lesion. After the lesion is identified, a diagnostic or operative hysteroscopy should be performed to correct the abnormality.

Uterine leiomyomas may contribute to infertility and miscarriage but the data are limited by the uncontrolled retrospective nature of the reports. Most IVF studies distinguish between submucosal (leiomyomas that distort the uterine cavity), intramural (leiomyomas confined to the myometrium with no cavity distortion), and subserosal leiomyomas (leiomyomas protruding from the serosal surface). Subserosal leiomyomas, which are not adjacent to the endometrium, do not decrease pregnancy rates or increase miscarriages rates. Submucosal leiomyomas, which protrude into the uterine cavity, have been shown to decrease IVF pregnancy and implantation rates when compared to nonprotruding intramural and subserosal myomas. Prior to starting an IVF cycle, removal of submucosal distorting myomas is strongly recommended. Depending on location, leiomyomas are removed abdominally or hysteroscopically.

The literature is controversial regarding the removal of intramural leiomyomas prior to an IVF cycle, especially if they do not distort the endometrial cavity. In retrospective studies in patients under 40 years of age with intramural myomas, there is a significant decrease in implantation rate. There is only a trend toward decreased live-birth rates in women with intramural myomas, independent of the size of the leiomyoma volume.

Debate remains as to whether endometriomas should be removed prior to IVF. The few retrospective studies performed have not shown an increase in pregnancy rates with removal of endometriomas. However, some studies have shown a decrease in peak estradiol, fertilization, and implantation rates with advanced stages of endometriosis, including endometriomas. Most experienced clinicians remove endometriomas prior to IVF because there appears to be a significant improvement in the recruitment of follicles. However, debulking endometriosis is not warranted before IVF except in cases of endometriomas or pelvic pain. Women with stage III or IV endometriosis have a decreased pregnancy rate and their embryos are often poor in quality with thickened zona pellucida.

EVALUATION OF MALE FACTOR INFERTILITY

Male factor infertility will affect 50% of infertile couples in some fashion. In the vast majority of cases, this diagnosis is known prior to IVF. During the initial IVF consultation, the male partner is encouraged to be present so we can review his medical history and any prior semen analyses. Men suspected of male factor infertility are typically evaluated with regard to the following:

- infertility history
- sexual history
- childhood and developmental history
- medical history
- surgical history
- prior infections
- gonadotoxins
- family history
- a review of systems.

Multiple semen analyses should be evaluated in addition to any appropriate hormonal and genetic screening.

Semen Analysis and Sperm Preparation

Semen samples should be collected after an abstinence interval of 2 to 3 days. WHO criteria are a rough guideline for evaluating semen samples. These criteria include assessment of volume, sperm concentration, motility, morphology, pH, and total sperm count. Sperm morphology has become a useful indicator of successful fertilization with IVF. Kruger coined the term “strict criteria,” which includes only morphologically normal sperm. In studies using strict morphologic criteria, men with greater than 14% normal forms had normal fertilization rates in vitro. Patients with 4% to 14% normal forms had intermediate fertilization rates, while men with less than 4% normal forms had fertilization rates of 7% to 8%. ICSI should be recommended for any factor or combination of factors that are abnormal, including count, motility and score, as well as sperm morphology. In men with poor sperm parameters, ICSI produces fertilization and pregnancy rates similar to conventional IVF.

Semen samples need to be washed and processed prior to their use in IVF. Washing techniques isolate motile capacitated sperm for insemination. Sperm isolation may be performed on ejaculated semen, sperm retrieved from the epididymis or testes, or cryopreserved samples. Several isolation techniques are currently used. The “swim-up” method is used for samples with normal concentration and motility. For low motility and decreased sperm counts, the semen sample is layered over discontinuous Percoll gradients (45% and 90%) and centrifuged. The resulting pellet separates normal spermatozoa from lymphocytes, epithelial cells, abnormal sperm, cell debris, and bacteria.

Many tests have been proposed to evaluate sperm function, including the immunobead test, the interspecies sperm penetration assay, a hemizona assay, the hypoosmotic swelling test, and the mannose binding assay. These are not part of a semen analysis and purportedly predict the ability of sperm to fertilize an oocyte. These tests have poor inter- and intralaboratory reproducibility and the information gained from these studies rarely changes management, which is ultimately to proceed to IVF either with or without ICSI. Even without these studies, the nonfertilization rate is less than 1%. If the semen analysis is normal, a fresh sample for IVF insemination will be produced the day of oocyte retrieval.

Azoospermic or severely oligospermic men will be further evaluated. If necessary, a sperm retrieval procedure may be required. One or two of these sperm samples will be cryopreserved prior to starting an IVF/ICSI cycle. At the time of oocyte retrieval, a frozen sample will be thawed for ICSI.

Genetic and Hormonal Evaluation of the Infertile Male

Azoospermic and severely oligospermic males require genetic and hormonal evaluation. Men with nonobstructive azoospermia or severe oligospermia have a Y chromosome microdeletion assay performed. Thirteen percent of men with nonobstructive azoospermia will have a deletion in the gene cluster termed *DAZ* (deleted in azoospermia), which resides in the AZFc region, within the *DAZ* gene cluster. Men with this Y chromosome deletion produce male offspring that are severely infertile or sterile. Prior to ICSI, we test for *DAZ*, and provide genetic counseling if needed. Nonobstructive azoospermic men often have karyotype abnormalities that cause reproductive failure. Ten percent of these men have a sex chromosome abnormality, with the most common being Klinefelter syndrome (47 XXY). Men who have obstructive azoospermia, with congenital bilateral absence of the vas deferens (CBAVD), require testing for mutations in the cystic fibrosis gene. Ninety percent of patients with CBAVD will have gene aberrations. Since these genes are transmitted in an autosomal recessive fashion, genetic counseling is advised for these men and their families. Evaluation of oligospermic and azoospermic men requires serum measurements of luteinizing hormone (LH), FSH, prolactin, and testosterone. These often aid in the diagnoses of testicular resistance or failure, and hypogonadotropic hypogonadism.

PREPARATION FOR IVF

A trial or “mock” embryo transfer should be performed with the same catheter used during the actual embryo transfer. This enables the physician to measure the uterine length and note the curvature of the cervix and uterus. The goal of this precycle trial transfer is to facilitate a nontraumatic embryo transfer which has been shown to increase pregnancy and implantation rates. If there is cervical stenosis precluding easy access to the uterine cavity, it will be detected before undergoing an IVF cycle. Severe cases of cervical stenosis may require dilation of the cervix with hysteroscopic guidance prior to starting the IVF cycle.

IVF PROTOCOLS

Many protocols have been described for COH designed to increase the number of mature follicles for retrieval. All protocols aim to maximize the number of mature oocytes retrieved per stimulation cycle. The information needed to make a protocol decision is based on:

- medical and surgical history
- results from laboratory tests (i.e., ovarian reserve testing)

- extensive review of any previous assisted reproduction cycles (stimulation response, embryo quantity and quality, fertilization rate, embryo transfer).

In general, patients fit into one of three groups—normal, high, and poor responders.

COH Medications and Strategies

Gonadotropin releasing hormone-agonists (GnRH-a) have revolutionized the use of gonadotropin-based stimulation protocols. Pregnancy rates per IVF cycle have been shown in meta-analyses to significantly improve with gonadotropins because of the increased number of oocytes retrieved. GnRH-a, such as leuprolide acetate, substitute amino acids at position 6 and 10 on the GnRH molecule. This decreases the degradation rate and increases the binding affinity of the agonist to the GnRH receptor. GnRH-a initially produce a surge or flare that increases circulating LH and FSH levels. The flare lasts 7 to 10 days, followed by down-regulation and desensitization, resulting in a hypogonadal state and eventual withdrawal bleeding. This suppression of endogenous gonadotropins prevents the spontaneous LH surge prior to oocyte retrieval. The flare protocols begin GnRH-a the day before or the first day of gonadotropin stimulation. Before the advent of GnRH-a, detection of the LH surge was necessary as 15% of IVF cycles were cancelled due to premature LH surges. Protocols using GnRH-a either capitalize on the down-regulation (long protocol) feature of GnRH-a or the flare (short protocol), which adds endogenous gonadotropins to those administered therapeutically.

At the present time, the majority of IVF cycles use GnRH-a in either a “long” or “short” protocol. GnRH antagonists have been introduced for COH. Third-generation antagonists (ganirelix and cetrorelix) are more complex than agonists, having substitutions on the GnRH molecule at positions 1, 2, 3, 6, and 10. They bind competitively to the GnRH receptor, decreasing gonadotropin secretion within 4 to 8 hours in a dose-dependent manner. GnRH antagonists prevent the risk of a premature LH surge by using either a “single-dose” or “multiple-dose” protocol. Both regimens initiate stimulation with gonadotropins on day 2 of a spontaneous menstrual cycle. The “single-dose” protocol uses 3 mg of cetrorelix based on follicle size and LH level, while the “multiple-dose” protocol uses 0.25 mg of antagonist, starting on stimulation day 6 and then daily up to and including the day of human chorionic gonadotropin (hCG) administration.

Large, prospective, randomized clinical trials comparing agonist to antagonist protocols have demonstrated no significant differences in fertilization, implantation, and pregnancy rates between the two analogues. With GnRH-a there can be difficulty timing cycles since the antagonist protocol depends on the initiation of a natural cycle. GnRH-a protocol requires 2 to 4 weeks for complete pituitary desensitization before starting stimulation, requires longer treatment, and increases total number of gonadotropin ampules needed to achieve follicular maturation. When compared to antagonists, long-acting agonists appear to have an increased risk of ovarian hyperstimulation syndrome (OHSS) and produce estrogen withdrawal effects. While the ideal stimulation protocol has yet to be developed, GnRH agonist and antagonist protocols will undoubtedly continue to be universally used.

There are two major classes of gonadotropins, urinary–derived human menopausal gonadotropins (hMG) which contain both LH and FSH, and recombinant gonadotropins which contain pure FSH. The goal of any gonadotropin therapy is to maximize follicular recruitment for oocyte retrieval. The urinary hMG typically has 75 IU of FSH and 75 IU of LH per ampule. Since FSH is the most important gonadotropin for folliculogenesis, newer preparations of hMG have decreased substantially or removed LH by purification techniques. This can result in a highly purified gonadotropin product with only negligible amounts of LH present (<0.1 IU LH/ampule). The newer recombinant gonadotropins are genetically engineered by inserting the human gene for FSH in cultured immortal mammalian cells. Mammalian cells are needed as bacteria are unable to glycosylate FSH and glycosylation is required for FSH to be biologically active. Recombinant gonadotropin products (r-FSH) are devoid of LH and are highly pure, have specific activity, maintain excellent batch-to-batch consistency, and are tolerated well upon injection. It remains uncertain whether the recombinant FSH products (r-FSH) or hMG (u-FSH and u-LH) preparations have any advantages in clinical pregnancy rates with IVF but if a difference exists, it is modest.

Metformin, an insulin-sensitizing agent, has been successfully used to induce ovulation in a small number of women with polycystic ovary syndrome (PCOS) and is now being investigated in women with PCOS undergoing IVF. Early reports suggest increased fertilization and pregnancy rates when using metformin in patients with PCOS who are resistant to clomiphene citrate. Metformin should be started at least 1 month prior to the IVF cycle with a slow increase to a therapeutic metformin dose to minimize the gastrointestinal side effects. Hopefully, this approach will result in fewer cases of OHSS due to a decreased number of small follicles and an increased number of larger follicles (>16 mm).

Those with a high response rate to gonadotropin stimulation are typically young and thin, and often have the diagnosis of PCOS. They are at risk for producing elevated estradiol levels (>5,000 pg/mL) with few mature preovulatory follicles. This results in cycle cancellation (withholding hCG), to avoid the development of OHSS. Poor responders recruit fewer oocytes than normal responders, and have decreased pregnancy rates. Patient characteristics that predict a poor response include women over 40 years of age, a prior cancelled standard long protocol IVF cycle, severe endometriosis (stage III or IV), diminished ovarian reserve, and cigarette smoking. Normal responders are often patients with unexplained infertility, mild endometriosis, tubal disease, or male factor infertility.

Normal and high responders use leuprolide (1.0 mg subcutaneous daily), given in the midluteal phase (7 days after a positive LH surge) of the menstrual cycle preceding their stimulation (Fig. 39.1). Patients who are on a contraceptive pill, for cycle control and gonadotropin suppression, simply overlap the last 7 days of their pill with leuprolide. The leuprolide dose is decreased to 0.5 mg per day on the day gonadotropin stimulation is continued until the day of hCG administration. An estradiol level and baseline transvaginal ultrasound are obtained. Gonadotropin stimulation is initiated when:

FIG. 39.1. Example of a long gonadotropin-releasing hormone (*GnRH*) protocol. The dosage of follicle-stimulating hormone (*FSH*) and human menopausal gonadotropin (*hMG*) will vary depending on the patient characteristics. *hCG*, human chorionic gonadotropin.

- the uterine lining is less than 6 mm
- no functional ovarian cysts are larger than 1 cm
- women are adequately suppressed with an estradiol level less than 20 pg/mL and an FSH less than 12.6 pg/mL.

Women with functional ovarian cysts larger than 1 cm should continue to be suppressed until the cysts are resolved before initiating gonadotropin stimulation. Those with an endometrial thickness greater than 6 mm should continue leuprolide for another week, and have a repeat scan. In the majority of cases the lining will then be sufficiently thin, allowing the start of gonadotropin stimulation.

To maximize follicular recruitment in normal and high responders, gonadotropin stimulation is started (day 2–3) at a dose between 3 to 6 ampules per day. The starting dosage of gonadotropin is based on age, prior stimulation cycles, and the patient's diagnosis. Women who are poor responders, with a history of pelvic adhesive disease or endometriosis stage III or IV will start at a higher dose (up to 8 ampules/d), while patients with PCOS start at a much smaller dose. The daily dose of gonadotropins is fixed until day 5 of stimulation.

After the first 5 days of stimulation, the daily dose of gonadotropin is adjusted based on the patient's ultrasound and estradiol level. When at least two lead follicles reach 18 mm, or one follicle becomes 19 mm, ovulation is triggered with 10,000 IU of hCG and the leuprolide is discontinued. In addition to follicular size, the decision to trigger ovulation depends upon the rate of follicular growth and estradiol rise. Oocytes are retrieved 35 hours later.

On occasion, high responders will hyperstimulate, producing multiple follicles with estradiol levels greater than 3,000 pg/mL. These patients are at risk for OHSS. Cancellation of the cycle prior to hCG stimulation almost always thwarts the development of OHSS. Another approach to avoid OHSS is to retrieve all of the patient's follicles after hCG, and cryopreserve the embryos for future frozen embryo transfers.

“Coasting” refers to withholding gonadotropin administration for 1 to 3 days while continuing leuprolide until the estradiol falls below 3,000 pgmL so as to be able to proceed with retrieval. Follicles at the time of coasting are typically 16 mm, and are able to continue developing without gonadotropin stimulation. If the estradiol level declines and the number of small follicles declines, hCG may be given and the cycle proceeds to retrieval. Very acceptable pregnancy rates with very few cancelled cycles for fear of OHSS can be achieved when employing “coasting” or cryopreserving all embryos for later transfer.

While antagonist protocols are becoming more commonplace in IVF centers, the efficacy of antagonist stimulation protocols only will be realized when supported by prospective randomized studies. Presently there are two antagonist protocols, a “single-dose” and a “multiple- dose” regimen, both of which are evolving as clinicians become more experienced. When using the “multiple-dose” protocol, antagonist is given when follicles reach 12 to 14 mm. From that day onward, the gonadotropin dose is adjusted depending upon ovarian response. At this point, one ampule of r-FSH is substituted for one ampule of hMG. The antagonist is given (0.25 mg of

ganirelix/d) until the triggering hCG injection. The natural cycle length of the patient is taken into consideration when deciding when to trigger ovulation.

Several protocols have been proposed for the poor responder. Simply increasing the dose of gonadotropins may increase numbers of follicles and oocytes, but pregnancy rates remain low. An alternative protocol and strategy is the flare-up or co-flare. The “co-flare” regimen, which is a short protocol, uses the initial increase of gonadotropins from leuprolide to begin follicular stimulation. Leuprolide is initiated on cycle day 2 after an estradiol and FSH are drawn. On day 3, eight ampules of gonadotropins are administered. Target follicle size is 16 to 17 mm, with a progesterone level below 1.0.

Ovulation is usually triggered on day 8 or later as a shorter interval is associated with immature oocytes. Poor responders often have estradiol levels that plateau associated with postmature oocytes. Most patients receive 10,000 IU hCG at 16 mm. Poor responders are most often placed on a “co-flare” protocol rather than a long, down-regulation protocol.

OOCYTE RETRIEVAL

Oocyte retrieval is performed 35 hours after hCG injection. Retrieval is performed in an operating room or procedure room using conscious sedation. The perineum and vagina are prepped with warm sterile saline prior to retrieval. Oocytes are retrieved by vacuum aspiration of follicles under transvaginal ultrasound guidance. A sharp 17-gauge needle is used, allowing precise penetration of the ovary. The ovary is stabilized with the vaginal probe prior to needle penetration. To reduce patient discomfort, follicles are usually aspirated through a single entry into each ovary (Fig. 39.2). Aspirates are collected into 15-mL heated collection tubes. The patient is discharged once she is tolerating liquids and has recovered sufficiently from the conscious sedation.

FIG. 39.2. Transvaginal ultrasound probe with needle-guided aspiration. Oocytes are removed through the needle and tubing using negative vacuum pressure.

In the laboratory, follicular aspirates are examined under a dissecting microscope and blood and cumulusgranulosa cells are removed. Oocytes are placed in culture media, and graded for maturity and quality. The optimum stage of oocyte maturity is metaphase II, with one polar body extruded. At this stage, conventional insemination or ICSI can be performed (Fig. 39.3). Oocytes are placed into culture media in microdroplets under oil. With conventional insemination, oocytes are inseminated 40 hours after hCG injection with 50,000 normal motile sperm per mL, with greater than 4% normal forms by strict Kruger criteria. One hour later, oocytes are removed from the insemination droplets and placed into clean, sperm-free microdroplets under oil. Fertilization is checked 18 hours later. Normal fertilized embryos are moved to individual microculture droplets and remain there until embryo transfer. Embryo transfer occurs 72 hours after insemination.

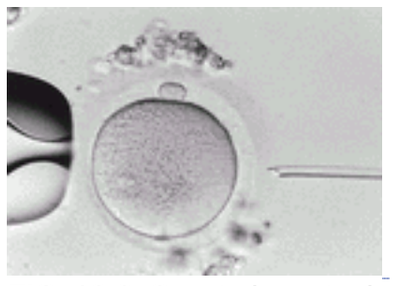

FIG. 39.3. Oocyte in metaphase II about to undergo intracytoplasmic sperm injection (ICSI). Ooplasm is clear with the first polar body at 12 o'clock. During ICSI, the introducing pipette (*right*) places a single sperm (at the tip of the pipette) into the cytoplasm of the egg. The holding pipette (*left*) holds the egg in place with gentle suction.

LUTEAL PROGESTERONE SUPPORT AFTER OOCYTE RETRIEVAL

The use of exogenous progesterone, during the luteal phase of an IVF cycle, to increase pregnancy rates is supported by large meta-analyses. Progesterone prepares the endometrial lining for implantation and pregnancy maintenance. The timing of progesterone supplementation seems to be critical and is started the evening of the day of retrieval. There has been much debate in the literature with regard to the route of administration of progesterone for IVF luteal support.

Proponents of intramuscular administration argue that levels are measured more accurately in the serum, helping clinicians modify progesterone administration throughout the luteal phase and early pregnancy. Physicians who prefer intravaginal progesterone point to its local effects on the uterus and endometrial lining.

Most programs prefer progesterone in oil (given intramuscularly), starting the night of oocyte retrieval and continuing until the patient has her first pregnancy test. If the peak progesterone level is greater than 40 µg/L, the supplementation is continued until the patient is 8 weeks pregnant and then a change to vaginal suppositories, 100 mg twice daily, is made until 12 weeks. If the progesterone level is less than 20 µg/L, 100 mg vaginal progesterone suppository twice a day is added. Levels will be rechecked in 1 week and are titrated accordingly.

ICSI AND SPERM RETRIEVAL TECHNIQUES FOR SEVERE MALE FACTOR

ICSI has given men with severe male factor infertility the ability to produce offspring. Prior to microinsemination techniques, severe male factor infertility was essentially untreatable. ICSI delivers a single sperm into the cytoplasm of an egg through the zona pellucida and egg membrane (see Fig. 39.3). Fertilization rates with ICSI using viable motile spermatozoa are very similar to rates achieved with conventional IVF with standard insemination.

Sperm retrieval techniques have given hope to men with obstructive and nonobstructive azoospermia. The etiology of obstructive azoospermia includes men with a previous vasectomy, ejaculatory duct obstruction, and congenital bilateral absence of the vas deferens. Sperm production is normal in these men, though sperm parameters may decrease with chronic obstruction. Sperm are extracted using both percutaneous sperm retrieval and open microsurgical techniques. In percutaneous epididymal sperm aspiration (PESA), sperm are aspirated through a butterfly needle that is placed into the caudal portion of the epididymis. Adequate numbers of sperm are often retrieved allowing for cryopreservation and future ICSI cycles. With the advent of microsurgical epididymal sperm aspiration (MESA), sperm are retrieved in higher numbers than with PESA, allowing for cryopreservation of large numbers of sperm. In our practice, PESA is attempted first since it is a less invasive procedure that often produces enough sperm for ICSI. If sperm collection fails, MESA is the second option. Men with nonobstructive azoospermia have an impairment of normal spermatogenesis. Their pregnancy and fertilization rates with ICSI are lower than for men with obstructive azoospermia. These men normally do not have sperm present in their epididymis for retrieval. Thus, testicular sperm retrieval is performed with either testicular fine- needle aspiration of the testes (TESA) or open testicular biopsy. Recovered sperm can either be used for ICSI or cryopreserved and thawed on the day of retrieval. Nonobstructive azoospermic patients need to be counseled that sperm retrieval techniques may fail to recover sperm. In the event that sperm is not retrieved, couples may opt for donor sperm.

ICSI uses a single washed sperm placed into a viscous solution of 10% polyvinyl pyrrolidine which impedes sperm movement. The spermatozoa flagellum is crushed, which causes immobilization and increases permeability of the sperm membrane, enhancing nuclear decondensation and pregnancy rates. A morphologically normal sperm is aspirated tail-first into an injecting pipette. The sperm is injected through the zona pellucida and into the ooplasm with the polar body at 12 o'clock (see Fig. 39.3). Injected sperm are placed into culture microdroplets under oil. Eighteen hours later, oocytes are examined for fertilization comparable to standard insemination in vitro. Normal fertilized eggs are moved to individual culture microdroplets under oil and transferred 72 hours from insemination.

ASSISTED HATCHING PRIOR TO EMBRYO TRANSFER

The majority of morphologically “normal” embryos do not implant. Other embryos may have decreased cell numbers, cleave slowly, or have impaired blastocyst hatching. The embryo “hatches” from the zona pellucida before implantation. Assisted hatching (AH) has been suggested to enhance the ability of viable embryos to implant after transfer in IVF cycles. AH is the process by which the zona pellucida is artificially breached or opened (e.g., drilling) (Fig. 39.4). This disruption of the zona pellucida theoretically facilitates the hatching of embryos by opening a hole and allowing blastomeres to more easily be extruded. Studies suggest that thick and hardened zona may prevent or reduce the efficiency of hatching of otherwise normally developing embryos and, hence, improve the rate of implantation. A thickened or hardened zona has been postulated to result from gonadotropin stimulation, the laboratory environment, culture techniques, age (>38), or in women with an elevated day 3 FSH. Most commonly, zona drilling is performed with acid Tyrode solution approximately 72 hours after oocyte retrieval, on the day of embryo transfer. This “drilling” creates a defect in the zona pellucida approximately 30 µm in diameter (see Fig. 39.4). Indications for AH include:

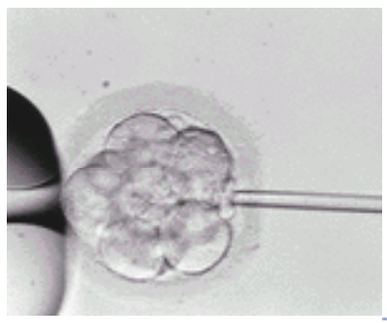

FIG. 39.4. Assisted hatching. The zona pellucida is opened with acid Tyrode solution. To the left is the holding pipette. The pipette on the right delivers acid Tyrode next to the zona pellucida.

- age greater than 38
- elevated day 3 FSH
- a prior failed IVF cycle with suspected implantation failure
- increased zona thickness on microscopy
- excess oocyte fragmentation.

AH for the selected indications may increase implantation and pregnancy rates but randomized trials are needed in order to determine the best candidates for AH.

EMBRYO TRANSFER

Embryo transfer melds the efforts of the clinician and laboratory. The success of implantation hinges in part on the success of the embryo transfer. The controversy remains as to the optimal timing of embryo transfer. Embryos can be transferred up to 6 days after fertilization. However, most embryos are transferred at 3 days, at the 8 to 10 cell stage (Fig. 39.5). Proponents of later embryo transfer argue that implantation and pregnancy rates are higher at the blastocyst stage as the embryo is further developed and the embryos that progress in vitro to this stage are healthier and more likely to implant. This has the theoretic advantage of decreasing the need to transfer more than one or two embryos, and thereby reduce the multiple pregnancy rate.

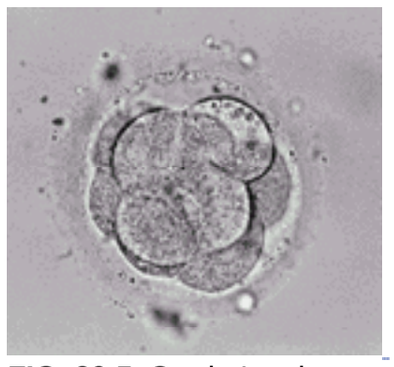

FIG. 39.5. Grade I embryo ready for transfer. This excellent embryo has 10 to 12 even cells and less than 15% fragmentation.

Embryos can be transferred with a variety of soft catheters. A soft-tipped catheter conforms to the contour of the cervix and endometrial cavity and reduces tissue trauma. The catheter is attached to a 1-mL syringe containing approximately 30 µL of transfer medium in a continuous column with the embryos placed toward the tip. Patients should have a full bladder prior to transfer which helps straighten out the angle between the uterus and cervix in women with an anteverted uterus. The cervix and vagina are prepped and draped and care is taken not to introduce blood, mucus, or bacteria with the catheter tip as these contaminants produce a poor environment for implantation. Using abdominal ultrasound guidance, embryos are deposited between 1 and 1.5 cm from the fundus without actually contacting it. Touching the fundus during transfer may cause uterine contractions thereby increasing the intrauterine pressure and expelling the embryos through the cervix, which reduces the pregnancy rate. Ultrasound guidance facilitates embryo transfer and confirms that the embryos are placed correctly high in the uterine fundus. There appears to be a significant increase in implantation and pregnancy rates using ultrasound-guided embryo transfer when compared to touching the fundus prior to transfer to determine the catheter tip location in the uterine fundus. After transfer, the catheter is checked for any retained embryos that were not expelled.

The best quality day 3 embryos are selected for fresh embryo transfer. The morning of transfer, embryos are graded and selected for transfer in order of their grade. They are graded as I, II, or III depending on the number and evenness of the dividing blastomeres, the percentage of extracellular fragmentation, and their cleavage rates. Ideally, grade I embryos (see Fig. 39.5) are selected first for transfer. These are “excellent” embryos with 8 even cells and less than 15% fragmentation, while grade II embryos have 6 to 8 even or slightly uneven cells with up to 25% fragmentation. Grade III embryos have less than 6 uneven cells and excessive fragmentation and are typically not transferred fresh or are cryopreserved because their obvious degeneration renders them virtually unable to develop further. If the patient has a significant number of excellent embryos or a uterine anomaly she may be offered day 5 embryo transfer with one or two embryos.

Patients 35 years and under are routinely transferred with two embryos; three embryos are transferred in women over age 35.

OOCYTE DONATION

Oocyte donation consists of oocyte retrieval with subsequent embryo transfer to a third party (the infertile patient or surrogate carrier). Oocyte donors can be either known or anonymous. Oocyte donation is used for women with:

- POF
- a history of surgical castration
- diminished ovarian reserve
- a risk of transmitting a heritable disease to an offspring
- older menopausal patients.

Donor-recipient IVF cycles typically have the highest pregnancy rates among all ARTs and the number of donor-recipient cycles is increasing. In 1999, the ASRMSART (American Society for Reproductive Medicine/Society for Assisted Reproductive Technology) registry reported that 10% (9,066) of all ART cycles used donor oocytes.

The success of donor recipient cycles is based on the tenet that the capacity to conceive is not based on uterine aging but on the quality of the oocyte. Younger donors have higher implantation and pregnancy rates when compared to older donors, with a decreased incidence of preclinical and clinical pregnancy loss. There does not

appear to be a decrease in the per cycle or cumulative pregnancy rates as endometrial receptivity is maintained and not altered by advancing maternal age. In addition, there was no association between cumulative pregnancy rates and the etiology of the infertility of the recipient.

Patients with Turner syndrome are a special class of patient using donor oocytes. They are infertile due to gonadal dysgenesis, with natural pregnancies occurring in approximately 2% of these women, usually in patients with mosaicism (XX,XO). Small studies comparing oocyte donation in patients with Turner syndrome to controls report conflicting pregnancy and implantation rates. There may be an inherent endometrial receptivity problem in Turner syndrome with lower implantation and pregnancy rates. Women with Turner syndrome should be carefully screened as cardiovascular abnormalities and arterial hypertension are common, with coarctation of the aorta seen in 10% of patients, and bicuspid aortic valve noted in about one-third of patients without coarctations. Even fatal aortic dissection has been reported in pregnancies established by oocyte donation in women with Turner syndrome.

Donor Oocyte Recipient Endometrial Preparation

Embryos are transferred into the recipient's uterus after exogenous endometrial preparation using sequential estrogen and progesterone and gonadotropin down-regulation if they are still cycling. This hormonal manipulation primes the endometrium for embryo transfer by mimicking the natural menstrual cycle. Leuprolide acetate (0.1 µg) is started on cycle day 21 for gonadotropin down-regulation. Bleeding will typically begin after adequate gonadotropin suppression and the decline in the luteal support. After a normal baseline ultrasound and low endogenous estradiol level is created, estrogen therapy is initiated, based on the date of anticipated embryo transfer. Transdermal estradiol patches (0.1 mg) are used in increasing doses that mimic the progressively increasing estradiol level in the follicular phase. By day 11, most women are using four patches.

Most IVF programs initiate aspirin (81 mg) at the start of stimulation in the hope of improving uterine and ovarian blood flow, implantation, and pregnancy rates. In an optimum fresh embryo transfer cycle, Lupron is maintained while transdermal estradiol is adjusted according to endometrial thickness and plasma estradiol levels. The recipient will receive between 2 and 3 weeks of estrogen for endometrial preparation. Once the endometrial lining is =8 mm (14 days) the recipient is ready for the pharmacologic conversion to luteal phase in coordination with the status of the oocyte donor. Both intramuscular (50 mg of progesterone in oil) and vaginal progesterone (100 mg b.i.d.) is started along with Medrol and tetracycline. The majority of fresh embryos are transferred on day 3 which translates into a day 18 transfer for cryopreserved embryos. After embryo transfer, the estradiol, the aspirin, and progesterone in oil are continued until the first pregnancy test, at which time the dose of progesterone is adjusted upward.

Oocyte donors must be screened prior to donation as outlined in the ASRM guidelines for gamete and embryo donation. Donors should be between the ages of 21 to 34 years. Screening for a personal genetic history as well as a sexual history is complemented by testing for infectious and genetic diseases. Psychological assessment by a qualified mental health professional for the donor and her partner is required. Minimal genetic laboratory screening is typically required.

Once prospective donors complete this initial evaluation, they are matched with potential recipients based on both physical and personal characteristics. Prior to starting a donor–recipient cycle, recipients have a precycle evaluation that includes an evaluation of the uterine cavity by sonohysterography or office hysteroscopy. If an intracavitary lesion or a hydrosalpinx is noted, surgical removal is conducted prior to embryo transfer.

Oocyte donation is not without risks to the donor. Donors are often concerned about the risks of ovulation-inducing drugs and ovarian cancer, although the aggregate of studies does not support any association. With COH, the risk of OHSS is always present, although it is decreased in donor oocyte cycles since conception does not ensue. Oocyte retrieval places the donor at risk for anesthetic complications, pelvic infection, and intraperitoneal hemorrhage. These complications are real, though exceedingly rare. There are also potential psychological risks that donors undertake. With appropriate pretreatment screening, we can hopefully minimize donors who may have feelings of ambivalence or regret after donation.

Recipients over 45 years of age are at an increased risk for obstetric complications including gestational diabetes mellitus, hypertensive disorders, cesarean delivery, intrauterine growth restriction, abruptio placentae, and preterm labor. These patients are referred to maternal–fetal medicine specialists for consultation prior to and after conception with IVF. Since there is an increasing risk of adverse pregnancy outcome with advanced maternal age, many centers do not perform donation for women over 50 years of age.

CRYOPRESERVATION

After COH and fresh embryo transfer, 60% of stimulated IVF cycles will produce excess viable embryos which are available for cryopreservation. Cryopreserved or frozen embryos can be thawed and transferred back into the uterus, during a subsequent frozen embryo transfer cycle. This allows for higher overall pregnancy rates per attempted IVF cycle. The indications for embryo cryopreservation include:

- storing excess embryos for future use after a fresh embryo transfer
- decreasing the risk of OHSS in a fresh embryo transfer cycle at very high risk of OHSS
- uterine conditions that are unfavorable for fresh embryo transfer after retrieval (e.g., uterine bleeding, polyps, leiomyomas, severe cervical stenosis, or a thin endometrial lining).

Uterine polyps, leiomyomas, and cervical stenosis are usually identified by sonohysterography, ultrasound, or at trial transfer prior to oocyte retrieval and corrected prior to IVF.

Cryopreservation techniques attempt to minimize cell damage to embryos during the freezing and thawing process with the aid of cryoprotectants. Embryos are frozen at a slow rate with the cryoprotectant. A gradient is induced that allows intracellular water to leave the cell. The embryo is dehydrated to avoid the formation of cytotoxic intracellular ice crystals. Once they are frozen, the embryos are loaded into cryostraws and stored in liquid nitrogen at -196°C. When embryos are needed for transfer, they are thawed rapidly to avoid formation of intracellular ice crystals. Typically, cryopreservation results in an 80% survival rate after thawing frozen embryos.

Patients should be extensively counseled prior to oocyte retrieval with regard to cryopreserving excess embryos. Informed consent is obtained as outlined in the ASRM committee opinion on elements to be considered in obtaining informed consent for ART.

Semen is cryopreserved in men who are not able to produce a sample on the day of oocyte retrieval (due to performance anxiety), who are oligospermic, or azoospermic (post-MESA, PESA, or TESA). Even with the use of cryoprotectants, freezing and thawing sperm samples can decrease motility by 50%. This is usually not a problem as original ejaculate samples contain large numbers of sperm. In men with azoospermia, epididymal or testicular samples are usually cryopreserved until the day of oocyte retrieval. On the day of oocyte retrieval, the semen sample(s) are thawed, the cryoprotectant is removed, and ICSI is performed.

FROZEN EMBRYO TRANSFER

The morning of “frozen embryo transfer,” embryos are thawed and surviving embryos are again graded. Pregnancy rates for fresh embryo transfer and frozen embryo transfer are very similar when similar grade embryos are transferred. This is due to selection criteria for embryo freezing. As discussed previously, day 3 embryos are graded as excellent (grade I), average (grade II), and poor (grade III). After the highest graded embryos are transferred fresh, the remaining grade I and II embryos are cryopreserved, while grade III embryos are not usually transferred or cryopreserved. The number of frozen embryos that are transferred is based on the same criteria as for fresh embryo transfer. Prior to frozen embryo transfer, the recipient will receive between 2 and 3 weeks of estrogen for endometrial preparation. Once the endometrial lining is =8 mm (14 days), intramuscular and vaginal progesterone is started for endometrial support.

RISKS OF IVF

Couples who present for ARTs are usually healthy with no significant medical history aside from their infertility. In the treatment of their infertility, they are asked to take significant risks. The two major complications of ARTs are OHSS and multiple gestation. There has been a proposed association between ovulation-induction drugs and gynecologic cancers, although this is not supported by well-controlled retrospective trials. Prior to initiating an IVF cycle, the risks and benefits of ARTs should be discussed, and formal written consent is obtained. In addition, patients should be counseled on fetal reduction of higher-order multiple pregnancies to decrease perinatal morbidity of infants and mother.

OHSS

OHSS is a potentially life-threatening complication of gonadotropin-induced COH. Although the signs and symptoms of impending OHSS usually become evident during stimulation, this syndrome does not become fully manifested until after hCG administration and oocyte retrieval. Patients typically resolve the OHSS within 10 to 14 days after onset of their initial symptoms. The syndrome is prolonged if a triggering dose of hCG is followed by a supplemental dose of hCG or if the patient

becomes pregnant and produces her own hCG.

Patients who develop OHSS complain of abdominal bloating and pain due to ovarian enlargement. The pathophysiology of OHSS includes increased capillary permeability with “third spacing” of protein-rich fluid. This can result in hemoconcentration and ascites with dramatic fluid accumulations in the abdomen, pleura, or pericardial spaces. Patients can develop nausea, vomiting, diarrhea, and a decrease in appetite if OHSS progresses. As significant amounts of “third spacing” ensue, we often see shortness of breath and decreased urine output. The precise pathophysiology of OHSS is still not completely understood, though vascular endothelial growth factor (VEGF) also known as “vascular permeability factor” has been implicated. It has been shown that follicular fluid from patients with OHSS produce VEGF in increased quantities which, in a dose-dependant manner, increase vascular permeability.

OHSS can be staged based on clinical signs and symptoms, ultrasound features, and laboratory findings and is used to help predict which women require hospitalization. Patients with mild OHSS present with abdominal discomfort, distention and pain, with ovaries enlarged up to 12 cm. Patients may have nausea, vomiting, or diarrhea. Moderate OHSS includes all the features of mild OHSS, but ultrasonographic evidence of ascites as well. Severe OHSS complicates less than 2% of stimulations. It includes features of mild and moderate OHSS as well as clinical evidence of ascites or hydrothorax and difficulty breathing. In addition, severe OHSS patients are at risk for hemoconcentration, coagulation and electrolyte abnormalities, diminished renal perfusion and function, and even adult respiratory distress syndrome.

Risk factors for developing OHSS include young age, low body mass index, and elevated estradiol levels with an increased number of stimulated follicles during COH. In addition, women with a previous pregnancy complicated by a history of OHSS are at great risk of recurrence. If early manifestations of OHSS appear (i.e., abdominal pain, rapidly increasing estradiol levels [>3,000 pg/mL], and extensive follicular recruitment), preventive treatment strategies are employed. On rare occasions, when follicular development and estradiol levels are excessively high early in the stimulation protocol, all stimulation medications are stopped and the cycle cancelled. More often, gonadotropin dosages are adjusted so that estradiol levels increase more slowly, or “freeze all” the embryos rather than transfer them as fresh embryos. Alternatively, using a “coast” by withdrawing gonadotropins and withholding hCG until the estradiol level decreases often allows retrieval and transfer of fresh embryos.

Once OHSS develops, a complete physical exam and ultrasound are performed including blood tests for sodium, potassium, creatinine, and hematocrit. On physical exam, patients often have abdominal distension and tenderness. Decreased breath sounds may be heard at the bases with pleural effusions. Ultrasound is performed to note the presence of ascites and ovarian size. Patients with OHSS can develop hyponatremia, hemoconcentration, hyperkalemia and even decreased renal perfusion. These patients are monitored as outpatients daily until the condition improves significantly. Patients with severe OHSS are admitted to the hospital for inpatient management using intravenous albumin. Patients are instructed to weigh and measure their abdominal girth daily, drink eight glasses of a high sodium drink, and maintain a high protein diet. In addition, they monitor their urine output, and are instructed to report any changes. An increase in abdominal pain or girth, nausea, vomiting, or decreased appetite necessitates a prompt phone call to the health care provider and an office visit.

Fertility Drugs and Cancer

The potential association between ovulation induction drugs and ovarian cancer remains controversial. The data suggesting an association have been based on meta-analyses, but more recent, well-done case-control studies reassuringly have not found any association when evaluating treatment of infertile women with fertility medications compared with infertile women not treated with ovulation-induction drugs. Patients should be informed about the available studies on this issue. It is appropriate to minimize the number of ovulation-induction cycles, both with clomiphene citrate and gonadotropins, as long as there is any concern surrounding ovulation-induction agents and ovarian cancer.

Multiple Pregnancy

Multiple pregnancies occur with a higher frequency in pregnancies resulting from ARTs than spontaneous conception. Since there is a low implantation rate per embryo (10%–25%) with IVF, more than one embryo is often placed into the uterus. The goal is to minimize the number of multiple pregnancies while maintaining good pregnancy rates. Multifetal gestations confer significant morbidity and mortality to both the mother and fetuses because of a high rate of prematurity and in utero mortality. Maternal risks include preterm labor, placental abruption and previa, cesarean section, postpartum hemorrhage, gestational diabetes, and preeclampsia. According to the U.S. Department of Health/Centers for Disease Control and Prevention's 1999 National Summary and Fertility Clinic Reports, 37% of all ART births using fresh nondonor eggs were multiple births (84% twins and 16% triplets and higher), while less than 3% of births in the general population are multiples.

Patients under 34 years of age with a history of a full-term pregnancy and no history of female infertility have the highest implantation rates with IVF. This includes women with previous tubal ligations, normal ovarian reserve testing, donor oocyte recipients, and couples with male factor infertility. In contrast, women older than 34 years of age, with no pregnancies, and extended histories of infertility, have lower implantation rates. Quite often these patients have a history of endometriosis, poor ovarian reserve, and previous failed IVF cyclesembryo transfers.

During the initial IVF consultation, the IVF success rates and the patient's infertility history are reviewed. Based on this information, the number of embryos we recommend transferring and the number of embryos a couple is willing to accept is defined. The goal is that each patient will have two excellent quality embryos replaced, adjusting (up or down) the number of embryos according to embryo quality and each patient's infertility history. Multifetal pregnancy reduction should be discussed as an option for couples with high-order multiple pregnancy. The aim is to reduce preterm deliveries by decreasing the number of fetuses a woman carries. Besides being an invasive procedure, pregnancy reduction, either transabdominal or transvaginal, risks the loss of the entire pregnancy. In experienced centers, pregnancy loss after transabdominal fetal reduction occurs in 6% to 8% of these pregnancies. In addition, the data suggest that pregnancies reduced to twins proceed as if the fetuses were naturally conceived as twins. There is a psychological toll on couples who are making decisions regarding multifetal reduction, especially in women who have experienced difficulty becoming pregnant. If fetal reduction is not acceptable to a patient under 40, a maximum of three embryos is transferred.

High-order multiple pregnancies (triplets and higher) can no longer be viewed as an acceptable risk of IVF and transferring two embryos will decrease the risk. Proponents of two-embryo transfers argue that pregnancy rates in large series are equivalent when compared to three-embryo transfers. Multiple pregnancy rates in patients 30 to 35 years of age are significantly increased from approximately 29% when two embryos were transferred to 40% with the transfer of three embryos. Interestingly, the twin birth rate with transfers of two and three embryos is 26% and 29%, respectively. Thus, a decrease in embryos transferred from three to two decreases the incidence of high-order pregnancies, but does not reduce the twinning rate.

Preimplantation Genetic Diagnosis

Preimplantation genetic diagnosis (PGD) enables couples who are carriers of genetic diseases to test embryos in vitro for genetic abnormalities prior to embryo transfer and select the embryos free of the genetic error for transfer. Traditionally, carrier couples have used chorionic villus sampling and amniocentesis, during the first and second trimesters respectively, to determine if they have a genetically abnormal fetus. The major disadvantage of this type of prenatal diagnosis is the need for second trimester pregnancy termination when genetically abnormal fetuses are detected. PGD provides couples the option to select genetically normal embryos for embryo transfer prior to transfer. PGD involves performing a blastomere biopsy and then genetic testing to determine the genetic complement of the embryo. Blastomeres can be removed from oocytes and embryos at three different stages, polar body analysis, 6- to 10-cell cleavage stage biopsy, and blastocyst stage biopsy. Cleavage stage biopsy is the most widely used technique. In order to biopsy a blastomere or polar body a hole is made in the zona pellucida using micromanipulation instruments with either acid Tyrode or laser. Since these embryos are transferred back into the uterus on day 4 or 5, a genetic diagnosis is determined within 48 hours. First and second polar body biopsies evaluate only maternal chromosomes. Crossover recombination events between homologous chromosomes can create improper diagnoses of heterozygous genetic defects. Presently, polar body biopsy is not performed by most centers offering PGD.

Cleavage stage biopsies are performed on one or two blastomeres of 6- to 10-cell stage embryos 3 days after insemination. These cells are used for diagnosis with polymerase chain reaction (PCR) or fluorescent in situ hybridization (FISH). PCR amplifies fragments of DNA for specific single gene defects. DNA amplification requires careful monitoring to avoid the problems of accidental contamination and allele dropout (ADO) leading to an erroneous genetic diagnosis. ADO or preferential amplification occurs when one of two alleles amplifies preferentially over the other. In a heterozygous cell, the normal allele may be amplified over the abnormal allele and the embryo would be diagnosed as “normal,” and then transferred. PGD has been applied to many monogenic diseases including autosomal recessive, dominant, and X-linked diseases. Examples include cystic fibrosis, Tay–Sachs, spinal muscular dystrophy, Huntington disease, Marfan syndrome, and fragile X syndrome.

Defining the number and structure of metaphase chromosomes is carried out by FISH, not PCR. FISH is used to examine chromosomes in embryos for aneuploidy in patients with male factor infertility and women of advanced maternal age, as well as to detect chromosomal translocations. Common aneuploidies occurring and creened for with FISH include defects in chromosomes 13, 16, 18, 21, 22,X, and Y. FISH uses fluorochrome-labeled probes that hybridize to complementary DNA sequences. The fluorescence produced by the probes allows a color and number notation of these probes which aids in diagnosis. PGD is successful in about 80% to 90% of biopsied embryos, with 50% of these embryos being unaffected and suitable for transfer. Amniocentesis and chorionic villus sampling continues to be recommended because of possible errors in cell sampling or technical difficulties with PCR or FISH. Despite this concern, the risk of carrying a genetically abnormal fetus is limited to the risk of a testing error which is far less than the spontaneous risk of the genetic disease.

SUCCESS RATES

The Fertility Clinic Success and Certification Act of 1992 required all clinics performing ARTs in the United States to annually report their success rates to the Centers for Disease Control and Prevention (CDC). Through SART, the CDC obtains clinic data. The CDC compiles these data and publishes a yearly report which is also available on the CDC website. The first year this clinical data became available for review was 1995. There is a 3-year lag between the time clinics report to the CDC and the time that these reports are available to the public which reflects the time for the last delivery in a calendar year and the subsequent time needed to compile and publish the data.

Each clinic reports on their “pregnancy success rates” based on the type of cycle performed (fresh embryos from nondonor eggs, frozen embryos from nondonor eggs, and donor eggs) as well as the age of the women (<35, 35–37, 38–40, and >40.). The number of ART cycles in the United States has steadily increased as well as the success rates. In 1995, 45,906 fresh nondonor IVF cycles were performed as compared to 65,751 in 1999 (Table 39.1). For patients using their own oocytes, pregnancy rates decrease with increasing age. It is difficult to directly compare the success rates between individual ART programs as they each treat different populations of infertile couples, they may focus on specific infertility factors rather than others (e.g., male factor, preimplantation genetic diagnosis, etc.), and different judgments are often made as to the number of embryos to transfer, IVF protocols, and success rates.

Live Birth Rate percentages per IVF Cycle with Respect to Age Using Fresh Nondonor Embryos				
1999	<35 years	35–37 years	38–40 years	41–42 years
	32.2%	26.2%	18.5%	9.7%
1995	<35 years	35–39 years	>39 years	
	25.3%	18.2%	8.0%	

CDC/SART, Centers for Disease Control and Prevention/Society for Assisted Reproductive Technology; IVF, in vitro fertilization.

TABLE 39.1. *1999 CDC/SART assisted reproductive technology success rates*

SUMMARY POINTS

- IVF was initially developed to treat tubal factor infertility but now represents the final therapy for virtually all infertile couples, regardless of the etiology.
- There is a significant maternal age-related decline in IVF pregnancy and delivery rate which should be taken into account when discussing infertility therapies.
- Day 3 FSH ± estradiol and clomiphene challenge test is a more accurate predictor of IVF success than simply maternal age.
- IVF with ICSI has allowed procreation in men with severe oligospermia and in azoospermic men after retrieval of sperm from the epididymis and testes.
- High-order multiple gestation significantly increases maternal and fetal morbidity and mortality. Careful consideration should be given to transferring the fewest number of embryos possible.
- Donor oocyte IVF is very successful for women with ovarian failure, limited oocyte reserve, advanced maternal age, and genetic disorders.
- Preimplantation genetic diagnosis is being increasingly performed using blastomere biopsy and genetic screening to avoid transferring embryos with aneuploidy and autosomal recessive or autosomal dominant gene mutations.

INTRODUCTION

Endometriosis is defined by the presence of endometrial glands and stroma outside the endometrial cavity and uterine musculature. The pelvis is the most common site of endometriosis, but endometriotic implants may occur nearly anywhere in the body. Although there are numerous theories to explain why women develop endometriosis, no one theory has been proven conclusively. Endometriosis is a common gynecologic problem in reproductive-age women who have pelvic pain, dyspareunia, or infertility. The management of endometriosis is controversial, but randomized clinical studies have substantiated some therapeutic approaches.

Pathogenesis

Several theories have been proposed to explain the histogenesis of endometriosis. The *implantation* theory proposes that endometrial tissue desquamated during menstruation passes through the fallopian tubes, where it gains access to and implants on pelvic structures. The incidence of retrograde menstruation is similar in women with and without endometriosis. Thus, the development of endometriosis could depend on the quantity of endometrial tissue reaching the peritoneal cavity, specific factors enhancing attachment of endometrial cells to the peritoneum and ovary, or the capacity of a woman's immune system to remove the refluxed menstrual debris.

The *direct transplantation* theory is the probable explanation for endometriosis that develops in episiotomy, cesarean section, and other scars following surgery. Endometriosis in locations outside the pelvis likely develops from dissemination of endometrial cells or tissue through lymphatic channels or blood vessels. The *coelomic metaplasia* theory proposes that the coelomic (peritoneal) cavity contains undifferentiated cells or cells capable of dedifferentiating into endometrial tissue. This theory is based on embryologic studies demonstrating that all pelvic organs, including the endometrium, are derived from the cells lining the coelomic cavity. The *induction* theory, an extension of the coelomic metaplasia theory, postulates that the refluxed endometrial debris releases a product that activates undifferentiated peritoneal cells to undergo metaplasia. There is no conclusive proof that peritoneum can undergo spontaneous or induced metaplasia.

Anatomic alternations of the pelvis that increase tubal reflux of menstrual endometrium increase a woman's chance of developing endometriosis. The incidence of endometriosis is increased in young women with genital tract obstructions that prevent expulsion of menses into the vagina and increase the likelihood of tubal reflux. Other studies have suggested that deficient cellular immunity results in an inability to recognize the presence of endometrial tissue in abnormal locations. Decreased natural killer cell activity resulting in decreased cytotoxicity to autologous endometrium has been reported in women with endometriosis. The presence of increased concentrations of leukocytes and their cytokine products in peritoneal fluid of women with endometriosis may play a role in the initiation and growth of the ectopic implants. The immune system clearly has an important, albeit unclear, role in the pathogenesis of endometriosis.

The possibility of a familial tendency for endometriosis has been recognized for several decades. If a patient has endometriosis, a first-degree female relative has a 7% likelihood of being affected similarly.

Epidemiology

The true prevalence of endometriosis in the general population is unknown. Estimates of its prevalence are based on visualization of the pelvic organs. Pelvic endometriosis is present in approximately 1% of women undergoing major surgery for all gynecologic indications, 6% to 43% of women undergoing sterilization, 12% to 32% when laparoscopy is performed to determine the cause of pelvic pain in reproductive-age women, and 21% to 48% of women undergoing laparoscopy for infertility. Endometriosis is found in 50% of teenagers undergoing laparoscopy for evaluation of chronic pelvic pain or dysmenorrhea.

The influence of age, socioeconomic status, and race on the prevalence of endometriosis remains controversial. The age at time of diagnosis is commonly 25 to 35 years, and endometriosis rarely is diagnosed in postmenopausal women. Many believe that endometriosis is more common in women of upper economic classes because they delay pregnancy, which is postulated to increase the risk of developing endometriosis. It is unknown whether this reflects a true increased incidence or results from greater access to medical care. Evidence indicates that blacks have a prevalence of endometriosis similar to that in whites when controlled for socioeconomic status.

Pathology

The most common sites of endometriosis, in decreasing order of frequency, are the ovaries, anterior and posterior cul-de-sac, posterior broad ligaments, uterosacral ligaments, uterus, fallopian tubes, sigmoid colon, appendix, and round ligaments. Other sites less commonly involved include the vagina, cervix, and rectovaginal septum. These latter lesions usually result from extension and invasion of posterior cul-de-sac implants. Uncommon locations include the inguinal canal, abdominal or perineal scars, ureters, urinary bladder, umbilicus, kidney, lung, liver, diaphragm, vertebrae, and extremities.

Macroscopic Appearance Endometriotic implants have a variety of appearances. Superficial lesions on the ovarian or peritoneal surface are commonly reddish maculae or nodules similar in consistency to normal endometrium. These implants vary from 1 millimeter to several centimeters in size. Collection of hemosiderin results in yellow-brown or black discoloration (“powder-brown” lesions). Nonpigmented disease appears as whitish opacified peritoneum, translucent blebs, or pinkish polyploid implants. Scarring with retraction of adjacent peritoneum and peritoneal pockets may occur. Endometriosis also may appear as a deeply infiltrative disease. Tumorlike masses form from invasion, and diffuse fibrosis usually develops in the posterior cul-de-sac, pelvic sidewall, or posterior broad ligament and ovary and may extend deep into the retroperitoneal space, occasionally constricting the ureter. Lesions in the cul-de-sac may invade the rectovaginal septum. The rectosigmoid and small bowel may become adherent to these areas. Endometriotic foci on the ovarian surface may develop a fibrous enclosure and manifest cyst formation as a result of accumulation of fluid and blood. These endometriotic cysts (endometriomas) vary from several millimeters to over 10 centimeters in size. Bleeding with menses gives the cyst a dark red or bluish hemorrhagic color. The degradation of blood pigment over time results in thick, tarry contents, hence the term *chocolate cysts.* Occasionally, the content changes to a yellow straw color or clear fluid. Filmy or dense fibroid adhesions from these cysts to the pelvic sidewall and fallopian tubes are common and may obscure visualization of the cyst.
Microscopic Appearance Endometriosis is histomorphologically similar to eutopic endometrium. The four major components of endometriotic implants are endometrial glands, endometrial stroma, fibrosis, and hemorrhage. The relative amount of each component is highly variable and dependent, in part, on the age and location of the lesions. Identifying the endometrial elements in individual implants requires an adequate tissue specimen, proper orientation, and often serial sections of the specimen. The endometrial glands in ectopic implants lack uniform size and shape. The glands may show normal cyclic change with mitotic figures and pseudostratification in response to estrogen, or vacuoles and intraluminal secretion in response to progesterone. The response to endogenous and exogenous hormones is inconsistent. This may imply differences in steroid hormone receptor content and function or a loss of the normal gland-stromal interaction. When glands are responsive, the epithelium becomes attenuated, and hemorrhage ensues at the time of menstruation. The stromal cell morphologies of ectopic and eutopic

endometrium are similar. Small arterioles, similar to the spiral arterioles of normal endometrium, usually are present in implants. Interstitial hemorrhage with accumulation of blood products and hemosiderin-laden macrophages is a frequent finding. Fibrosis may occur in older endometriotic implants. This is very common in the lining of endometriomas, where the only histologic finding may be fibroblast proliferation and hemosiderin pigment deposition.

Symptoms

The common signs and symptoms of endometriosis are pelvic pain, dysmenorrhea, dyspareunia, abnormal uterine bleeding, and infertility. The type and severity of symptoms are dependent on the extent of disease, the location, and the organs involved. Even limited amounts of disease may cause significant symptomatology.

Endometriosis is present in approximately one third of patients with chronic pelvic pain. The pain may be described as crampy, dull, or sharp and usually increases around menses. The discomfort may be unilateral or bilateral, and many patients complain of rectal pressure or low backache. Acute abdominal pain may result from hemorrhage secondary to a ruptured endometrioma.

Dysmenorrhea is a more frequent complaint than dyspareunia. There is some correlation between the extent of disease and the severity of pain. The morphologic appearance of an endometriotic implant appears to be unrelated to pain symptomatology. Dyspareunia is more common in women with invasive endometriotic nodules in the cul-de-sac, uterosacral ligaments, rectovaginal septum, and vagina.

Abnormal uterine bleeding occurs in up to one third of women with endometriosis with symptoms of oligomenorrhea, polymenorrhea, and midcycle or premenstrual spotting. The abnormal bleeding likely results from conditions associated with endometriosis: oligoanovulatory, luteinized unruptured follicles, luteal phase defects, and other pathology such as uterine fibroids.

Endometriosis involving the gastrointestinal or urinary tracts and extrapelvic sites causes symptoms characteristic of the location of disease. Bladder involvement is associated with frequency and urgency. Invasion of the mucosa results in hematuria. Ureteral and rare cases of renal endometriosis occasionally cause flank pain or gross hematuria. Symptoms suggestive of gastrointestinal involvement include, in decreasing order of frequency, diarrhea, rectal bleeding, constipation, and dyschezia. All symptoms usually are exacerbated catamenially.

There are numerous case reports of extrapelvic endometriosis. Pulmonary endometriosis causes catamenial hemoptysis and dyspnea. Cutaneous lesions are associated with catamenial bleeding, tenderness, and swelling.

It is estimated that 25% to 50% of infertile women have endometriosis, and 30% to 50% of women with endometriosis are infertile. Although the association of endometriosis and infertility is well recognized, the pathophysiologic mechanisms are poorly understood. Endometriomas and endometriosis with adhesions distort pelvic anatomy and impair tubal ovum pickup, which is an acceptable explanation for infertility. In less severe cases, there are several theories to explain the observed subfecundity (Table 40.1).

Anatomic distortion and tubal obstruction
Anovulation, luteal phase defects, and hormonal abnormalities
Galactorrhea or hyperprolactinemia
Autoimmunity
Peritoneal leukocytes and the peritoneal inflammatory response
Peritoneal fluid prostaglandins
Peritoneal fluid cytokines
Embryo implantations defect and spontaneous abortions

Source: Adamson GD, Pasta DJ. *Am J Obstet Gynecol* 1994;171:1488–1505, with permission.

TABLE 40.1. *Proposed mediators and mechanisms of infertility*

Research to explain the subfertility has focused on peritoneal fluid leukocytes and their cytokine products. Studies have suggested that constituents in the peritoneal fluid inhibit sperm function, fertilization, embryonic development, and implantation. The clinical significance of these findings has not been established.

Diagnosis

Endometriosis usually is diagnosed during the third and fourth decades of life. It has not been found in prepubertal girls and rarely is diagnosed in postmenopausal women unless they are taking replacement hormones. Endometriosis should be suspected in any woman having the classic symptoms of pelvic pain, dysmenorrhea, dyspareunia, abnormal menstrual bleeding, and infertility. These symptoms are present in other gynecologic disorders. No one constellation of signs or symptoms is pathognomonic of endometriosis. Many women with endometriosis are completely asymptomatic, and endometriosis should be considered in all reproductive-age women with infertility or an adnexal mass.

Physical findings in women with endometriosis are variable and dependent on the location and severity of disease (Table 40.2). Frequently there are no obvious findings on pelvic examination. When findings are present, the most common is tenderness when palpating the posterior fornix. Nodules of endometriosis on the uterosacral ligaments, enlarged ovaries as a result of endometriotic cysts, and a uterus fixed in the cul-de-sac by adhesions may be detected during a pelvic examination. Uterosacral implants are best palpated during a rectovaginal examination. On the other hand, some patients with these clinical findings turn out not to have endometriosis.

Localized tenderness in the cul-de-sac or uterosacral ligament
Palpable tender nodules in the cul-de-sac, uterosacral ligament, or rectovaginal septum
Pain with uterine movement
Tender, enlarged adnexal masses
Fixation of adnexa or uterus in retroverted position

TABLE 40.2. *Clinical signs*

The optimal way to diagnose endometriosis is by direct visualization of the site of suspected involvement. Because endometriosis is located primarily in the pelvis, laparoscopy is the preferred technique to make an accurate diagnosis. A double-puncture technique is necessary to view adequately all structures that may contain implants. Peritoneal fluid should be aspirated to see the entire cul-de-sac. Adhesions should be lysed to view the entire surface of the ovaries and the fossa ovarica. These sites are commonly involved with endometriosis when the ovary is adherent to the pelvic sidewall. Suspected endometriomas should be aspirated and resected to confirm the diagnosis. Biopsy and histologic study of any suspicious areas are helpful when the diagnosis is questionable, but often the visual diagnosis by the surgeon is more accurate than histologic sections of small peritoneal biopsies.

Transvaginal ultrasonography can be used to identify ovarian endometriomas, but it is of little utility to diagnose peritoneal implants. The use of other radiologic studies and blood tests to diagnose endometriosis rarely is required. Radioimmunoassay for the tumor marker CA-125 has been used, but the test is not sufficiently sensitive or specific, and patients having conditions other than endometriosis may have positive results.

Classification

A number of classifications have been developed for staging endometriosis. The most widely used system was introduced by the American Society for Reproductive Medicine (ASRM) in 1979 and revised in 1985 and in 1997. This system assigns a point score for the size and location of endometriotic implants and associated adhesions. The new ASRM endometriosis classification for infertility includes the morphologic appearance of the implant. There is a form published by the ASRM to assist in the management of endometriosis in the presence of pelvic pain.

Endometriosis is classified as minimal, mild, moderate, and severe. Mild disease is characterized by superficial implants less than 5 square centimeters in aggregate scattered on the peritoneum and ovaries. Minimal or no adhesions are present. Moderate forms are characterized by multiple implants, both superficial and invasive. Peritubal and periovarian adhesions may be evident. Severe forms are characterized by multiple superficial and deep implants, including large ovarian endometriomas.

Filmy and dense adhesions are usually present. However, no staging system has been validated to correlate with the symptoms of pain or infertility.

Treatment

The treatment of endometriosis is dependent on (a) the severity of symptoms, (b) the extent of disease, (c) the location of disease, (d) the patient's desire for pregnancy, and (e) the age of the patient. Treatment options are presented in Table 40.3.

Expectant Management
Medical Therapy
Progestins
Danazol
GnRH analogs
Surgical Therapy (laparoscopy or laparotomy)
Conservative: retains uterus and ovarian tissue
Definitive: removal of uterus and possibly ovaries
Combination Therapy
Preoperative medical therapy
Postoperative medical therapy

GnRH, gonadotropin-releasing hormone.

TABLE 40.3. *Treatment options*

Expectant Management Avoiding specific therapy is considered when patients have minimal or no symptoms and have suspected minimal or mild endometriosis. Patients in this category may benefit from cyclic oral contraceptives to retard progression of the disease and protect against unwanted pregnancy. Minor pain may be controlled by nonsteroidal antiinflammatory drugs and/or analgesics. Infertile women having suspected limited disease may be observed without treatment. One study suggests that surgical treatment of mild endometriosis results in higher pregnancy rates than expectant management. Another study with fewer subjects failed to confirm the benefit of laparoscopic surgery for infertile women with endometriosis. If pregnancy occurs, regression or complete resolution of the disease is common. Perimenopausal women may be managed expectantly even when the disease is advanced, because endometriotic implants usually regress in the absence of ovarian hormone production after menopause.

Medical Therapy Endometriotic implant growth is highly dependent on ovarian steroids. Medical therapy attempts to “induce” pseudopregnancy or menopause, the two physiologic states believed to inhibit or delay progression of endometriosis by interrupting cyclic ovarian hormone production. Progestins alone or in combination with estrogen hormonally mimic pregnancy. Danazol and gonadotropin-releasing hormone (GnRH) analogs induce a state of pseudomenopause. Medical therapy has the following advantages over surgery: (a) avoidance of the surgical risks of damaging pelvic organs and causing postoperative adhesions, and (b) treatment of implants that are not visible at surgery. Disadvantages of medical therapy are the associated side effects, high recurrence rates following discontinuation of treatment, lack of an effect on endometrioma and adhesions, and inability to conceive because of medically induced anovulation. Medical therapy never has been shown to enhance fertility (Fig. 40.1). Thus, it is not appropriate for women with advanced stages of endometriosis and adhesions causing symptoms or women desiring pregnancy. The medications used most commonly to treat endometriosis are continuous oral contraceptives, progestins, including oral contraceptives, danazol, and GnRH analogs. They should be considered after a definitive diagnosis of endometriosis has been made by direct visualization of the implants.

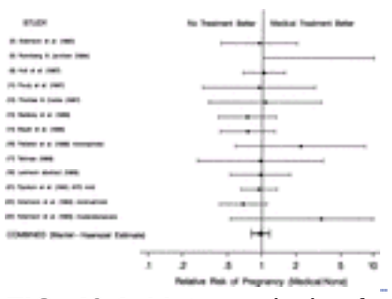

FIG. 40.1. Meta-analysis of studies comparing medical treatment with no treatment.

Progestins inhibit endometriotic tissue growth by a direct effect on the implants, causing initial decidualization and eventual pseudodecidual necrosis or atrophy (progestins). Progestins also inhibit pituitary gonadotropin secretion and ovarian hormone production. Treatment may consist of medroxyprogesterone acetate (10 mg 3 times a day) or norethindrone acetate (5 mg daily for 2 weeks), then increase by 2.5 milligrams per day every 2 weeks until a daily dose of 15 milligrams is reached. Depot-medroxyprogesterone may also be given as an injection (100 to 150 mg monthly). Treatment usually is continued for at least 6 months. Side effects include irregular menstrual bleeding, nausea, breast tenderness, fluid retention, and depression. The effectiveness of continuous oral contraceptives or progestins in eliminating implants and the risk of recurrent endometriosis following treatment are not precisely known. Over 80% of women have partial or complete pain relief. Low-dose cyclic oral contraceptives are effective in relieving dysmenorrhea in women with endometriosis, but they are less likely to relieve dyspareunia. Pregnancy rates in patients with less severe stages of disease are equivalent to those following expectant management. Danazol is the isoxazole derivative of 17a-ethinyltestosterone. Danazol has the following three mechanisms of action: (a) inhibition of pituitary gonadotropin secretion, (b) direct inhibition of endometriotic implant growth, and (c) direct inhibition of steroidogenic enzymes. Danazol is given orally in divided doses, from 400 to 800 milligrams daily, generally for 6 months. Most women taking danazol have side effects, but only a small percentage of patients discontinue the drug because of unwanted effects. Side effects, in decreasing order of frequency, include weight gain, muscle cramps, decreased breast size, acne, hirsutism, oily skin, decreased high-density lipoprotein levels, increased liver enzyme levels, hot flashes, mood changes, and depression. Danazol decreases the size of implants, especially in treating mild or moderate stages of disease. Endometriomas and adhesions do not respond well to danazol treatment. More than 80% of patients experience relief or improvement of pain symptoms within 2 months of treatment. Pregnancy rates following treatment approximate 40% and are independent of the disease severity. However, danazol is no more effective than expectant management for treating infertility. The GnRH analogs profoundly suppress ovarian estrogen production by inhibiting pituitary gonadotropin secretion. These medications are administered by nasal spray or depot injections. The usual dosage is 400 to 800 milligrams daily for nasal nafarelin, 3.6 milligrams for monthly subcutaneous goserelin, and 3.75 milligrams for monthly intramuscular leuprolide. Side effects of the hypoestrogenemia are common and include hot flashes, vaginal dryness, decreased libido, insomnia, breast tenderness, depression, headaches, and transient menstruation. In addition, GnRH analog treatment for the recommended 6-month period decreases bone density and total body calcium, but most of the bone loss is reversible. Hypoestrogenic side effects and bone loss may be prevented by “add-back” therapy with high-dose norethindrone (10 mg daily) or the daily combination of low-dose norethindrone (2.5 mg), sodium etidronate (400 mg), and calcium carbonate (500 mg) (Table 40.4). The GnRH analogs effectively reduce the size of endometriotic implants, even with add-back therapy. Recurrence rates over 5 years range from 37% for patients with mild disease to 74% for severe disease. The GnRH analogs are as affective as other medical therapy in relieving pain symptoms, but they do not enhance fertility.

Norethindrone acetate	5–10 mg/d
Norethindrone acetate	2.5 mg/d
Sodium etidronate	400 mg/d
Calcium carbonate	500 mg/d
Conjugated estrogen	0.3–0.625 mg/d
Medroxyprogesterone acetate	5 mg/d
Micronized estradiol	2 mg/d
Medroxyprogesterone acetate	5 mg/d
19β-Estradiol	25 μg twice weekly
Medroxyprogesterone acetate	5 mg/d

TABLE 40.4. *Endometriosis “add-back” therapy*

Surgical Management Surgery for endometriosis is considered conservative when the uterus and as much ovarian tissue as possible are preserved. Definitive surgery involves hysterectomy with or without removal of the fallopian tubes and ovaries. Surgery is indicated when the symptoms are severe, incapacitating, or acute and when the disease is advanced. Surgery is preferred over medical therapy for advanced stages of disease with anatomic distortion of the pelvic organs, endometriotic cysts, or obstruction of the bowel or urinary tract. Women who are older than 35 years, infertile, or symptomatic following expectant or medical management should be treated surgically. Laparoscopy is the preferred approach to perform conservative surgery. Treatment of endometriosis is possible during the initial laparoscopy, used to diagnose the condition. This offers the advantage of ablating the implants and adhesions, while avoiding possible progression of disease or symptoms and the expense and side effects of medical therapy. Disadvantages include possible damage to bowel and bladder, infection, and mechanical trauma that may result in adhesion formation. Conservative surgery involves excision, fulguration, or laser ablation of endometriotic implants and removal of associated adhesions. The goal is to restore normal pelvic anatomy. Laparoscopic treatment offers advantages over laparotomy, including shorter hospitalization, anesthesia, and recuperation times. Laparotomy is advisable to deal with extensive adhesions or invasive endometriosis located near structures such as the uterine arteries, ureter, bladder, and bowel. Ancillary procedures include presacral neurectomy or uterosacral transection for interruption of sensory nerves innervating the pelvis to relieve midline pelvic pain. The Cochrane Review of three trials involving destruction of pelvic nerve pathways concluded that there is insufficient evidence to recommend these procedures. Uterine suspension may be performed to avoid adhesion formation from the cul-de-sac to the posterior surface of the uterus, tubes, and ovaries. Surgery effectively removes pathology and restores normal anatomy in most cases. The disease recurrence risk is estimated to be as much as 40% with 10 years of follow-up. Pain relief is achieved in 80% to 90% of patients. Presacral neurectomy provides additional pain relief, but its benefit is not lasting, and bladder dysfunction occasionally occurs after the procedure. The chance for pregnancy following surgery is related to the stage of disease and presence of other infertility factors. Approximate pregnancy rates after surgery in patients with mild, moderate, and severe endometriosis are, respectively, 60%, 50%, and 40%. Surgery is preferred over expectant or medical management for infertile women with endometriosis (Fig. 40.2).

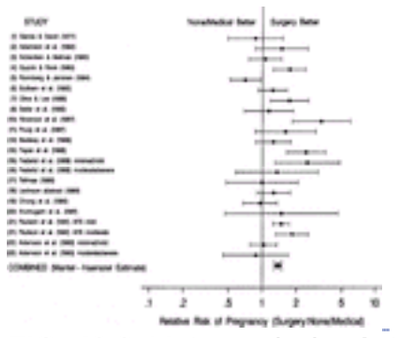

FIG. 40.2. Meta-analysis of studies comparing surgical treatment (operative laparoscopy or laparotomy) with nonsurgical treatment (medical treatment or no treatment).

Definitive surgery for treatment of endometriosis is indicated when significant disease is present and pregnancy is not desired, when incapacitating symptoms persist following medical therapy or conservative surgery, and when coexisting pelvic pathology requires hysterectomy. The decision to perform hysterectomy is dependent primarily on the patient's interest in maintaining childbearing potential and the severity of her symptoms. The ovaries may be conserved in younger women to avoid the need for estrogen replacement therapy. Removal of both ovaries is appropriate when the ovaries are damaged extensively by endometriosis or when menopause is approaching. Endometriosis may recur even with castration, presumably from microscopic foci of disease not visible at surgery. Menopausal hormonal replacement is indicated when the ovaries are removed, even when surgery has not removed all endometriotic implants. The chance for symptomatic recurrence in these cases is small except when endometriosis involves the bowel.

Combination Medical and Surgical Therapy Medical therapy is used before surgery to decrease the size of endometriotic implants and thus reduce the extent of surgery. When complete removal of implants is not possible or advisable, postoperative medical therapy is used to treat residual disease. Progestin, danazol, or GnRH analogs may be used in conjunction with conservative or definitive surgery. Preoperative medical therapy may decrease the amount of surgical dissection required to remove implants, but it does not prolong pain relief, increase pregnancy rates, or decrease recurrence rates. Postoperative treatment with GnRH analogs will delay somewhat the recurrence of pelvic pain, but there is no evidence to support its use in infertile patients.

SUMMARY POINTS

- The histogenesis of endometriosis is poorly understood, but emerging evidence supports the causative role of retrograde menstruation and implantation of endometrial tissue.
- Endometriosis is common in women with pelvic pain or infertility.
- Laparoscopy is the optimal technique to diagnose pelvic endometriosis.
- In most cases, surgical therapy at the time of initial diagnosis effectively relieves pain and may enhance fertility.
- Alternatively, medical therapy with progestins, danazol, or GnRH analogs will ameliorate pelvic pain, but they do not enhance fertility.
- Endometriosis is a recurrent disease, and definitive treatment with removal of pelvic organs may be necessary.

The ovary is unique in that the age associated with decline in function (to frank failure) appears to have remained constant despite the increase in longevity experienced by women over the last century. Because the loss of ovarian function has profound impact on the hormonal milieu in women and on the subsequent risk for the development of disease via the loss of estrogen production, improving our understanding of reproductive aging is critical to care for all women.

Human follicles begin their development during the fourth gestational month. Approximately 1,000 to 2,000 germ cells migrate to the gonadal ridge and multiply, reaching a total of 5 to 7 million around the fifth month of intrauterine life. At this point, replication stops and follicle loss begins, declining to approximately 1 million by birth. In the human male, the dividing germ cells will become quiescent and maintain their stem cell identity. In women, between the weeks of 12 and 18, the germ cells will enter meiosis and differentiate. Thus, in the female, all germ stem cells have differentiated prior to birth. In the adult woman, the germ cells may remain quiescent, be recruited for further development and ovulation, or undergo apoptosis. Over time, the population of oocytes will be depleted, without regeneration, through recruitment and apoptosis until fewer than a thousand oocytes exist and menopause ensues. Approximately 90% of women experience menopause during the early 50s. The other 10% of women experience menopause prior to 46 years (often termed *early menopause*), with 1% of women experiencing menopause at an age less than 40 years *(premature menopause* or *premature ovarian failure)*.

Menopause occurs at a median age of 51.4 years, with the age range in normal women being 42 to 58 years. The age of menopause appears to be determined largely by genetics and is due to exhaustion of the oocyte pool. Menopause and the years preceding are characterized by hormonal changes, decline in reproductive potential, and increased risk for physical and psychological changes.

The average age of menopause has remained constant throughout recorded history. It does not appear to be related significantly to race, parity, height, weight, socioeconomic status, or age at menarche. Evidence suggests that genetic and environmental factors influence age of menopause, although the specific nature of these relationships is poorly characterized. Given the strong association between age at menopause between mothers and daughters, this is likely a largely genetically determined trait. Environmental factors may not have a significant effect in themselves, but the interplay among environmental factors such as smoking (known to accelerate the age of menopause by 1.5–2 years), body mass index (BMI), alcohol use, and socioeconomic status and genetic risk, may be important.

According to the 2000 census data, 35% of the population is age 45 or older and 21% are over 55 years of age. Of the population, 7.3% are women 65 years or older (approximately 20 million women in the United States). Over 50 million women in the United States are in the menopausal transition or menopause.

REPRODUCTIVE STAGES

Reproductive aging is a continuum beginning in utero and ending with menopause. The stages along this continuum have been difficult to define. Numerous terms have been used clinically, including *perimenopause, menopausal transition, climacteric, menopause*, and *postmenopause*, to describe the end of this continuum. The Stages of Reproductive Aging Workshop (STRAW) was convened in July 2001 to address the lack of a pertinent reproductive staging system and to establish a nomenclature and guidelines, a consistent reproductive aging system for health practitioners, the medical research community, and the public.

The staging system developed takes into account menstrual cyclicity, endocrinology and symptomatology beginning with menarche and ending with a woman's demise. The foundation of the staging system is the final menstrual period (FMP). Five stages precede the FMP and two follow it, for a total of seven stages. Stages -5 to -3 are called the *reproductive interval*, stages -2 to -1 are termed the *menopausal transition*, and stages +1 and +2 are known as the *postmenopause* (Fig. 41.1).

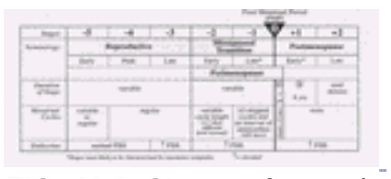

FIG. 41.1. Stages of reproductive aging. (From Soules MR, Sherman S, Parrott E, et al. Stages of Reproductive Aging Workshop (STRAW). J Womens Health Gend Based Med 2001;10:843–848, with permission.)

The menopausal transition begins with variation in the menstrual cycle length (>7 days different from normal) in a woman with an elevated follicle stimulating hormone (FSH) level. This stage ends with the FMP, which cannot be determined conclusively until after 12 months of amenorrhea. Early postmenopause is defined as the first 5 years following the FMP. Late postmenopause is variable in length, beginning 5 years after the FMP and ending with the woman's death.

Although this staging system is said to include endocrinologic aspects of ovarian aging, it still depends largely on menstrual cyclicity as a key indicator of ovarian aging. It does include measurement of FSH; however, by the time FSH is elevated, even with cyclic menstrual cycles, oocyte depletion already has proceeded to such an extent that fertility (as a marker of reproductive aging) is diminished significantly. As noted above, evidence suggests that genetic and environmental factors influence both age of menopause and the decline in fertility, although the specific nature of these relationships is characterized poorly. Premature menopause can be due to a failure to attain adequate follicle numbers in utero or to an accelerated depletion thereafter. Potentially, either of these factors could be affected by genetic and

environmental risk. The timing of menopause has a consistent impact on overall health with respect to osteoporosis, cardiovascular disease (CVD), and cancer risk. Over the next decade, it's estimated that more than 40 million women will enter menopause.

Oocyte Depletion

As discussed above, the leading theory regarding the onset of menopause relates to a critical threshold in oocyte number. Approximately 1,000 to 2,000 germ cells migrate to the gonadal ridge and multiply, reaching a total of 5 to 7 million around the fifth month of intrauterine life. At this point, replication stops and follicle loss begins, with a reduction to approximately 1 million by birth and 500,000 to 600,000 by menarche. As the number of oocytes in the reserve pool continues to decline, menstrual irregularity, followed by cessation, will occur. The theory that menopause is triggered primarily by ovarian aging is supported by the coincident occurrence of follicular depletion, elevated gonadotropin levels, and subsequent menstrual irregularity with ultimate cessation of bleeding.

A mathematical model that predicts the rate of follicular decline has been developed (Fig. 41.2). It utilized existing data, which ultimately showed a bi-exponential decline, with an acceleration in oocyte loss when the remaining oocyte number equaled approximately 25,000. In this model, the decline occurred at 37.5 years of age. At this point, the rate of follicular atresia accelerates. In the absence of this acceleration, the model suggests menopause would be delayed until age 71. The cause of this accelerated depletion is not well defined. It is also clear that if the factor influencing the rate of decline is follicle number and not age, other factors which might account for a diminished follicle number (genetic risk and possible toxic exposure) would lead to an earlier rate of accelerated decline and an earlier age of menopause.

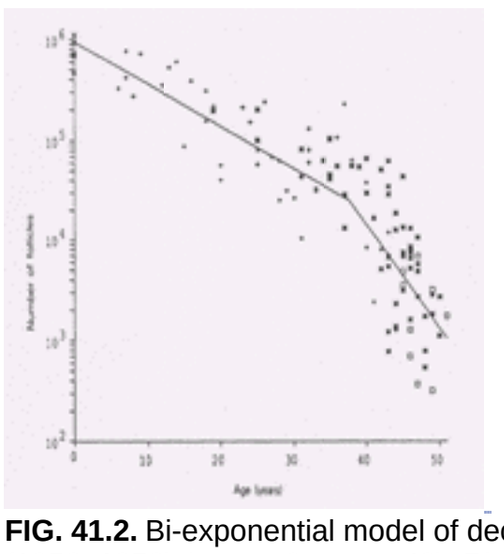

FIG. 41.2. Bi-exponential model of declining follicle numbers in pairs of human ovaries from neonatal age to 51 years old. Data were obtained from the studies of Block (1952, 1953) (*x*, n = 6; +, n = 43), Richardson and others (1987) (squares, n = 9), and Gougeon (unpublished) (*, n = 52). (From Faddy MJ, Gosden RG, Gougeon A, et al. Accelerated disappearance of ovarian follicles in mid-life: implications for forecasting menopause. Hum Reprod 1992;7:1342–1346, with permission.)

Coincident with the decline in the number of follicles in the ovary, there appears to be an increase in random genetic damage within these structures. Evidence for this comes from an observed increase in aneuploidy in the offspring of older mothers and the observation that, in women over 40 years old, oocytes harvested for in vitro fertilization are karyotypically abnormal approximately 40% of the time. Further examples in nature, such as Turner syndrome, shed some light on the process of oocyte aging. Individuals with this syndrome are, by and large, born with dysgenetic gonads which are devoid of follicles. Ninety-five percent of these individuals are aborted spontaneously prior to birth. If one examines the ovaries of a 20-week abortus, a full compliment of oocytes is present. Two factors have been isolated from the ovary: oocyte maturation inhibiting factor (OMI) and luteinizing inhibitor, which may control the rate of maturation of follicles. It has been suggested that individuals with dysgenetic gonads may fail to produce adequate OMI, thus allowing all follicles to progress prematurely toward maturity. The control mechanisms are conceptual rather than factual at this juncture, and new information will have to accumulate before the factors governing human oocyte atresia are elucidated more clearly.

Endocrinology

The entire endocrine system changes with advancing age. The somatotrophic axis begins to decline during the fourth decade prior to the loss of ovarian function. This decline in growth hormone is accelerated during ovarian failure and may, itself, accelerate the ovarian failure. However, pituitary concentrations of growth hormone, as well as adrenocorticotropic hormone and thyroid stimulating hormone, remain constant into the ninth decade. Although the thyroid gland undergoes progressive fibrosis with age and concentrations of T3 decline by 25% to 40%, elderly patients remain clinically euthyroid. Beta-cell function also undergoes degeneration with aging such that, by age 65 years, 50% of subjects have an abnormal glucose tolerance test result. Frank diabetes is rare, however, occurring in only 7%. The female reproductive system, on the other hand, undergoes virtually complete failure at a relatively early age.

As noted above, during the late fourth decade, FSH levels begin to rise even when cyclic menses continue. The most likely cause is a decrease in functional granulosa cells from the oocyte pool, with a decrease in inhibin B negative feedback allowing a monotropic rise in FSH. Early on, there is also a decline in luteal phase progesterone levels. As ovarian aging progresses, estradiol levels may be quite variable, with chaotic patterns and, occasionally, very high and very low levels. This dramatic variability may lead to an increase in symptomatology during the perimenopause (stages -2 to -1). As peripheral gonadotropin levels rise, luteinizing hormone (LH) pulsatile patterns become abnormal. There is an increase in pulse frequency with a decrease in opioid inhibition.

Estrogens The main circulating estrogen during the premenopausal years is 17ß-estradiol. These levels are controlled by the developing follicle and resultant corpus luteum. Oophorectomy will reduce peripheral estradiol levels from 120 to 18 pg/mL, which suggests more than 95% of circulating estradiol is derived from the ovary. Other sources include the peripheral conversion of testosterone and estrone. Very small amounts are secreted by the adrenal gland. Because the two-cell theory requires aromatization of androgens produced by the theca in the granulosa cell, follicular exhaustion is associated with gradual declines in estradiol concentrations. The predominant estrogen in the postmenopausal woman is estrone, which has a biologic potency of approximately one third that of estradiol. Estrone is derived largely from peripheral conversion of androstenedione. Extraglandular aromatase is found in liver, fat, and some hypothalamic nuclei. This activity increases with aging and with a higher fat content (also an age-related change). Estrone and estradiol production rates during the postmenopause are 40 and 6 µg/day, respectively. This compares with 80 to 500 µg/day for estradiol during the reproductive years. Essentially, all the estradiol in the postmenopausal women is derived from conversion of estrone.
Androgens Dehydroepiandrosterone (DHEA) and its sulfated conjugate, DHEAS, have been shown to decrease, along with adrenal corticotropin responsiveness, with aging. DHEAS levels decrease in both men and women. The decline is greater in women and may be due to the relative estrogen deprivation. Ovarian failure, at any age, accelerates this decline. Evidence suggests physiologic levels of DHEA may protect against neoplasia, enhance insulin action, protect against osteoporosis, increase immune competency, and offer some cardioprotection. Changes in DHEA levels also have been associated with alterations in body composition which, in themselves, appear to impact cardiac and breast cancer risk. DHEAS levels may also have an impact on “sense of mental well-being.” Androstenedione is the predominant androgen during the reproductive years and production declines from 1,500 to 800 pg/mL in postmenopausal women. The postmenopausal ovary contributes only 20% to the circulating androstenedione. Testosterone levels also decline after menopause, but not to the same extent as estradiol levels. Postmenopausal testosterone is derived from the ovary (25%), the adrenal gland (25%), and extraglandular conversion from androstenedione (50%). The postmenopausal ovary produces a larger percentage of testosterone (50%) than does the premenopausal ovary.

Systemic Effects of Declining Ovarian Function

The decline in ovarian function brings about profound changes in secondary sexual organs. The endometrium becomes atrophic and the uterus decreases in size. Evidence is accumulating in animal models that the uterus may be partially responsible for the initial decline in reproductive capacity. On the other hand, data from human oocyte donor programs have shown that transfer of ova from younger donors to menopausal recipients produced normal gestations and offspring. It should be noted that these women are stimulated with an artificial sequential overlapping regimen of estrogen and progesterone. This produces an endometrium that is indistinguishable from that of the premenopausal state. Our own data have shown high implantation rates in older women with a hormonally induced endometrium. Only those women who receive pelvic irradiation have responded poorly, suggesting an alteration of the microvascular system.

The postmenopausal vagina, devoid of estrogen treatment, becomes smaller in both length and caliber. There is decreased elasticity of the vaginal wall, and the karyopyknotic index changes to show fewer superficial cells. The fallopian tubes contain both ciliated and secretory components. After age 60, cilia begin to disappear in the isthmic region, although they remain until a very old age in the ampulla infundibulum. The mammary gland develops secretory potential at the time of puberty and maintains this function until menopause. Like other secondary sex organs, it is dependent on female sex steroids for its maintenance. With cessation of the production of estrogen and progesterone, glandular, ductal, and stromal involution occurs. The basement membrane thickens and the luminal space becomes obliterated.

Connective tissue of the lobule becomes indistinguishable from other types of connective tissue. There is an accumulation of adipose tissue in the breast, which occurs simultaneously with this involutional process.

Despite the involutional changes of the breast, 6% of patients with breast carcinoma are over the age of 50, with a median of 55. There is evidence for a bimodal distribution of breast carcinoma, with the first peak occurring at 45 years of age and the second at 65 years of age. The portion of estrogen receptor–positive breast cancers increases until ages 60 to 74 years. Therefore, a dichotomy appears to exist that ducts and glands, rapidly undergoing involution, the result of failing steroid production, become susceptible to malignant transformation while retaining a receptor molecule (E_2), which normally is self-induced.

PREMATURE OVARIAN FAILURE

Premature ovarian failure (POF) is a unique entity in which a woman undergoes changes consistent with menopause, such as amenorrhea, elevated FSH levels, and depletion of ovarian follicles, prior to the age of 40. POF occurs in 0.1% of women under 30 years of age and 1% of women by age 40.

Genetic factors are thought to have a strong relationship with POF. There is a higher incidence of family history of early menopause and a suggestive increase in the family history of infertility, as well as an increased incidence of familial cases of early menopause amongst patients with idiopathic POF. Twin studies have likewise noted a strong genetic component to the age of menopause. Although inheritance appears to be either X linked or autosomal dominant sex limited, paternal transmission cannot be excluded. Women who have idiopathic early menopause (between the ages of 40 and 45) have a genetic pattern similar to whose with POF. These observations support the hypothesis of common underlying genetic factors, which may lead to an early decrease in fertility, early menopause, and POF.

POF may not be the same as age-appropriate menopause, which results from the depletion of the primordial follicle pool, because POF may be reversible, with follicles in the ovary, estradiol production, and even pregnancies long after the diagnosis. When using ultrasonography to evaluate the follicles in women with POF compared with age-appropriate menopausal and young women on oral contraceptives (OCPs), the mean ovarian volumes were smaller in patients with POF compared with women on OCPs, but not different from the women with age-appropriate menopause. Approximately 40% of patients with POF had follicles in the ovary, albeit fewer than in the normal premenopausal women.

Menstrual Cycle

Prior to the menopausal transition, the average length of a menstrual cycle ranges from 21 to 35 days. The menopausal transition is defined partially by menstrual irregularity that occurs in response to changes within the ovary, specifically, a dramatic decline in follicle number (and granulosa cell content). As a result, inhibin B levels fall, decreasing negative feedback on FSH, causing a monotrophic rise in FSH. This early cycle rise in FSH may shorten the follicular phase due to accelerated folliculogenesis. Estradiol levels remain relatively constant with age until the menopausal transition, when they initially rise in response to increased FSH levels. As the ovary fails, progesterone levels decline, leading to a shortened (or inadequate) luteal phase. Thus, an early sign of waning ovarian function may be a decreased intermenstrual interval. Precycle spotting may also signal deficiencies in progesterone production. These clinical signs of reproductive aging indicate a poor prognosis for those women still interested in reproduction. As the FMP approaches and the oocyte complement declines to a critical level, estradiol levels fall, leading to hot flashes, vaginal atrophy, and accelerated bone mineral density (BMD) loss. Also, as the FMP approaches, there is a steady trend toward an increased mean cycle length. In a woman's final 10 to 20 cycles, average cycle lengths are characteristically 40 to 42 days.

As menstrual irregularity increases during the menopausal transition, many women seek medical care. Treatment can be approached in several ways. After a complete history and physical examination, bleeding irregularities can be treated with different hormonal regimens including OCPs, cyclic hormone replacement therapy (HRT), or progestin-only therapy. Many of these patients continue to ovulate, albeit irregularly, so the addition of cyclic progestin (without estrogen) may further increase cycle irregularity and does not offer contraceptive protection. Thus, treatment with OCPs or a combined, cyclic estrogen-progestin regimen is advisable.

There is always the risk of endometrial hyperplasia in this age group. Patients considered high risk (history of chronic anovulation or obesity, or suspicious bleeding patterns such a watery, bloody discharge) should undergo endometrial sampling. Pelvic ultrasonography for measurement of endometrial stripe thickness is not a reliable predictor of risk in cycling women. For those who have a relatively new onset of bleeding irregularity (consistent with the menopausal transition in a previously ovulatory woman), consideration can be given for initial hormonal treatment, with endometrial biopsy reserved only for those whose cycles fail to normalize after 3 months of therapy.

Postmenopausal bleeding always should be considered abnormal and must be evaluated accordingly. Bleeding can occur from the rectum, vagina, cervix, urethra, or uterus. A thorough history and physical examination is crucial. If the source of bleeding is uterine, a transvaginal ultrasonographic examination can be very helpful. If the endometrial stripe is thinner than 5 mm, the bleeding is typically the result of an atrophic endometrium. If the endometrium is 5 mm or thicker, it is imperative to perform a diagnostic test, either an endometrial biopsy or dilation and curettage, to sample the endometrium.

Menopausal Syndrome

Given the above endocrinologic changes with aging, many symptoms associated with aging in women are due to estrogen deficiency, but the decline in adrenal androgens and growth hormone may contribute. Symptoms definitely due to estrogen deprivation include vasomotor symptoms and urogenital atrophy. Osteoporosis is likely, largely due to estrogen deficiency, but this may be exacerbated by the relative growth hormone decline. The same may be said for the hormone-related changes of increasing atherosclerotic CVD and psychosocial symptoms including insomnia, fatigue, short-term memory loss, and depression. Both DHEAS and growth hormone may well have an impact on these age-related symptoms.

Vasomotor Symptoms Vasomotor instability in the form of a hot flash (flush) is one of the most consistent and bothersome symptoms that women face as they enter the menopausal transition and subsequent menopause. Hot flashes result from estrogen deficiency and a resetting of the hypothalamic thermoregulatory set point. They occur in 65% to 76% of women who undergo spontaneous menopause or surgical oophorectomy. Symptoms may begin during the menopausal transition, when estrogen levels may fluctuate dramatically from cycle to cycle and even day to day. A hot flash usually is characterized by intense warmth, described as “heat or burning” that usually begins in the head, neck, and thorax and can spread in waves over the entire body. It may be preceded by pressure in the head and may be accompanied by heart palpitations. The hot flash usually is followed by an outbreak of sweating, followed by chills as the body's thermostat resets. The length of the episode varies from seconds to approximately 5 minutes, although episodes as long as 30 minutes have been described. The event frequency varies from a few per year to 30 per day. For most women, the hot flashes commence prior to the FMP, although initially this may be perceived only as a sleep disturbance. In general, the episodes are noted more frequently at night, and the dysfunctional sleep pattern that follows may result in fatigue, irritability, loss of concentration, and depression, symptoms that often are elicited from patients in the menopausal transition. More than 80% of women who experience hot flashes will experience them for longer than 1 year. Twenty-five percent of women complain of severe hot flashes. Without treatment, the symptoms usually subside slowly over 3 to 5 years. Investigators in 25-year longitudinal study from Gothenburg, Sweden, with 1,462 participants, found the prevalence of hot flashes a maximum of 60% at 52 to 54 years of age. Interestingly, 9% of subjects still reported hot flashes at age 72. The etiology of hot flashes seems to be the withdrawal of estrogen rather than the state of hypoestrogenism. For example, women with Turner syndrome who have not been treated with exogenous estrogen do not experience hot flashes. Those who are treated with estrogen, which is later withdrawn, will experience symptoms of vasomotor instability. Obese women seem to be less symptomatic than matched controls with lower BMI. The explanation may be that obese women are less hypoestrogenic secondary to peripheral conversion of adrenal androgens into estrone or that obesity lowers sex hormone-binding globulin levels, allowing a greater proportion of their estrogen to remain unbound and able to act on target tissues. Studies of hot flashes with external monitoring of skin temperature and resistance have shown a frequency of approximately 54 plus or minus 10 minutes. This frequency has been shown to interrupt random eye movement sleep and potentially contributes to some of the psychosocial complaints. Hot flashes are correlated temporally with pulses of LH; however, exogenous LH does not induce a flash, suggesting there is some central mediator leading simultaneously to hot flashes and LH pulses. Several biochemical alterations are associated with the hot flash. During the actual episode, there is evidence of a rise in plasma LH, epinephrine, corticotropin, cortisol, androstenedione, DHEA, ß-lipotropin, ß-endorphin, and growth hormone. Levels of estradiol, estrone, prolactin, thyroid stimulating hormone, FSH, and norepinephrine are unchanged.

Treatment Vasomotor symptoms are the most common indication for use of estrogen treatment in menopause and are also a U.S. Food and Drug Administration (FDA)-approved indication. Estrogen therapy, in either oral or transdermal form, has a greater than 95% efficacy for the treatment of hot flashes. Hot flash frequency is first notably reduced after 2 weeks of treatment, and the full effect of a certain dosage can be determined reliably after 4 weeks. Due to concerns over the risk-benefit analysis of HRT use, it is recommended that women be treated for vasomotor symptoms for short periods (1-4 years) and then gradually tapered, because symptoms often recur when treatment is discontinued abruptly. For patients with contraindications to estrogen use, vasomotor symptoms can be treated, albeit less efficiently, with progestins, a2-adrenergic agonists (clonidine, methyldopa, lofexidine) and, possibly, antidepressants (selective serotonin reuptake inhibitors [SSRIs], venlafaxine hydrochloride [Effexor]). The role of serotonin (5-hydroxytryptamine [5-HT]) in symptoms of menopause is being investigated increasingly. Serotonin levels fall with menopause, either naturally or surgically induced, and replacement estrogen is known to increase serotonergic tone. The 5-HT_{2A} receptor subtype is thought to underlie changes in thermogenesis. Stimulation of this receptor may lead to changes in the set-point temperature, leading to autonomic changes which cool the body. An increased skin temperature and sweating may result. Thus, an involvement for the 5-HT_{2A} receptor in the etiology of hot flashes has been suggested. A theoretical model, illustrating a role for 5-HT in the mechanism of the hot flash, is shown in Figure 41.3.

FIG. 41.3. Possible mechanism by which a hot flush is induced. (From Berendsen HH. The role of serotonin in hot flushes. Maturitas 2000;36:155–164, with permission.)

Most studies using SSRIs for the treatment of vasomotor symptoms have been in patients with breast cancer. The differential between the antidepressant effects of these agents versus a direct effect on vasomotor symptoms may be more difficult to detect in this population.

Genitourinary Atrophy

Vagina A decrease in circulating estrogen levels has deleterious effects on urogenital epithelium. Up to 50% of postmenopausal women experience symptoms of vaginal atrophy. The most common symptoms include dryness, irritation, itching, burning, and dyspareunia. Atrophic vaginitis is associated with a rise in vaginal pH, which can lead to more frequent infections and worsening, irritative symptoms. A concurrent decrease in vaginal lubrication can lead to bleeding and decreased sexual comfort and pleasure. Estrogen replacement therapy (ERT) is an effective treatment for vaginal atrophy. The systemic dosage necessary for vaginal protection is somewhat higher than needed for bone protection (see below) and, thus, topical therapy by means of creams or vaginal rings may be advisable to limit systemic absorption. Unless systemic HRT is required for vasomotor instability, local estrogen therapy can be used effectively to treat urogenital atrophy. Vaginal estrogen cream or tablets can be used daily for approximately 2 to 3 weeks, and then twice weekly after initial symptoms have improved and vaginal vascularization (hence, hormone uptake) have increased. Treatment is usually long term, because symptoms tend to recur when estrogen is discontinued. The twice-weekly estrogen regimen can be used without supplemental progestin without an increase in endometrial thickness. The dosage should be kept low, however, because the well-vascularized vagina is extremely efficient in the absorption of steroids. The new low-dose vaginal ring may also be used without progestin protection of the endometrium. Vaginal estrogen frequently will improve symptoms of urinary frequency, dysuria, urgency, and post-void dribbling. A direct effect to improve urinary incontinence is less clear. Alternatives to estrogen include vaginal moisturizers and lubricants. There is no evidence to support the use of agrimony, black cohosh, chaste tree, dong quai, witch hazel, or phytoestrogens for the treatment of atrophic vaginitis.

Urinary Tract Infections Urinary tract infection (UTI) is common among women of all ages. Worldwide, an estimated 150 million UTIs occur annually. In the United States, UTIs account for more than $6 billion in health care costs. The incidence is highest in 18- to 24-year-old women at 17.5% and is 9% for women older than 50 years. In younger women, the major risk factors for recurrent UTI are sexual intercourse and spermicide exposure. In older, institutionalized women, the most important risk factors include urinary catheterization and functional status. Healthy, postmenopausal women have different risk factors for recurrent UTI than those mentioned above. Recurrent UTIs in healthy postmenopausal women are associated with urinary incontinence, cystocele, and increased post-void residual volumes. Other significant risk factors include at least one episode of UTI prior to menopause, urogenital surgery, and reduced urinary flow. From the Heart and Estrogen/progestin Replacement Study (HERS) of postmenopausal women with coronary heart disease (CHD), additional risk factors included diabetes, vaginal itching, and vaginal dryness. Changes in the vaginal environment after menopause may also predispose to UTI. These alterations include the absence of lactobacilli, elevated vaginal pH, and increased rate of vaginal colonization with *Enterobacteriaceae.* The intravaginal administration of estrogen has been shown to reduce the rate of recurrent UTI by normalizing the vaginal environment. Low-dose oral hormone therapy, with conjugated estrogen plus medroxyprogesterone acetate (MPA), does not reduce the frequency of UTIs in older women.

Urinary Incontinence The prevalence of urinary incontinence in menopausal women is estimated to be in the range of 17% to 56%. Urinary incontinence is the eighth most prevalent chronic medical condition among U.S. women. Anatomic and physiologic alterations associated with aging and incontinence include thinning of the urethral mucosa, reversal of the proteoglycan-to-collagen ratio in the paraurethral connective tissue, decrease in urethral closure pressure, and changes in the normal urethrovesical angle. Many risk factors have been associated with incontinence. Menopause often is considered to be one of these risk factors, especially because a prevalence peak in midlife has been reported by many authors. Epidemiologic studies generally have not found an increase in the prevalence of urinary incontinence in the menopausal transition. A risk factor for incontinence is an increased BMI. This is an especially important factor, because it is modifiable. Vaginal delivery is associated with transient postpartum incontinence, as well as an increased risk of incontinence later in life. Interestingly, a study of nulliparous nuns, with mean age of 68, found that 50% of the nuns had urinary incontinence. Meta-analyses have found an association between hysterectomy and urinary incontinence, with an increase in incontinence of 60%. Considering that more than 600,000 hysterectomies are performed yearly in the United States and that approximately 40% of women have undergone hysterectomy by age 60, these results are quite relevant. Women should be counseled about this relationship prior to undergoing hysterectomy. Other significant risk factors include history of UTI and depression.

Treatment Oral ERT has been shown to restore the genitourinary connective tissues to that of premenopausal women, but it seems to have little short-term clinical benefit in regard to urinary incontinence. Interestingly, oral estrogen replacement is associated consistently with an increased risk of incontinence in women aged 60 years and older in epidemiologic studies. This increase may reflect that women with more severe symptoms seek medical care and HRT more often than asymptomatic women. It is also possible that the local levels of estrogen in these studies was too low to benefit fully the urogenital system, given the data suggesting higher systemic dosages may be needed for a vaginal effect.

Osteoporosis Osteoporosis is a condition in which bone loss has been sufficient to allow mechanical fracture with limited stress. The likelihood of developing osteoporosis is dependent on the combination of peak bone density (stressing the importance of bone building in the young) and the rate of loss (accelerated with estrogen deficiency). Primary, or “senile,” osteoporosis usually affects women between the ages of 55 and 70 years. The most common sites include the vertebrae and the long bones of the arms and legs. Secondary osteoporosis is caused by a specific disease (such as hyperparathyroidism) or medication usage (glucocorticoids, thyroid hormone excess, anticonvulsants). Menopausal bone loss begins before the FMP during stage -1. Postmenopausal osteoporosis causes over 1.3 million fractures annually. Most of the 250,000-plus hip fractures are due to primary osteoporosis. Excess mortality may exceed 20% within a year of a hip fracture and, because 75% of patients lose their independence, the social costs, not to mention the financial costs, are great. Bone loss following natural menopause is approximately 1% to 2% per year, compared with 3.9% per year following oophorectomy. A woman's genetic background, lifestyle, dietary habits, and coexisting disease will impact the development of osteoporosis. Cigarette smoking, caffeine use, and alcohol consumption are associated with increased bone loss, while weight-bearing activity appears to slow it. Approximately 30% of postmenopausal women have osteoporosis. The World Health Organization has defined osteoporosis as a hip BMD value, as measured by dual x-ray absorptiometry (DEXA), that is greater than 2.5 standard deviations below the adult peak (mean level for young, white women: *t*-score). Women with existing fractures, regardless of BMD, are also classified as osteoporotic. Both groups are at increased risk for fractures. Those patients with a low *z*-score (age-matched comparison) should be investigated for secondary causes of osteoporosis. Peak bone mass in women is achieved by the end of the third decade and is an important contributor to bone strength in later life. Adolescence is a critical period of rapid skeletal growth during which almost one half of the adult bone mass is accrued. Many factors contribute to a woman's peak skeletal mass including heredity, diet, physical activity, and endocrine milieu. Hormones which may be a factor in peak bone mass attainment include insulinlike growth factor (IGF)-1, which regulates skeletal growth, and gonadotropins which stimulate sex steroid production and epiphyseal maturation. Estrogen deficiency and amenorrhea can decrease peak bone mass, whereas weight-bearing exercise leads to an increase. Early influences, including birth weight and poor childhood growth, are linked directly to risk of hip fracture. Independent predictors of low peak bone mass include low body weight, menarche at over 15 years of age, and physical inactivity as an adolescent. Early intervention during childhood and adolescence may reduce a woman's risk for osteoporosis in later life—this includes adequate calcium intake and education regarding diet, ideal weight, and physical activity.

Treatment *Hormone Replacement Therapy.* HRT has been used widely for the prevention of osteoporosis and is FDA approved for this indication. It is clear that HRT helps prevent bone loss, as indicated by increased BMD. Whether these benefits translate into decreased fracture risk has been an important topic of research for the past decade. Observational studies have shown lower vertebral and nonvertebral fracture rates in women receiving estrogen compared with those not receiving this therapy. The addition of a progestin does not alter these results. However, observational studies may be biased, because women using HRT have better access to medical care and maintain healthier lifestyles in general. Estrogen therapy acts via an inhibition of bone resorption. Although both BMD and fracture rate are improved with estrogen therapy, there is a rapid and progressive loss of bone mineral content after cessation of estrogen therapy. By 4 years after therapy, bone density is no different from that of patients who were never treated with estrogen. Although estrogen is approved for *prevention* of osteoporosis, there is some evidence to support its usage in *treatment.* Dosages of 0.625 mg of conjugated estrogen and, more recently, as low as 0.3 mg have been shown to slow bone loss and provide adequate protection against the development of osteoporosis. Higher dosages may be required to *treat* existing disease. Meta-analysis of randomized trials shows an overall 27% reduction in nonvertebral fractures in a pooled analysis, with the effect being greater in women under 60 years of age. The HERS trial showed no evidence of reduction in incidence of fractures or rate of height loss in older women with CHD not selected for osteoporosis. The Women's Health Initiative (WHI), the first randomized primary prevention trial studying the effects of postmenopausal HRT, showed a significant reduction in hip fracture (hazard ratio [HR] = 0.66; CI = 0.45–0.98). It seems clear that HRT must be taken indefinitely to preserve bone mass. *Calcitonin.* Calcitonin is a hormone normally secreted by the thyroid gland and responsible for calcium homeostasis. Calcitonin is now available as a nasal spray, specifically developed to decrease local side effects caused by the earlier subcutaneous injection. Intranasal calcitonin has been shown to improve spinal bone density and decrease the vertebral fracture rate in women with established osteoporosis. The increase in bone density appears to peak in as little as 12 to 18 months. This may be due to down-regulation of the calcitonin receptors and the development of neutralizing antibodies. Although few studies have been performed and no data are available regarding calcitonin-related reductions in hip fracture, calcitonin does seem to be especially beneficial for women with a recent and still painful vertebral fracture. Unfortunately, it appears some patients do not respond to this therapy and those nonresponders cannot be identified prospectively. *Bisphosphonates.* These nonhormonal compounds are analogs of pyrophosphates which have an affinity for hydroxyapatite in bone. The basic molecular structure of bisphosphonates allows a large number of manipulations, producing different types of bisphosphonates which vary considerably in their potency. The first one used clinically was etidronate, the least potent. In succeeding order of development were pamidronate, alendronate, and risedronate, which is the most potent of these compounds. Etidronate, if given continuously for more than 6 months, impairs

mineralization of bone and may cause osteomalacia. There have been occasional reports of pamidronate also causing impairment of mineralization of bone. However, continuous administration of either alendronate or risedronate has not caused osteomalacia. Alendronate has been evaluated more extensively than calcitonin and has a proven track record, reducing the risk of all major fracture types (vertebral and nonvertebral) in women with osteoporosis. In one study, risk of hip fracture was reduced by 53%, clinical vertebral fracture by 45%, and wrist fracture by 30%. For all fracture types, some reduction in fracture risk was evident within the first year of treatment. Bisphosphonates have only a modest effect on BMD early in the treatment course. Because alendronate is effective so quickly in reducing fracture risk, mechanisms other than increased BMD, such as changes in bone remodeling rates, may play a role in fracture reduction. Alendronate has been shown to inhibit markers of bone remodeling and to increase BMD at the lumbar spine, hip, and in all other bones. Bone density increases with alendronate are greater than with calcitonin and are equal to that with HRT. The escape phenomenon seen with calcitonin is not seen with alendronate, which has the advantage of oral administration. The recommended daily dosage of 10 mg, however, must be taken according to a very strict dosing schedule (in the morning on an empty stomach, with the patient required to remain upright for 30 minutes thereafter). The medication has very poor bioavailability (approximately 1%) and, thus, these restrictions must be followed precisely. Alendronate also has a propensity for irritation of the esophagus and stomach, especially in women with preexisting esophageal reflux or gastric or duodenal disease. A newer formulation allows for once-weekly administration, and development of a once-yearly intravenous formulation may further decrease side effects and administration difficulties. Risedronate has been shown to reduce substantially the risk of both vertebral and nonvertebral fractures, also. Bone density is increased in both early postmenopausal women and those with established osteoporosis. The final remaining question concerning bisphosphonates has to do with the near-permanent changes in bone with the incorporation of this agent into the bone matrix. Although short-term fracture data appear favorable, the long-term effects of these agents and the ability of bone treated with bisphosphonates to heal (e.g., following hip fracture) are not known. *Raloxifene.* Raloxifene is the first of a new generation of compounds known as selective estrogen receptor modulators (SERMs) to have a treatment indication for osteoporosis. It is likely that there will be an explosion in the development of SERMs in the years to come. They may represent a new alternative for our patients with breast cancer or for long-term use in *all* patients. These new agents act as selective estrogen receptor *agonists* on the bone and possibly the heart and *antagonists* of estrogen action on the breast and uterus. Effects on the brain are not well characterized and likely will vary among compounds (see below). Data on raloxifene suggests good preservation of bone density, albeit less than seen with alendronate or HRT, and fracture data further supports a protective effect. It is believed that the differential effect of estrogen agonists (estrogens) and estrogen antagonists (“anti”-estrogens) is related to the transcriptional activation of specific estrogen-response elements. There appear to be two different domains of the estrogen receptor (AF-1 and AF-2) responsible for this transcriptional activation. Estrogen agonists and estrogen antagonists appear to act via different domains, resulting in their differential effects. Both appear to act to maintain bone density, at least partially, via regulation of the gene for transforming growth factor-ß. It has further been suggested that there may be a *raloxifene-response element*, which is distinctly different from the estrogen-response element. In women with osteoporosis, the 60-mg or 120-mg daily dose of raloxifene increases bone mass density in the spine and femoral neck and reduces the risk of vertebral fracture by 30% to 50% over no treatment. However, as with estrogen use, women receiving raloxifene have an increased risk of deep vein thrombosis compared with women receiving placebo. *Calcium and Vitamin D.* Calcium and vitamin D are important components of all three antiresorptive agents (calcitonin, bisphosphonates, SERMs). Decreased ability to absorb calcium among older women is due, in part, to impaired vitamin D activation and effect. In addition, older women may have limited exposure to sunlight, and their dietary vitamin D intake may be lower than that of their younger counterparts. Daily calcium intake of 1,500 mg and 400 to 800 IU of vitamin D per day is, in and of itself, probably sufficient to reduce the risk of fragility fractures by about 10%.

Summary-Osteoporosis Most current strategies regarding osteoporosis treatment have focused on identifying postmenopausal women who have low BMD and are already at increased risk for fracture. An evidence-based approach is to recommend appropriate calcium and vitamin D intake, smoking cessation, weight-bearing exercise, moderation in alcohol consumption, and fall prevention. If pharmacologic therapy is indicated, one of the above FDA-approved regimens should be instituted (Table 41.1 and Table 41.2). An alternative (complementary) approach to prevention is to focus on intervention beginning in childhood and adolescence, with attention to achieving maximal peak bone mass and minimizing premenopausal and postmenopausal bone loss.

TABLE 41.2. *Magnitude of Effect on Nonvertebral Fractures*

Cardiovascular Disease CVD is the number one killer of both men and women in Western societies and is attributed primarily to age and lifestyle. Lifestyle modifications are well known to decrease the incidence of CVD. For women, CVD is largely a disease of the after menopause. Women will now spend more than a third of their lives beyond menopause and, thus, preventive measures are paramount. A large body of observational evidence supports a protective effect of ERT on CVD. Observational data, however, are limited by the confounding variables of patient self-selection. Animal and in vitro studies, as well as assessment of surrogate markers in women, have shown a positive effect of estrogen and (less so) HRT against CVD development. Approximately 2.5 million women in the United States are hospitalized each year for cardiovascular illness. CVD claims the lives of 500,000 women annually. One half of these deaths are due to CHD, making this the most frequent cause of death among U.S. women. CVD can be separated into two categories, (a) CHD and (b) noncoronary CVD, such as stroke, valvular heart disease, peripheral vascular disease, congestive heart failure, and sudden death from cardiac causes. A woman's risk of heart disease is far lower than a man's risk until after menopause. This change in incidence of heart disease may be related to advancing age, changes in hormonal milieu, or other unknown factors. CHD entails a worse prognosis for women than for men following either medical or surgical therapies. These sex discrepancies may reflect the older age, smaller body size, more frequent and severe coexisting illnesses of women and, perhaps, a higher incidence of delayed or suboptimal care. Chest pain or tachycardia may be overlooked as benign problems in women, potentially caused by depression, anxiety, or panic disorders. These misperceptions may lead to bias in evaluating women with chest pain. Chest pain in women may also have atypical clinical pictures compared with the more “classic” symptomatologty in men. Chest pain, regardless of symptoms compatible with angina pectoris, warrants evaluation for CHD, regardless of sex. If a woman seeks treatment for typical, or atypical, signs and symptoms of myocardial ischemia, a careful clinical history, including assessment of cardiac risk factors, should be taken. Electrocardiographic exercise testing is recommended for women who give a history typical of angina pectoris if the resting electrocardiogram findings are normal. When the resting electrocardiogram results are abnormal, the patient should be referred for either perfusion imaging studies or coronary arteriography. No screening test is of value for asymptomatic patients, even when risk factors are present. Fewer symptomatic women than men undergo diagnostic coronary arteriography and therapeutic angioplasty or bypass surgery. Women who do undergo bypass surgery more often require emergency surgery and typically are sicker than men at the time of intervention. They have increased operative mortality rates and postoperative complications. It seems that women are referred for revascularization procedures at a later, more symptomatic, stage of illness. Both coronary angioplasty and coronary bypass surgery have a comparable long-term survival for men and women who survive the initial hospital stay. Beta-blockers and aspirin are equally efficacious in both sexes in preventing reinfarction after myocardial infarction. Women should be encouraged to seek medical attention if they have any symptoms suggestive of myocardial ischemia. Physicians should emphasize the importance of modifiable risk factors for CHD, most notably weight management, fat restriction, increased physical activity, treatment of hypertension, and smoking cessation. Randomized, controlled studies have failed to support a protective role for HRT. This is in conflict with earlier observational studies, studies utilizing surrogate markers, and animal studies. The differences may be due to the unbiased sample of subjects taking HRT in these newer studies and, hence, may be a more realistic reflection of the impact of HRT on CVD. However, other potential confounders may be present, even in these studies, such as the menopausal stage when treatment was begun, the particular HRT regimen selected, and the individual risk factors of each subject (although the results may be more reasonably generalized, this may not accurately reflect clinician practice). The first reported trial evaluated HRT for secondary prevention. The HERS trial evaluated daily HRT (0.625 mg conjugated estrogen + 2.5 mg MPA) in 2,763 postmenopausal women with a mean age of 66.7 years and documented preexisting vascular disease. The study failed to demonstrate any overall difference in subsequent vascular events. This occurred despite improvements in lipid parameters in those patients receiving HRT. Although some have questioned the negative impact of the progestin, in this trial, the Estrogen Replacement and Atherosclerosis (ERA) trial published in 2000, compared 3.2 years of treatment with estrogen, combined estrogen and progestin, and placebo. Study participants were postmenopausal women aged 42 to 80 years. This, again, was a secondary prevention trial and also failed to demonstrate a significant difference in the rate of progression of coronary atherosclerosis among the three groups. The importance of this study was the inclusion of an estrogen-only arm. The WHI is the first large, randomized study to look at primary prevention. The same combined HRT regimen used in the HERS trial was evaluated. This study was stopped when interim analyses demonstrated an unacceptable risk profile for a drug in a prevention trial. There was an increase in the incidence in breast cancer (an increase of 8 cases per 10,000 women), with no cardiovascular protection (and potentially increased cardiovascular risk). There was an increase in the absolute number of blood clots, strokes, and CHD. The risk of stroke and clot continued for the 5 years of study, while most of the CHD was limited to the first year of treatment. Whether these finding were related to the intrinsic properties of HRT, the oral administration route, or the unique regimen tested is not clear. There were, however, documented decreases in the risk of fracture and colon cancer. Management for cardiovascular risk for women should parallel that for men. In other words, lifestyle modifications should be made and antihypertensive therapy given as needed. If hyperlipidemia persists, statin therapy should be instituted. And, as above, ß-blockers and aspirin should be given to prevent recurrent myocardial infarction. There is no evidence from well-designed prospective trials supporting a role for either ERT or HRT for the primary indication of cardiovascular protection.

HORMONE REPLACEMENT

Introduction

Approximately 38% of U.S. women aged 50 to 74 use HRT of some description. Of those surveyed, 59% of users had undergone a hysterectomy and 19.6% had a uterus. In 2000, Premarin (conjugated equine estrogen [CEE]) was the second most widely prescribed drug in the United States, accounting for 46 million prescriptions and over $1 billion in sales. Historically, patients desiring hormone treatment for menopausal symptoms were supplemented initially with unopposed estrogen, regardless of the presence of a uterus. This therapy was proven clearly to increase a woman's risk of endometrial cancer, which was eliminated with the addition of either cyclic or continuous low-dose progestin. Women who have undergone hysterectomy can, and should, be treated with estrogen alone.

According to the FDA, approved indications for ERT-HRT include treatment of menopausal symptoms (e.g., hot flashes and genital tract atrophy) and the prevention of osteoporosis. During the past 30 years, it has become popular to prescribe ERT-HRT to prevent a range of chronic diseases, most notably heart disease. As above, evidence has been accumulating which suggests that estrogen-progestin therapy for prevention of chronic diseases is not evidence based.

Benefits

With the publication of the WHI data, HRT risks and benefits have been examined critically (Fig. 41.4). HRT benefits include reduction in hot flash frequency and severity, improvement of atrophic vaginitis and UTIs, and prevention of osteoporosis and fractures. Neither vasomotor symptoms nor vaginal atrophy were evaluated in the WHI, although likely occurrence was low, because the participants were asymptomatic and not taking HRT when enrolled. The WHI results did support an additional benefit of decreased risk of colorectal cancer.

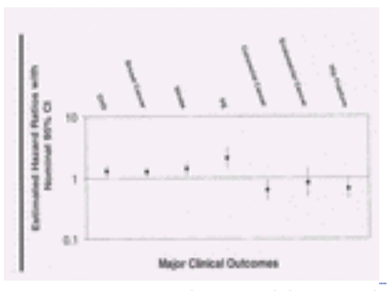

FIG. 41.4. Estimated hazard ratios for major clinical outcomes in the Women's Health Initiative trial of hormone replacement therapy. CHD, coronary heart disease; PE, pulmonary embolism. (Source: Writing Group for the Women's Health Initiative investigators. From Grimes DA, Lobo RA. Perspectives on the Women's Health Initiative trial of hormone replacement therapy. *Obstet Gynecol* 2002;100:1344–1353, with permission.)

A variety of areas have been studied in postmenopausal women, including estrogen effects on depression and Alzheimer disease (AD). The cognitive benefits of HRT remain more controversial than benefits in other areas. A meta-analysis from 1998 incorporating all studies published between 1966 and 1997 suggests several mechanisms by which estrogen may affect cognition, including maintenance of neural circuits, favorable lipoprotein changes, prevention of cerebral ischemia, and promotion of serotonergic and cholinergic activity in the brain. It is also possible that cognition improves in estrogen users during the menopausal transition because vasomotor symptoms improve, because there does not appear to be a clear benefit in asymptomatic women receiving HRT. The HERS data also support a cognitive benefit, concluding that the effects of HRT on emotional measures, of quality of life, depend on the presence of menopausal symptoms. The Seattle Midlife Women's Health Study showed that perceived memory functioning is more closely related to depressed mood, perceived stress, and perceived poor health than to age or reproductive stage.

AD is an enormous public health concern that intensifies as the population ages. In 1997, AD cases in the United States numbered 2.32 million, with 68% of individuals being female. In 1998, the annual number of new cases was 360,000. Interventions that could prevent this disease, or delay its onset, would have a major public health impact.

Women with high serum concentration of unbound (bioavailable) estradiol are less likely to develop cognitive impairment than women with low concentrations. Randomized trials studying estrogen use and AD are limited but suggest that estrogen users have a reduced risk of *developing* AD. However, there is no therapeutic benefit of estrogen usage in women with preexisting AD. Larger randomized trials are needed to evaluate the true significance of estrogen use and dementia. The WHI includes a memory study, and these results should be available in 2005.

Risks

As more randomized trials of HRT are conducted, the risk profile has broadened. CHD was once a main off-label indication for HRT, and former guidelines from the American College of Physicians even suggested that HRT be considered for all women. The HERS trial and, more importantly, the WHI have shown that nonfatal cardiac events are increased in HRT users in the regimen tested. These studies have also reemphasized known risks of HRT including pulmonary embolus, stroke, deep vein thrombosis, and gallbladder disease.

CONTROVERSIES

Cardiovascular Disease

During the 1990s, HRT was prescribed increasingly to postmenopausal women for CHD prevention. Much of this enthusiasm was based on a meta-analysis published in 1992 that concluded that “there is extensive and consistent observational evidence that estrogen use reduces risks for CHD about 35%.” This same year, the American College of Physicians published guidelines recommending that all postmenopausal women should consider HRT. They emphasized that those who are at increased risk of CHD are especially likely to benefit. Further observational studies have supported this recommendation. For example, the Nurse's Health Study of 1996 confirmed a 40% to 60% reduction in cardiovascular events in women taking HRT.

The HERS was a randomized, blinded, secondary prevention, clinical trial with results published in 1998. The study population was 2,763 postmenopausal women with documented CHD. The average age was 67 and all women had a uterus. Subjects were randomly assigned to receive either 0.625 mg CEE with 2.5 mg MPA daily or placebo. The average follow-up was 4.1 years. The investigators found that the women assigned to receive CEE plus MPA had a 50% increased risk of coronary events during the first year of the trial compared with the placebo group. The risk was greatest during the first 4 months. The risk returned to baseline over the next 2 years and seemed to be lower in the hormone-treated group beginning in the third year of the study. The changes could have occurred by chance or may be due to detrimental effects of the hormone replacement, the specific regimen studied, or the procoagulant effect associated with oral administration. An initial prothrombogenic effect was thought to be the cause of early morbidity, and there was some expectation that longer treatment would document an improved outcome. However, HERS II, which continued to follow this group (6.8 years of follow-up), failed to see a developing protective effect of HRT.

The WHI is the first randomized, primary prevention trial studying the effects of a specific postmenopausal HRT regimen (the daily regimen of 0.625 mg CEE plus 2.5 mg MPA). In contrast to the HERS trial, these 50- to 79-year-old women were considered healthy, with only a small proportion (7.7%) of subjects having clinical signs or symptoms of CHD. The subjects were randomized to receive the HRT regimen or placebo if they had a uterus. Women without a uterus received either the estrogen alone or placebo. The planned duration of the trial was 8.5 years, but the estrogen-plus-progestin arm (16,608 women) was stopped after 5.2 years because of concerns regarding cardiovascular events and breast cancer. “The test statistic for invasive breast cancer exceeded the stopping boundary for this adverse effect and the global index statistic supported risks exceeding benefits.” Estimated HRs for diseases other than breast cancer, including CHD, were also significant. The HR results were as follows: CHD, 1.29 (95% CI = 1.02–1.63); breast cancer, 1.26 (1.00–1.59); stroke, 1.41 (1.07–1.85); pulmonary embolus (PE), 2.13 (1.39–3.25); endometrial cancer, 0.83 (0.47–1.47); colorectal cancer, 0.63 (0.43–0.92); hip fractures, 0.66 (0.45–0.98).

This important study suggests that breast cancer, nonfatal CHD events, stroke, and PE are all significantly increased in the overall cohort, of women 50 to 79 years old using combined estrogen and progestin therapy. It showed that colorectal cancer and hip fracture risk are reduced significantly in the same group. Ultimately, the data suggest that the use of this combined HRT regimen for primary prevention of CHD is not justified.

In 2001, the American Heart Association published guidelines regarding HRT and CVD. They have taken a cautious stance. These recommendations were made prior

to the publication of the WHI results.

American Heart Association Recommendations
Secondary Prevention

- HRT should not be initiated for the secondary prevention of CVD.
- The decision to continue or stop HRT in women with CVD who have been undergoing long-term HRT should be based on established noncoronary benefits and risks and patient preference.
- If a woman develops an acute CVD event or is immobilized while undergoing HRT, it is prudent to consider thromboembolic prophylaxis while she is hospitalized to minimize risk of a venous thromoembolism associated with immobilization. Reinstitution of HRT should be based on established noncoronary benefits and risks, as well as patient preference.

Primary Prevention

- Firm clinical recommendations for primary prevention await the results of ongoing randomized clinical trials.
- There are insufficient data to suggest that HRT should be initiated for the sole purpose of primary prevention of CVD.
- Initiation and continuation of HRT should be based on established noncoronary benefits and risks, possible coronary benefits and risks, and patient preference.

There is still some question about whether WHI was really assessing “primary” prevention based on concern about the preexistence of atherosclerotic disease. Enrollees were asymptomatic and older (mean age, 63 years) than the typical HRT-ERT user. Some vascular biologists have suggested the early institution of HRT may inhibit the *development* of atherosclerotic plaque and that a delay in treatment for several years after menopause, after plaque formation is well established, would not only not offer benefit but might increase risk by destabilizing existing plaque, leading to plaque rupture and thrombosis. Although this thesis is consistent with animal studies, little human data are available to support or repute it. It is yet another consideration for patients and physicians in making this difficult decision.

Breast Cancer

A woman's lifetime risk of breast cancer is 1 in 8. There are 192,000 new cases of breast cancer per year, accounting for 41,000 deaths per year. It is the second leading cause of cancer death after lung cancer and the leading cause of death among women ages 40 to 55.

The most compelling reason to believe that long-term use of postmenopausal estrogen increases the risk of breast cancer is the inherent biologic plausibility. Many of the risk factors associated with breast cancer are thought to be linked to increased duration of exposure to estrogen over a woman's lifetime. These risk factors include early menarche, late menopause, nulliparity, and older age at the birth of her first child. Oophorectomy can induce breast tumor regression and early oophorectomy is protective against breast cancer, which seem to support further the notion that estrogen is involved, but this remains controversial. All of these risk factors take ovarian function into account, but not necessarily estrogen exposure, because the ovary is responsible for the formation of many other compounds which may influence the risk, such as androgens.

The association of estrogen therapy and breast cancer remains controversial, despite the publication of over 50 epidemiologic studies during the past 25 years. This subject is of great public health concern because of women's understandable fear of breast cancer and the complexity of the decision-making process regarding hormone therapy.

A reanalysis of the world's data on HRT-ERT and breast cancer was performed in 1997. A team of epidemiologists invited all investigators who had previously studied the association of postmenopausal hormone use and the risk of breast cancer (51 studies) to submit their original data for a collaborative combined reanalysis, an undertaking more rigorous than a standard meta-analysis (Collaborative Group of Hormonal Factors in Breast Cancer).

This analysis reached the following conclusions:

- Ever users of postmenopausal hormones had an overall increased relative risk of breast cancer of 1.14.
- Current users for 5 or more years had a relative risk of 1.35 (CI = 1.21–1.49), and the risk increased with increasing duration of use.
- Current and recent users had evidence of having only localized disease (no metastatic disease) and ever users had less metastatic disease.
- There was no effect of a family history of breast cancer.
- There was no increase in relative risk in past users.
- The increase in relative risk in current and recent users was greatest in women with lower body weights.

The WHI has brought even greater attention to any relationship between breast cancer and HRT use. The estrogen-progestin versus placebo arm of the study was stopped early, due primarily to an increase in breast cancer risk with a HR of 1.2. No similar effect was noted in the estrogen-only arm of the study, which is ongoing. Whether or not women in this category will also have an increased risk of breast cancer is unknown at this time. There is other epidemiologic evidence to suggest combined, continuous HRT may confer a higher risk of breast cancer than either cyclic estrogen-progestin regimens or those with estrogen only.

The comparison between the collaborative epidemiologic analysis described above and the WHI is interesting (relative risk, 1.35 vs. 1.26). Another relevant point the authors from the collaborative reanalysis make is that the quantitative effect of their conclusion is similar to the impact of raising the age of menopause. According to their calculations, current and recent hormone use was associated with a 2.3% increase in breast cancer risk per year, and the effect of age of menopause was equivalent to a 2.8% increase in risk per year of delay.

The presence of only localized disease, in the collaborative study, raises concern regarding screening bias and whether ERT-HRT treatment simply accelerated the detection of tumors already present. All of these studies that have examined the mortality rates of women who were taking estrogen at the time of breast cancer diagnosis have documented improved survival rates. This reflects earlier diagnosis in users, because the greater survival rate in current users is associated with a lower frequency of late-stage disease. There has been a suggestion that estrogen users develop better differentiated tumors and the surveillance-detection bias is not the only explanation for better survival. This suggests that hormone treatment accelerated the growth of a malignant locus already in place, which appears clinically at a less virulent and aggressive stage.

Selective Estrogen Receptor Modulators

The controversy regarding HRT-ERT has heightened the call for alternatives. The term *hormone-estrogen replacement* implies the replacement of the beneficial aspects of premenopausal estrogen. SERMs make up a class of compounds that act like estrogen agonists on some tissues and estrogen antagonists on others. SERMs act by causing dimerization and conformational changes in the estrogen receptor, altering the interaction with the promoter regions on DNA. These conformational changes further impact function through their interactions with co-regulators and co-repressors. This is illustrated in cartoon form in Figure 41.5.

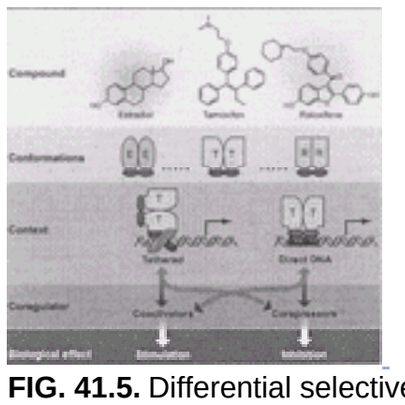

FIG. 41.5. Differential selective estrogen receptor modulator activity (stimulation and inhibition) is determined by the specific tissue, the endogenous milieu, and the impact of conformational changes on the interaction with regulatory sequences of DNA and co-regulatory proteins (co-activators and co-repressors). (From Katzenellenbogen BS, Katzenellenbogen JA. Defining the “S” in SERMs. Science 2002;295:2380–2381, with permission.)

The search for the “ideal” SERM, with positive (estrogenic) effects on the heart, bone, and brain and negative (antiestrogenic) effects on the breast and uterus, continues. Improved scientific knowledge regarding estrogen receptor function (more like a rheostat than an “on-off” switch), two receptor types (a and ß), more than 50 transcription factors, over 20 modifying proteins, and different response elements should enhance the development of therapeutic agents for selective clinical applications.

The beneficial aspects of raloxifene, the most studied SERM, with respect to osteoporosis, already have been discussed. There are evolving data with respect to CVD. Both raloxifene and tamoxifen decrease total cholesterol and low-density lipoprotein levels. Neither has an effect on high-density lipoprotein or triglyceride levels. Interestingly, raloxifene is either neutral or decreases two inflammatory markers (homocysteine and C-reactive protein), which might participate in the increase in cardiovascular events seen with the institution of HRT-ERT.

The available data about SERMs and CVD are, again, based on surrogate markers. A prospective study, Raloxifene Use in The Heart (RUTH), is ongoing. This study will evaluate 10,000 at-risk women and will add information to guide treatment strategies and, hopefully, increase our treatment options.

Limited data have suggested SERMs may have a beneficial effect on cognition. Although raloxifene is known not to improve (and potentially worsen) vasomotor symptoms, there is some preliminary evidence to suggest a neuroprotective effect. The extent and mechanism of this effect is not well characterized and awaits further study.

There is no doubt that the available SERMs are antiestrogenic at the breast. Tamoxifen is used primarily in the United States for cancer chemoprevention and treatment. Raloxifene also appears to decrease the incidence of estrogen receptor-positive cancer development. The Study of Tamoxifen and Raloxifene (STAR) should yield direct information regarding the benefit of raloxifene in women at risk for breast cancer as the available data are derived from osteoporosis trials. Lastly, it should be remembered that both tamoxifen and raloxifene increase the risk of thromboembolic phenomena, and this may have an impact on cardiovascular risk.

SUMMARY

The WHI did not address the effect of hormone treatment on hot flashes and vaginal atrophy. Clearly, there are alternatives for the treatment of osteoporosis and CVD that have less risk if CVD prevention is the sole reason for using HRT. Each woman should discuss with her health care provider the optimal treatment management to address her individual goals. This obviously would need to take into account medical and family history, as well as symptomatology.

If HRT-ERT is selected by the patient, progestin should be used only for those women with a uterus. Furthermore, in developing an overall treatment strategy, physicians should utilize the full armamentarium of medications (conjugated estrogens, estradiol, MPA, norethindrone, micronized progesterone, and androgens), routes of administration (oral, vaginal, transdermal), and cyclic patterns (continuous, intermittent, monthly, quarterly) available, including low-dose aspirin and statins. Duration of hormone therapy would also be an individual decision based on the original indication for treatment and its persistence. It can be recommended uniformly that menopausal women maintain appropriate nutrition, a healthy body weight, and regular exercise, including both weight-bearing aerobic exercise and muscle-strengthening exercise. This should be associated with moderation in alcohol intake and cessation of smoking.

SUMMARY POINTS

- Estrogen production in women is related to follicular maturation and the number of ovarian follicles is fixed, with declining numbers of follicles associated with hypoestrogenism.
- Declining ovarian estrogen production is associated with vasomotor instability, hot flashes, urogenital tract atrophy, and accelerated loss of BMD.
- Treatment of the symptoms associated with declining ovarian estrogen production is optimal with ERT in women without a uterus and estrogen with progestin regimens in women with a uterus.
- Although primary or secondary prevention of CVD has been suggested in observational studies, it has not been demonstrated in randomized treatment trials (HERS and WHI).
- A slight increase in the risk of breast cancer has been associated with HRT, albeit with a lower mortality likely secondary to earlier detection at a less aggressive stage of disease.
- Decisions regarding the use or ERT-HRT should be individualized, based on the woman's goals of therapy, and reevaluated periodically to ensure that the risk-benefit analysis continues to favor hormone use.

> W. H. Masters and V.E. Johnson, *Human Sexual Response*, 1966

Sexuality and satisfying sexual functioning are important aspects of a woman's general health and feelings of well-being. However, the reluctance to engage in open discussions about sex extends even to physicians. Surveys of primary care physicians reveal that less than 50% ask new patients about sexual practices and concerns. Nevertheless, a thorough understanding of the normal sexual response and evaluation and treatment of common sexual dysfunctions is imperative to provide comprehensive gynecologic care.

ANATOMY

Female pelvic anatomy demonstrates pronounced changes during sexual arousal (Fig. 42.1). During sexual arousal there is a pronounced alteration of these anatomic structures. The vaginal walls assume a darker coloration due to vascular engorgement, the inner two-thirds of the vagina lengthen and distend, the labia minora increase in size, and the clitoris swells. Pelvic vasocongestion, swelling of external genitalia, and lubrication occurs. Contrary to findings by Masters and Johnson, magnetic resonance imaging (MRI) studies during either coitus or masturbation, revealed that the size of the uterus does not increase in size, but does elevate in the pelvis. The vagina lengthens by 1 cm, and after further arousal, the vaginal opening constricts secondary to vascular engorgement, called the “orgasmic platform”. The “orgasmic platform” undergoes a series of clonic contractions with the first three to six being strong and having an intercontractile interval of 0.8 seconds with subsequent periods lengthening before the strength of the contractions recede. However, the actual presence of a physical “orgasmic platform” has been questioned.

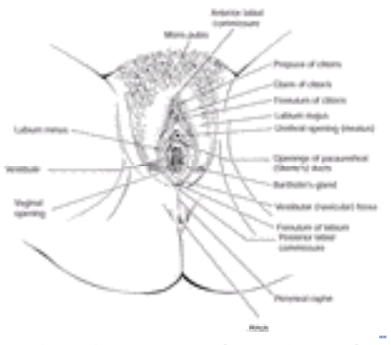

FIG. 42.1. Female external anatomy.

These anatomic changes noted in response to sexual arousal involve four functional groups of muscles. The first group consists of the ischiocavernous and bulbospongiosus. These muscles insert anteriorly on the shaft and crura of the clitoris which pulls the clitoris down to compress venous drainage and facilitate engorgement. The second group is the transverse perinea (superficial and transverse), which supports the perineum. The levator ani (the medial pubococcygeus and the lateral iliococcygeus) comprises the third set of musculature and forms the anterior pelvic diaphragm. The levator ani fixes the vesicular neck, anorectal junction, and vaginal fornices to the side wall of the pelvis. During sexual intercourse, vaginal distention from the penis evokes the vaginolevator and vaginal puborectalis reflex causing contraction of the levator ani muscles. This contraction leads to upper vaginal ballooning which acts as a receptacle for semen, elevates the uterus, and narrows and elongates the vagina. The development of the pubococcygeus muscle has been advocated to increase sexual pleasure and orgasm during coitus. Kegel proposed that underdevelopment of the pubococcygeus resulted in less pleasurable vaginal sensation during coitus and “every woman with a sexual complaint should be evaluated for possible pubococcygeal dysfunction.” The fourth set of muscles is the smooth muscle fibers of the upper two thirds of the vagina and the striated lower third. These four muscle groups vary considerably in size, strength, and volitional control among women. Although these muscle groups are well-defined anatomically, their exact impact on sexual functioning remains poorly understood.

Erectile Tissues

Erectile tissues, or cavernous bodies, are present in the clitoris and the vestibular bulbs. These areas become engorged with blood when successful sexual arousal occurs. The clitoris is comprised of three parts: the outermost glans, the midline corpus, and the innermost crura. The paired crura are called corpora cavernosa and are separated by a connective tissue septum. The clitoris is suspended to the anterior abdominal wall by a suspensory ligament, and is exquisitely sensitive to touch, temperature, and pressure. The autonomic innervation of the clitoris arises from the pelvic and hypogastric plexuses, employing both sympathetic and parasympathetic fibers. The clitoris has a dense concentration of pacinian corpuscles, as well as Merckles tactile discs, free nerve endings, and Meissner corpuscles. Sensory innervation to the clitoris travels from the skin via the dorsal nerve of the clitoris to the pudendal nerve, and subsequently to the spinal cord (Fig. 42.2.) Other erectile tissues are the paired vestibular bulbs. Located laterally to the vaginal orifice and directly beneath the skin of the labia, the vestibular bulbs are homologous to the corpus spongiosum of the penis.

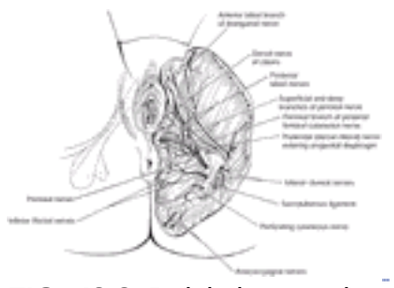

FIG. 42.2. Pelvic innervation.

Role of the Cervix/Uterus

The role of the cervix in sexual functioning has been widely debated. The cervix has a rich vascular and nerve supply, and it appears plausible that loss of the cervix may have an adverse effect on sexual arousal. In the widely reported Finnish cohort study from 1979, total abdominal hysterectomy was performed on 105 women and supracervical hysterectomy on 107. The only statistically significant finding was a decrease in orgasm frequency in the total hysterectomy group. The proportion of women that could not achieve orgasm in more than 75% of their coital encounters increased from 30% prior to the total abdominal hysterectomy to 47% at 1 year following the operation. Both groups had a statistically significant decrease in dyspareunia and no change in coital frequency. It is difficult to draw a definitive conclusion from this study as the treatment groups were not blinded and there were demographic differences between the two study groups. A subsequent study comparing 532 women after total abdominal hysterectomy with 146 women after supracervical hysterectomy found no differences. Attempting to define the role of the cervix and uterus in sexual functioning is a challenge, and the existing studies are methodologically flawed. A randomized, controlled trial will be necessary to further elucidate this issue.

Graefenberg Spot

The existence of a G-spot or Graefenberg spot refers to an allegedly highly erogenous region on the anterior vaginal wall, approximately one-third of the distance from the introitus. The concept of a G-spot is widely accepted among the public, however there is little objective evidence to support its existence.

The anterior vaginal wall has more innervation than the posterior wall, however this innervation is subepithelial; intraepithelial innervation would be expected if a sensitive region existed. Thus, sketchy clinical findings and no anatomic evidence exist to document the existence of a G-spot. Nonetheless, the reader is reminded that each woman is an individual and sexually unique and universal anatomic axioms should not dictate clinical care.

SEXUAL RESPONSE CYCLE

The Masters and Johnson Hypothesis

The classic approach to the female sexual response was proposed by William Masters and Virginia Johnson in 1966 when they arbitrarily divided the sexual response into four stages. These stages of excitement, plateau, orgasm, and resolution were presented as a continuum, with each stage progressing into the next.

The excitement phase was defined as sexual arousal or tension resulting from psychogenic or somatic stimuli. Pelvic vasocongestion and increased muscle tension is evident. Vaginal lubrication occurs, the vaginal walls assume a darker coloration due to engorgement, and the uterus elevates slightly. The inner two thirds of the vagina lengthen and distend, the labia minora increase in size, and the clitoris swells. Masters and Johnson noted a two- to three-fold increase in the labia minora diameter. Often the nipples become erect and a sex flush may occur.

During the plateau phase, the vaginal opening constricts due to vaginal engorgement. The clitoris often retracts, and if stimuli are adequate, orgasm occurs.

The orgasmic phase is described as the few seconds at climax in which sexual tension is relieved in a wave of intense pleasure, often accompanied by myotonia. This is an involuntary reflex that demonstrates uterine and vaginal contractions, and often varies in duration and intensity. Rhythmic pelvic thrusting may occur.

Following the release of sexual tension, there is often a feeling of well-being and satisfaction. This resolution stage follows orgasm and the body returns to its baseline state. Relaxation occurs, the sex flush disappears, and vasocongestion reverses. The clitoris and vagina resume their original size and shape.

The Kaplan Hypothesis

In 1974, Helen Kaplan became unsatisfied with the four stages of sexual response described by Masters and Johnson as she concluded that the sexual responses of patients did not appear to consist of an orderly sequence of separate events but consisted of two fundamentally separate components. The two distinct and relatively independent components are a genital vasoconstrictive reaction causing vaginal lubrication followed by the reflexive, clonic striated and nonstriated muscular contractions at orgasm. Kaplan also proposed a three-phase integrated model to include desire, arousal, and orgasm. She describes desire as an urge to seek out, initiate, or respond to sexual stimulation. Kaplan defines sexual desire as “a motivational or drive state that is generated by specific neurological processes in the brain—similar to other drives or appetites that subserve individual and species survival, not simply a subjective sensation or merely a mental event.” Kaplan's definitions of arousal and orgasm are similar to those proposed by Masters and Johnson; however, Kaplan focuses on the integration of these stages as opposed to occurring in a strict chronologic sequence.

The Basson Hypothesis

More recently, Basson has outlined an alternative sexual response cycle that emphasizes the role of sexual interaction with a partner in enhancing emotional closeness. The cycle begins with a state of “sexual neutrality” and if the woman seeks or is receptive to sexual stimuli, she will experience arousal and subsequent desire. Once desire is accessed, receptivity to sexual stimuli increases, which leads to further and more intense arousal. Emotional and physical satisfaction can then be attained, which facilitates emotional intimacy. The mental feedback of emotions, physical and genital arousal, mutual excitement, and cognition provide stimuli that modulate the ongoing sexual response. The focal point of this paradigm is “enhanced emotional intimacy,” and orgasm is not imperative for the experience to be satisfying.

NORMAL SEXUAL PHYSIOLOGY

Objective evidence of sexual arousal begins with increased clitoral length and diameter and vasocongestion of the vagina, vulva, clitoris, and uterus. The corpora cavernosa of the clitoris consists of a fibroelastic network and bundles of trabecular smooth muscle. Pelvic nerve stimulation results in clitoral smooth muscle relaxation and arterial smooth muscle dilation. With arousal there is an increase in the clitoral cavernosal artery inflow and an increase in the clitoral intercavernous pressure that leads to tumescence and extrusion of the clitoris. Engorgement of the genital vascular network increases pressure inside the vaginal capillaries and results in lubrication of the epithelial surface of the vaginal wall by a transudate of serum.

The vaginal fluid demonstrates significant changes in its ionic content before and after sexual arousal. Sodium and chloride levels increase significantly. Although most lubrication is from the transudate, which is passively transported through intraepithelial spaces, and appears on the surface of the vagina, a small amount of additional lubrication arises from the mucus secretions of the Bartholin glands.

These objective physiologic changes that occur with arousal are initiated by the medial preoptic, anterior hypothalamic region and related limbic-hippocampal structures within the central nervous system (CNS). Once activated, these centers transmit signals via the parasympathetic and sympathetic nervous systems to the clitoral and vaginal tissues. Serum concentrations of epinephrine and the norepinephrine metabolite, vanillylmandelic acid, increase prior to intercourse and remain elevated over baseline for up to 23 hours following sexual activity. Peripheral adrenergic stimuli may selectively “prepare” the body for genital responsiveness. Interestingly, anorgasmic women demonstrate an inhibition in physiologic sexual arousal under conditions of CNS activation. This may indicate that CNS activation may have a different influence on women with and without anorgasmia, and may have important implications for cardiac patients who take antihypertensive medications with high affinities for a-adrenergic receptors.

Another neuropeptide that impacts sexual function is serotonin (Table 42.1). Activation of the serotonin-2 receptor appears to impair sexual functioning and stimulation of the serotonin-1a receptor facilitates sexual functioning. Nefazodone (Serzone) is a selective serotonin reuptake inhibitor (SSRI) as well as a serotonin-2 receptor antagonist, and reportedly causes fewer sexual side effects than traditional SSRIs. The mechanism of action may be that nefazadone produces both a reduction in the number and activity of serotonin-2 receptors as well as an up-regulation in serotonin-1a receptors. The sexual side effects of SSRIs however, may be through a peripheral effect. Ninety-five percent of serotonin receptors are located in the periphery of the body, and peripheral serotonin acts on vascular smooth muscle to produce vasodilation and vasocongestion, acts on the smooth muscles of the genitals, and is active in peripheral nerve function.

Generic name	Trade name	Incidence of sexual dysfunction (%)
Sertraline	Zoloft	62.9
Fluvoxamine	Luvox	62.3
Fluoxetine	Prozac	57.7
Paroxetine	Paxil	70.7
Citalopram	Celexa	72
Venalafaxine	Effexor	67.3
Mirtazapine[b]	Remeron[b]	24.4
Nefazadone[b]	Serzone[b]	8

[a]All of the selective serotonin reuptake inhibitors are implicated in disorders of sexual arousal, desire, and anorgamia.

TABLE 42.1. *Selective serotonin reuptake inhibitors* [a] *and incidence of sexual dysfunction*

Dopamine is probably the most frequently studied of the neurochemicals that collectively regulate sexual activity, and while serotonin is generally inhibitory to sexual behavior, dopamine is regarded as facilitative. Dopamine generally enhances sensorimotor integration by removing tonic inhibition. Although steroid hormones increase the responsiveness of certain hormones, those neurons cannot fully respond to stimuli unless the tonic inhibition is removed. Therefore, dopamine does not directly affect sexual behavior; rather it allows hormonally primed output pathways to have access to sexually receptive stimuli. Dopamine agonists have been shown to increase mounting behavior and increase sexual behavior in sexually satiated male rats. Antiparkinsonian medications act as dopamine agonists and have been reported to increase sexual desire in human men. Bromocriptine, which decreases prolactin levels and is also a long-acting dopamine agonist, facilitates erectile functioning. Delayed or inhibited orgasm in women has been associated with antipsychotic medications that decrease dopamine activity. Cocaine enhances dopamine activity by blocking the presynaptic autoreceptor and, in low doses, is believed to enhance sexual pleasure. At higher doses, cocaine impairs sexual functioning and often leads to anorgasmia, perhaps a result of the vasoconstrictive effects of the drug.

Women with elevated prolactin levels frequently report a decrease in sexual interest that is often reversed with bromocriptine treatment. A significant two-fold increase in prolactin levels occurs in women following orgasm and prolactin remained elevated when measured 60 minutes after sexual arousal. Circulating oxytocin increases during sexual arousal and orgasm. In female animals, oxytocin injected either centrally or peripherally facilitates sexual behavior as measured by increases in a lordosis response. Blood cortisol levels appear unchanged during female sexual arousal or orgasm; however, hypercortisolism has been associated with decreased libido or erectile dysfunction in men.

Sexual stimuli involve a complex interplay between neurotransmitters and steroid hormones. The steroid hormones facilitate a sexual response by biasing sensorimotor integration so that a sexual stimulus is more likely to produce a sexual response. Testosterone administration to female-to-male transsexuals and androgen deprivation in male-to-female transsexuals support the theory that androgenic hormones play an important role in sexual desire. The androgens influence sexual desire, but are not sufficient alone as oral contraceptives and androgen antagonists do not consistently suppress libido, and patients with hypoactive sexual desire do not have lower androgen levels than women with normal sexual function. However, women report that their sexual desire diminishes following surgical menopause, and this desire can be restored with testosterone administration. Further evidence of androgen's effect on libido is illustrated when administration of dehydroepiandrosterone sulfate (DHEA-S) to postmenopausal women increases subjective ratings of sexual arousal when compared to placebo, although vaginal blood flow measures are unaffected. In premenopausal women, the effect of androgens is conflicting. There is a positive relationship between midcycle testosterone levels and coital frequency as well as testosterone levels and masturbation.

In contrast to the role of androgens, estrogens appear to have little direct effect on sexual desire and functioning. Exogenous estrogen, particularly when administered orally, increases sex hormone binding globulin which in turn reduces free testosterone and estradiol. No differences in estradiol levels have been found in women with or without hypoactive sexual desire, or as a function of coital frequency. Estradiol levels influence central and peripheral nerve transmission and exert a vasoprotective effect on pelvic vasculature. Estrogen is necessary to maintain the function of the vaginal epithelium, stromal cells, and smooth muscles of the muscularis as well as thickness of the vaginal rugae and vaginal lubrication. Estrogen deficiency may negatively impact sexual functioning by resulting in atrophy of the vaginal epithelium causing decreased lubrication and dyspareunia.

The role of progesterone on female sexual response still remains to be elucidated. Progesterone treatment does not appear to have a significant impact on sexual response, although there are some reports of diminished sexual desire with oral contraceptives or progestin implants.

Other chemical mediators have been proposed to augment and initiate sexual motivation. Pheromones are chemical substances released by one member of a species to communicate with another member, to their mutual benefit, and are secreted from the glands at the anus, breasts, urinary outlet, and mouth. Studies of these chemicals secreted by insects and animals have led to speculation that perhaps these substances would affect human sexual behavior. The main olfactory system in humans may respond to odor cues with behavior significance. There is a strong olfactory input to the prefrontal cortex and decision making in this region of the brain appears to be influenced by emotional signals. Investigation of the role of pheromones in humans has found no evidence of any change in sexual behavior.

It is apparent that the female sexual response is a complex integration of endocrine, neural, and neurochemical mediators. The steroid hormones appear to allow a permissive state to exist so that a sexually relevant stimulus can more likely elicit a sexual response. The long-term steroid effects may then induce a rapid physiologic change by altering levels of neurotransmitters. These chemical mediators are then communicated via multiple neural pathways which induce genital responses and sexual motivation. These complex interactions must be considered when attempting to define sexual functioning and to elucidate causes of sexual dysfunction.

SEXUAL DYSFUNCTION

Clearly, the complexity of the normal sexual response eschews a simple cause and effect, search and find, approach to human sexual dysfunction. Indeed, sexual dysfunction is a multicausal and multidimensional problem combining biological, interpersonal, and psychological components. It is not surprising that the prevalence is high. A 1992 study of adult sexual behavior in the United States (National Health and Social Life Survey) revealed 43% of women exhibit sexual dysfunction. Approximately 20% of women reported sex was not pleasurable, nearly one-fourth were consistently unable to achieve orgasm, and 8% to 21% experienced pain during intercourse. Often women will experience more than one sexual dysfunction, as marked overlap exists.

Risk Factors

Several risk factors are known to lead to sexual dysfunction. These include emotional or stress-related problems, deterioration in economic position, history of sexual trauma, and lower educational levels. Postmarital (divorced, separated, or widowed) status is associated with an elevated risk of orgasmic difficulties when compared to married women, and married women are one and a half times more likely to achieve orgasm than unmarried women. Black women tend to exhibit higher rates of hypoactive sexual desire compared to white women (44% vs. 29%) who report more sexual pain disorders (16% vs. 13%). Hispanic women, in contrast, consistently report lower rates of sexual dysfunction.

Evaluation

History Obtaining a thorough history for the evaluation of sexual dysfunction is imperative. The physician should ensure that the patient is comfortable and is assured of strict confidentiality. The interview can begin with open-ended questions and gender inclusive terminology should be used, so as not to assume heterosexuality. An introductory question such as “Most people experience sexual concerns or problems at times during their lives. What problems, if any, have you experienced?” can be helpful. The expectations and goals of the patient and her partner, the patient's degree of commitment to the relationship, and the presence or extent of extramarital relationships should be ascertained. Inquiring as to what the patient believes is the etiology of her sexual dysfunction may provide some insight, as the patient may simply admit that she is not attracted to her partner or has an underlying fear of pregnancy. The patient should be asked to define specifically what she perceives as the sexual difficulty. When she noted the onset of the problem, precipitating circumstances, the frequency and intensity, and whether she has experienced difficulty with other partners should be determined. Early sexual development and education should be discussed. Severely negative family attitudes toward sex (often associated with religious orthodoxy), traumatic prior sexual experience, or gender identity confusion are relevant. Relationship issues should be explored, such as whether the

couple has divergent sexual preferences or concerns of partner fidelity, and if there is any underlying hostility or abuse. Cognitive factors such as ignorance of sexual anatomy or sexual response and acceptance of cultural myths impact greatly upon therapy and should be addressed from the outset. The physician should inquire about ongoing illnesses, prior injuries, surgical and psychiatric history, and alcohol and recreational drug use. A thorough medication history is crucial, specifically the use of ß- adrenergic blockers, CNS depressants, anticholinergics, or antidepressants (Table 42.2). It should also be noted if the patient breast-feeding, or if she has recently undergone menopause.

Medications that Cause Disorders of Desire
Psychoactive medications
Antipsychotics
Barbiturates
Benzodiazepines
Selective serotonin reuptake inhibitors
Lithium
Tricyclic antidepressants
Cardiovascular and antihypertensive medications
Antilipid medications
Beta blockers
Clonidine (Catapres)
Digoxin
Spironolactone (Aldactone)
Hormonal preparations
Danazol (Danocrine)
GnRh agonists (e.g., Lupron, Synarel)

TABLE 42.2. *Medications and female sexual dysfunction*

Assessment Scales Several self-report questionnaires are available for assessing sexual dysfunction, all with some advantages and limitations. The Sexual Evaluation Scale is a 16-item scale that pertains to global factors of sexual interest, arousal, and performance, but does not address the factors of sexual drive and satisfaction. The Brief Index of Sexual Functioning is lengthier and includes weekly assessment of sexual function. However, it contains sexually explicit questions that may contribute to patient noncompliance. The Arizona Sexual Experience Scale is a brief five-question scale designed to evaluate psychotropic drug-induced changes in sexual functioning, and is helpful in patients who have recently initiated antidepressant therapy. The Female Sexual Function Index (FSFI) is a brief, self-reported measure of sexual function with a high degree of internal consistency and construct validity. The FSFI evaluates desire, orgasm, arousal, sexual pain, lubrication, and sexual satisfaction (Appendix A).

Examination A detailed examination should be performed in the presence of a chaperone. The internal/external genitalia are examined closely and evidence of vaginal atrophy should be noted. A cotton swab can be used to elicit painful areas, particularly in patients reporting entry dyspareunia, and the vestibular areas, Bartholin ducts, Skene ducts, and the urethral meatus should be carefully checked. Areas of erythema or tenderness should be noted. Some women have minute papillae of the vestibular skin which is a normal variant that does not represent viral or other disease entities. A vaginal exam is performed using one finger prior to the bimanual exam to minimize confusion arising from abdominal tenderness. Vaginismus may be apparent during the exam, however approximately 25% of women who tolerate vaginal exams or tampon insertion experience involuntary spasms during coitus. The lateral walls of the vagina are palpated along the bladder anteriorly, the posterior wall, and vaginal fornices. The vagina is visually evaluated using a narrow, warmed, and well-lubricated speculum. The presence or absence of vaginal rugae, fissures, or friable tissue should be noted. Characteristics such as skin elasticity, pubic hair, labial fullness, and evaluation of the introital and vaginal depth offer an assessment of vaginal atrophy. Inspecting the cervix may detect dysplastic lesions or evidence of infection, which warrants further evaluation, including a Pap smear, cultures, or wet mounts. The vaginal fornices around the cervix are palpated for nodularity which is suggestive of endometriosis or may represent fixed adnexa from pelvic inflammatory disease. Muscle tone and Kegel strength are ascertained in addition to the bulbocavernosus reflex and genital/perineal sensation is assessed. With two examining fingers in the vagina, locate the levator muscles which are at the 5- and 7-o'clock positions just superior to the hymeneal ring. The patient is then instructed to contract these muscles. To assist in proper muscle group isolation, various verbal cues can be tried, such as “squeeze as if you are trying to stop your urine stream” or “squeeze as if you are trying to prevent flatus” or “pull my examining fingers up into the vagina.” A correctly performed pelvic floor contraction is demonstrated by cephalad retraction of the perineum and anus, posterior rotation of the clitoris, and anterior displacement of the examining fingers. Once the patient is able to contract the muscles properly, ask her to contract as strongly as possible for as long as possible in order to assess baseline pelvic floor function. This maximal effort is rated according to a pelvic muscle rating scale (Table 42.3).

	1	2	3	4
Pressure	None	Weak	Moderate	Strong
Duration	None	< 1 sec	1–5 sec	> 5 sec
Displacement	None	Slight anterior	Whole anterior	Gripped

TABLE 42.3. *Pelvic muscle rating scale*

The bulbocavernosus reflex is evaluated by squeezing the clitoris and feeling (or seeing) the anal sphincter and perineal muscles contract. Alternatively, the reflex may be initiated by suddenly pulling the balloon of a Foley catheter against the vesicle neck. The absence of this reflex in a man is almost always associated with a neurologic lesion, but the reflex is not detectable in up to 30% of otherwise normal women (Table 42.4).

Examination	Condition
External genitalia	
Assess muscle tone	Vaginismus
Assess skin color and texture	Vulvar dystrophy, dermatitis
Assess skin turgor and thickness	Atrophy
Assess pubic hair thickness and distribution	Atrophy
Expose clitoris	Clitoral adhesions
Assess for ulcers	Herpes simplex virus
Perform cotton swab test of vestibule	Vulvar vestibulitis
Palpate Bartholin glands	Bartholinitis
Assess posterior fourchette and hymenal ring	Episiotomy scars, strictures
Monomanual	
Palpate rectovaginal septum	Rectal disease, endometriosis
Palpate levator ani	Levator ani myalgia, vaginismus
Palpate bladder/urethra	Urethritis, interstitial cystitis, urinary tract infection
Assess for cervical motion tenderness	Infection, parametritis
Assess vaginal depth	Postoperative changes, postradiation changes, stricture
Bimanual	
Palpate uterus	Retroversion, leiomyomata, endometriosis
Palpate adnexa	Masses, cysts, endometriosis, tenderness
Perform rectovaginal examination	Rule out endometriosis
Obtain guaiac test	Bowel disease
Speculum	
Evaluate discharge, pH	Vaginitis, atrophy
Evaluate vaginal mucosa	Atrophy
Perform Pap smear	Human papillomavirus infection, dysplasia
Assess for prolapse	Cystocele, rectocele, uterine prolapse

TABLE 42.4. *Gynecologic causes of female sexual dysfunction and method of gynecologic examination*

More involved evaluation includes determination of vaginal pH, vaginal wall compliance, genital vibratory perception thresholds, and genital hemodynamics. The use of Semmes-Weinstein monofilaments to assess vulvar sensitivity to pressure and touch has been proposed. These 20 nylon monofilaments are all of equal length but varying diameters. The filament is pressed against the skin until it bends, providing a consistent reproducible application of force. The filaments are inexpensive, convenient, easy to use, and associated with a high degree of patient compliance. This technique reveals that women with sexual dysfunction have significant diminished vulvar sensitivity to pressure/touch compared to women without sexual dysfunction. Blood flow to the clitoral, labial, urethral, vaginal, and uterine arteries can be recorded and both blood velocity and venous pooling may be compared pre- and poststimulation. While it may be possible to demonstrate these differences objectively, in order for these assessments to be clinically relevant, a patient must be able to recognize these changes as sexual arousal, and their absence must be significant enough to interfere with sexual functioning (Fig. 42.3).

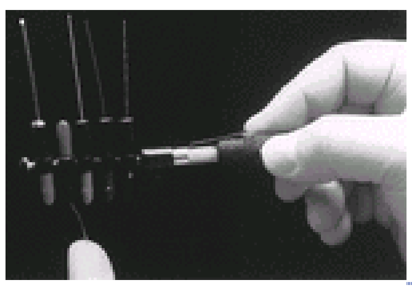

FIG. 42.3. Semmes-Weinstein monofilaments for detection of tactile neuropathy. (Photograph provided by Semmes-Weinstein Corp.)

Laboratory Evaluation Measurements of estradiol, follicle-stimulating hormone, prolactin, and testosterone are often obtained in patients with sexual dysfunction; however, there is little evidence to support a direct correlation between sexual dysfunction and hormonal parameters. Most researchers agree that estrogen plays only a minimal role in female sexual desire, yet estrogen deficiency does affect genital vasocongestion and lubrication and may induce atrophy of vaginal epithelium. Androgens and their role in sexual desire have yielded conflicting results (see Normal Sexual Physiology). With natural menopause, androgen levels (testosterone, DHEA-S) have been positively correlated with sexual interest; however, no significant differences in circulating testosterone levels have been demonstrated in normal women compared to women without hypoactive sexual desire.

Hemodynamic Testing Vaginal blood flow may be measured indirectly via vaginal photoplethysmography, pulsed wave Doppler ultrasonography, and measures of heat dissipation. Most of these techniques are reserved for the research setting. Vaginal photoplethysmography is the most studied technique in which a clear acrylic tampon is inserted into the vagina. This tampon contains either an incandescent light source or an infrared light-emitting diode as a light source and photosensitive light detector. The light source illuminates the capillary bed of the vaginal wall and the phototransistor detects the light that is reflected back from the vaginal wall and the

blood circulating within it. Disadvantages of this method are an inability to detect subtle changes in vaginal blood flow and often there is motion artifact. Measurement of tissue perfusion by measuring the cooling of a heated metal disk is another noninvasive technique that has been adapted for vaginal studies. A silver disk electrode is applied against the vaginal mucosa and maintained electrically at a temperature that exceeds body temperature. The electrical power needed to maintain this elevated temperature is then recorded. Increased blood perfusion under the disk will increase heat loss from the disk and require more power to maintain temperature. This power output therefore becomes an index of local blood perfusion. This technique is not affected by movement to the same degree as photoplethysmography.

Classification

The two primary classification systems for sexual dysfunction are the World Health Organization's *International Statistical Classification of Diseases, 10th Revision* (*ICD-10*) and the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition DSM-IV* (*DSM-IV*). The *ICD-10* definition of sexual dysfunction includes “the various ways in which an individual is unable to participate in a sexual relationship as he or she would wish.” Categories are lack or loss of sexual desire (F52.0), sexual aversion disorder (F52.1), failure of genital response (F52.2), orgasmic dysfunction (F52.3), nonorganic vaginismus (F52.5), nonorganic dyspareunia (F52.6), and excessive sexual drive (F52.7).

The *DSM-IV* defines sexual dysfunction as a “disturbance in sexual desire and in the psychophysiologic changes that characterize the sexual response cycle and cause marked distress and interpersonal difficulty.” The described disorders include hypoactive sexual desire (302.71), sexual aversion (302.79), female arousal disorder (302.72), dyspareunia (302.76), vaginismus (306.51), and female orgasmic disorder (302.73).

An interdisciplinary consensus, known as the International Consensus Development Conference on Female Sexual Dysfunction: Definitions and Classification, was convened to address the shortcomings and problems associated with the *DSM-IV* and *ICD-10* classifications of sexual dysfunction. The panel consisted of representatives from a wide range of disciplinary backgrounds—endocrinology, family medicine, gynecology, pharmacology, psychiatry, psychology, physiology, urology, and rehabilitative medicine. The panel preserved the general structure of the *DSM-IV* and *International Classification of Diseases, Ninth Revision* (*ICD-9*) classifications and expanded/altered the traditional definitions of sexual disorders. A new category of sexual pain disorder was added to include noncoital sexual pain disorder. Diagnosis of these disorders requires the component of “personal distress”. The diagnoses were also subtyped as (a) lifelong versus acquired, (b) generalized versus situational, and (c) for etiology—organic, psychogenic, mixed, or unknown (Table 42.5).

Desire Disorders
Hypoactive sexual desire
Sexual aversion disorder
Arousal disorder
Orgasmic disorder
Pain disorders

Noncoital pain
Subtypes
A. Lifelong vs. acquired
B. Generalized vs. situational
C. Etiology: organic, psychogenic, mixed, unknown

TABLE 42.5. *Classification of sexual dysfunction*

Desire Disorders Hypoactive sexual desire is the persistent or recurrent deficiency/absence of sexual fantasies/thoughts or desire for/receptivity to sexual activity which causes personal distress. Hypoactive sexual desire is the most commonly encountered dysfunction, seen in approximately 40% of patients in sexual counseling. Sexual desire is affected by many conditions such as medication use, life stages with accompanying hormonal changes, medical conditions, and interpersonal issues. Individuals with hypoactive sexual desire will also frequently exhibit difficulty with arousal and achieving orgasm. While obtaining a history, the physician should ask the patient how often she has felt sexual desire or interest, and inquire what she would rate her level of sexual interest on a scale from 1 to 5. The average population reports sexual desire approximately 3.4 times per month and a desire level of 3.5, as based on the FSFI control group. Hypoactive sexual desire is common in the female partners of men suffering from erectile dysfunction, and it is important to inquire regarding the partner's sexual functioning. Inquire regarding the presence of depression in the patient or partner, as decreased libido disproportionately affects patients with depression. In patients with major depression being evaluated for sexual dysfunction prior to the initiation of antidepressant therapy, only 50% of women and 75% of men reported sexual activity during the preceding month. Over 40% of men and 50% of women report decreased sexual interest. Reduced levels of arousal were more common in both depressed men and women (40% to 50%) than ejaculatory or orgasm difficulties. On physical exam the estrogen status of the external genitalia can carefully be evaluated by assessing the presence or absence of vaginal rugae, fissures, or friable tissue. Characteristics of skin elasticity, pubic hair, labial fullness, and evaluation of the introital and vaginal depth offer a further assessment of estrogen status. An extreme form of hypoactive sexual desire is sexual aversion disorder, which is the persistent or recurrent phobic aversion to and avoidance of sexual contact with a partner that causes personal distress. The etiology of sexual aversion disorder is often related to a history of traumatic sexual assault, such as a rape or child abuse.

Arousal Disorders Sexual arousal disorder is the persistent or recurrent inability to attain or maintain sufficient sexual excitement causing personal distress which may be expressed as a lack of subjective excitement or genital (lubrication, swelling) or other somatic responses. Arousal difficulties may be physiologic or psychological. Insufficient foreplay, emotional distraction, lack of vaginal lubrication, decreased clitoral or labial sensation or engorgement, lack of vaginal smooth muscle relaxation, pelvic trauma, medication use, and postsurgical changes may all contribute to diminished sexual arousal. Arousal disorder can be elucidated by inquiring how often the patient felt sexually aroused over the preceding 4 weeks, how she would rate her sexual arousal on a scale from 0 to 5, and how satisfied she is with her level of arousal during sexual intercourse. The physician should ascertain how often the patient was able to become lubricated during sexual activity (0 = never to 5 = always), and how difficult it was to maintain lubrication (0 = very difficult to 5 = not difficult). Most women without sexual difficulty will report an average score of approximately 4 on these questions. On physical exam, careful attention should be paid to the estrogen status of the external genitalia and the degree of vulvar sensation and muscle tone.

Orgasmic Disorders Orgasmic disorder is the persistent or recurrent difficulty, delay in, or absence of attaining orgasm following sufficient stimulation and arousal, which causes personal distress. Fifty percent of women report intermittent or situational difficulties in achieving orgasm and nearly 10% of sexually active women are incapable of attaining orgasm. There appears to be both physical and psychological components; as compared to orgasmic women, anorgasmic women report (a) greater discomfort in communicating with a partner regarding sexual activities involving direct clitoral stimulation, (b) more negative attitudes toward masturbation, (c) greater endorsement of sex myths, and (d) greater sexual guilt. Orgasmic disorders may be primary (never experiencing an orgasm) or secondary. The physician should inquire as to how often the patient was able to attain orgasm during the preceding 4 weeks (0 = never to 5 = always), and how difficult it was to achieve orgasm (0 = impossible to 5 = not difficult). Women without sexual difficulty report a score assessment of approximately 4 for each question. Inquire as to the ability of the patient's partner to maintain an erection, or if there is difficulty with premature ejaculation. Assess if there is a history of alcohol or drug abuse, and what prescription medications the patient is taking. On physical exam specifically evaluate muscle tone and review clitoral anatomy with the patient.

Pain Disorders Sexual pain disorders encompass dyspareunia, vaginismus, and nonsexual pain categories. Dyspareunia is recurrent or persistent genital pain associated with sexual intercourse, and may result from genital stimulation, attempted entry, deep thrusting, or occur immediately after intercourse. Endometriosis, vestibulitis, hypoestrogenism, ovaries adherent in the cul-de-sac, and pelvic or urinary infections may be etiologic factors. Often women with chronic pelvic pain that were scheduled for laparoscopy are evaluated for interstitial cystitis by cystoscopy with hydrodistention and biopsy. Interstitial cystitis is diagnosed in approximately one third of women with a combination of urgency, frequency or nocturia, and positive cystoscopic findings. If sensation is impaired, neurologic referral may be indicated as disorders such as multiple sclerosis, spinal cord, or peripheral nerve injury may lead to sexual dysfunction. There is also a psychological component associated with these disorders as the anticipation of pain leads to decreased arousal and subsequent lack of desire. Vaginismus, the recurrent or persistent involuntary spasm of the musculature of the outer third of the vagina that interferes with vaginal penetration, is another sexual pain disorder leading to personal distress. The diagnosis of vaginismus however, does not require the presence of pain. Spasm of the pubococcygeus and levator ani muscle render vaginal penetration difficult, if not impossible. Frequently, this disorder is situational in that the patient may tolerate speculum or digital exams, but is unable to tolerate vaginal penetration during intercourse. This may be the function of either a psychological component or a conditioned response to painful stimuli. The final subgroup under the pain disorders is noncoital pain which includes such diagnoses as noncoital sexual pain that is recurrent or persistent genital pain induced by nonpenetrating sexual stimuli. To determine the degree of pain being experienced, the physician should inquire as to how often the patient has pain with and immediately following intercourse (1 = always to 5 = never). Most women on the FSFI report an average score of 4.6. Inquire if the pain is noted with entry or deep penetration, and if it varies with position. Ask if the patient experiences difficulty with lubrication or experiences discomfort with tampon insertion? Determine if the pain is localized specifically to the introitus or more pronounced during micturation? In addition to the general pelvic exam, the anterior vaginal wall should be carefully palpated to examine for the presence of a urethral diverticulum. The pathognomonic finding is a tender cystic swelling on the anterior vaginal wall. Patients in whom urethral diverticulum is strongly suspected may undergo voiding cytourethrography, followed by possible positive pressure urethrography, ultrasound, or MRI. Determine if the pain is superficial, deep, or vaginal, and attempt to reproduce the pain. Look for evidence of a poorly healed episiotomy scar or evidence of friable tissue at the vaginal cuff in a hysterectomy patient. A prolapsed fallopian tube into the cuff often results in significant dyspareunia. A biopsy and pathologic analysis of the tissue would be diagnostic. Aggressively seek the diagnosis of an underlying etiology, even if laparoscopy is required. Davis and Telinde state that “the most important single diagnostic instrument for the discovery of a suburethral diverticulum is a high index of clinical suspicion.”

ETIOLOGY OF SEXUAL DYSFUNCTION

The interplay of vasogenic, musculogenic, neurogenic, hormonal, and psychogenic factors influences the female sexual response, and a disruption in any of these components may cause sexual dysfunction.

Neurogenic sexual dysfunction may result from spinal cord trauma or disease. In a complete transection of the spinal cord, no afferent impulses from the genitals can occur, however sexual fantasy and erotica have induced orgasm in some patients. Complete upper motor neuron injuries preclude vaginal lubrication, however women with incomplete injuries still maintain lubricating ability. Peripheral nervous system disease such as diabetes may impact nerve endings in the external genitalia precluding adequate arousal and the ability to achieve orgasm.

Hormonal alterations have a significant impact upon sexual functioning. Surgical or medical menopause, premature ovarian failure, hormonal contraceptive use, hypothalamic–pituitary–axis dysfunction, and postpartum states may induce marked hormonal fluctuations and result in vaginal dryness, altered arousal, and decreased desire. Hypoestrogenism, from any cause, results in atrophy of the vaginal epithelium and a decrease in genital vasocongestion and lubrication. Administration of both androgen and estrogen to medically or surgically menopausal women has been shown to restore sexual desire; however estrogen treatment alone has not been shown to be successful. The role of exogenous androgens is still debated, as several studies have rendered somewhat mixed results. With natural menopause, androgen levels have been positively correlated with sexual interest, and there is a small but positive correlation between midcycle testosterone levels and intercourse frequency. These results are contrary to the lack of difference in testosterone levels between women with and without clinically diagnosed hypoactive sexual desire, and from studies that show oral contraceptives and androgen antagonists do not consistently suppress libido. There is a subset of women with hypoactive sexual desire in which testosterone treatment appears to be useful. Elevated levels of prolactin appear to suppress libido in women, and restoration of libido is noted with dopamine agonist therapy.

Vascular-mediated effects are noted on sexual arousal in patients with high blood pressure, smoking, elevated cholesterol, and cardiac disease. Aortoiliac or atherosclerotic disease diminish pelvic blood flow and may reduce lubrication and clitoral engorgement. Cardiovascular disease may interfere with intercourse secondary to dyspnea. Traumatic injury to the arterial bed from fractures, surgical disruption, blunt trauma, or chronic perineal pressure from bicycle riding can result in diminished blood flow and subsequently sexual dysfunction.

Impairments in pelvic floor musculature contribute to sexual dysfunction. When the levator ani muscles are hypertonic, vaginismus may result leading to dyspareunia and other sexual pain disorders. If hypotonic, urinary incontinence or anorgasmia can result. A poorly healed episiotomy site or vaginal delivery of a macrosomic infant may contribute to muscular dysfunction.

The psychogenic component of sexual response is a critical one. Body image, self-esteem, and relational issues impact sexual arousal, as does emotional conflict such as anxiety, fear, anger, or guilt. An existing mood disorder is further compounded by the effects of psychotropic medications, which tend to inhibit sexual functioning in up to 75% of patients. SSRIs have been associated with decreased arousal, decreased genital sensation, and anorgasmia. Tranquilizers such as diazepam inhibit sexual function secondary to antidopaminergic action. Previous unresolved negative experiences such as sexual assault or domestic abuse will impact desire and arousal, and may manifest as a sexual aversion disorder or vaginismus.

TREATMENT

A multidisciplinary approach is imperative in thorough evaluation and treatment of sexual dysfunction. Psychiatric consultation is necessary for patients with a suspected assault history or evidence of depressive symptomatology. Urologic referral, particularly in patients with pelvic pain may reveal the presence of interstitial cystitis or a urethral disorder such as a urethral diverticulum. After arriving at a working diagnosis, diagnosis-specific treatment is most efficacious.

Desire Disorders

Pharmacologic Treatment

Hormone Replacement Therapy Indicated for use in postmenopausal women, estrogen replacement therapy results in improved clitoral sensitivity, increased libido, and decreased pain during sexual intercourse. Estrogen creams or the vaginal estradiol ring (Estring) may reduce complaints of vaginal irritation, pain, or dryness secondary to atrophy. Long-term use of estrogen vaginal creams is considered an unopposed estrogen treatment in women with an intact uterus and requires progesterone opposition. An oral progesterone, such as medroxyprogesterone 5 mg daily for 10 days a month (or equivalent), may be used initially, with frequency or dose adjustment if breakthrough bleeding occurs. The estradiol ring has little systemic absorption and does not require the addition of progesterone. Patients who are uncomfortable wearing the ring during the day often achieve relief with night use only.

Testosterone Testosterone replacement therapy has been prescribed for menopausal woman with symptoms of inhibited sexual desire, dyspareunia, and decreased lubricating ability. In women in whom menopause had been surgically induced, supraphysiologic doses of testosterone enanthate given by injection alone or in conjunction with estrogen increase arousal, desire, sexual activity, orgasm frequency, and fantasies more than estrogen alone. Transdermal testosterone (300 µg) given to women following hysterectomy and oophorectomy results in increased sexual frequency and orgasm despite an appreciable placebo response. The percentage of women with sexual fantasies, masturbation, or coitus at least once per week increases two to three times above baseline. Transdermal testosterone has no significant effects on the serum concentration of high-density lipoprotein, total cholesterol, low-density lipoprotein, triglycerides, liver function tests, or fasting insulin/glucose levels. Serum free and bioavailable testosterone increase to normal values. Dihydrotestosterone and total testosterone increase to above normal with treatment. This is not a treatment approved by the Food and Drug Administration (FDA), and no treatment guidelines for testosterone replacement therapy exist. Many physicians are concerned about the lack of safety data on the role of testosterone in breast cancer and hepatic side effects; however hepatocellular damage or carcinoma is rare at prescribed dosages, and the development of breast cancer has not been reported clinically. Potential side effects of testosterone, which may occur in 5% to 35% of patients, include lipoprotein alterations, acne, hirsutism, clitoromegaly, and voice deepening. Before initiating testosterone treatment, physicians should discuss the potential and theoretic risks as well as the individual risk and benefit assessments with the patient. In general, patients with current or previous breast cancer, uncontrolled hyperlipidemia, liver disease, acne, or hirsutism should not receive testosterone therapy (Table 42.6).

TABLE 42.6. *Dosages for testosterone administration* [a]

Arousal Disorders

Pharmacologic Treatment

Sildenafil Citrate Sildenafil citrate (Viagra) is a selective inhibitor of phosphodiesterase-5 and therefore enhances and prolongs the cellular effects of the second messenger substrate cyclic guanosine monophosphate (cGMP), the specific substrate for this enzyme. The guanylyl cyclase/cGMP pathway is the signal transduction mechanism activated by nitric oxide (NO). NO is released by the endothelial cells and the postsynaptic parasympathetic cavernosa neurons in males and leads to a cascade of chemical reactions that ultimately relaxes smooth muscle, dilates arteries, and engorges the corpora cavernosa. Therefore, once the psychological and physical arousal set in motion these chemical events in the corpora cavernosa, sildenafil, when taken 1 hour prior to sexual activity, helps maintain erections in men. Research has also identified phosphodiesterase-5 in human clitoral tissue. In women, there is the potential that sildenafil may be useful in treating orgasm delay and anorgasmia by facilitating lubrication, clitoral perfusion and engorgement, and the swelling and engorgement of the female genitalia. The role of sildenafil in treating sexual dysfunction in women, however, remains to be determined. In women experiencing psychotropic medication-induced sexual dysfunction, there may be a role for sildenafil. There may be some improvement in sexual functioning in women who reported sexual dysfunction since initiating antidepressant or antipsychotic medication therapy. Further clinical studies evaluating the safety and efficacy of sildenafil for treatment of female sexual dysfunction are needed.

Nonpharmacologic Treatment The EROS-CTD (Clitoral Therapy Device, Urometrics, Inc. St Paul, MN) is the first FDA-approved therapy for female sexual dysfunction. This small, battery-powered vacuum device is designed to enhance clitoral enlargement, increase blood flow to the clitoris, and improve sexual arousal. Women with sexual arousal disorder noted improvement in all symptoms of female sexual arousal disorder, and patients without such disorder also report similar changes in sensation, lubrication, ability to orgasm, and overall satisfaction.

Orgasmic Disorders

Anorgasmia treatment relies on maximizing stimulation and minimizing inhibition. Stimulation may include masturbation with prolonged stimulation (initially up to 1 hour) with the use of a vibrator as needed. Surveys of young women reveal that the most effective techniques for triggering orgasm are manual and oral stimulation of the clitoris, and that joining the male's thrusting pattern without additional clitoral stimulation was one of the least effective methods. Muscular control of sexual tension such as alternating contraction and relaxation of the pelvic musculature during high sexual arousal has proven helpful. The volitional muscle control is similar to Kegel exercises (Table 42.7). Methods to minimize inhibition include distraction by fantasy or listening to music. Past failure to achieve orgasm can elicit self-defeating and distracting thoughts about whether the patient will be able to achieve orgasm. The patient mentally monitors her own and her partner's physical response, unable to relax and enjoy the sexual stimulation for its own sake. Such behavior makes the patient more a spectator than a participant in her own sexual pleasure. Masters and Johnson coined the term “spectatoring,” which they describe as a major deterrent to effective sexual functioning. Kaplan suggests this obsessive self-observation

arising out of fear of failure to be the single most immediate cause of female orgasmic dysfunction.

Teaching Kegel exercises
Instructional examination with examiner's finger in vagina
Initial patient home exercise with the patient's finger in the vagina
Slow count to 10, with movement directed "in and up"
Hold for count of 3
Slow release to count of 10
Repeat 10–15 times daily
Consider vaginal weights, biofeedback clinics
Maintaining Kegel exercises
Advise repetitions during routine activities (standing in line, at stop lights, etc.)
Schedule follow-up appointments to discuss progress

TABLE 42.7. *Kegel exercises*

Masters and Johnson's approach to anorgasmia used a temporary ban on orgasm and sexual intercourse until permitted by their sensate focus program. Their exercises focused on “non-demand pleasuring” and attempted to improve sexual skills while avoiding goal-oriented behavior. Their program also included assertiveness training, modeling, behavioral reversal, and education. Although widely accepted among sex therapists, their “success” rates of 80% could not be reproduced by other therapists. Group therapy and erotic fantasy have also been proposed.

Pain Disorders

Vestibulitis Several treatment modalities have been employed in the treatment of pain disorders. The most common type of premenopausal dyspareunia is vulvar vestibulitis. The most commonly used treatments are cognitive-behavioral therapy, biofeedback, and vestibulectomy. Typical cognitive–behavioral interventions aim at reducing pain and improving sexual functioning and include Kegel exercises, vaginal dilation, and relaxation techniques. Surface electromyographic biofeedback has been applied to dyspareunia. Vestibulectomy, in which the painful tissue of the vulvar vestibule is excised, has variable success rates, ranging from 43% to 100%.
Vaginismus Treatment of vaginismus consists of smooth muscle relaxation and vaginal dilation. Muscle relaxation can be taught during an exam by having the patient isolate and alternatively contract and relax the pelvic musculature around the examiner's finger. Commercial dilators or tampons of increasing diameter may be placed in the vagina for 15 minutes twice daily to facilitate muscle relaxation and dilation (Fig. 42.4).

FIG. 42.4. Vaginal dilators. (Photograph provided by Milex Products Inc.)

Interstitial Cystitis Mild symptoms of interstitial cystitis may respond to dietary modifications, stress reduction, biofeedback, and bladder retraining. Avoiding acidic, alcoholic, or carbonated beverages or spicy foods and artificial sweeteners have been reported by some patients to reduce their interstitial cystitis pain. The only oral medication currently FDA-approved to treat interstitial cystitis is pentosan polysulfate sodium (Elmiron), and other medications such as tricyclic antidepressants that have analgesic properties, antiinflammatory drugs, antihistamines, antispasmodics, and muscle relaxants may offer relief. More invasive treatments include hydrodistention of the bladder done at time of cystoscopy, bladder instillation with dimethyl sulfoxide (DSMO), or an implantable sacral nerve stimulator. Surgical procedures such as bladder augmentation or urinary diversion are used as a last resort.

Appendix A—Female Sexual Function Index (FSFI) [a]

Questions

Q1: Over the past 4 weeks, how *often* did you feel sexual desire or interest?

5 = Almost always or always

4 = Most times (more than half the time)

3 = Sometimes (about half the time)

2 = A few times (less than half the time)

1 = Almost never or never

Q2: Over the past 4 weeks, how would you rate your *level* (degree) of sexual desire or interest?

5 = Very high

4 = High

3 = Moderate

2 = Low

1 = Very low or none at all

0 = No sexual activity

Q3: Over the past 4 weeks, how *often* did you feel sexually aroused (“turned on”) during sexual activity or intercourse?

5 = Almost always or always

4 = Most times (more than half the time)

3 = Sometimes (about half the time)

2 = A few times (less than half the time)

1 = Almost never or never

0 = No sexual activity

Q4: Over the past 4 weeks, how would you rate your *level* of sexual arousal (“turn on”) during sexual activity or intercourse?

5 = Very high

4 = High

3 = Moderate

2 = Low

1 = Very low or none at all

0 = No sexual activity

Q5: Over the past 4 weeks, how *confident* were you about becoming sexually aroused during sexual activity or intercourse?

5 = Very high confidence

4 = High confidence

3 = Moderate confidence

2 = Low confidence

1 = Very low or no confidence

0 = No sexual activity

Q6: Over the past 4 weeks, how *often* have you been satisfied with your arousal (excitement) during sexual activity or intercourse?

5 = Almost always or always

4 = Most times (more than half the time)

3 = Sometimes (about half the time)

2 = A few times (less than half the time)

1 = Almost never or never

0 = No sexual activity

Q7: Over the past 4 weeks, how *often* did you become lubricated ("wet") during sexual activity or intercourse?

5 = Almost always or always

4 = Most times (more than half the time)

3 = Sometimes (about half the time)

2 = A few times (less than half the time)

1 = Almost never or never

0 = No sexual activity

Q8: Over the past 4 weeks, how *difficult* was it to become lubricated ("wet") during sexual activity or intercourse?

0 = No sexual activity

1 = Extremely difficult or impossible

2 = Very difficult

3 = Difficult

4 = Slightly difficult

5 = Not difficult

Q9: Over the past 4 weeks, how often did you *maintain* your lubrication ("wetness") until completion of sexual activity or intercourse?

5 = Almost always or always

4 = Most times (more than half the time)

3 = Sometimes (about half the time)

2 = A few times (less than half the time)

1 = Almost never or never

0 = No sexual activity

Q10: Over the past 4 weeks, how *difficult* was it to maintain your lubrication ("wetness") until completion of sexual activity or intercourse?

0 = No sexual activity

1 = Extremely difficult or impossible

2 = Very difficult

3 = Difficult

4 = Slightly difficult

5 = Not difficult

Q11: Over the past 4 weeks, when you had sexual stimulation or intercourse, how *often* did you reach orgasm (climax)?

5 = Almost always or always

4 = Most times (more than half the time)

3 = Sometimes (about half the time)

2 = A few times (less than half the time)

1 = Almost never or never

0 = No sexual activity

Q12: Over the past 4 weeks, when you had sexual stimulation or intercourse, how *difficult* was it for you to reach orgasm (climax)?

0 = No sexual activity

1 = Extremely difficult or impossible

2 = Very difficult

3 = Difficult

4 = Slightly difficult

5 = Not difficult

Q13: Over the past 4 weeks, how *satisfied* were you with your ability to reach orgasm (climax) during sexual activity or intercourse?

5 = Very satisfied

4 = Moderately satisfied

3 = About equally satisfied and dissatisfied

2 = Moderately dissatisfied

1= Very dissatisfied

0 = No sexual activity

Q14: Over the past 4 weeks, how *satisfied* have you been with the amount of emotional closeness during sexual activity between you and your partner?

5 = Very satisfied

4 = Moderately satisfied

3 = About equally satisfied and dissatisfied

2 = Moderately dissatisfied

1= Very dissatisfied

0 = No sexual activity

Q15: Over the past 4 weeks, how *satisfied* have you been with your sexual relationship with your partner?

5 = Very satisfied

4 = Moderately satisfied

3 = About equally satisfied and dissatisfied

2 = Moderately dissatisfied

1= Very dissatisfied

Q16: Over the past 4 weeks, how *satisfied* have you been with your overall sexual life?

5 = Very satisfied

4 = Moderately satisfied

3 = About equally satisfied and dissatisfied

2 = Moderately dissatisfied

1= Very dissatisfied

Q17: Over the past 4 weeks, how *often* did you experience discomfort or pain during vaginal penetration?

0 = Did not attempt intercourse

1 = Almost always or always

2 = Most times (more than half the time)

3 = Sometimes (about half the time)

4 = A few times (less than half the time)

5 = Almost never or never

Q18: Over the past 4 weeks, how *often* did you experience discomfort or pain following vaginal penetration?

0 = Did not attempt intercourse

1 = Almost always or always

2 = Most times (more than half the time)

3 = Sometimes (about half the time)

4 = A few times (less than half the time)

5 = Almost never or never

Q19: Over the past 4 weeks, how would you rate your *level* (degree) of discomfort or pain during or following vaginal penetration?

0 = Did not attempt intercourse

1 = Very high

2 = High

3 = Moderate

4 = Low

5 = Very low or none at all

Scoring System

The individual domain scores and full scale score of the FSFI are derived by the computational formula outlined in the table below. Individual domain scores are obtained by adding the scores of the individual items that comprise the domain and multiplying the sum by the domain factor (see below).

The full scale score is obtained by adding the six domain scores. It should be noted that within the individual domains, a domain score of zero indicates that no sexual activity was reported during the past month.

Domain	Questions	Range	Factor	Min Score	Max Score
Desire	1,2	1–5	0.6	1.2	6.0
Arousal	3,4,5,6	0–5	0.3	0	6.0
Lubrication	7,8,9,10	0–5	0.3	0	6.0
Orgasm	11,12,13	0–5	0.4	0	6.0
Satisfaction	14,15,16	0 (or 1)–5	0.4	0	6.0
Pain	17,18,19	0–5	0.4	0	6.0

OVARIAN REMNANT SYNDROME
- Pain of Uterine Origin

Science has produced many drugs, therapies, and surgeries in attempts to relieve the suffering associated with chronic pelvic pain (CPP). Unfortunately, only modest success has been achieved. This likely is due, in part, to the heterogeneity that exists in this ill-defined population of patients, as well as our limited understanding of pain modulation. Often, when standard therapies fail, or when no visible pathology can be identified, other specialties such as gastroenterology, urology, neurology, or psychiatry are consulted. Patients eventually may be referred to centers specializing in CPP or empiric pain management, wherein neurolytic or opioid therapy may be commenced without finding a specific cause for pain.

Along the course of therapy and referral, frustration is often a byproduct of treating a supposedly remediable pain state only to have pain persist. Furthermore, a confusing aspect of CPP is that its definition implies that no etiology can be found; however, most textbooks list several causes for CPP (adhesions, endometriosis, pelvic inflammatory disease [PID], etc.). Therefore, the clinical challenge is to decipher which of the following is most likely:

1. A defined pain state exists but has been improperly diagnosed and treated.
2. A defined pain state exists, has been correctly identified, but happens to be present in an incidental form.
3. A neuropathic pain processing state is present.

GLOSSARY

Allodynia: pain due to a stimulus which does not normally provoke pain.
Central pain: pain initiated or caused by a primary lesion of dysfunction in the central nervous system.
CPP: nonmenstrual pain of 6 months' duration or greater, localized to the pelvis, anterior abdominal wall below the pelvis, or lower back, severe enough to result in functional disability or require medical or surgical treatment.
Dysesthesia: an unpleasant abnormal sensation, whether spontaneous or evoked.
Endometriosis: the existence of two or more of the following outside of the endometrium: (a) endometrial epithelium, (b) endometrial stroma, (c) endometrial glands, (d) hemosiderin-laden macrophages.
Hyperalgesia: an increased response to a stimulus which is normally painful.
Myofascial pain syndrome: a heterogeneous pain-producing disorder characterized by localized, reproducible, hyperirritable trigger points within a muscle or its investing fascia.
Neuropathic pain: pain initiated or caused by a primary lesion, dysfunction, or transitory perturbation in the peripheral or central nervous system.
Neuralgia: pain in the distribution of a nerve or nerves.
Pain: an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of damage.

CONTEMPORARY PAIN THEORIES

Until the 1960s, pain was considered a sensory response to tissue damage. It is now widely accepted that pain has a reactive or emotional as well as sensory component, which is influenced by genetic differences, experiences, gender, anxiety, or expectation. The perception of and response to pain are believed to be determined by four simultaneous processes which include: transduction (depolarization of a peripheral sensory nerve ending to generate an impulse), transmission (neural events to carry the impulse), modulation (neural events that control transmission neurons), and perception (event processing influenced by behavioral and emotional factors).

The theory most widely accepted to explain the mechanism whereby pain transmission occurs was described by Melzak and Wall as the gate-control theory. This theory suggests that the modulation of nociception at the spinal cord is mediated by descending signals for high centers within the brain through neurotransmitters. It describes a bidirectional gate at the level of the spinal cord, rather than merely unidirectional pain transmission as previously held by the Cartesian theory.

PUTATIVE PELVIC PAIN STATES

Adhesions

Pelvic inflammatory disease, endometriosis, inflammatory bowel disease, or surgery may cause adhesions; yet, in up to 50% of cases there may be no significant antecedent event. Although adhesions commonly are found in patients with CPP, it may be difficult to assess whether they are contributing to pelvic pain or are merely incidental findings.

Several studies have raised questions about the surgical treatment of adhesions. First, in a prospective study which involved second-look laparoscopy following laparotomy for reproductive surgery, 51% of patients developed de novo adhesions. Therefore, the possibility exists that treating adhesions may lead to more adhesions. Secondly, there is evidence to suggest that the lysis of adhesions may not result in significant pain relief. A randomized, prospective study of patients with CPP and known stage II to IV (moderate to severe) pelvic adhesions assessed the efficacy of surgical adhesiolysis on patients with CPP. Patients either underwent minilaparotomy adhesiolysis or no treatment. At 9- to 12-month follow-up, using the McGill Pain Scale to compare outcomes, there was no difference in the treatment group (n = 24) compared with controls (n = 24). After stratification, the authors acknowledged a trend toward a benefit in patients with well-vascularized or thick adhesions involving the intestinal tract, the pain hypothesis being symptoms of intermittent small bowel subileus. This small study lacks the power to answer definitively

the question as to whether treatment of adhesions is beneficial.

In a case-control study of 100 consecutive laparoscopies in patients with CPP and 88 laparoscopies for infertility, pelvic adhesions were found more often in the control group (26% versus 39%). Trimbos and others studied 200 asymptomatic women undergoing laparoscopic sterilization and found a 14% incidence of pelvic adhesions. In a prospective cohort study of 102 women undergoing laparoscopy, wherein the surgeons were blinded as to the indications, which were pain (64%), infertility (35%), previous abnormal findings (19%), and sterilization (15%), adhesion scores were no different in the CPP group compared with controls.

In an uncontrolled, prospective study of 30 women undergoing laparoscopic adhesiolysis for CPP with a mean follow-up interval of 8.2 months, there was an overall improvement of pain in 63%. There was a trend toward greater improvement in the group with CPP, compared with the group exhibiting CPP syndrome. CPP syndrome was defined as having at least four of the following (a) pain longer than 6 months' duration, (b) previous treatments unsuccessful in relieving pain, (c) diminished physical activity (work, exercise, sex), (d) at least one vegetative sign of depression (sleep dysfunction, decreased appetite, psychomotor retardation), (e) altered family role.

Laparoscopic pain mapping under conscious sedation provides additional information to better define whether a patient's adhesions are associated with pain. This technique employs local anesthesia at trocar sites in combination with intravenous opioids and benzodiazepines to enable the conscious patient to tolerate laparoscopic surgery. Pelvic structures can be mapped using a verbal analog pain scale (VAPS) from 0 to 10 to determine whether pain can be generalized to the pelvic viscera or to a focal point or adhesion. It is important to distinguish between surgically induced pain and pain which truly mimics the patient's chronic pain.

Taking these studies into consideration we can learn some valuable lessons. (a) The more surgery that is performed, the more likely adhesions are to occur. (b) Adhesions may be present in asymptomatic patients. (c) Adhesions may be incidental in symptomatic patients. (d) Although some case series have shown some benefit to adhesiolysis, the only randomized clinical trial of adhesiolysis in patients with CPP showed no treatment benefit. (e) Conscious sedation pain mapping surgery may better enable us to determine which adhesions are painful. (f) Judgment is critical as to whether or not to perform surgery in patients who have had multiple laparoscopic procedures, weighing the risks and benefits.

Endometriosis

Endometriosis is one of the most enigmatic of gynecologic disorders. Not only is there little correlation between the extent of disease and the degree of pain, but it often is found in asymptomatic women. The noted exception is deep, infiltrating endometriosis in the rectovaginal septum, which has been shown to have a direct correlation to pain.

Endometriosis may have several appearances, ranging from the more typical “powder burn,” blue-gray lesions, to atypical lesions which may be clear, red, or white. Various explanations have been proposed to account for endometriosis-related pain including inflammation, prostaglandin production, neuronal involvement, and adhesions. Data from conscious sedation laparoscopic pain mapping have demonstrated areas of pain well beyond the visible endometriosis.

Symptoms associated with endometriosis include cyclic pelvic pain or dysmenorrhea. The pain associated with endometriosis may precede the menses, occur with menses, and continue after menses. Tenesmus may be associated with involvement of the rectosigmoid colon. Other clinical manifestations may include dyspareunia or ovarian mass (endometrioma).

Conservative medical treatment is recommended as the initial therapy for endometriosis or presumed endometriosis. This may include nonsteroidal antiinflammatory drugs (NSAIDs), oral contraceptive pills (OCPs), danazol, progestins, or gonadotropin-releasing hormone (GnRH) agonists. These medications have been shown to reduce the size of endometriotic lesions and, thus, the stage; however, they have not been shown to eliminate disease. There are no convincing data to suggest that one form of medical suppressive therapy is superior to another. Usually, the agent with the lowest side effect profile, such as an NSAID or OCP, is selected as first-line therapy.

Oral contraceptive pills may be used in a cyclic (standard) or continuous fashion. Continuous use refers to the ingestion of active pills every day for 3 to 6 months, rather than allowing menses to occur during placebo administration. This usually allows the patient to avoid the dysmenorrhea which may occur with the cyclic regimen. If OCPs are not effective after 3 months, danazol (600–800 mg/d) or GnRH agonists may be used.

The use of danazol for endometriosis-associated pain was evaluated by Cochrane Database reviewers, wherein four trials were found to have study design adequate for inclusion. The reviewers concluded that danazol is effective in treating the symptoms and signs of endometriosis; however, its use is limited by the occurrence of androgenic side effects. GnRH agonists such as leuprolide or goserelin generally are used for 6 months if a favorable response is noted. The main concern about prolonged use of these agents is the loss of bone mineral density. The treatment window may be extended to 12 months with the use of add-back therapy (addition of norethindrone acetate with or without conjugated equine estrogens).

Surgery generally is reserved for refractory cases. If surgery is to be performed, it should be tailored toward the patient's reproductive wishes. If the patient desires to preserve her childbearing capacity, endometriotic lesions may be destroyed or removed by vaporization or excision laparoscopically or by laparotomy. It is argued by some that vaporization may treat only the “tip of the iceberg,” with the potential to leave deep, infiltrating endometriosis behind. To date, there are no convincing data to recommend one laparoscopic therapy over the other. Unfortunately, a significant number of patients treated conservatively (without hysterectomy and bilateral salpingo-oophorectomy) will develop recurrent symptoms 12 months after surgery.

Laparoscopic surgery for the treatment of endometriosis-associated pain was reviewed in the Cochrane Database. Only one study was deemed adequate for evaluation; therefore, most of our understanding stems from level 3 data (case series and opinions of experts). The review concluded that laparoscopic laser treatment of endometriosis was more effective than expectant treatment of endometriosis, but the reviewers included a caution about the interpretation of results due to the lack of any corroborating studies.

Hysterectomy with or without adnexectomy may be appropriate in cases in which childbearing is no longer an issue.

Pelvic Inflammatory Disease

PID is a significant health problem (approximately 1 million cases per year), resulting in an expense of $3.5 billion annually in the United States alone. It clearly can be a cause of acute pain, yet it also may be asymptomatic. The most likely mechanism for pain is from inflammation and distension of the fallopian tubes. A distended, fluid-filled fallopian tube or hydrosalpinx will sometimes persist for months or years and may cause CPP. It is less clear why pain persists in patients with treated PID, who subsequently have normal-appearing reproductive organs and whose culture results are negative for causative microorganisms. It is theorized that the initial inflammatory insult may have started a cascade of signals within the pelvis, spinal cord, and brain, resulting in visceral neuropathic pain.

One study estimated that as many as 15% to 25% of patients with PID will go on to have CPP (relative risk = 3.0–5.0). There are no good studies addressing how to treat patients with laparoscopy-negative, culture-negative presumed persistent PID. They, therefore, often are treated with NSAIDs, neurolytic agents, or opioids. The patient's partner should be treated, also, to avoid reinfection. Persistent hydrosalpinx usually is treated surgically by salpingectomy.

Myofascial Pain

Myofascial pain is common in patients with a history of abdominal trauma or multiple surgeries and often is overlooked as a cause for CPP. Myofascial pain syndrome is a heterogeneous pain-producing disorder characterized by localized, reproducible, hyperirritable trigger points within a muscle or its investing fascia. The clinical sign of the trigger point is that it is tender when compressed, and has characteristic referred pain patterns, referred tenderness, motor dysfunction, or autonomic dysfunction.

Abdominal wall myofascial pain is detected best by isolating the rectus abdominus muscles, by having the patient flex her abdomen by lifting her feet or head and shoulders off the examination table while in the supine position. A one-finger search along the anterior abdominal wall is performed to identify painful trigger points. When localized, trigger points can be treated successfully with icing, stretching exercises, and with local anesthetic injection. One to two milliliters of a 50:50 mixture of 1% lidocaine and 0.25% bupivacaine may be injected into the muscle and fascia with a 22- or 25-gauge needle to achieve a diagnostic and therapeutic block. Slocumb reported on the successful treatment of 89% of 131 patients with CPP who had trigger point injections. Most patients obtained relief within five injections. Physical therapy also has been successful in treating myofascial pain syndrome.

Pelvic Congestion

Patients with pelvic congestion syndrome typically complain of pelvic pain and aching which becomes progressively worse throughout the day, and they also may complain of dyspareunia or postcoital aching. Pelvic congestion syndrome as a cause for CPP has been a controversial entity since it was first described by Taylor in 1949. One reason for skepticism is the observation that some women who demonstrate dilated vessels at the time of surgery or during pregnancy are asymptomatic.

Beard and co-workers proposed a more objective method of diagnosing pelvic varicosities using transcervical pelvic venography to measure vessel diameter, vessel tortuosity, and dye transit time, suggesting that vein diameter alone is not the only significant finding of pelvic congestion syndrome. Subsequent studies by these authors propose diagnostic criteria for pelvic congestion syndrome and pathophysiologic mechanisms for pain production. It has been postulated that pain from vascular congestion is caused by vasoactive nociceptive peptides, such as substance P and calcitonin gene-related peptide. In a study by Reginald and colleagues of patients with venographically diagnosed pelvic congestion syndrome injected with a potent vasoconstrictor (dihydroergotamine), a 35% reduction in vein diameter, decreased dye transit time, and up to 4 days of pain relief was demonstrated when compared with patients injected with placebo. They hypothesized that vasoconstriction allows clearance of nociceptive vasoactive peptides.

Conservative treatment of pelvic congestion includes medroxyprogesterone acetate in 30- to 50-mg daily doses. Ultimately, surgery may be necessary. In Beard's series of 36 patients treated with hysterectomy and bilateral salpingo-oophorectomy, 67% obtained complete relief of pelvic pain. Only 1 of the remaining 12 patients had significant pain.

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is a common gastrointestinal disorder affecting approximately 15% of adults in the United States, yet only 25% of persons with questionnaire-detected IBS actually seek health care. It has been defined as lower abdominal pain, which is present for at least 12 weeks (not necessarily consecutive) out of the past year, that cannot be explained by structural or biochemical abnormalities. At least two of the following clinical features are needed for diagnosis: (a) pain relief with defecation, and onset associated with a change in (b) frequency or (c) consistency of stools.

Theories to explain a putative mechanism for IBS include visceral hyperalgesia, infection, an imbalance of neurotransmitters, and psychological factors. More recently, growing evidence suggests that these patients have a gastrointestinal sensory-reflex dysfunction as a common pathophysiologic mechanism, which may be manifested by different forms depending upon specific pathways involved. This may explain why some individuals are more pain prone, while others may be more prone to have diarrhea or constipation.

Rectal and sigmoid balloon distension studies have shown a lower threshold for pain, referred to as *visceral hypersensitivity*, in patients with IBS compared with controls. However, when balloon testing is performed, only 40% to 60% of patients with IBS report pain at levels of distension below the range of normal values; therefore, gut wall distension my not be the only stimulus to cause IBS.

Therapy for IBS involves treating symptoms, whether one is diarrhea prone or constipation prone. Diarrhea-prone patients respond to loperamide, hyoscyamine, and desipramine, whereas constipation-prone patients respond to fiber therapy or cisapride. Patients with a pain predominance may be treated with tricyclic antidepressants, NSAIDs, anticholinergic agents, calcium channel blockers and, in some cases, opioid analgesics. Newer agents are under development, such as visceral antinociceptive agents, ?-opioid agonists, and 5HT3 and 5HT4 receptor antagonists.

Patients who have rectal bleeding, persistent occult fecal blood, or failure of medical therapy should be referred to a gastroenterologist to rule out malignancy or inflammatory bowel disease.

Ovarian Remnant Syndrome

Ovarian remnant syndrome may result from incomplete removal of ovarian tissue at the time of oophorectomy and can be associated with CPP in premenopausal women. Patients with this syndrome usually have a history of extensive endometriosis or pelvic inflammatory processes, resulting in a technically difficult oophorectomy. Cyclic pelvic pain caused by ovarian remnant syndrome most commonly is associated with the development of ovarian follicles within hormonally active ovarian tissue. This diagnosis is suspected when serum levels of follicle-stimulating hormone and luteinizing hormone are normal. Hormone replacement therapy should be discontinued at least 10 days before assessing serum gonadotropin levels. Clomiphene citrate and GnRH agonists have been used to stimulate ovarian tissue, which assists in making an ultrasonographic diagnosis of ovarian remnant syndrome.

Surgical treatment usually requires extensive intraperitoneal adhesiolysis and retroperitoneal dissection to remove all ovarian tissue. In a series of eight patients treated surgically for ovarian remnant syndrome, three required large bowel resection, cystotomy was performed in three and a ureteroneocystostomy in one, and one required a small bowel resection. Outcome data regarding postoperative pain relief after surgical resection are limited to small case series, but cure rates as high as 90% are reported.

Residual Ovary Syndrome

Residual ovary syndrome originally was described by Grogen in 1958. It is characterized by the development of pain in one or both ovaries conserved at the time of hysterectomy, theoretically caused by perioophoritis with a thickened ovarian capsule. It has been postulated that pain is produced by the cyclic expansion of the ovary encased in adhesions.

The most common complaint in women with residual ovary syndrome is chronic lower abdominal pain, dyspareunia, and radiation of pain to the back or anterior thigh. A tender mass may be palpated on bimanual examination. This syndrome may occur in as many as 3% of women who have undergone hysterectomy with ovarian conservation. Treatment typically has been oophorectomy rather than lysis of adhesions, to avoid recurrent adhesion formation. Care should be taken to avoid ureteral damage, because retained ovaries often are near the ureter. Outcome data are limited regarding pain relief after surgery for retained ovaries (level 3 data). Postoperative pain relief has been reported in over 80% of patients after oophorectomy.

Pain of Uterine Origin

In the United States, approximately 18% of hysterectomies are performed for CPP, with endometriosis cited as the most common indication. Carlson and co-workers demonstrated significant reduction in pain following hysterectomy for CPP of all causes. In patients with pelvic pain who underwent hysterectomy, 85% complained of frequently occurring pain preoperatively, compared with 13% at 12 months postoperatively. In a prospective cohort study comparing surgical to nonsurgical treatment, 49% of medically managed patients with CPP had continued symptoms compared with 3% treated by hysterectomy. Moreover, 25% of patients in the nonsurgical group underwent hysterectomy within 1 year.

Stovall and others reported a 78% success rate in patients undergoing hysterectomy for pelvic pain of presumed uterine origin. In this retrospective study, patients were excluded for nonuterine pain such as endometriosis. A prospective multicenter cohort of 308 women undergoing hysterectomy for CPP reported resolution of pain in 74% and improvement in 21%. Risk factors for continued pain included age 30 or younger, history of pelvic inflammatory disease, and use of public assistance. These studies are helpful because they underscore the importance of investigating other, nongynecologic causes for CPP, and they provide guidelines for preoperative counseling.

Hysterectomy may be indicated in the absence of significant pathology, as long as a diagnostic laparoscopy has been performed, and the patient's pain has persisted for longer than 6 months with a serious negative impact on the quality of life. Prior to undergoing a hysterectomy the patient should be treated medically (oral contraceptives, NSAIDs, and induced amenorrhea) and should be evaluated for urinary, gastrointestinal, musculoskeletal, and psychological causes for pain. Possible causes of pain of uterine origin are listed in Table 43.1.

Adenomyosis
Chronic endometritis
Degenerating leiomyomata
Pelvic congestion

TABLE 43.1. *Possible causes of pain of uterine origin*

PSYCHOLOGICAL ASPECTS OF CHRONIC PELVIC PAIN

Patients sometimes get the message “your pain is all in your head.” Whether patients are actually told this or whether they hear this is irrelevant. This concept reflects what physicians were taught historically as the somatic model of pain, wherein there was a direct relationship between tissue damage and pain intensity. This model does not account adequately for the discrepancy between objective physical findings and the perception of pain severity. A more contemporary approach recognizes the central models of pain, which include the effect of peripheral nociception and central pathways that determine disability and distress.

The psychological aspects of CPP can be significant. It is, therefore, worthwhile to distinguish among co-morbid states such as depression, anxiety, and panic attacks. It often is helpful to obtain consultation from an interested psychiatric health care professional. However, some screening tests can be done by primary care physicians, such as the Beck Depression Inventory or Zung Depression Index.

Clinical depression associated with CPP usually is manifested by sleep disturbance (insomnia or hypersomnia), loss of interest in pleasurable activities, guilt feelings, loss of energy, diminished concentration, appetite changes (decreased or increased), psychomotor changes, and possible suicidal ideation. The mainstays of therapy include the use of serotonin reuptake inhibitors, tricyclic antidepressants, and psychotherapy. Clinicians who prescribe these medications should be aware of diagnostic criteria for depression and be familiar with the side effects and contraindications of these medications.

PATIENT HISTORY

A thorough patient history is one of the most helpful tools in the evaluation of patients with CPP. The COLDERR acronym may be used to gain a general understanding of the patient's history of present illness.

Character—What does the pain feel like? (sharp, dull, crampy)
Onset—Does the pain come on suddenly or gradually? Is it cyclic or constant?
Location—Is the pain localized or diffuse?
Duration—How long has the pain been present and how has it changed over time?
Exacerbation—What activities or movements make it worse?
Relief—What medication, activities, and positions make it better?
Radiation—Does the pain radiate anywhere (back, groin, flank)?

There are several important aspects of taking a detailed pain history and reviewing organ systems. Comprehensive history and physical examination forms are available through the International Pelvic Pain Society Web site and can be downloaded at http://www.pelvicpain.org/. Establishing whether the pain is cyclic or not is helpful is narrowing the list of possible causes (Table 43.2). If the patient has poor insight into the nature of her pain, a pain calendar may be used prospectively to chart her symptoms during the month.

Adenomyosis
Endometriosis
Irritable bowel syndrome
Mittelschmerz
Ovarian remnant syndrome
Pelvic congestion syndrome

[a] Not necessarily limited to being cyclic.

TABLE 43.2. *Cyclic causes for chronic pelvic pain* [a]

Reviewing past surgeries is helpful for gaining information about which organs can be eliminated from consideration and what effect surgery had on their pain. It may help establish a causal relationship between surgery and pain, which is common among patients with myofascial pain syndrome.

A thorough review of systems is important to exclude nongynecologic causes for CPP. Gastrointestinal complaints should be explored with specific questions about bowel frequency, consistency, associated pain, and to exclude a history of blood in the stool, which would alert the clinician to rule out neoplasm (Table 43.3). Likewise, urinary complaints such as dysuria, hematuria, nocturia, enuresis, and increased frequency should be probed for urologic causes of CPP (Table 43.4).

Cholecystitis
Chronic appendicitis
Constipation
Diverticulitis
Irritable bowel disease
Inflammatory bowel disease
Neoplasm
Pseudomembranous enterocolitis
Ulcer (duodenal, gastric)

TABLE 43.3. *Gastrointestinal causes for chronic pelvic pain*

Bacterial cystitis
Detrusor dyssynergia
Interstitial cystitis
Neoplasm
Urethral caruncle
Urethral diverticulum
Urethral syndrome
Urolithiasis

TABLE 43.4. *Urologic causes for chronic pelvic pain*

PHYSICAL EXAMINATION

Observing a patient's gait, body language, and facial expression can provide valuable information. Myofascial pain syndrome can result in or be a result of musculoskeletal dysfunction as seen with abnormalities in gait, body posture, leg lengths, or sacroiliac joint mobility. Such abnormalities warrant evaluation by a physiatrist or physical therapist.

A one-finger abdominal examination is performed on the anterior abdominal wall to detect trigger points, as described in the myofascial pain section. In addition, abdominal wall hernias may be diagnosed using this technique. Trigger points should be marked on the patient's skin with a soft pen tip and then mapped in the patient's chart for future comparison. Trigger points also may be found within the muscles of the back and buttocks.

A cotton-tipped applicator is useful in the examination of the vulvar vestibule to elicit painful areas or sites of vulvar vestibulitis. Special attention should be given to Bartholin ducts and Skene glands. On speculum examination, the vaginal fornices, or vaginal cuff in the posthysterectomy patient, can also be examined for tenderness using a cotton-tipped applicator. Any cervical discharge should be noted, examined by microscopy, and cultured. The posterior vaginal fornix should also be inspected visually to identify endometriosis. This sometimes is possible only with the aid of a tenaculum.

It is helpful to perform a “unimanual” examination prior to the bimanual examination to avoid “cross-contamination” from anterior abdominal wall pain signals. This consists of examining the vagina, cervix, and pelvic floor muscles with the hand in the vagina, without using the hand on the abdomen. The pelvic floor muscles should be examined individually to include the levator ani group, coccygeus, obturator internus, and the piriformis muscles. The uterus, tubes, and ovaries should be examined for localized pain. The pelvis should then be examined using the bimanual technique.

The rectovaginal examination is particularly useful to evaluate nodular or infiltrating endometriosis. If there is no tenderness in the cul-de-sac or along the uterosacral ligaments, yet endometriosis is strongly suspected, the patient should be reexamined during the menses.

PAIN MANAGEMENT

Pain management may include the use of NSAIDs, neurolytic agents, and narcotics. Knowledge of drug interactions, contraindications, and side effects are important aspects of successful pain management.

NSAIDs

NSAIDs are usually a safe category to start with, realizing there are several contraindications to these drugs, especially in patients with gastrointestinal disorders. The newer COX-2 (cyclooxygenase inhibitor-2) drugs have the advantage of fewer adverse effects on the gastrointestinal tract (Table 43.5).

Ibuprofen 400–800 mg qlth, maximum dosage = 2,400 mg/d
Naproxen sodium 250–500 mg qlth, maximum dosage = 1,500 mg/d
Mefenamic acid 500 mg initially, then 250 mg q6h
Rofecoxib 50 mg/d
Celecoxib 100–200 mg b.i.d.
Ketorolac 10 mg q6h, not to exceed 5 days
Tramadol 50–100 mg q6h

NSAIDs, nonsteroidal antiinflammatory drugs.

TABLE 43.5. *Oral NSAIDs*

Neurolytic Agents

Neurolytic agents encompass a number of drug categories used in the treatment of neuropathic pain, which include tricyclic antidepressants, serotonin reuptake inhibitors, and ion channel blockers. Table 43.6 lists some of these drugs which have been studied in patients with chronic pain.

Drug class	Drug dosage
Antidepressants	
Tricyclic	
Amitriptyline	65–100 mg/d
Imipramine	100–200 mg/d
Desipramine	100–200 mg/d
Selective Serotonin Reuptake Inhibitors	
Paroxetine	20–40 mg/d
Fluoxetine	20–60 mg/d
Citalopram	10–40 mg/d
Ion Channel Blockers	
Mexiletine	150–600 mg/d
Carbamazepine	200–1,000 mg/d
Phenytoin	300 mg/d
Lamotrigine	400 mg/d
Gabapentin	1,200–3,600 mg/d

TABLE 43.6. *Oral Neurolytic Agents*

Narcotics

Narcotics often are thought of as appropriate for acute pain only; however, in some instances under careful supervision, patients with chronic pain may be candidates for narcotic therapy (Table 43.7). When narcotics are used, narcotic contracts are often helpful. Patients who demonstrate drug abuse behavior are not candidates for narcotic therapy. A patient who repetitively loses her prescription, uses multiple physicians for obtaining narcotic prescriptions, or routinely runs out of narcotics early is not considered a narcotic candidate. Patients who use narcotics over the long term should regularly report the symptoms on a VAPS and should report their degree of functionality. They should be encouraged regularly to wean from these agents.

Drug	Dosage
Intermediate Potency	
Propoxyphene	65 mg q3–4h p.r.n.
Codeine	15–60 mg q4–6h p.r.n.
High Potency	
Hydrocodone	5–30 mg q4–6h p.r.n.
Oxycodone	5–30 mg q4–6h p.r.n.
High Potency—Long Acting	
Methadone	5–20 mg q12h
Oxycodone SR	10–80 mg q12h

SR, sustained release.

TABLE 43.7. *Oral narcotics*

Narcotic Agreements

When long-term narcotic therapy is used for pain management, it is useful to have the patient enter into a pain agreement to prevent misunderstandings and to help both the physician and patient comply with the federal laws regarding controlled substances.

When the agreement is entered, it is understood that if the patient terminates the agreement, the physician will discontinue narcotic therapy but will taper the medicine over a period of several days, as necessary, to avoid withdrawal symptoms. Also, a drug-dependence treatment program should be recommended. The patient agrees to describe the pain character and intensity, the effect of the pain on her daily life, and how well the narcotic is helping to relieve the pain. The patient also agrees not to use any illegally obtained controlled substances, and not share, sell, or trade medication with anyone.

Opioids, controlled stimulants, or antianxiety medication must not be obtained from any other doctor. The patient must agree to safeguard her pain medicine from loss or theft with knowledge that lost or stolen medicines will not be replaced. She should understand that prescriptions will be made only at the time of an office visit or during regular office hours and that no refills will be available during evenings or on weekends. This is helpful for covering physicians who receive calls from patients asking for narcotics. The pharmacy name, location, and telephone number are recorded and a log of the dosage, quantity, and prescription date is recorded in the patient's chart.

SUMMARY POINTS

- CPP is a complex entity, often without obvious, visible pathology.
- A distinction must be made between putative causes of CPP, which will respond to specific treatment, versus CPP associated with incidental pathology.
- Treatment of CPP with incidental pathology may result in failure and, in some cases, removal of otherwise normal organs. In such cases, treatment may take a more general and empiric course, resulting in the use of neurolytic medications and possibly the judicious use of narcotics.

INTRODUCTION

> “One important key to success is self-confidence. An important key to self-confidence is preparation.”
>
> Arthur Ashe

In this country, obstetrician-gynecologists are the primary surgeons in over 3.6 million pelvic operative procedures completed on an annual basis (Table 44.1). These procedural volumes, when combined with the many thousand minor office and obstetric procedures, are testimony to the enormous potential physical, psychological, and economic impact of surgery and potentially preventable adverse events on women's health care. Importantly, nearly 50% of all adverse perioperative events are preventable. The sheer numbers undeniably suggest that risk prevention should be the ultimate goal of every surgeon. Assuming the role of primary care physician and surgical subspecialist for women, obstetrician-gynecologists should accept responsibility for developing, instituting, and completing all aspects of perioperative management. As an important step to improve quality of care, we should be cognizant of the potential role and benefits that allow objective discussion of nonsurgical options, as well as understand appropriate surgical indications for pelvic disease processes.

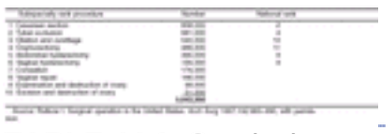

TABLE 44.1. *Surgical procedures in obstetrics and gynecology*

Our primary goals should consist of prospective preoperative recognition, evaluation, and management of the significant clinical aspects of existing medical comorbidities and development of operative techniques to form a flexible multifaceted surgical skill set that increases the opportunity for safe completion of the procedure, regardless of inherent technical difficulty. Finally, pelvic surgeons should be capable of devising a postoperative care plan that further minimizes the risk of an adverse perioperative outcome, enhances the early recognition of acute perioperative problems, and lessens the risk and the intensity of potentially catastrophic perioperative complications. This care plan should be formalized prior to entering the preanesthetic area or the operating suite, and its execution should contain enough clinical alternatives to ensure a successful result, regardless of the intraoperative findings or postoperative complications encountered. The volumes of existing published literature on surgical alternatives and indications establish a clear message: “optimal” perioperative care is a moving target. Every treatment plan and intervention requires careful aim if the goals of improved quality and optimal patient outcome are to be attained. Mastery of these perioperative planning processes only serves to improve the individual and collective quality of patient care. Proper implementation should result in decreased individual, regional, and national health care expenditures.

SURGICAL INDICATIONS AND CONSENT FOR SURGERY

It is the ultimate responsibility of every obstetrician-gynecologist to evaluate thoroughly the patient's reproductive tract complaints prior to entering the possibility of surgical management. In addition to evaluating the pelvic condition, it is vital to conduct a preoperative search for physical or psychological comorbidities. Only when armed with this global information can the surgeon objectively present the risks and realistically relate the expected outcome of the entire spectrum of accepted medical and surgical options. This information should be processed and presented to the patient (and other support persons when appropriate) in a manner that is not demeaning, using understandable language that allows and facilitates an informed decision and consent process. Although the preoperative diagnostic period may be deemed routine by the surgeon and staff, many women consider the prediagnostic interval to be the most stressful time of treatment. This psychological stress contributes to difficulty in understanding the importance and results of diagnostic studies or results and potentially clouds the information discussed during preoperative discussions. Decisions, options, and alternatives, as they relate to the potential need for postoperative therapy, can be lost. The preoperative use of illustrative drawings, pamphlets, videos, or other visual educational materials often can be of assistance in improving patient (and family) comprehension of medical alternatives, operative indications, associated risks, and expected treatment outcomes. Typically, this preoperative encounter (or encounters) to discuss surgical options and obtain consent is best undertaken in a private setting, completed in a manner that is conducive of a two-way flow of communication. Eye contact, a caring touch, an unhurried approach, and other “soft” physician behaviors lower communication barriers and facilitate patient and “significant other” comprehension. The complexity of preoperative discussion and necessary time expenditure may vary dramatically with the surgical indications, as well as with the medical alternatives to the proposed

procedure. Regardless, the algorithm of care, surgical risks and outcome expectations should be detailed, recognizing that modification may be required secondary to important or imperative patient desires (e.g., a patient desiring retention of ovaries or fertility). Regardless of the extent of preparation and best surgical technique, any unexpected or adverse intraoperative or postoperative event can alter dramatically the final surgical procedure and ultimate result. The apparently “simple” laparoscopic salpingo-oophorectomy may be complicated by uncontrolled abdominal wall, intraperitoneal, or retroperitoneal bleeding, intestinal injury, or the finding of an ovarian malignancy. Postoperative myocardial infarction (MI), infection, or thromboembolism may occur. A good rule of thumb is to discuss during the explanation of surgical risks adverse events that occur at a frequency of 1% or more. Any preoperative consent discussion should include the risk of death or permanent disability. Failure to address any or all of these risks can result in misunderstanding, fear, and anxiety and fosters mistrust. As important as the consent process, the resultant preoperative patient education decreases the need for postoperative analgesia and is associated with less anxiety and earlier ambulation. Unless the clinical situation is emergent or life-threatening, these discussions are best undertaken at a time remote from the day of surgery. Timely entered, legible chart documentation should follow any and all of these discussions.

Following the mutual decision to bypass medical management, the surgeon is faced with a number of other important procedural questions including the route (i.e., vaginal versus abdominal versus laparoscopic approach), as well as who should perform the procedure. It is intuitive and reported data confirm that, even among subspecialists, individual surgical skills and outcomes of specific procedures differ dramatically. These differences may relate to the surgeon's innate technical ability, the specifics of the individual's previous training, patient selection, or factors unrelated to the physician. Without placing blame, the training demands of our subspecialty have altered the overall extent of residency surgical experience, resulting in fewer major operative procedures being completed per trainee. These educational changes have resulted in a noticeable decrease in resident surgical skill acquisition. Importantly, these relative deficiencies noted by senior observers may not be perceived or recognized by the individual trainees. Coupled with the increasing ratio of postresidency physicians to annual operative procedures and the increasing technical procedural subspecialization, it is easily understood how difficult it is for the pelvic surgeon to obtain, maintain, or refine new surgical skills, even in our restricted subspecialty where the surgical focus is entirely on reproductive tract procedures. These factors lend credence to the adage, “no one can be all things to all people,” and each physician must individualize the decision to operate, consult, or refer. Specific referral guidelines citing evidence-based data have been created to assist practicing obstetrician-gynecologists in the care of women with selective diagnoses. Additionally, a favorable outcome of many procedures is related to increasing surgical experience, surgical volume, and expertise. Although disease-specific guidelines may not relate to “routine procedures,” it is logical and scientific that improved perioperative outcomes should follow increased surgical case volume. Although these effects may be surgeon or program related, arguments against consultation or referral have little scientific merit and may not be in the patient's best interest. Although circumstances may prohibit actual patient referral, the ready availability of curbside, personal, telephone, and internet consultation should encourage information dissemination, and utilization of available resources should improve patient care.

HISTORY AND PHYSICAL EXAMINATION

> “Listen to women and they will tell you what's wrong with them.”
>
> Charles E. Flowers

Every operative procedure requiring anesthesia should be viewed as a physiologic stress test. The intensity of the stress response varies in direct proportion to the extent of the actual surgical procedure and is associated with a clinically and biochemically measurable adverse effect. Nearly every organ system is affected adversely by general anesthesia. The associated 20% reduction in resting heat production and increased surface heat loss predispose patients to hypothermia, increasing the risk of an adverse cardiac event, altered pulmonary response to hypercarbia and hypoxemia, impaired coagulation, and poor wound healing. The untoward anesthesia-related pulmonary effects of impaired oxygenation and altered lung mechanics are likely well tolerated by the 40 year old, but they may have catastrophic consequences in the elderly or in those with coexisting pulmonary disease. Most inhalational drugs directly create increased cardiac risk by altering myocardial oxygen supply and demand kinetics. Myocardial depression, increased arrhythmogenicity (as high as 27% incidence), and altered neural tone form the triad for predisposing women to adverse cardiovascular effects. Importantly, these risks are not lessened with regional anesthesia use. Reduction in renal blood supply (decreased by 30 to 70%), suppression of the immune system, ileus, and stress-related gastric ulceration represent but a few of the other quantitative adverse effects of anesthesia. Many of these effects can be correlated with the duration of operation, and every effort should be made to increase operative efficiency in an attempt to safely shorten the procedure and minimize risks.

Despite these anesthesia-enhanced risks, only a small percentage of operative deaths are attributable solely to anesthesia. Less than 18% of surgical mortality is directly attributable to the surgical procedure. The vast majority of surgical mortality (79%) can be related directly to problems created in great part from the patient's coexisting medical disease. This mortality risk further illustrates the need to undertake a diligent preoperative search to identify and potentially modify the adverse effects of any significant coexisting medical condition.

The literature is inundated with articles espousing the proposed benefits of preoperative radiologic testing and laboratory evaluation; however, the diagnostic power contained in a carefully obtained history and a thorough physical examination is enormous. The reproducible validity of this simple, easily obtainable evaluation is underscored when recognizing that as many as 98% of abnormalities found with preoperative laboratory and radiologic screening can be predicted by historical or physical findings.

Although studies relating to the pelvic process (i.e., urodynamics) frequently are necessary to delineate the need for surgery, attempts to obtain important historical information regarding diagnosed medical comorbidities and clinically silent medical disease are vital to direct additional preoperative evaluation. Review of pertinent medical records combined with initial direct questioning about previous hospitalizations, current treating physicians, concurrent diagnoses, use of prescribed and over-the-counter medications, and allergies will assist in the detection of coexisting medical disease. This information may be vital to the preoperative plan regarding the continuation (e.g., cardiac, hypertensive) or discontinuation (e.g., aspirin, oral contraceptives, anticoagulant) of medications. Over-the-counter and herbal medication usage can create the potential for additional untoward complications and should be evaluated (Table 44.2). Conducting a pointed review of systems allows the determination of performance status and aids in the diagnosis of significant but previously undetected medical disease. Although intended to cover multiple systems, simple questions as to the patient's ability to walk a mile, climb two flights of stairs, or blow out a match from 12 inches away may suffice as a screen for significant cardiopulmonary disease. Historical information obtained by questionnaire can be considered valid; however, the presence or absence of important symptoms should be confirmed during the office visit.

Sympathomimetic Effects
Ephedra sinica (ma-huang)
Panax ginseng (ginseng)
Glycyrrhiza glabra (licorice)
Hydrastis canadensis (goldenseal)
Potentiate Bleeding
Tanacetum parthenium (feverfew)
Allium sativum (garlic)
Ginkgo biloba (ginkgo)
Zingiber officinale (ginger)
Prolong Sedative Effects
Valeriana officinalis (valerian)
Piper methysticum (kava-kava)
Hypericum perforatum (St. John's wort)

TABLE 44.2. *Herbal medicines: possible adverse effects*

A thorough multisystem physical examination is an essential part of every preoperative evaluation. Specific attention to the cardiopulmonary system assists in the detection of important coexisting disease that may alter outcome adversely and directs additional investigation. Every system carries some import, and abnormal findings allow for appropriate morbidity-reducing, cost-effective adjustments in the perioperative plan.

LABORATORY INVESTIGATION

The primary goal of preoperative laboratory preparation is to obtain results that allow reduction of those inherent risks related to the proposed procedural component, as well as those risks associated with occult or recognized coexisting medical morbidities. It has become apparent that a “broadly cast net” preoperative laboratory screening strategy confers little patient benefit for the following reasons. (a) The majority of laboratory abnormalities can be predicted by findings noted in the history and physical examination. It is rare to detect an unexpected abnormality. (b) The physiologic, psychological, and economic costs associated with the evaluation of abnormal laboratory (including false-positive) studies brings little value, and it rarely influences clinical care. (c) As many as 60% of abnormal preoperative test results are not known or evaluated preoperatively, creating potential liability. Multiple reports suggest that nearly 70% of ordered preoperative laboratory tests are not indicated by facts obtained in the history and physical examination.

This information reiterates the importance of the history and physical examination and suggests that a directed preoperative laboratory testing strategy (Table 44.3) for routine procedures is both safe and cost effective. Obviously, special studies such as tumor markers (e.g., CA-125) are appropriate during evaluation and management

of women with pelvic malignancies, because they offer diagnostic assistance, facilitate decisions regarding patient triage, are potentially prognostic, and are of significant value during postoperative management. Although care should be individualized, it has become apparent that directed preoperative laboratory testing forms a firm foundation for quality preoperative care for patients undergoing elective procedures.

TABLE 44.3. *Preoperative testing strategy*

Although advances in blood banking technology have lessened the risk of transfusion and favorably affected the outcomes of many surgical procedures, it is apparent that women do not need to have a type and crossmatch performed prior to the majority of obstetric or gynecologic surgical procedures. Although maximal surgical blood order schedules have been established, they should be validated at each institution. When deemed necessary, a type and screen allows for identification of specific antibodies and assures rapid availability (=20 min) of red blood cell products. Individual decisions regarding blood bank strategies should be related to the patient's preoperative status (i.e., hemoglobin and hematocrit, blood volume), anticipated losses, and existing comorbidities that might carry an early transfusion trigger. Anemia is not uncommon among women undergoing pelvic surgery. Although it may constitute an indication (menorrhagia, associated with leiomyomas) or result from an indication (cervical cancer), its presence should prompt an evaluation. As deemed appropriate, a preoperative search for other causes or losses should be undertaken. Additionally, preoperative discussions regarding procedure-associated blood loss and its attendant risks represent an important aspect of informed consent.

Critically ill patients may benefit from having their serum hemoglobin levels maintained at about 10 g/dL, but data suggest little effect of transfusion on survival in patients whose hemoglobin levels are between 8 and 10 g/dL. The majority of women can safely undergo elective procedures without a type and screen.

RADIOLOGIC INVESTIGATION

Routine imaging studies can be obtained safely as directed by findings of the history and physical examination. The indications for a preoperative chest radiograph are relatively straightforward, and abnormalities are associated with an increased risk of perioperative pulmonary complications. Unfortunately, unnecessary chest radiographs and many additional, sometimes unnecessary, undirected diagnostic preoperative imaging studies are obtained frequently.

Diagnostic ultrasonographic examination, pelvic and abdominal computed tomography (CT), and magnetic resonance imaging studies are performed in patients with suspected or known gynecologic malignancies. These studies may suggest the benefit of preoperative triage to a subspecialist but rarely influence the surgical approach. Their results should not be considered binding, typically contribute little to clinical care, and often add significantly to health care costs. Although the radiologist's suggestions for additional studies are noted frequently, the astute pelvic surgeon should combine physical findings, patient symptoms, and laboratory results to develop the perioperative care plan, based on necessity and benefit of histologic confirmation of a radiologic abnormality.

Although proponents of preoperative “radiologic staging studies” suggest relative accuracy, the pelvic surgeon must recognize the subjective aspects of interpretation. In general, their routine use has not been associated with an alteration in perioperative clinical care. Although findings may alter approach, negative results do not exclude the finding of significant pathology. Not to condone or condemn, the value and use of other noncardiac imaging studies have not been evaluated adequately. However, it appears that in specific situations CT scans have a significant false-negative result rate (e.g., for the evaluation of extraovarian disease). Radiologic investigation adds little to clinical care in patients with endometrial cancer in the absence of physical findings. There is little clinical value for intravenous pyelography (IVP) to evaluate ureteral location or displacement, because it is not a substitute for intraoperative ureteral identification. In the absence of malignancy, hydronephrosis is likely related to displacement and is easily corrected or managed during the operative procedure.

The exception is an abnormal finding on a clinically indicated routine cancer screening study (e.g., mammography), in which test results may have a significant impact on clinical care, particularly in those women undergoing “elective pelvic procedures.”

ENDOSCOPIC EVALUATION

There is little evidence to suggest the value of multiple endoscopic procedures prior to most routine gynecologic procedures. However, it is certainly appropriate to consider obtaining history-directed or disease-specific (e.g., inflammatory bowel disease, previous colon cancer) or recommended cancer screening endoscopic procedures prior to elective procedures. For example, endoscopy performed prior to rectovaginal or vesicovaginal fistula repair may render significant and important information and cause the physician to alter the surgical approach or initiate referral.

CARDIAC DISEASE

Preoperative assessment to detect undiagnosed heart disease and direct appropriate perioperative treatment of women with longstanding or newly diagnosed cardiac disease is of vital importance. The majority of inhalational anesthetics are myocardial depressants, modify neural tone, and are arrhythmogenic, creating risk even in the healthy patient. Nearly 50,000 perioperative MIs occur annually. Approximately 20,000 are fatal, and hundreds of thousands of related serious extracardiac complications occur, resulting in poor outcome. The prevalence of cardiovascular disease increases directly with increasing age, and within the aging population serous cardiac events occur regularly. Although no age group is risk free, gynecologic procedures in the aging population are estimated to result in a 25% increase in the incidence of necessary major intraabdominal procedures, potentially increasing the absolute risk of cardiac morbidity. Although heart disease may not be readily apparent, the answers to carefully framed historical questions can assist in unmasking occult cardiac risk factors. Gynecologists should feel compelled to become familiar with the important aspects of perioperative cardiac care, to improve individual patient outcome as well as the overall health of the entire female population.

Proper preoperative cardiac assessment requires a systematic approach, typically undertaken in close coordination with qualified consultants. Attention to history, physical findings, and the effects of comorbid diseases forms the foundation for initial evaluation. These findings assist in the direction of ordering ancillary cardiac studies, which can clarify risk and improve predictive power for perioperative morbidity associated with the proposed gynecologic surgery. They also allow institution of a sound plan for perioperative monitoring and management A disease-specific approach is important, specifically addressing signs, current symptoms, and management of coronary artery disease (CAD), hypertension, heart failure, valvular heart disease, arrhythmias, pacemakers, pulmonary vascular disease, and type and extent of surgery.

General Considerations

Particular energy should be directed preoperatively to elicit historical or physical evidence of cardiac ischemia. Important elements include angina, a history of MI, past or current signs or symptoms suggesting congestive heart failure, unexplained palpitations, evidence of previous cardiac intervention, and renal impairment. Important aspects of noncardiac diseases that increase the incidence of cardiac risk factors, including diabetes mellitus, hypertension, hypercholesterolemia, family history of CAD, and obesity, should be evaluated. Age greater than 70 years, MI within the preceding 12 months, and evidence of congestive heart failure significantly increase postoperative cardiac complications in patients undergoing gastrointestinal, urologic, and gynecologic surgery. Concurrently, the pelvic surgeon should attempt to determine the patient's “functional capacity.” The simple inability to walk three blocks or climb two flights of stairs portends a poor functional status. Physical examination evaluating the patient's overall status is mandatory. This evaluation, coupled with laboratory and radiologic information and an electrocardiogram (ECG), provides a baseline estimate as to actual perioperative cardiac risk. Numerous schema from Goldman and others intended to quantify cardiac risks have been designed, reported, and verified in an attempt to quantitate perioperative cardiac risk. The American College of Cardiology-American Heart Association (ACC-AHA) published revised practice guidelines based on qualitative analysis. Specific risk categories include ischemic heart disease, congestive heart failure, high-risk surgery, diabetes mellitus, renal insufficiency, and poor functional status (Table 44.4). They define clinical risk stratification for noncardiac surgical procedures. Noncardiac procedures with high (>5%), intermediate (<5%), and low (<1%) risk of cardiac morbidity or mortality have been categorized (Table 44.5).

TABLE 44.4. *Factors that increase the risk of perioperative cardiac complications in patients undergoing noncardiac surgery and indications for the use of perioperative ß-blocker therapy*

High (Reported Cardiac Risk Often >5%)
Emergent major operations, particularly in the elderly
Aortic and other major vascular
Peripheral vascular
Anticipated prolonged surgical procedures associated with large fluid shifts or blood loss or both
Intermediate (Reported Cardiac Risk Generally <5%)
Carotid endarterectomy, head and neck
Intraperitoneal and intrathoracic
Orthopedic
Low (Reported Cardiac Risk Generally <1%)
Endoscopic procedures
Superficial procedure (i.e., dilation and curettage)
Breast

TABLE 44.5. *Cardiac risk stratification for noncardiac surgical procedures*

Data prompting development of these guidelines suggest that coronary artery bypass surgery or other invasive interventions (i.e., coronary angioplasty) are appropriate only in an effort to reduce cardiac risks following the stress of noncardiac surgery when they would be indicated for symptoms or to manage test-related cardiac disease nonsurgically. Specific disease states requiring strong consideration of presurgical revascularization include poorly controlled angina pectoris (despite maximal medical therapy), high-risk left main coronary artery stenosis (>50%), severe two- or three-vessel CAD (with involvement of the proximal left anterior descending artery) with greater than 70% stenosis, easily induced myocardial ischemia on preoperative stress testing, and left ventricular systolic dysfunction at rest.

Cardiac Disease–Specific Approach

Coronary Artery Disease CAD commonly occurs at a lower incidence in females than in males; however, diabetic women are risk equivalent to men. The mortality of an acute MI is greater for women and increases dramatically in the aged patient. Importantly, MIs occurring during the perioperative period carry a higher mortality risk than those occurring otherwise. Many surgical patients have diagnosed CAD or risk factors for CAD. Women who are potential candidates for attempts at preoperative myocardial revascularization may benefit from noninvasive cardiac testing performed to determine the amount of myocardium in jeopardy, the patient's ischemic threshold, and the objective determination of ventricular function. Test results should be used to assist in stratifying prognostic information and determining the extent and benefit of perioperative surgical or medical intervention and postoperative monitoring.

Hypertension As the training and practice of obstetricians-gynecologists increasingly stresses the importance of primary care, the preoperative evaluation and the management of hypertension has become a major focus on the gynecologic patient's problem list. Although the identification of early-stage hypertension should lead to the institution of appropriate medical therapy, the ACC-AHA guidelines suggest that those with stage II or milder hypertension (systolic blood pressure below 180 mm Hg and diastolic blood pressure below 110 mm Hg) are not at increased risk for perioperative cardiovascular complications. Surgical delay for medical treatment of women with stage I or II hypertension is not necessary or beneficial. However, elevated blood pressure in patients with stage III hypertension (systolic blood pressure 180 mm Hg or higher and a diastolic blood pressure 110 mm Hg or higher) should be controlled prior to surgery. The administration of ß-adrenergic blockers in this clinical situation results in rapid, effective control of severe blood pressure elevation and perioperative hypo- or hypertension, either of which is associated with an increased risk of coronary ischemia. Regardless of actual measured systemic pressures, the ACC-AHA guidelines suggest that the blood pressure of patients with significant hypertension who require urgent surgery be controlled. The goal is to avoid the ischemic complications associated with perioperative blood pressure fluctuations that commonly occur in the surgical patient who has uncontrolled hypertension.

Heart Failure Ventricular failure is an important predictor of and prognostic factor for perioperative cardiac morbidity. The initial attempt to identify women with ventricular dysfunction begins with a detailed history and organ-specific physical examination. Determination of ventricular status is mandatory in those with evidence or history of congestive heart failure, because the physiology of perioperative ventricular failure portends an ominous situation. Perioperative subspecialty consultation, pharmacologic manipulation to maximize cardiac oxygen supply–demand ratio, careful administration of intravenous fluids, and cardiac monitoring may benefit these patients. During preoperative investigation, gynecologic surgeons should not exclude the possibility of rare causes of cardiomyopathy, including hypertrophic obstructive cardiomyopathy, because their appropriate medical management decreases morbidity. Echocardiography, to obtain an estimate of ventricular function and to rule out anatomic abnormalities, should be considered and may be necessary for the perioperative assessment for those women with suspected, known, or history of heart failure or cardiomyopathy.

Valvular Heart Disease Although interpretation of the physical findings can be challenging, the gynecologic surgeon should attempt to identify significant heart murmurs. Echocardiography aids in defining the anatomic abnormality and in detailing the need and benefit of antibiotic endocarditis prophylaxis (Table 44.6). Failure to diagnose any significant valvular dysfunction or to administer appropriate antimicrobial prophylaxis increases the risk of a catastrophic perioperative consequence.

Endocarditis Prophylaxis Recommended
High-risk Category
Prosthetic cardiac valves, including bioprosthetic and homograft valves
Previous bacterial endocarditis
Complex cyanotic congenital heart disease (e.g., single-ventricle states, transposition of the great arteries, tetralogy of Fallot)
Surgically constructed systemic pulmonary shunts or conduits
Moderate-risk Category
Most other genital cardiac malformations (other than those listed above and below)
Acquired valve dysfunction (e.g., rheumatic heart disease)
Hypertrophic cardiomyopathy
Mitral valve prolapse with valvular regurgitation, thickened leaflets, or both
Endocarditis Prophylaxis Not Recommended
Negligible-risk Category (Risk No Greater Than That of the General Population)
Isolated secundum atrial septum defect
Surgical repair of atrial septal defect, ventricular septal defect, or patent ductus arteriosus (without residual beyond 6 months)
Previous coronary artery bypass graft surgery
Mitral valve prolapse without valve regurgitation
Physiologic, functional, or innocent heart murmurs
Previous Kawasaki syndrome without valve dysfunction
Previous rheumatic fever without valve dysfunction
Cardiac pacemakers (intravascular and epicardial) and implanted defibrillators

TABLE 44.6. *Cardiac conditions associated with endocarditis*

Aortic stenosis poses the greatest valvular risk for poor postoperative cardiac outcome. Cardiac morbidity in women with untreated aortic stenosis undergoing noncardiac surgery approaches 10%, sufficient to persuade every pelvic surgeon to diagnosis this condition. ACC-AHA practice guidelines advise postponement of elective surgery in women with severe or symptomatic aortic stenosis until valve replacement, the accepted standard intervention, can be performed. In emergent situations, aortic valvuloplasty may be employed but has less certain success. In general, surgical correction of mitral stenosis is not indicated prior to noncardiac surgery unless the severity would warrant treatment in a nonsurgical setting. If deemed necessary, balloon valvuloplasty is an appropriate corrective option for those with severe mitral stenosis. Mild to moderate mitral stenosis requires control of perioperative heart rate to reduce the risk of heart failure. Significant aortic regurgitation requires attention to intravascular volume control and attempts at medical afterload reduction. In contrast to mitral stenosis, bradycardia should be avoided or aggressively treated to avoid left ventricular backfill. Mitral regurgitation most commonly is associated with papillary muscle dysfunction and mitral valve prolapse. Prior to surgical procedures, antimicrobial prophylaxis may be indicated for those with mitral valve prolapse and demonstrable clinical evidence of regurgitation or echocardiographic evidence of anatomic mitral valve leaflet abnormalities. Women with significant mitral regurgitation murmurs require careful monitoring of the left ventricular ejection fraction, because the low-resistance regurgitant valve predisposes perioperative patients to retrograde cardiac flow, resulting in pulmonary edema and high pulmonary artery pressures. Invasive perioperative cardiac monitoring may be necessary, because echocardiography tends to overestimate ejection fraction in patients with mitral regurgitation. Patients with prosthetic mitral valves receiving systemic anticoagulants require intervention to lessen the risk of endocarditis and intracardiac coagulation. The fifth consensus conference on anticoagulation suggests:

1. For minimally invasive surgical procedures, reduce the international normalized ratio to subtherapeutic range and resume the normal dosage of oral anticoagulation immediately postprocedure.
2. Perioperative heparin is recommended for patients when significant bleeding is anticipated or the risk of thromboembolism is high. These clinical situations include women with a mechanical valve in the mitral position (low flow rate), a Bjork-Shiley valve, or history of thrombosis or embolus associated with valvular replacement during the past year. Systemic anticoagulation is appropriate if three risk factors are present, including atrial fibrillation, previous embolus, hypercoagulable condition, or mechanical prosthesis with left ventricular function of less than 30%.

3. For patients whose clinical condition falls between these extremes, the risk–benefit ratio of anticoagulation should be considered individually.

Arrhythmias Every gynecologic surgeon will encounter perioperative cardiac arrhythmias. The majority are considered benign, but their underlying etiology should be sought aggressively, because undiagnosed cardiac ischemia may initially become clinically evident as a perioperative arrhythmia. Perioperative arrhythmias may worsen existing ischemia by increasing myocardial demand or decreasing cardiac efficiency. Pulmonary disease, metabolic derangements, or drug toxicities are common causes. Monitoring and treatment is important, because an unstable arrhythmia such as atrial fibrillation occasionally may deteriorate into a life-threatening rhythm (i.e., ventricular fibrillation). In addition to conferring a therapeutic cardiac morbidity risk reduction in patients with CAD, ß-blockers may reduce arrhythmia-related perioperative morbidity and mortality. Premature ventricular contractions occurring at a rate of fewer than 6 per minute are presumably “benign.” Even short and spontaneously converting runs of ventricular tachycardia may not predispose patients to perioperative death from MI. However, underlying coronary ischemia may be unmasked by the occurrence of these rhythms, making it imperative that the underlying etiology of a perioperative arrhythmia be ascertained, even if these are not treated by antiarrhythmic agents other than ß-blockade. Atrioventricular (AV) block, especially Mobitz type II or third-degree heart block, may increase operative risk. Patients with type I second-degree AV block, first-degree AV block, and left and right bundle branch blocks are usually asymptomatic and their arrhythmias rarely contribute to postoperative morbidity and mortality. It is reasonable to consider early subspecialty consultation to diagnose and treat women who develop perioperative cardiac arrhythmias. Patients with known or previously treated or untreated congenital heart disease or pulmonary vascular disease deserve close evaluation. Individuals with previous surgical correction of a ventricular septal defect, patent ductus arteriosis, or tetralogy of Fallot may be at increased operative cardiac risk, possibly due to decreased pulmonary vasculature reactivity to hypoxia.

Risk Stratification According to Type of Surgery

Although individually weighted, existing patient risk factors, the type and extent of operation, and the operative circumstances are important to delineate the risk of perioperative cardiac morbidity. Intuitively, the decision to operate and the choice of operation or operative approach should be made in an attempt to offer the most effective treatment while minimizing patient cardiac risk. Other medical conditions should be addressed to lessen any indirect impact or perioperative cardiac outcome.

Every surgical intervention should be biased by or based on acute or chronic patient-specific factors. Although emergent surgical indications lessen available evaluation time, urgency does not absolve the responsibility to search diligently for significant risk factors. The young woman in shock with a ruptured ectopic pregnancy may provide the physician with only a brief opportunity for cardiac evaluation; however, cardiac risk factors are uncommon in this population, minimizing the necessity for or benefit of an extensive evaluation. The elderly patient with acute intestinal obstruction and strangulated bowel related to ovarian carcinoma may harbor significant cardiac risk factors but may require life-saving surgery despite significant coronary risk and a high potential for morbidity.

Perhaps more problematic is evaluation of those patients who require diagnostic or therapeutic surgery for pelvic malignant neoplasms and who are discovered to have cardiac disease during the presurgical evaluation. The clinical situation surrounding this or semi-urgent gynecologic procedures may preclude the benefit of extensive intervention (i.e., coronary artery bypass grafting [CABG]). In this situation, consultation and maximal medical therapy can improve the patient's perioperative cardiac condition and lessen risks.

Perioperative evaluation of women undergoing elective pelvic surgery should consider the risk of an adverse cardiac event in relation to the extent of the necessary surgical procedure. The benefit of medical management of the gynecologic condition should always be considered carefully. A minimally invasive or a vaginal surgical approach carries less physiologic stress and less risk of associated cardiac morbidity when compared with more extensive intervention (e.g., an abdominal approach). Although it requires planning and technical flexibility, matching the patient's gynecologic and medical conditions to a proper surgical approach should be every surgeon's goal. Good matches most frequently result in good outcomes.

Risk Assessment and Treatment

The ultimate objective of preoperative cardiac risk assessment is to rule out serious CAD that requires cardiac intervention remote from the need for noncardiac surgery. Preoperative evaluation should be designed to recognize existing disease, expose occult underlying heart disease, and provide an opportunity for appropriate cardiac assessment.

Noninvasive Testing ACC-AHA recommendations for those undergoing noncardiac surgery provide a short-cut to the appropriate application of noninvasive cardiac testing, which is indicated by two of three listed risk factors. This testing schema assumes that the identification of a high-risk patient will identify those who would benefit from preoperative coronary revascularization or maximization of medical therapy. Either would contribute to improving the patient's long-term quantity and quality of life. Noninvasive studies include the 12-lead electrocardiogram, echocardiography, contrast ventriculography, radionuclide angiography, exercise stress testing, nonexercise stress testing, myocardial perfusion imaging, and dobutamine stress echocardiography. The ACC-AHA evaluation guidelines algorithm can be applied to all patients. In general, the gynecologic surgeon should consider the role of noninvasive testing after consultation with qualified specialists to assist in the evaluation, interpret the results of noninvasive testing, and recommend intervention for those patients with cardiac risk factors.

Coronary Artery Bypass Graft-Specific Interventions The decision to perform CABG prior to noncardiac surgery should be based on potential risks versus the short- and long-term benefits of coronary revascularization. Eagle and colleagues reporting on 3,368 patients (Coronary Artery Surgery Study database) with CAD, found that patients undergoing minimally invasive procedures have a cardiac-related mortality rate of less than 1%, regardless of previous CABG. In contrast, major procedures including abdominal surgery carried a significantly higher risk of cardiac morbidity and mortality. The risk of death (1.7 vs. 3.3%, $P = .03$) and nonfatal MI (0.8% vs. 2.7%, $P = .002$) was significantly lower after CABG. The ACC-AHA task force has recommended that preoperative coronary revascularization be employed in specific clinical situations: in those women with acceptable risks of coronary revascularization and a suitable amount of viable myocardium, those with left main coronary artery stenosis, those with three-vessel CAD in conjunction with left ventricular dysfunction, those with two-vessel disease involving severe proximal left anterior descending artery obstruction, and when intractable coronary ischemia persists despite maximal medical therapy. These practice guidelines also suggest that the timing of coronary revascularization be weighed against the clinical urgency and extent of noncardiac surgical intervention. Patients requiring elective noncardiac procedures of intermediate or high surgical risk who have significantly abnormal coronary anatomy should be referred for surgical revascularization prior to noncardiac surgery. Those same patients undergoing low-risk noncardiac surgical procedures or patients with less severe coronary artery lesions should not undergo preoperative coronary artery revascularization.

Preoperative Prophylactic Coronary Intervention The ACC-AHA task force has recommended that percutaneous transluminal coronary angioplasty (PTCA) be used in the perioperative setting in a manner identical to that proposed outside of the perioperative setting. Although debate exists as to the most appropriate interval from PTCA to the pelvic surgical procedure, delay for at least 2 to 4 weeks should be allowed to ensure healing and exclude restenosis of the treated vessel. However, extended delays of more than 6 to 8 weeks after PTCA may allow restenosis of the treated vessel and further increase the risk of perioperative ischemia. If a coronary artery stent is placed, ACC-AHA recommendations suggest postponing surgery for to 2 to 4 weeks to allow stabilization and to exclude the risks of stent site stenosis. The 2-week delay allows completion of a full course of thienopyridine and aspirin therapy and lessens the risk of subsequent stent thrombosis. There is little evidence available to describe the perioperative effect of prophylactic coronary intervention months to years before noncardiac surgery; however, coronary restenosis is unlikely to occur within 8 to 12 months after prophylactic coronary intervention, with or without stent placement. Obviously, patients with previous cardiac intervention remain at risk to develop subsequent additional coronary artery lesions. The Bypass Angioplasty Revascularization Investigation (BARI) compared the outcomes of noncardiac surgical procedures following CABG (250 patients) versus PTCA (251 patients) in 1,049 surgeries. The median time interval between the most recent coronary revascularization procedure and noncardiac surgery was 29 months. There were no significantly different outcomes when evaluating morbidity, in-hospital morbidity, and hospitalization costs, suggesting equivalence of revascularization procedures. However, the risk of cardiac death or MI was lower (0.8% vs. 3.6%) when noncardiac surgery was performed less than 4 years after revascularization, emphasizing the need for thoughtful preoperative cardiac evaluation in this patient population.

Perioperative Medical Therapy Several prospective randomized trials have evaluated the effects of perioperative ß-blocker administration. Poldermans and others administered bisoprolol to the 146 patients with high cardiac risk. The risks of both cardiac death (17% vs. 3.4%) and nonfatal MI (0 vs. 17%) were lowered significantly with treatment. Oral atenolol has been compared with placebo for 7 perioperative days. Although there was no significant decrease in MI or cardiac death, a significant decrease in ischemia (24% vs. 39%) was apparent in those receiving atenolol. This report also detailed a significant decrease in the subsequent 6-month death rate (1% vs. 10%) in those treated with atenolol. Ace inhibitors were also evaluated in two studies which showed no demonstrable benefit. Although randomized prospective clinical trials of ß-blockade in a gynecologic population are not available, it seems reasonable to extrapolate the benefits of these interventions to those discovered to have a high cardiac risk during preoperative evaluation prior to a pelvic operation. ACC-AHA practice guidelines recommend perioperative ß-blocker treatment for patients with angina, symptomatic arrhythmias, untreated hypertension, known CAD, or major risk factors for CAD. The potential effect of a-antagonist perioperative cardiac protection has also been evaluated. A randomized placebo-controlled multicenter trial study of mivazerol use during the perioperative period in 2,854 patients with known CAD or significant risk factors reported no difference in MI incidence; however, the cardiac death rate was reduced by nearly 50% ($P = .04$). The Perioperative Ischemia Research Group also reported a significant reduction in perioperative cardiac ischemia in patients given high-dose perioperative mivazerol. This new information suggests that the perioperative administration of a-antagonists may have a future role in cardiac protection.

Arrhythmias The perioperative goal of cardiac arrhythmia or conduction disturbance management relates to the desire and need to prevent the deterioration of a given rhythm into one that is incompatible with life, to prevent cardiac ischemia, and to prevent thrombosis and endocarditis. Electrophysiology studies with ablation of aberrant conduction foci may be necessary for women with demonstrable supraventricular arrhythmias. Advanced Cardiac Life Support (ACLS) guidelines can be used for the pharmacologic treatment of perioperative supraventricular arrhythmias. Electrical or pharmacologic cardioversion may be necessary if patients are symptomatic or hemodynamic compromise is present. Beta adrenergic or calcium channel blockade also may be indicated for rate control in the absence of successful electrical cardioversion. Depending on the extent of surgery, patients with atrial fibrillation receiving systemic anticoagulation require evaluation and, perhaps, presurgical reversal. Simple discontinuation of the oral anticoagulant (72 hours prior) usually will suffice. However, fresh frozen plasma or parenteral vitamin K may be necessary

to reverse anticoagulation and ensure hemostasis. Frequent asymptomatic premature ventricular contractions or short runs of ventricular tachycardia may not require antiarrhythmic treatment because they do not, in general, increase perioperative cardiac risk. Although other lesser arrhythmias do not require treatment, the gynecologist should be diligent in pursuing causes of new arrhythmias to rule out myocardial ischemia. Sustained ventricular tachycardia should be treated following ACLS guidelines using lidocaine, procainamide, or other agents such as amiodarone. Care of perioperative arrhythmias is likely optimized with close communication and consultation with appropriate internal medicine, cardiac, or critical care consultants.

Other Situations

Implanted Pacemakers and Implantable Cardiac Defibrillators Occasionally the gynecologic surgeon will encounter a surgical candidate with a pacemaker or implantable cardiac defibrillator. Lack of familiarity with the device and its function can cause perioperative anxiety, particularly when combined with the intraoperative use of electrocautery. General ACC-AHA recommendations include the following. (a) Patients should have the implanted device evaluated before and after surgical procedures to determine the underlying rhythm, program settings, and battery status. If the pacemaker is programmed in a rate-responsive mode, the device should be inactivated during surgery. (b) If patient is pacemaker dependent, the pacing threshold should be determined and evaluated appropriately. (c) Implantable cardiac defibrillators should be turned off during surgery and on again after recovery from anesthesia.

Pulmonary Artery Catheters Invasive cardiac monitoring, including the use of a pulmonary artery catheter, provides instantaneous information, which may contribute to successful postoperative decision making. Unfortunately, the risks of catheter insertion and malfunction are significant and the rate of complications are operator dependent. Additionally, information generated from pulmonary artery catheterization is sometimes esoteric, and decisions based on the cardiac function data are limited by some degree of observer subjectivity. Evidence does not support the routine perioperative use of a pulmonary artery catheter; however, placement should be considered in specific high-risk patient subsets. It may have particular benefit in those in whom the gynecologic disease (e.g., ovarian cancer) or the surgical procedure (e.g., exenteration) is associated with large fluid shifts in those with a compromised medical condition.

Surveillance for Perioperative Myocardial Infarction A significant proportion of perioperative MIs are silent but carry a higher mortality rate (40%–70%) than those occurring in a nonsurgical setting. Electrocardiography, cardiac-specific biomarkers, echocardiography, and radioisotope studies have all been proposed and used for detection of postoperative MIs. Although many of these studies used alone or in combination are effective, false-positive findings are common. The measurement of creatinine phosphokinase myocardial bands alone is less diagnostic of MI than the evaluation of serum troponin levels. Guidelines call for standard surveillance in low-risk patients without documented CAD and normal preoperative ECG or serum biomarker findings. However, patients with high or intermediate clinical risks who have known or suspected CAD and are undergoing high- or intermediate-risk procedures are followed appropriately with an ECG obtained in the recovery room and on the first two postoperative mornings, combined with a cardiac troponin level obtained 24 hours postoperatively and on day 4 or at hospital discharge, whichever comes first. If infarction occurs, rapid reperfusion of the myocardium is the cornerstone of therapy. Unfortunately, thromboembolic therapy cannot be used in the immediate postoperative setting, leaving medical therapy (to maximize cardiac oxygen supply–demand ratio), angiography, and revascularization as the only available therapeutic interventions.

Arrhythmia and Conduction Disorders An arrhythmia should be addressed immediately to determine its etiology and managed according to ACLS guidelines. Tachyarrhythmias should prompt the immediate assessment of potential contributing factors including hypotension, hypoxia, or metabolic derangements. An ECG with rhythm strip should assist in identifying the exact features of the arrhythmia. Narrow-complex regular arrhythmias are likely due to AV node reentry tachycardia or supraventricular tachycardia. Vagal maneuvers should be employed initially. Pharmacologic management consists of administering adenosine or AV nodal blockade using ß-blockers, calcium channel blockers, or class I-A or I-C antiarrhythmic agents. Atrial fibrillation and flutter are unstable rhythms, which often produce a rapid ventricular response. Initial management should be aimed at control of ventricular rate by AV node blockade. Evaluation of the underlying etiology is paramount, and the use of cardioversion should not be entertained until the underlying etiology (e.g., hypothyroidism hypokalemia, hypomagnesemia) has been found and corrected. Infrequent premature ventricular contractions do not require treatment; however, long runs of ventricular tachycardia may require antiarrhythmic therapy, particularly if symptoms or hemodynamic compromise occurs. In general, ventricular arrhythmias should be treated according to ACLS guidelines in conjunction with appropriate cardiology or internal medicine consultation. Cardiac pacing should be considered when warranted by hemodynamic compromise, symptoms including chest pain, or pulmonary edema. The pelvic surgeon assumes great responsibility for perioperative care of the patient with cardiac risks. Although performing the best-suited procedure for the gynecologic condition is imperative, an understanding of the factors that influence overall results, the appropriate intervention, and the timely use of consultants can only improve operative outcome.

PERIOPERATIVE PULMONARY EVALUATION

Postoperative pulmonary complications (PPC) commonly occur following abdominal or pelvic surgery. Pulmonary dysfunction occurs in as many as 80% of patients, and clinically significant PPCs include atelectasis, bronchospasm, the need for prolonged ventilatory support, pneumonia, and worsening pulmonary function due to exacerbation of an underlying problem. The combination of general anesthesia and abdominal surgery results in a morbid alteration of pulmonary physiology, with effects that are compounded by postoperative immobilization, narcotics, or inadequate pain relief.

Patient-related Risk Factors

All patients, even those without underlying known pulmonary disease, remain at significant risk following general endotracheal anesthesia and abdominal surgery. Numerous comorbidities have been linked to the risk of developing PPC (Table 44.7). Although the physiologic and economic costs are significant, unfortunately, the ability to qualitatively or quantitatively evaluate or modulate pulmonary risks is not that of cardiac risks.

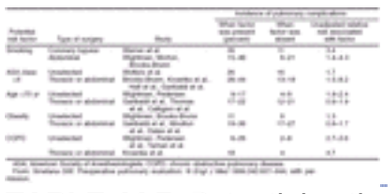

TABLE 44.7. *Potential patient-related risk factors for postoperative pulmonary complications*

Tobacco abuse is a risk factor for PPC, even without clinically apparent pulmonary disease. When compared with nonsmokers, the relative risk of PPC for smokers increases as much as four-fold following abdominal surgery. Although difficult at best, prolonged smoking cessation reduces the risk of PPC by nearly 50% Unfortunately, many of the physiologic effects of smoking are long lasting, and little benefit is gained unless smoking is stopped at least 8 weeks prior to surgery.

A patient who is unable to exercise is at increased risk for PPC following abdominal surgery. The inability to climb a flight of stairs or blow out a match at 6 inches (equals an FEV <1.76 L) suggests a very high pulmonary risk. The Goldman cardiac risk index and the American Society of Anesthesiologists classification reasonably predict pulmonary risk but not necessarily the severity of PPC. Clinically evident chronic obstructive pulmonary disease has been associated with four- to five-fold relative risk of PPC in patients undergoing surgery. Despite common belief, age and obesity, when controlling for other existing comorbidities, do not contribute significantly to the development of PPC.

Active asthma, when severe, can be among the most difficult respiratory conditions to manage, although its presence does not necessarily herald an increase in perioperative bronchospasm if appropriate prophylaxis is administered. Preoperative improvement of small airway patency, as evidenced by freedom from wheezing and a peak flow greater than 80% of predicted value, may minimize pulmonary risk in these patients. A short course of oral steroids may assist in achieving this preoperative goal. Even though history and physical examination may detect those at risk for PPC, no spirometric or other test detects those patients whose abdominal surgery should be canceled. Most patients can undergo surgery even if at high risk.

Although the optimal reduction regimen is unknown, the realization that postoperative pneumonia is extremely morbid and occasionally lethal in even a healthy patient demands adequate attention to perioperative pulmonary management.

Procedure-related Pulmonary Risk Factors

Limitation of surgery to the lower abdomen greatly reduces the extent of pulmonary dysfunction and the risk of developing PPC. Upper abdominal incisions increase this risk by as much as 40% in general surgery patients. A laparoscopic approach significantly reduces the risk of PPC by as much as 33%

The type of anesthesia, anesthetic pharmaceutical agent, and length of surgery play important roles in patient risk. Although reports have shown mixed results, spinal conduction anesthesia (spinal or epidural anesthesia) offers pain relief, improves pulmonary mechanics, and may significantly reduce the chance of PPC when compared with general endotracheal anesthesia.

Preoperative Evaluation

Using findings from the history and physical examination, one can select the majority of patients who are at risk for developing PPC. Although not considered a standard part of routine preoperative evaluation, preoperative pulmonary function testing may be indicated in specific patient subsets. The American College of Physicians has recommended spirometry to determine forced expiratory volume (FEV) in patients who have significant pulmonary risk factors or in those undergoing high-risk surgical procedures, particularly if requiring abdominal or thoracic incisions. Others have suggested minimal benefit of this intervention. These studies may delineate the etiology of pulmonary dysfunction; however, they rarely add value in terms of altering clinical management. Some have recommended that perioperative P_aCO_2 monitoring can assist in the management of those who are chronic CO_2 retainers. Although hypercarbia is a significant risk for PPC, no validated published studies suggest a CO_2 threshold which prohibits surgery. Baseline CO_2 determination may be useful for postoperative ventilator management.

Although individual risk factors are important, several risk indices have been developed. Unfortunately, none has been validated scientifically to quantitate actual pulmonary risks. Included in these indices are abnormal findings during examination, risks related to Goldman cardiac risk assessment, and the Charleston comorbidity index. The time expenditure and expense of any invalidated algorithm are not justified in clinical practice.

Risk Reduction Strategies

The inability to quantify pulmonary risk highlights the importance for the gynecologist to develop clinical acumen in an effort to reduce pulmonary complications. Several risk-reduction strategies have been proposed (Table 44.8). Attention to maneuvers that enhance postsurgical lung expansion combined with adequate pain control to reduce splinting and subsequent atelectasis are the vital components of good postoperative pulmonary care. Preoperative education engages the patient in her care, increases her willingness and active participation, and assists in overcoming a major psychological obstacle to postoperative pulmonary health. The potential benefits of incentive spirometry, chest physiotherapy, and inhalational nebulizer treatments can be explained and understood preoperatively.

Preoperative
Encourage cessation of cigarette smoking for at least 8 weeks prior to surgery.
Treat airflow obstruction in patient with chronic obstructive pulmonary disease or asthma.
Administer antibiotics and delay surgery if respiratory infection is present.
Begin patient education regarding lung expansion maneuvers.
Intraoperative
Limit duration of surgery to less than 3 hours.
Use spinal or epidural anesthesia.[a]
Avoid use of pancuronium.
Use laparoscopic procedures when possible.
Substitute less ambitious procedure for upper abdominal or thoracic surgery when possible.
Postoperative
Use deep breathing exercises or incentive spirometry.
Use continuous positive airway pressure.
Use epidural analgesia.[a]
Use intercostal nerve blocks.[a]

[a]This strategy is recommended, although variable efficacy has been reported in the literature.

TABLE 44.8. *Postoperative pulmonary complication risk-reduction strategies*

RENAL DISEASE

The anatomic relation of the urinary tract to the reproductive organs places it at risk for extrinsic (disease-related) or iatrogenic complications. Although intraoperative technique should be designed to decrease injury risk, perioperative renal insufficiency or failure is among the most foreboding postoperative complications faced by the gynecologic surgeon. The overall risk of urinary tract injury is procedure related and is not uncommon (=2%). Preoperative urologic studies may reveal congenital anatomic or other abnormalities and a rare renal cancer. Importantly, radiographic evidence of ureteral deviation, displacement, or hydronephrosis should not be considered a substitute for good operative technique and cannot be equated with lessening the risk of injury. The 3% incidence of serious adverse events associated with IVP and its lack of cost effectiveness (approximately 833 IVPs necessary to potentially prevent 1 ureteral injury) draw attention to its routine use.

Total cessation of renal function (i.e., bilateral ureteral obstruction) results in a daily increase of 1 to 2 mg/dL in serum creatinine. Although the postoperative dynamics of measured serum creatinine are complex, lesser degrees of elevation (i.e., > 0.3 mg/dL per day) should raise suspicion for a unilateral ureteral injury.

Although overt oliguric renal failure rapidly becomes clinically obvious, lesser degrees of renal insufficiency may occur silently. Although all patients are at risk, the geriatric patient is at particular risk of perioperative renal insufficiency secondary to an age-related decrease in glomerular filtration rate, a decrease in urinary concentrating ability, and narrowed limits for sodium, potassium, and acid excretion. This population should be monitored carefully to maintain euvolemia and minimize the electrolyte load found in many medications.

Research has detailed the predominant biochemical and physiologic changes occurring in the patient with acute renal failure. Recognizing the important effects of medullary hypoxia, tubular cell injury, and alterations associated with diuretics and electrolytes assists in understanding the mechanisms of disease; however, the clinical usefulness of this new information has yet to make a significant impact on daily practice. Thus, the classic approach of evaluating intrinsic renal, prerenal, or postrenal etiologies of perioperative renal failure remains useful. Prerenal azotemia results from any condition which prevents adequate blood flow to the renal unit. Hypovolemia, renal artery atherosclerotic disease, and pharmacologic etiologies (e.g., a combination of ace inhibitors and diuretics) interfere with normal renal perfusion. Hypovolemia may occur as a result of intrinsic cardiac failure, general anesthesia, excessive blood loss, pre-, intra- or postoperative volume contraction, or physiologic vasodilation (e.g., as in septic shock). Most postoperative causes of prerenal azotemia are reversible with the correction of intravascular volume deficits, minimizing the effect of left ventricular dysfunction or the reversal of anesthesia.

Postrenal failure, which can be related to outflow tract obstruction at any level of the renal collecting system, carries significant importance following pelvic surgery. Functional obstruction due to a neurogenic bladder or the inability to void spontaneously may be related to existing deficits or postsurgical changes. Urethral catheterization typically reverses this problem. Postobstructive oliguria related to causes proximal to the bladder requires significant ureteral obstruction. Although this situation can occur with bilateral renal calculi, bilateral or unilateral obstruction can occur after prolapse surgery and it is most frequently encountered with advanced carcinoma of the cervix or in idiopathic retroperitoneal fibrosis. Renal ultrasonography is an easily obtained diagnostic study. Acute management of most causes of postrenal failure involve appropriate diversion of the urinary units, either by transvesical ureteral stenting or percutaneous nephrostomy, to preserve existing renal function.

Lastly, intrinsic renal dysfunction may be due to acute tubular necrosis, interstitial nephritis, and acute glomerulonephritis. Intrinsic renal failure most often is due to renal parenchymal ischemia or the effects of nephrotoxic agents, including aminoglycoside antibiotics, vancomycin, amphotericin B, and cisplatin. Radiocontrast agents and heme pigments are two agents commonly associated with acute tubular necrosis. The former may have intrinsic parenchymal effects and create a diuresis that aggravates existing volume deficits. Interstitial nephritis associated with an allergic drug reaction, autoimmune diseases, infiltrative diseases, and infectious agents represents another form of intrinsic renal failure. When present, withdrawal of the offending agent usually results in reversal; however, glucocorticoid administration may hasten recovery. Finally, acute glomerular nephritis, rare in the gynecologic patient, may also be responsible for intrinsic renal failure and should be entertained in the differential diagnosis of postoperative renal insufficiency, particularly in the absence of other causes.

Diagnosis, Morbidity, and Mortality

The initial diagnostic evaluation of women with perioperative renal insufficiency requires a systematic method of investigation. Intraoperative suspicion and assessment with cystoscopy (or cystotomy) and methylene blue or indigo carmine dye injection is an important initial step. Postoperative hypovolemia may be obvious. However, volume status determination may be difficult when based on history, physical examination, and quantitation of perioperative input and output data. The urinalysis in those with prerenal azotemia shows a high osmolality (>500 milliosmoles per kilogram), a fractional sodium excretion of less than 1%, and proteinuria. Elevated serum blood urea nitrogen out of proportion to creatinine (greater than 20:1 ratio) is strongly indicative of prerenal azotemia. Renal azotemia often is associated with minimal proteinuria; however, urine osmolality will be less than 350 milliosmoles per kilogram and fractional excretion of sodium will be greater than 1. The surgeon's degree of suspicion based on operative findings and events is an important aspect of assessment to exclude postrenal azotemia, particularly when the procedure required a difficult pelvic dissection, repair of a prolapse, or treatment of a malignancy. Renal ultrasonography can determine quickly the extent of unilateral or bilateral hydronephrosis and eliminate the possibility of clinically significant ureteral ligation or kinking. If an ultrasonograph is not diagnostic, an IVP may answer important questions, although the administration of contract may worsen the clinical condition of a patient with intrinsic renal insufficiency.

Nonoliguric and oliguric renal insufficiency can occur in the postoperative patient, and physicians should not assume that “adequate” urine production indicates intact renal function. Importantly, oliguric renal failure portends a worse prognosis than nonoliguric renal failure. Using low-dose dopamine to increase renal perfusion (and convert an oliguric problem to a nonoliguric situation) has no proven efficacy and, if unsuccessful, should be discontinued, because it creates a propensity for cardiac

arrhythmias and alters blood supply to other vital organs.

The morbidity and mortality (fivefold) of renal failure in the postoperative patient is higher than that of individuals treated medically. These adverse outcomes probably are related to many factors, from perioperative ischemic insults to the volume depletion and other changes associated with contrast used for preoperative testing (i.e., IVP, CT) or mechanical bowel preparation. Common predisposing comorbid illnesses, including diabetes mellitus, hypertension, and cardiopulmonary insufficiency, carry their own inherent risks for causing renal insufficiency. Medications such as ace inhibitors and nonsteroidal antiinflammatory drugs, used frequently in the perioperative patient, also increase risk.

Methods to promote perioperative renal protection include practicing good surgical technique, limiting the use of nephrotoxic drugs, maximizing cardiopulmonary function by paying attention to intraoperative blood and volume losses, and replacing intravascular losses. Although invasive monitoring to guide fluid replacement may be helpful, its use and the administration of pharmacologic agents (dopamine, mannitol, furosemide) or other interventions has not been conclusively proven beneficial. Hopefully, continued research on adenosine and prostaglandin administration will prove fruitful.

Women with chronic renal insufficiency are at risk for acute renal insufficiency during the perioperative period. Preoperative internal medicine or nephrology consultation should be considered in an attempt to optimize volume, use dialysis strategically, and manage coexisting morbidities.

Management

Dialysis is the cornerstone of perioperative management of renal insufficiency once postrenal obstructions are relieved. Specialists should be consulted to treat acidemia, recalcitrant hyperkalemia, symptomatic volume overload, or impending cardiovascular failure. All medication dosages and schedules should be reviewed regularly to maximize efficacy and minimize toxicity.

In conclusion, although perioperative renal failure represents a significant danger to the operative patient, insufficient scientific data exist to identify patients at risk and to develop guidelines for postoperative renal surveillance and management. The surgical community awaits a more specific definition of renal failure, additional research regarding renal protection strategies, and better, less invasive treatments for patients with perioperative renal insufficiency.

WOUNDS AND INCISIONS

Once surgery has been deemed appropriate therapy, selecting the operative approach is possibly the most important initial surgical decision. Choice of approach is related primarily to physician bias and comfort, related to previous teaching and experience. However, surgical indications, disease process, previous abdominal incision (and resultant adhesions), patient preference, and existing medical comorbidity should be considered carefully prior to solving this sometimes complex problem. Adequate intraoperative exposure must be a primary consideration. Although a vertical lower midline incision should be the first consideration, some, particularly those with a large body mass index, may be best managed with an upper abdominal incision, avoiding trauma to the infection-prone panniculus. A panniculectomy may be necessary or appropriate. It is evident that many, if not most, gynecologic (even oncologic) and obstetric procedures can be completed safely through a more cosmetic transverse lower abdominal approach. The transverse approach may offer the additional advantage of less pain and diminished postoperative pulmonary dysfunction. Although the Pfannenstiel incision, when combined with a table-stabilized self-retaining retractor, will often suffice, preoperative consideration of a Maylard (rectus muscle splitting) incision or intraoperative conversion to a Cherney (rectus splitting–incision at pubic insertion) may be necessary. Regardless of the initial approach, to avoid hernia risks the incision should not be placed perpendicular to a previous incision. Placing the long axis of the incision in the direction of maximal skin tension creates the most aesthetically pleasing scar.

A more contemporary approach to numerous gynecologic procedures involves laparoscopy. Many, if not most, routine procedures and a significant proportion of complex procedures used for the management of benign or malignant disease can be safely completed laparoscopically, with less physiologic stress, less pain, and a more rapid return to normal activity. Although there are many correct answers to surgical incision placement, performing an incomplete procedure because of a compromised incision is an unacceptable alternative and should be avoided by immediate conversion to a more accommodating approach (e.g., hand-assisted laparoscopy or an open operation).

Operative laparoscopy and abdominal approach are associated with additional inherent surgical risks, so they should not replace vaginal surgery. Although laparoscopy may be complementary to “convert” abdominal procedures and to complete (extensive) operations, stand-alone vaginal surgery should remain an important arm of the obstetrician-gynecologist's surgical repertoire, because it results in less morbidity. Vaginal surgery will suffice for many, if not most, gynecologic procedures. Although lesser invasive (laparoscopic or vaginal) surgical approaches are associated with diminished physiologic stress, their use does not negate the need for appropriate preoperative evaluation, preparation, and management.

Wound Preparation

Although many rituals of preoperative skin preparation exist, only a few add documented value to patient care. Preoperative hair removal is not deemed necessary; however; if performed, clipper removal at a time close to surgery avoids microinjury and is associated with a lower risk of wound infection than is razor preparation.

Routine preoperative skin antisepsis is necessary to minimize the infectious potential of normal flora, as well as of pathogens. Bacterial concentrations in moist body areas (i.e., perineum) reach $10^{6}/cm^{2}$ of tissue and are greater than those in drier (abdomen) areas, reaching $10^{3}/cm^{2}$ of tissue. These areas also harbor different ratios of aerobic to anaerobic bacteria. Preparation solutions differ significantly in the immediate or late (>3 hours) mean bacterial reduction. Regardless of solution used, the preparation should be allowed to “set” for no less than 5 minutes to attain its maximal activity and bacterial reduction.

Surgical Technique

Creating an abdominal incision with a single bold knife stroke through the skin and subcutaneous tissue avoids a stairstep effect in the subcutaneous tissues. The use of multiple knife blades to create the incision offers little benefit and contributes to expense. Avoiding the creation of subcutaneous dead space is important because dead space increases the risk of wound infection and poor wound outcome, even when closed. The use of electrical or laser coagulation techniques to create an incision saves little time and adds little value. Their use creates “devitalized” tissue, which may contribute to an adverse wound environment and increase the risk of surgical site infection, resulting in acute or late poor wound outcome. Surgical technique may be of specific impact in those already at high risk because of thick (=3.0 cm) subcutaneous tissues.

The rationale for proper suture selection rests on the need for tensile strength, the duration of retained tensile strength, and the biologic effects on the involved tissue (Table 44.9). In general, the suture's chemical composition is more important than the physical configuration, although braided and multifilament sutures may potentiate infection. When compared with other absorbable materials, polyglycolic acid suture is associated with less inflammation and decreased pain, and in animal models it lessens the risk of infection. The incorporation of permanent suture material creates an increased risk of (˜10%) chronic wound problems (i.e., pain, wound sinus); however, their use is associated with a lessened risk of developing a fascial hernia. Vascular pedicle ligation can be accomplished safely using short-term absorbable sutures, because the risk of bleeding (1.5-mm vessels) is minimal 96 hours after ligation. There is little clinical benefit to be gained from peritoneal closure.

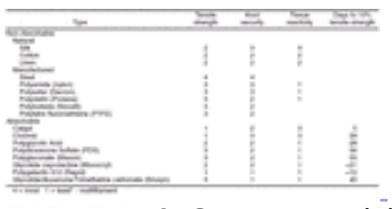

TABLE 44.9. *Suture material*

Suture size selection should be based on specific needs. Excluding fascial closure, there is little rationale for using suture larger than 2-0. Additional wound suture material increases the inflammatory response and may predispose to infection, and the tensile strength of a 2-0 absorbable suture is adequate for nearly all pedicle ligations.

Although it seems basic, correct suture-tying techniques can contribute to surgical outcome. Complex knots (e.g., surgeon's) impart greater tensile strength than multiple simple square knots. Avoiding excess knots minimizes the amount of suture material, lessens inflammatory volume, and potentially decreases the risk of poor

wound outcome. Although all knots should be secure, tightly tied fascial sutures strangulate the incorporated tissues, increase ischemia, and lessen wound strength. Although good surgical technique always has been tied to attempts to prevent adhesion formation, the development of hyaluronic acid products for adhesion prevention has opened new avenues.

The astute surgeon recognizes the different tissue-related healing curves and selects a suture designed to promote good outcome. Although short-term wound results are important, the risk of late problems (e.g., hernia) can be minimized with appropriate closure technique. A suture length–to–wound length ratio of greater than 4 decreases the risk of hernia formation and can be accomplished by placing sutures at least 1.5 cm from the fascial edge and 1.5 cm apart.

Subcutaneous tissue closure is typically unnecessary. If required to lessen tension on wound edges, small minimally reactive sutures should be chosen. Closed suction and subcutaneous drain placement are of little apparent benefit, and drains increase the risk of surgical site infection.

The best method or material for epithelial approximation should be related to the potential time, cost, need for return visits, and cosmetic results.

GASTROINTESTINAL CARE

Perioperative management of the gastrointestinal tract during pelvic surgery focuses on the following three aspects: (a) avoidance of operative injury and reduction of subsequent complications, (b) the role of early feeding, and (c) the appropriate diagnosis and management of patients with liver disease.

Excluding the need to address important aspects of coexisting intestinal diseases (e.g., inflammatory bowel disease) and issues related to cancer screening, gastrointestinal preparation values the decisions related to the incorporation of bowel preparation. Mechanical intestinal preparation offers a number of potential benefits (Table 44.10). Although suboptimal preparation may increase the risk of contamination, most pelvic surgeons are inclined to use a mechanical bowel preparation when the risk of manipulation or injury is substantial. Several regimens are used. Fleets Phospho-Soda (90 mL) is cost effective, well tolerated, and gives excellent results.

Remove fecal material.
Lower bacterial load.
Improve handling.
Reduce spillage, contamination.
Lessens risk of mechanical disruption.
Facilitates intraoperative palpation.
Allows intraoperative colonoscopy.
Aids laparoscopic handling.

TABLE 44.10. *Mechanical bowel preparation potential benefits*

Intestinal bacterial flora colony counts are high in the colon and distal ileum, decreasing dramatically in the more proximal small intestine unless obstructed. Classically the mechanical regimen is combined with oral antibiotics, typically including erythromycin or neomycin or both, to reduce luminal bacterial content. Although debate persists, the benefit of oral antibiotics over intravenous antibiotics is apparently small, and oral use is associated with significant gastrointestinal symptoms.

Early Oral Feeding and Nasogastric Suction

Nasogastric suction often has been incorporated into the postoperative care of women undergoing difficult pelvic operations. Reports not only question its use but deny its benefit as it relates to symptomatic relief, lessened risk of ileus, need for reinsertion, and protection of intestinal anastomosis. Regardless of procedure, fewer than 10% of patients require nasogastric suction, and it appears to be of little benefit to the other 90%. As importantly, early oral feeding is well tolerated, does not increase the risk of ileus or symptoms, and may shorten hospital stay.

Liver Disease

The preoperative detection of liver disease may not be easy, because serum enzymes (transaminase) may not be elevated in patients with late-stage disease. However, the historical and physical findings of significant alcohol intake or exposure to hepatotoxins should raise suspicion. Physical evidence of malnutrition, signs of hepatic encephalopathy, or jaundice usually signify advanced disease. Laboratory evidence of hepatic dysfunction includes an elevated (10-fold) increase in serum transaminase levels, abnormal coagulation study results, elevated total bilirubin values, and low serum albumin levels. Classic surgical risk indices have been based on the Child classification, initially detailed in the 1960s to determine risks associated with surgical management of those with esophageal varices. These indices have been applied to the risks in those with liver disease who are undergoing abdominal surgery.

Perioperative management of women with hepatic disease requires particular attention to drugs (and to their dosing and scheduling) which are metabolized by the liver. For example, patients receiving benzodiazepines and narcotics are at risk for drug accumulation and overdosage due to poor hepatic clearance.

Patients with acute liver disease (vital or other) should not undergo elective surgery until stabilization of liver dysfunction has been secured. Those with chronic liver disease and hepatic encephalopathy in an attempt to stabilize liver function may benefit from subspecialty consultation.

INFECTION

Perioperative surgical site infection occurs in the practice of every gynecologic surgeon. Knowledge of prophylactic measures and the optimal treatment regimen for those with active or acquired infection are expected of every pelvic surgeon. Numerous factors including obesity, diabetes, use of steroids, and even length of preoperative hospitalization are all risk factors for infectious perioperative morbidity (Table 44.11). Although addressing each of them is beyond the scope of this chapter, numerous technical methods can modulate these risks. Proper use of prophylactic antibiotics lessens infectious risks in many pelvic procedures. Numerous antibiotics and regimens are efficacious. In most situations a single dose, administered properly, is as effective as most multiple regimens. However, in longer procedures (i.e., =3 hours) when the duration of the procedure is longer than the half-life of the chosen drug or if blood loss exceeds 1,500 milliliters, repeat dosing improves its benefit. The use of antibiotics prophylactically can result in patient hypersensitivity and the development of resistant strains of bacteria. Although careful thought is never to be discouraged, the potential benefit of controlling operative site infection with antibiotic prophylaxis usually outweighs other patient risks. The authors use a second-generation cephalosporin, which has better anaerobic coverage than first-generation cephalosporins and minimizes the loss of Gram-positive coverage that typically occurs with third-generation cephalosporins, recognizing the lack of enterococcus coverage. Patients allergic to penicillin have an 8% risk of cross-reactivity with cephalosporins, but anaphylaxis risk is estimated at 0.0001% to 0.1% in non–penicillin-allergic patients to 0.02% in penicillin-allergic patients. Doxycycline or metronidazole represents an excellent alternative in patients undergoing abdominal or vaginal hysterectomy. Although the benefit of antibiotic prophylaxis has not been demonstrated in patients undergoing laparoscopy-assisted hysterectomy, it would seem prudent to use these drugs. The recommendation of prophylaxis for other procedures varies (Table 44.12). Specific prophylaxis for those women at risk for endocarditis is imperative (Table 44.13).

Surgeon Related	Patient Related
Preoperative Stay	Age
Preparation	Nutritional Status
Patient	Diabetes
Staff	Renal Insufficiency
Incision	Hepatic Insufficiency
Placement	Radiation Therapy
Method	Chemotherapy
Hemostasis	Hypoxemia

Experience	

TABLE 44.11. *Infection risk factors*

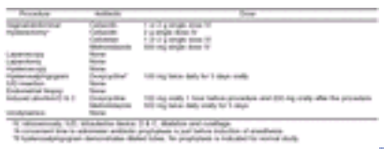

TABLE 44.12. *Antimicrobial prophylactic regimens by procedure*

TABLE 44.13. *Prophylactic regimens for prevention of endocarditis in susceptible patients undergoing genitourinary or gastrointestinal procedures.*

Treatment for Existing Infection

Prophylactic drugs are administered to patients in the absence of preoperative evidence of active infection. However, gynecologic patients with an obvious infection prior to surgery should receive an antibiotic treatment regimen appropriate for the type of infection. For example, patients with tuboovarian abscess should be treated with a broad-spectrum antibiotic regimen covering Gram-positive, Gram-negative, and anaerobic bacteria with a single or multiple drug regimen, according to patient acuity.

Postoperatively, antibiotics should be given for documented infection. It is clear that most postoperative febrile illness is not related to a documented infection. When postoperative fever, leukocytosis, and clinical picture suggest postoperative infection, an examination to identify potential sources should be performed. Source-directed therapy is appropriate. Adjunctive procedures, including CT or ultrasonographically guided drainage, may hasten recovery in patients with fluid collections or abscesses. In general, patients should receive adequate, broad-spectrum antibiotic treatment prior to surgical intervention.

THROMBOEMBOLISM

Thromboembolic phenomena, including deep venous thrombosis (DVT) and pulmonary embolism (PE), are inevitable following gynecologic surgery. A 1988 meta-analysis estimated a 6% to 7% proximal DVT risk and a 0.5% to 0.8% fatal PE risk in unprotected patients over 40 years of age undergoing abdominal surgery. This risk makes surgeons anxious because of the difficulty of diagnosing venous thromboemboli and the potential catastrophic outcome of fatal PE.

The impact and importance of postoperative thromboembolic prophylaxis is no longer a question. In a survey by the American College of Surgeons, approximately 96% of surgeons claimed they regularly used antiembolic prophylaxis. However, patient poll and chart review suggest that only one third of patients received adequate prophylaxis.

Despite the perception that venous emboli are a rare and unimportant event, all gynecologic patients should be considered at risk. The misconception regarding incidence is fostered by the high occurrence (˜50%) of DVT and PE postdischarge. Additionally, surgeons have been anxious about the potential side effects of prophylaxis, because low-dose unfractionated heparin or low-molecular-weight heparin administration has been associated with postoperative bleeding and wound hematomas. The infrequent occurrence of heparin-induced thrombocytopenia also has created some anxiety regarding prophylaxis. Finally, the initial or primary cost of thromboprophylaxis has deterred some from its use, although some have agreed that prophylaxis is cost effective. Thromboembolic phenomena can be clinically silent, whereas complications related to prophylaxis are not easily missed by the gynecologic surgeon or the patient. Furthermore, according to the Rochester Epidemiology Project and other studies, the incidence of PE and DVT is increasing as women age. Prophylaxis in the gynecologic practice will become more important during the next decade.

Despite these common misperceptions, principles of good gynecologic perioperative care demand careful attention to the role and benefit of thromboprophylaxis. The American College of Chest Physicians published guidelines regarding perioperative thromboprophylaxis. Risk factor stratification (Table 44.14) allows delineation of low risk, moderate risk, high risk, and highest risk categories, with coincident risk of developing DVT, clinical PE, and fatal PE. Proposed recommendations for thromboprophylaxis strategies ranged from aggressive mobilization in the lowest risk patients, to the use of pneumatic compression hose, elastic stockings, or pharmaceutical methods with heparin (unfractionated or low-molecular- weight). Patients at highest risk are deemed candidates for combined mechanical and heparin prophylaxis.

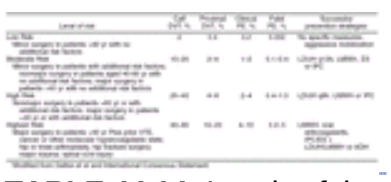

TABLE 44.14. *Levels of thromboembolism risk in surgical patients without prophylaxis*

A report suggested that the frequency of DVT following gynecologic procedures was approximately 16% (a range of 4%–38%). Fatal PE was reported in only 0.4% of the pooled sample. The cited risks for postoperative thromboembolic event included age greater than 40, history of venous embolism, surgery for cancer, and an abdominal surgical procedure. It was suggested that gynecologic oncology patients were at particularly high risk, fulfilling Virchow's triad of advanced age, cancer, and the hypocoagulable state; venostasis related to pelvic mass compression; vascular injury due to lymph node dissection; postoperative immobility; and the thrombogenic effect of chemotherapy. Importantly, the authors noted a 75% reduction in fatal PE (from 0.4% to 0.1%) with the use of appropriate thromboprophylaxis. The strongest evidence presented for thromboprophylaxis was a relative risk reduction of 64% with use of low-dose unfractionated heparin (reductive from 20% of patients to 7%). A dose response was suggested. Gynecologic cancer patients derived less protection than the noncardiac patients from the twice daily administration of low-dose unfractionated heparin. It would appear that dosing 3 times a day is more appropriate. Although of concern, the potential risk of bleeding complications was not reproducible. Importantly, aspirin use was deemed insufficient for thromboprophylaxis. Low-molecular-weight heparin has been associated with fewer bleeding complications and is being studied in comparison with low-dose unfractionated heparin. However, low-molecular-weight heparin, although extensively studied, did not meet the criteria for study inclusion by the American College of Chest Physicians, so it was not included in their recommendations.

In general, patients undergoing brief procedures require no prophylaxis except early mobilization. Patients having major gynecologic procedures for benign disease without additional risk factors should receive low-dose unfractionated heparin twice daily, low-molecular-weight heparin, or perioperative external pneumatic compression hose. For the highest risk patients, dual prophylaxis with either low-dose unfractionated heparin plus elastic stockings or external compression hose, low-dose unfractionated heparin 3 times daily, or low-molecular-weight heparin given in daily doses of at least 3,400 anti-Xa units may be useful for DVT/PE prevention. The duration of antithrombotic therapy in the highest risk patients is being studied, because there is some speculation that anticoagulation continued beyond the intermediate postoperative period may reduce the risk of thromboembolic phenomena as well as the risk of death.

NEUROLOGIC COMPLICATIONS

Avoiding serous perioperative neurologic sequelae, including stroke, seizure, altered mental status, and operation-associated nerve injury, is a vital aspect of perioperative management. Most general anesthetics adversely affect central nervous system function. Even short-term anesthetic use impairs psychomotor performance for 5 hours and sleep patterns for 24 hours or more. Women at risk for cerebrovascular disease (as evidenced by transient ischemic attacks, peripheral vascular disease, or other events) may require specific preoperative evaluation and neurologic consultation. Although an asymptomatic carotid bruit may signal the need for imaging studies or consultation, it does not, by itself, increase perioperative risk. Presurgical neurologic and radiologic evaluation, extracranial carotid endarterectomy, systemic anticoagulation, and platelet inhibition are some of the potential perioperative risk-sparing procedures to be considered. Central nervous system function is important for those women with arterial disease who are at risk for other thrombotic events and, regardless of risk, the adverse effect of perioperative hypotension (even of short duration) should be avoided. The overall risk of recurrent stroke approaches 3.0% but, fortunately, the risk of stroke is 0.2% to 0.7% in those with no such history.

Cerebral blood flow is unstable and brain metabolism is depressed for 6 to 8 weeks following a completed stroke, making it prudent to avoid any significant elective

operations during this interval. The risk of a second infarct may approach 20%, and the mortality rate is high (˜25%). Preoperative central nervous system (CNS) scanning may assist in determining the time of resolution of the initial infarct, when operative procedures are less likely to result in repeated infarct. Emergency procedures in those at risk for CNS infarct should completed in a perioperative environment that maintains an elevated blood pressure and avoids events that may increase the risk of CNS hypoperfusion.

Vertebral basilar ischemic episodes are associated with a lower perioperative stroke risk than is carotid ischemia. Although perioperative neurologic evaluation may be appropriate, these patients usually are managed medically, with minimal surgical risks.

Operative Neurologic Deficits

Nearly 2.0% of gynecologic procedures are associated with postoperative lower extremity neurologic deficits, regardless of attention paid to preoperative care or positioning. Multiple nerves are at risk, regardless of positioning, surgical duration, or approach. Mechanisms of nerve injury include prolonged compression (e.g., femoral nerve), excessive traction, stretch (e.g., sciatic nerve) or transection (e.g., lateral femoral cutaneous nerve). Regardless of the extent of injury, attention to positioning, or retractor placement, these problems occur and are managed by evaluation and rehabilitation. Fortunately, most resolve. Attention to minimizing hip flexion and external rotation potentially lessens the risk of traction injury. Ilioinguinal and iliohypogastric nerve injuries can be diagnosed with relief after local infiltration of nerve block or excision.

SUMMARY POINTS

- The primary goal of the pelvic surgeon involves prospective preoperative recognition, evaluation, and management of existing medical comorbidities. Every pelvic surgeon should commit to the development of operative techniques that form a surgical skill set geared to the safe completion of indicated surgical procedures.
- Appropriate consultation should be sought if the level of qualification does not fit the necessary procedure.
- A thorough, multisystem physical examination is an essential part of the preoperative evaluation to detect important coexisting disease. The suspicion or diagnosis of coexistent morbidities which have not been diagnosed previously requires preoperative investigation. Laboratory and radiologic investigation should be conducted patiently and procedures directed in a safe, cost-effective manner.
- Coexisting or occult cardiac disease represents a significant contributor to perioperative morbidity. Particular attention to the detection, evaluation, and management of cardiac risk factors including CAD, hypertension, congestive heart failure, valvular disease, arrhythmias, and hypercholesterolemia is imperative. Particular attention to ACLS guidelines is important. Perioperative assistance by personnel experienced in cardiac care should be invoked when necessary.
- Perioperative pulmonary care is an important concern. The procedure should be designed to minimize pulmonary risks when possible. Postoperative attention to pulmonary toilet may render the best possible outcome.
- Perioperative renal failure is associated with high morbidity and mortality. No intervention, including prophylactic low-dose dopamine, mannitol, or furosemide therapy, has been shown to be of any benefit in reducing the incidence of perioperative renal insufficiency.
- The optimal surgical incision is chosen according to the procedure done, existing comorbidity, disease process, and patient preference. Appropriate preoperative skin antisepsis is necessary and, in combination with intravenous antimicrobial agents, will decrease the incidence of wound infection. Good surgical technique is mandatory for wound health and maximizing patient outcome.
- Classically, bowel preparation (mechanical, with or without antibiotic) is undertaken prior to many gynecologic procedures. Nasogastric suction has not been shown to lessen the risk of ileus, and only 10% of patients require insertion of a nasogastric tube postoperatively. Most patients can be managed without nasogastric suction.
- Proper use of prophylactic antibiotics lessens infectious risks in many pelvic procedures. Single-agent broad-spectrum antibiotic use, such as cephalosporin, doxycycline, or metronidazole, appears to be safe and effective for women undergoing abdominal or vaginal hysterectomy.
- The American College of Chest Physicians published guidelines regarding perioperative thromboprophylaxis. Patients at low risk should be mobilized aggressively postoperatively. Those at moderate and high risk should use pneumatic compression hose, elastic stockings, or pharmaceutical methods. Patients at highest risk may also benefit from combined mechanical and pharmaceutical prophylaxis.
- Approximately 2% of gynecologic procedures are associated with postoperative lower extremity neurologic deficits. Special attention should be paid to patient positioning, surgical duration, proper use of surgical retractors to prevent excessive traction and stretch, and careful operative techniques.

INTRODUCTION

Pelvic organ prolapse is a condition unique to the field of obstetrics and gynecology. It has helped define our specialty and continues to lie in the exclusive province of the obstetrician-gynecologist. Although often discussed as a purely mechanical phenomenon, prolapse is associated with significant functional problems. Stress urinary incontinence, micturition difficulties, and problems with defecation are all associated with prolapse. These functional derangements are not simply results of altered support of the bladder and rectum but have to do with the innervation and musculature of the urinary and intestinal tracts, as well. This chapter reviews the structural and functional aspects of prolapse necessary to understand and manage these conditions.

PELVIC FLOOR AND THE NATURE OF GENITAL PROLAPSE

The pelvis lies at the bottom of the abdominopelvic cavity, and the pelvic floor closes the canal within the bony pelvis (Fig. 45.1). The pelvic floor forms a supportive layer that prevents the abdominal and pelvic organs from falling through the opening within the pelvic bones. Its structural role can best be appreciated by considering a surgeon's hand placed through a transabdominal incision that pushes caudally on the pelvic organs. All of the structures that prevent this hand from passing through the pelvic canal constitute the pelvic floor. In addition to this supportive role, the pelvic floor must accommodate conception and parturition, while also controlling storage and evacuation of urine and feces. To understand the pelvic floor and genital prolapse, it is necessary to understand the mechanical strategies that evolution has put in place to prevent downward descent of the pelvic organs, as well as the process by which genital prolapse occurs. As Victory Bonney pointed out, the phenomenon of prolapse is similar to the maneuver that a scrub nurse uses to evert the in-turned finger of a surgical glove (Fig. 45.2). Compressing the air within the glove drives the invaginated finger outward in much the same way that increases in intraabdominal pressure force the vagina and the uterus to prolapse. It is not the weight of the uterus that is important in the development of prolapse, but rather the forces placed on the pelvic floor by increases in intraabdominal pressure.

FIG. 45.1. Sagittal section of the abdomen and pelvis shows the relation of the pelvic floor to the abdominal cavity. (From Kelly HA. *Gynecology.* Baltimore: Appleton

and Co, 1928:64, with permission.)

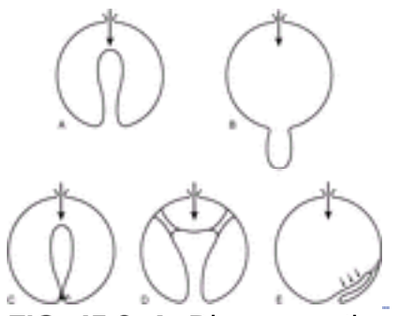

FIG. 45.2. A: Diagrammatic representation of the vagina within the abdomen shows how increases in abdominal pressure *(arrow)* force the vagina to prolapse. **B:** This prolapse may be prevented by **(C)** constricting the lower portion of the vagina, **(D)** suspending the vagina from the pelvic walls, and **(E)** forming a flap-valve closure, wherein the vagina is pinned against surrounding structures.

Two mechanical principles explain how the pelvic floor prevents prolapse (see Fig. 45.2). First, the uterus and vagina are attached to the walls of the pelvis by a series of ligaments and fascial structures that suspend the organs from the pelvic sidewalls. Second, the levator ani muscles constrict the lumina of these organs, forming an occlusive layer on which the pelvic organs may rest. It is a combination of these two factors—suspension of the genital tract by the ligaments and fasciae and closure of the pelvic floor by the levator ani—that holds the vagina over the levator ani muscles and forms a flap-valve closure. This flap-valve mechanism is instrumental in keeping the posterior cul-de-sac closed and preventing the development of an enterocele.

Epidemiology of Surgically Managed Pelvic Organ Prolapse and Urinary Incontinence

Prevalence

Olsen and colleagues reported the prevalence of surgery for pelvic organ prolapse and urinary incontinence within a defined population. They studied 149,554 women over 25 years of age who were members of the Kaiser Permanente Northwest Health Maintenance Organization. During 1995, they identified 384 women who had surgical treatment for either pelvic organ prolapse or urinary incontinence, or both of these problems. A woman's lifetime risk for needing a single operation by age 80 years was 11.1%. Among this group of women, there was great variety in types and sizes of prolapse (Table 45.1), and the overall incidence of surgery increased with age (Fig. 45.3). The higher incidence was primarily due to the increase in surgery among older women for prolapse rather than for incontinence. Repeated operation was remarkably common, with 29.2% of patients requiring a second surgery. There is increasing risk of pelvic organ prolapse with subsequent parity (Fig. 45.4), and the study of the obstetric factors that cause pelvic floor injury has been neglected.

TABLE 45.1. *Preoperative prolapse severity according to operative site*

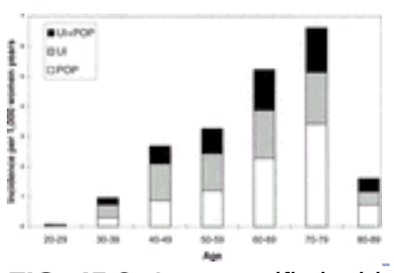

FIG. 45.3. Age-specific incidence of surgery for pelvic organ prolapse or urinary incontinence. (From Olsen AL, Smith VJ, Bergstrom JO, et al. Epidemiology of surgically managed pelvic organ prolapse and urinary incontinence. Obstet Gynecol 1997;89:501, with permission.) UI, urinary incontinence; POP, pelvic organ prolapse.

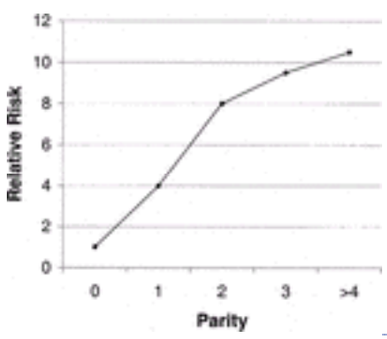

FIG. 45.4. Increase in risk of needing surgery for prolapse with increasing parity. (From Mant J, Painter R, Vessey M. Epidemiology of genital prolapse: observations from the Oxford Family Planning Association study. Br J Obstet Gynaecol 1997;104:579–585, with permission.)

These data show the remarkable frequency with which women require surgery for incontinence and prolapse but certainly underestimate the prevalence of these problems within the population. One would expect that many women who have prolapse and incontinence choose not to have surgery, so these data represent only those women operated on. Therefore, serious consideration needs to be given these conditions.

Vaginal Delivery and Pelvic Organ Prolapse

It is commonly accepted that vaginal delivery increases the likelihood that pelvic organ prolapse will develop. Mant, using the Oxford family planning cohort, found that the likelihood of a woman developing prolapse increased approximately eight-fold after two vaginal births and about 12-fold with four or more vaginal deliveries. Timonen and co-workers compared information concerning parity in 1,422 patients operated on for prolapse in their hospital between 1955 and 1965 with national parity data in Finland; these data are displayed in Figure 45.5. Only 4% of women with prolapse are nulliparous, while among the Finnish population 13.3% of women are nulliparous. In addition, they evaluated the size of the largest infant delivered by women in whom prolapse subsequently developed (Fig. 45.6) and compared that with birthweight information for Finland (N = 52,955) during the same period (1957–1958). These data lend some sense of the degree to which vaginal birth influences pelvic organ prolapse.

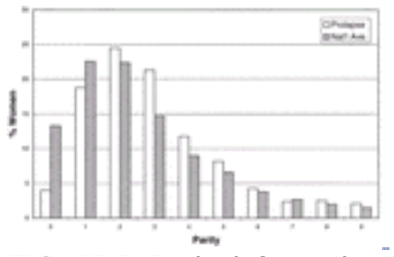

FIG. 45.5. Parity information for women operated on for pelvic organ prolapse compared with national average. (From Timonen S, Nuoranne E, Meyer B. Genital prolapse: etiological factors. Ann Chir Gynaecol Fenn 1968;57:363, with permission.)

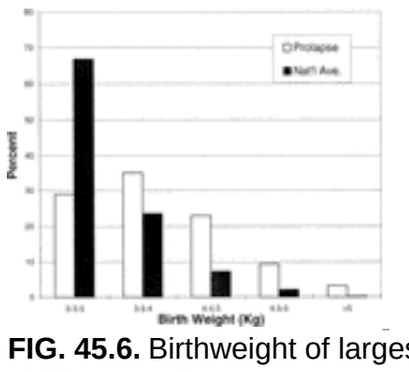

FIG. 45.6. Birthweight of largest infant delivered vaginally to women with pelvic organ prolapse and normative birthweight data for Finland. (From Timonen S, Nuoranne E, Meyer B. Genital prolapse: etiological factors. Ann Chir Gynaecol Fenn 1968;57:363, with permission.)

BASIC ANATOMY AND PATHOPHYSIOLOGY OF THE PELVIC FLOOR

Viscerofascial Layer

The topmost layer of the pelvic floor is a combination of the pelvic viscera and their connections to the pelvic walls and will be referred to as the viscerofascial layer. Although it is common to speak of the fasciae and ligaments as separate from the pelvic organs, unless these fibrous structures have something to attach to (e.g., the pelvic organs) they have no structural integrity.

The uterus and vagina are attached to the pelvic walls by the fibrous tissue referred to as the *endopelvic fascia.* It forms a sheetlike mesentery that is continuous from the uterine artery to the point at which the vagina fuses with the levator ani muscles as it passes through the urogenital hiatus. The tissues that connect the uterus are called the *parametria*, and those that attach to the vagina are the paracolpium. Although they are given regional names, they are actually one continuous entity. The parametria comprise the cardinal and uterosacral ligaments. These are two different elements of the same tissue (Fig. 45.7). The uterosacral ligaments are the visible and palpable medial margin of the cardinal–uterosacral ligament complex. As is true of the remainder of the parametria, they contain smooth muscle, nerves, and blood vessels and are not the same type of tissue seen in the fascia of the rectus abdominus muscle, which is dense regular connective tissue.

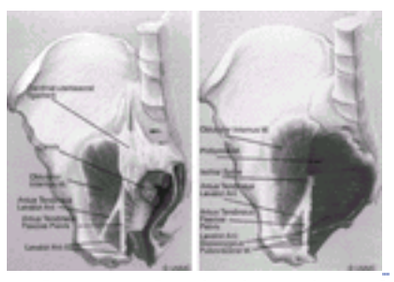

FIG. 45.7. Sagittal section of the pelvis shows the support structures of the genital tract. **A:** The bladder, urethra, and uterine corpus (above the cervix) have been removed. **B:** All of the pelvic organs have been removed to show the levator ani muscles.

Opposite the external cervical os, the sheet of tissue that attaches the genital tract to the pelvic wall arbitrarily changes name from the parametrium to the paracolpium. The paracolpium has two portions (Fig. 45.8). The upper portion (i.e., level I) consists of a relatively long sheet of tissue that suspends the vagina by attaching it to the pelvic wall in an area similar to that of the cardinal–uterosacral ligament complex. It is this portion that prevents the upper vagina from prolapsing after the uterus has been removed.

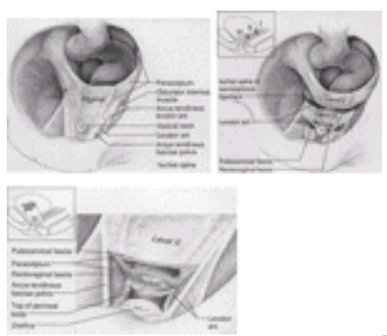

FIG. 45.8. Support structures of the vagina after hysterectomy. The bladder has been removed to expose the vagina. **A:** The paracolpium. **B:** The different levels of support structures. **C:** The details of the pubocervical and rectovaginal fasciae after a wedge of vagina and urethra has been removed **(inset).** (From DeLancey JOL. Anatomic aspects of vaginal eversion after hysterectomy. Am J Obstet Gynecol 1992;166:1717, with permission.)

In the midportion of the vagina, the paracolpium attaches the vagina laterally and more directly to the pelvic walls (i.e., level II). This stretches the vagina transversely between these two lateral attachments (see Fig. 45.8B). This arrangement has functional significance. The structural layer that supports the bladder (i.e., pubocervical fascia) is composed of the anterior vaginal wall and its attachment through the endopelvic fascia to the pelvic wall. The term *fascia* is used commonly, but this is not a layer separate from the vagina. A term has been proposed for this layer, the *fibromuscular layer* of the vagina, that contains both smooth muscle and connective tissue. We use these terms interchangeably in the remainder of the text, because the surgeon generally refers to this layer as *fascia.* Similarly, the posterior vaginal fibromuscular layer and its connection to the pelvic walls forms the restraining layer that prevents the rectum from protruding forward. In the distal vagina (i.e., level III), the vaginal wall is attached directly to surrounding structures without any intervening paracolpium.

The support that lies under the urethra has special importance for urinary incontinence. The endopelvic fascia in this region is better developed and is tougher than the tissues of the upper vagina, in the area under the bladder. This provides better support for the vesical neck than for the bladder. This layer of suburethral endopelvic fascia attaches laterally to the arcus tendineus fasciae pelvis and also to the medial border of the levator ani muscles. Loss of this normal support of the urethra at the vesical neck is responsible for stress incontinence of urine.

Levator Ani Muscles

Below the uterus, vagina, bladder, and rectum lie the levator ani muscles (see Fig. 45.7B). The medial portion of the levator ani muscles frequently has been called the *pubococcygeus*, but the *puboviscera*l *muscle* is a better term because it extends from the pubic bone and attaches to the vagina and rectum, with only a few

insignificant fibers ending in the coccyx (Lawson, 1971). This strong, robust, fatigue-resistant striated muscle starts on the inner surface of the pubic bone near the midline and passes behind the rectum, to return to the pubic bone on the other side. The lateral walls of the vagina are attached to this muscle, which then inserts into the anus in the intersphincteric groove between the internal and external anal sphincter, as well as passing around its dorsal surface in a slinglike loop. The normal resting tone of this muscle squeezes the rectum, vagina, and urethra closed by compressing them against the pubic bone. The pubo-rectalis muscle originates lateral to the pubovisceral muscle and forms a sling behind the rectum at the anorectal angle. Arising from the lateral pelvic walls (at the tendineus arch of the levator ani muscles) is the iliococcygeal muscle that forms a horizontal shelf on which the upper pelvic organs rest.

Interaction Between the Muscles and Fasciae

The interaction between the pelvic floor muscles and ligaments is critical to proper function. As long as the pelvic floor musculature functions normally, the pelvic floor is closed, and the ligaments and fasciae are under no tension. They simply act to stabilize the organs in their position above the levator ani muscles. When the pelvic floor muscles relax or are damaged, the pelvic floor opens. The vagina lies between the high intraabdominal pressure and low atmospheric pressure, where it must be held in place by the ligaments. Although the ligaments can sustain these loads for short periods, if the pelvic floor muscles do not close the pelvic floor, then it is more likely that the connective tissue will become damaged and eventually fail to hold the vagina in place.

ISSUES RELATING TO INCONTINENCE

The mechanisms of urinary and fecal incontinence are more difficult to explain than the mechanical basis of genital tract support, and they are not understood entirely. As is true for genital prolapse, urinary continence depends on both support of the urethra and its ability to remain closed as a result of its innate constriction. Normal support of the urethra allows it to be compressed closed by increases in abdominal pressure (i.e., pressure transmission). Although both support of the urethra and pressure transmission are important for stress urinary continence, they are not the only factors involved. Stress incontinence may occur in women with normal urethral support of the vesical neck and urethra but with inadequate constriction by the muscles within the urethral walls. If the a-adrenergically innervated smooth muscle of the vesical neck does not function normally and the vesical neck is open, this is referred to as type III incontinence. This type of incontinence is differentiated from types I and II incontinence, which involve different degrees of support loss. When the proximal urethra is patent at rest, urine already lies below the area where pressure transmission has its effect and, therefore, bypasses this mechanism of continence.

The support of the urethra is not due exclusively to fascial structures; active muscle contraction plays an important role in urethral support. In addition, the musculature of the urethra contracts during a cough and increases urethral closure. Therefore, neuromuscular mechanisms play an important role in the pathophysiology of stress incontinence and must be considered in understanding this group of diseases.

By the same token, anal continence can be explained only partially by the mechanical structures that support the anorectum and by preservation of the anorectal angle through contraction of the puborectalis. Anal incontinence can occur with normal support of the anorectum and preserved anorectal angle. There are other important factors in maintaining anal continence, including normal integrity of the muscles of the anal sphincter complex and their innervation.

CAUSES OF PELVIC FLOOR DAMAGE

Several factors influence the development of genital prolapse and urinary incontinence (Table 45.2). The inherent strength of the muscles and connective tissue of an individual, damage to these structures that occurs with birth, the rate at which they deteriorate with age, and the loads that they are subjected to during life all play a role in the development of genital prolapse and incontinence. Understanding the interplay among these various factors is critical to appreciating the pathophysiology of genital prolapse.

Inborn strength of connective tissue and muscle
Loss of connective tissue strength
Damage at childbirth
Deterioration with age
Poor collagen repair
Loss of levator function
Neuromuscular damage during childbirth
Metabolic diseases that affect muscle function
Increased loads on the supportive system
Prolonged lifting
Chronic coughing from chronic pulmonary disease
Disturbance of the balance of the structural parts
Alteration of vaginal axis by urethral suspension
Failure to reattach the uterosacral—cardinal ligament complex at hysterectomy

TABLE 45.2. *Factors involved in pelvic organ prolapse*

Although it is obvious that the native strength of the levator ani muscles and endopelvic fascia plays an important role in prolapse, the changes that vaginal birth causes in the pelvic floor deserve specific examination. Distension of the vagina during vaginal birth usually is blamed for prolapse, yet the cervix undergoes a much greater degree of dilation during parturition but recovers sufficiently so that forceful dilation is needed if dilation and curettage is done later in life. Damage to the levator ani muscles and their innervation is common during vaginal birth, and loss of the muscle's ability to support the pelvic organs and unload the ligaments may be partially responsible for the breakage and elongation of the ligaments later in life.

Certainly, some damage to the connective tissue of the parametria and paracolpium occurs during childbirth and can contribute to subsequent prolapse. Although usually thought of as stretching, prolapse also includes instances in which the connective tissue supports rupture. This acute injury mechanism is much more likely than stretching, because usually it is rupture that occurs with overload of other ligaments in the body (e.g., knee). Chronic injury through attenuation of the endopelvic fascia with age contributes and explains why prolapse occurs many years after childbirth. Failure of connective tissue to heal the many minor injuries that occur from day to day may also play a role. Age and chronic disease may cause weakening of the tissues, and heavy lifting or chronic coughing may cause progressive damage. This wear and tear on the connective tissues depends on the magnitude of the stresses placed on them, as well as how well damage is repaired by the body.

DIAGNOSIS AND CLASSIFICATION

Determining the type and severity of prolapse in any given patient is a skill that should be acquired through practice and careful observation. Characterizing the degree of support loss as normal or abnormal depends on comparisons with the findings in normal multiparous women in the examiner's experience. It is, therefore, helpful to perform the same examination on a sufficient number of asymptomatic patients without prolapse to become familiar with the range of normal support. In performing an examination to determine the type and severity of prolapse, the practitioner has two important points to consider:

- Examination must be made with the patient straining forcefully enough that the prolapse is at its greatest.
- The examiner must examine each element of support independently.

If a patient is not able to strain sufficiently in the lithotomy position so that the prolapse is at its largest, examination in the standing position may be necessary. This is a critical point, because it is only when the prolapse can be seen in its fullest extent that all of its various elements can be assessed. If the entire extent of the prolapse is not observed, some element may be overlooked. For example, a large cystocele may be seen initially when the patient strains. It may be only with continued effort by the patient that an enterocele and prolapse of the vaginal apex can be demonstrated. To make sure all aspects of the prolapse can be evaluated, the patient should be asked how large her prolapse is at its largest, and the physician should persist in the examination until that size is achieved. Once the prolapse is visible, the elements of the vagina and pelvic organs that have prolapsed can be evaluated. The examination should then focus on what specific defects in support are present and how severe the prolapse is, and there should be some evaluation of the cause of the prolapse. Once the prolapse is maximally developed, the physician should begin by identifying how much the anterior wall, cervix, and posterior wall have prolapsed. The anterior and posterior walls should be examined separately by retracting the opposite wall with the posterior half of a vaginal speculum. A stepwise, site-specific examination is important because a large cystocele, for example, may hold a potential rectocele in place and, therefore, hide it. If a rectocele is not recognized preoperatively, its repair may be overlooked and the defect can become symptomatic postoperatively. These observations have been confirmed on dynamic colpoproctography imaging studies of the pelvic floor, with contrast placed in the bladder and rectum while the patient strains in the standing position. If the patient has a full bladder when imaging is performed, a rectocele can be obstructed and will not be evident until the patient empties her bladder. Care must also be taken to assess how much of the loss of support is from a defect of the apical (level 1) support. It is not uncommon to correct the apical defects and find that much of what was considered a cystocele and rectocele have been corrected. Examination while under anesthesia is used to evaluate pelvic masses, but it is not the optimal time to identify defects caused by prolapse because of the patient's inability to perform the Valsalva maneuver and because of loss of normal levator tone.

EVALUATING INDIVIDUAL ELEMENTS OF SUPPORT

Anterior Vaginal Wall

Examination of the anterior vaginal wall should establish the status of urethral support, as well as bladder support. The urethra is fused with the lower 3 to 4 cm of the vaginal wall, and abnormal support in this region is properly referred to as a *urethrocele* (Fig. 45.9). Defective support of the upper portion of the vagina is called a *cystocele*, because the bladder lies adjacent to this portion of the vaginal wall (Fig. 45.10). The urethrovesical crease, normally visible on examination, forms the line of demarcation between these two areas of support (Fig. 45.11). When support of the entire anterior wall is defective, the term *cystourethrocele* is used.

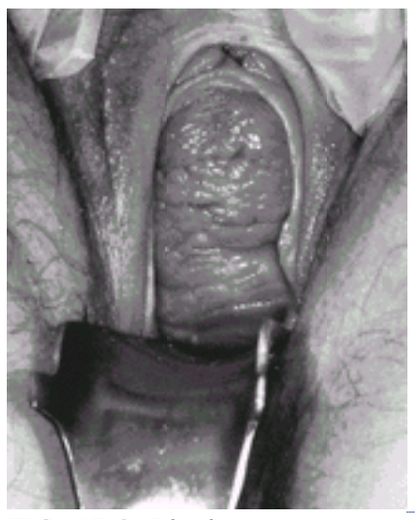

FIG. 45.9. Displacement cystourethrocele with intact rugal folds caused by lateral detachment of the pubocervical fascia. (Copyright © DeLancey, 1993.)

FIG. 45.10. Distension cystourethrocele caused by midline failure of the pubocervical fascia. (Copyright © DeLancey, 1993.)

FIG. 45.11. Angulation in the anterior vaginal wall, called the urethrovesical crease *(arrow)*, indicates the location of the urethrovesical junction. (Copyright © DeLancey, 1993.)

The anterior vaginal wall should be above the hymenal ring during straining. Descent of the lower anterior vaginal wall to the level of the hymenal ring during straining is characteristic of a urethrocele and is seen often in patients with stress urinary incontinence. This is due to loss of urethral support and corresponds to the loss of the posterior urethrovesical angle on radiographic studies of patients with stress incontinence. The lower anterior vaginal wall is mobile in all women and may move significantly in continent multiparas. Therefore, motion of this region does not establish stress incontinence but rather indicates the degree to which the support of the urethra has failed. Descent below the hymenal ring is definitely abnormal and indicates a cystourethrocele whether or not stress incontinence is present.

The anterior vaginal wall above the urethrovesical crease usually lies in a flat plane at about a 45-degree angle from the horizontal (see Fig. 45.11). Descent below the level of the hymenal ring is significant. This descent can be caused by one of three entities:

- Separation of the paravaginal attachment of the pubocervical fascia from the white line due to detachment from the ischial spine
- Loss of the vagina's attachment to the cervix
- Tearing in the pubocervical fascia that results in herniation of the bladder through this layer

Uterus and Vaginal Apex

The vagina and cervix are fused with one another, and prolapse of the uterine cervix is associated invariably with prolapse of the upper vagina, as well. When the uterus descends below its normal level, the term *uterovaginal prolapse* is appropriate, although *uterine prolapse* commonly is used. In patients in whom the uterus has been removed, descent of the vaginal apex below its normal position in the pelvis is referred to as *prolapse of the vaginal apex*, and when the vagina turns entirely inside out, the term *vaginal eversion* is used.

The location of the cervix customarily is used to gauge the severity of uterine prolapse (Fig. 45.12). Its position relative to the hymenal ring should be noted while the prolapse is at its greatest. If the cervix is not visible because of a cystocele or rectocele, then its location may be palpated while having the patient strain. When the cervix descends to within 1 cm of the hymenal ring, there is a significant loss of support. In instances in which the uterus is not necessarily going to be removed, uterine support should be tested before it is assumed that the uterus is well supported. This can be done by grasping the cervix with a tenaculum or ring forceps and applying

traction until it stops descending. Occult prolapse, in which the cervix comes below the hymenal ring, can be detected in this way.

FIG. 45.12. Uterine prolapse with the cervix extending 3 cm below the hymen. (Copyright © DeLancey, 1993.)

In addition to determining how far the cervix descends, its length should be measured. Cervical elongation is frequent in individuals with prolapse, and the uterine corpus often may lie in its normal location. Awareness of cervical elongation preoperatively will allow the surgeon to proceed expeditiously with the hysterectomy, rather than hoping with every pedicle that the uterine arteries will soon appear.

Posterior Vaginal Wall

The posterior vaginal wall is the site of both rectoceles and enteroceles. Evaluation and correction of these two problems challenge even the most experienced gynecologic surgeon, and they are probably the most difficult to understand of all pelvic support defects. Because dyspareunia can follow repair, correction of asymptomatic posterior wall defects is not without risk. On the other hand, having a rectocele or enterocele develop after vaginal hysterectomy and anterior colporrhaphy is an undesirable outcome, and careful consideration of the support of the posterior vaginal wall is important.

Three questions should be asked by the physician when examining the posterior wall.

- Is it supported normally?
- If not, is it a true rectocele or a pseudorectocele?
- Is an enterocele present?

A rectocele is present when the anterior rectal wall and overlying vagina protrude below the hymenal ring. An enterocele exists when the cul-de-sac becomes distended with the intestine and bulges the posterior vaginal wall outward. There are also occasions in which the posterior wall appears to bulge into the vagina, not because of poor support of the rectal wall but because of a deficiency in the perineal body. This has been referred to by Nichols and Randall as a pseudorectocele and can be differentiated easily from a true rectocele because the anterior rectal wall contour is normal on rectal examination. Another type of pseudorectocele may be suspected when there is apical descent of the upper vagina or cervix and apparent loss of posterior support. However, often when the normal apical support is restored (by temporarily supporting it with ring forceps in the office or after surgical repair of the apical descent), a suspected rectocele is not evident. This is important to determine preoperatively, because loss of tone of the levator ani muscle and anal sphincter muscle with muscle paralyzing agents during anesthesia make it harder to establish the existence of a true rectocele.

Enterocele

There is always a cul-de-sac between the upper vagina and the rectum. This allows a culdocentesis to be performed and a colpotomy to be made through the posterior vaginal wall at the beginning of a vaginal hysterectomy. The peritoneal pouch normally extends 3 to 4 cm beyond the junction of the vagina and cervix. Therefore, the absence of an enterocele in normal women must be explained by factors that keep the cul-de-sac closed rather than by the absence of a peritoneal space between the upper vagina and rectum. It is the suspension of the upper vagina near the sacrum in a position where it may rest over the rectum and intact levator plate that keeps this space closed.

There are two types of enteroceles: pulsion enterocele and traction enterocele. A pulsion enterocele exists when the cul-de-sac is distended and appears as a bulging mass that is inflated by increases in abdominal pressure. This may occur with either the vaginal apex or uterus well suspended, in which case the cervix or vaginal apex is at a normal level and the enterocele dissects between the vagina and the rectum. When an enterocele is associated with prolapse of the uterus or vaginal apex, then the prolapse and enterocele occur together.

A traction enterocele represents a situation in which prolapse of the uterus pulls the cul-de-sac peritoneum down with it, but there is no bulging or distension of the cul-de-sac when abdominal pressure rises. This condition usually is found at the time of vaginal hysterectomy when the cervix has prolapsed. It represents a potential enterocele rather than an actual enterocele, because there is no bulging mass separate from the uterus.

Unlike uterine prolapse, which is obvious because of the protrusion of the easily recognized uterine cervix, enteroceles and rectoceles rarely are evident on examination. Therefore, the key to detecting an enterocele lies in actively looking for it whenever a patient who has prolapse is examined. Detection of an enterocele is performed best in the awake, straining patient by noting a mass of small intestine between the rectum and vagina; it may not be suspected in a supine individual at rest.

Anatomically, an enterocele extends from the apex of the vagina downward, whereas a rectocele typically begins in the lower portion of the vagina. An enterocele sometimes is evident as a bulge that overrides the more caudal rectocele (Fig. 45.13). Careful inspection of the posterior vaginal wall with a speculum retracting the anterior wall sometimes can suggest that an enterocele is present. The key to detecting a pulsion enterocele lies in palpating the small bowel between the vagina and rectum during rectovaginal examination, with the patient straining so that the prolapse is protruding. To do this, an index finger is placed in the rectum and a thumb is placed in the vagina. Then, with the patient straining, the rectovaginal space may be palpated to detect the bulge of the enterocele and the presence of small bowel, omentum, or large bowel.

FIG. 45.13. “Double hump” sign of an enterocele overriding a rectocele. (Copyright © DeLancey, 1993.)

Rectocele

The hallmark of a typical rectocele is the formation of a pocket that allows the anterior rectal wall to balloon downward through the introitus. When a rectal examination is performed with the prolapse fully developed, a rectocele exists if there is an extension of the rectal lumen below the axis of the anus (Fig. 45.14). This not only provides the diagnosis but also illustrates the mechanism by which rectoceles create their symptoms. As long as the anterior rectal wall has a smooth contour and no sacculation, even though it may be more mobile than normal, stool will pass through the anus. However, when a pocket develops as the patient strains, stool becomes trapped in it, and difficulty with evacuation can occur.

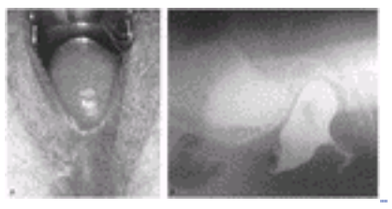

FIG. 45.14. A: Pelvic examination shows a rectocele. **B:** Lateral bead chain cystourethrogram with the patient supine and with contrast in the vagina and rectum shows a protruding rectocele. (Copyright © DeLancey, 1993.)

Prolapse Subsequent to Hysterectomy

Special consideration should be given to patients who have prolapse after hysterectomy to assess whether or not prolapse of the vaginal apex is present. When the uterus is in situ, the cervix calls attention to the poor support of the cervix and upper vagina. In instances of posthysterectomy vaginal prolapse, descent of the vaginal apex is more easily missed. If it is overlooked and an anteroposterior colporrhaphy is not accompanied by suspension of the vaginal apex, the colporrhaphy will fail to cure the apical prolapse, and the problem is not corrected. Overlooking apical support loss also can lead to overly aggressive excision of vaginal tissues during anteroposterior colporrhaphy and a shortened vagina. Examination of patients who have previously had a hysterectomy should include a specific effort to determine the location of the vaginal apex when the prolapse is at its largest. The apex is identified by the vaginal scar at the hysterectomy site (Fig. 45.15). Vaginal prolapse is present when the hysterectomy scar lies below the level of the hymenal ring. If the apex descends to within the lower one third of the vagina with straining, a significant deficit in support of the apex is present, and the vagina should be resuspended during repair.

FIG. 45.15. Eversion of the vagina after hysterectomy. Note that the vaginal apex, indicated by the puckered scar where the cervix had been removed, lies below the hymenal ring. (Copyright © DeLancey, 1993.)

PELVIC ORGAN PROLAPSE CLASSIFICATION

Several classification systems have been used to describe the sizes and types of pelvic organ prolapse in an individual woman. Because many of these systems use similar words to indicate different degrees of prolapse, confusion has arisen concerning the size of prolapse. For example, grade 2 uterine prolapse in some systems indicates that the cervix descends halfway between its normal position and the introitus. In other classifications, grade 2 can mean that one half of the uterus is outside the introitus. A system that standardizes terminology has been adopted by several groups, including the International Continence Society, the American Urogynecologic Society, and the Society of Gynecologic Surgeons. This standardized terminology (Pelvic Organ Prolapse Quantification, or POP-Q) provides a system that can describe the type of prolapse, as well as quantify the degree of prolapse in each area. Although this standardized system seems somewhat cumbersome when described in writing, in actual practice it is quite simple. The following section first considers the measurements that describe the type and size of prolapse and then discusses the measurements concerned with the changes in the urogenital hiatus in the levator ani muscles through which the prolapse descends.

Measurements Describing Prolapse Type and Size

To describe the nature of a woman's prolapse, it is necessary to do the following: (a) document what part or parts of the genital tract have prolapsed and (b) indicate how far down each part of the vaginal wall or cervix has descended.

Prolapse description must include a consideration of anterior vaginal wall descent, posterior wall descent, and uterine descent (or prolapse of the vaginal apex after hysterectomy). Furthermore, because different parts of the anterior wall might suffer support damage, the system provides for determining the status of each level of vaginal support. For example, the distal anterior vaginal wall adjacent to the urethra may be well supported, while the portion of the vagina under the bladder may prolapse. This system addresses the need to make individual assessments of different parts of the vaginal wall.

The three levels of vaginal support (see Fig. 45.8) must be assessed, corresponding to the different anatomic regions of vaginal support.

- Level I: support of the vaginal apex and uterus
- Level II: support of the bladder and rectum
- Level III: support of the urethra and perineal body

In levels II and III, the anterior and posterior vaginal wall are considered separately, while in level I the cervix (or vaginal apex) and posterior fornix must be assessed.

To understand the POP-Q classification system, refer to Figure 45.16. The size and type of prolapse are measured by determining the location of a series of points on the anterior and posterior vaginal walls relative to the hymenal ring. Points at each of the three levels are measured. Positive numbers reflect measurements of the vaginal points that have prolapsed below the level of the hymen and negative numbers reflect measurements above the hymen. It should be noted that this descriptive scheme does not distinguish between rectocele and enterocele but simply provides a way to quantify the amount of vaginal wall descent in each specific area. Additional examination and written comments concerning these important differences should be made.

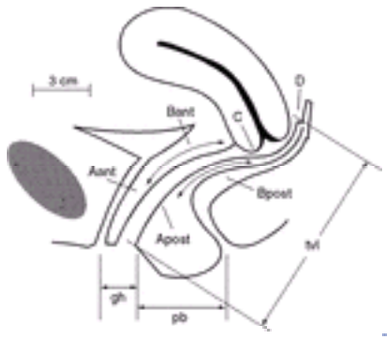

FIG. 45.16. Six sites (points *A* $_{ant}$, *B* $_{ant}$, *C, D, B* $_{post}$, and *A* $_{post}$), genital hiatus *(gh)*, perineal body *(pb)*, and total vaginal length *(tvl)* used for pelvic organ support quantitation.

A summary of the measurements obtained during the POP-Q examination is noted in Table 45.3.

Stage 0	No prolapse is demonstrated. Points A_{ant}, A_{post}, B_{ant}, and B_{post} are all at −3 cm and either point C or D is between − total vaginal length (tvl) cm and − (tvl–2) cm (i.e., the quantitation value for point C or D is ≤ − [tvl–2] cm)
Stage I	The criteria for stage 0 are not met, but the most distal portion of the prolapse is >1 cm above the level of the hymen (i.e., its quantitation value is >−1 cm)
Stage II	The most distal portion of the prolapse is between 1 cm above and 1 cm below the plane of the hymenal ring (i.e., its quantitation value is ≥−1 cm but ≤+1 cm)
Stage III	The most distal portion of the prolapse is >1 cm below the plane of the hymen but protrudes no farther than 2 cm less than the tvl in centimeters (i.e., quantitation value is >+1 cm but <+ [tvl–2] cm)
Stage IV	Essentially, complete eversion of the total length of the lower genital tract is demonstrated. The distal portion of the prolapse protrudes to at least (tvl–2) cm (i.e., its quantitation value is <−1 cm)

TABLE 45.3. *Stages of pelvic organ prolapse based on measurement of specific sites*

I. Vaginal points (vaginal profile): patient straining maximally
   A. Level I: apex and cervix: points C and D (D is omitted if patient has had a hysterectomy)
   B. Level II: midvaginal points
      1. Anterior wall: B $_{a}$ or B $_{ant}$
      2. Posterior wall: B $_{p}$ or B $_{post}$
   C. Level III: distal vagina (perineum and urethrovesical neck)
      1. Anterior wall: A $_{a}$or A $_{ant}$
      2. Posterior wall: A $_{p}$ or A $_{post}$
      3. External measurements: obtained with patient at rest and again straining
   A. Genital hiatus: length gh
   B. Perineal body: length: pb
II. Internal digital measurements: obtained with patient at rest with vaginal apex restored to normal position
   A. Total vaginal length: tvl

To measure the lower third of vaginal support (level III), the location of a pair of points that normally lies 3 cm above the hymenal ring is assessed. Points measured at level III are called *points A.* One can imagine marking these vaginal points 3 cm above the hymen with a marker and then recording the position of these points in relation to the hymen with the subject straining maximally. Anteriorly, this corresponds to the approximate location of the urethrovesical junction, and this measurement assesses urethral descent (A $_{a}$ or A $_{ant}$). Posteriorly, this region is normally occupied by the tissues of the perineal body (A $_{p}$ or A $_{post}$). By definition, the highest possible position of either point A $_{ant}$ or A $_{post}$ is 3 cm above the hymen (-3), and the lowest position is 3 cm below the hymen (+3).

To assess midvaginal support (level II), the most dependent part of the vaginal wall above point A $_{ant}$ is used. This point is called B $_{a}$, or B $_{ant}$, on the anterior wall and B $_{p}$, or B $_{post}$, on the posterior wall. This is, therefore, not a fixed point along the surface of the vagina, but rather it is marked at whatever location is the most caudal (distal) portion of that vaginal segment at maximal prolapse protrusion. In a normally supported vagina, this will be the same as point A $_{ant}$, whereas in a woman with procidentia it will be the same as point C. The same is true for the posterior vaginal wall at point B $_{post}$. Point C corresponds to the most distal portion of the uterine cervix or of the hysterectomy scar in the vagina in those patients who have had the uterus removed. Point D denotes the posterior fornix (that point at which the posterior vaginal wall changes direction). In addition to the positions of these points, the total length of the vagina is noted. Once these data have been gathered, a simple line diagram can be constructed by plotting these points relative to the hymen to provide a graphic representation of the prolapse (Fig. 45.17).

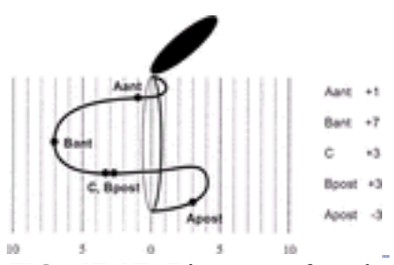

FIG. 45.17. Diagram of prolapse sites. (From Viereck V, Peschers U, Singer M, et al. Metrische Quantifizierung des weiblichen Genitalprolapses: eine sinnvolle Neuerung in der Prolapsdiagnostik? *Geburtshilfe Frauenheilk* 1997;57:177, with permission.)

So far, each element of the prolapse has been considered separately. It is also possible to give an overall description to the size of the prolapse by looking at the most dependent part of the protruding vagina or uterus. In this way, different stages—stage 0 through stage IV-can be defined; a description of these is shown in Table 45.3. A briefer version of the original description of the POP-Q staging system has been summarized, also.

The choice of the term *stage* here is somewhat unfortunate, because most women with stage I and II support are anatomically normal. The implication that they have a stage of prolapse is incorrect. Hopefully this problem with terminology will be corrected in the future.

Pelvic Floor Measurements

In normal women, the levator ani muscles close the pelvic floor. In women with pelvic organ prolapse, the urogenital hiatus within the levator ani muscles is the opening through which the vagina prolapses. This hiatus is enlarged in women with pelvic organ prolapse. The size of the urogenital hiatus and thickness of the perineal body can easily be measured to describe the changes that have occurred in the pelvic floor. The anteroposterior diameter of the genital hiatus extends from the arch of the pubic bone to the front of the perineal body, while the thickness of the perineal body is measured from the anterior margin of the perineal body to the center of the anal verge. The urogenital hiatus is held closed by the constant activity of the levator ani muscles, and the diameter of this opening enlarges in many women with prolapse.

This classification system is detailed and specific. It requires careful examination and assessment. Although at first it seems quite detailed, it is simply the quantitative documentation of the individual defects that experienced surgeons always have found necessary to assess. Some clinicians will not find it expedient to measure each of these sites, but intelligent, detailed analysis of each site of support is important to plan properly any repair for pelvic organ prolapse.

SYMPTOMS

All types of prolapse have several symptoms in common. Once the vagina prolapses below the introitus, it becomes the structural layer between the high pressures in the abdominal space and the relatively low atmospheric pressure. The downward force that this pressure differential creates puts tension on the fasciae and ligaments that support the vagina and uterus. This results in a dragging sensation where the tissues connect to the pelvic wall, usually identified by patients as occurring in the groin, and in sacral backache caused by traction on the uterosacral ligaments. This type of discomfort resolves when the patient lies down and the downward pressure is reduced. In addition, exposure of the moist vaginal walls leads to a sensation of perineal wetness that may be confused with urinary incontinence, and it also can give rise to ulceration of the vaginal wall. Most patients have an underlying sense of insecurity that is difficult for them to describe and is often expressed as a feeling that “something is just not right.” Sometimes patients who feel the cervix or vagina protruding have fears that they have a cancer and may be relieved to find that the condition is related to prolapse. Although patients may find it difficult to put their symptoms into words, the symptoms can cause significant distress and should not be ignored.

Symptoms of Anterior Wall Prolapse

The symptoms of cystourethrocele are varied, and the two primary ones are paradoxical. On the one hand, loss of support of the urethra and the lower vaginal wall is associated with stress urinary incontinence, whereas loss of support of the upper anterior vaginal wall and bladder base can cause difficulty in emptying the bladder. This inability to empty the bladder completely is probably related to voiding by the Valsalva maneuver. If there is a detrusor contraction, there should be no reason for a woman with a cystocele not to empty her bladder, and many women with a significant cystocele have normal postvoid residual urine volumes. When a woman strains to void, however, the cystocele simply gets bigger, and no impulse is provided for urine to flow through the urethra.

In addition to these functional symptoms, many patients with a cystourethrocele complain of urinary urgency and frequency. This probably arises from stretching of the bladder base that accompanies its prolapse through the vaginal introitus; it is often less pronounced at night when patients are supine.

Patients have a varying amount of support loss under the urethra or bladder, and symptoms vary along the spectrum from incontinence to urinary retention. As is true for other forms of prolapse, it is important to correlate a patient's symptoms with the physical findings so these problems can be addressed.

Symptoms Associated With Prolapse of the Uterus, Prolapse of the Vaginal Apex, or Enterocele

Few specific symptoms are related to prolapse of the uterus, prolapse of the vaginal apex, or enterocele. Patients with these conditions usually complain of the generalized symptoms of prolapse mentioned above. Some have urgency and frequency, probably related to pressure of the prolapse on the bladder base, but this is variable. In addition, patients with large, thin enteroceles occasionally have a sense of impending rupture. Although this is an uncommon problem, it should not be overlooked.

Symptoms of Rectocele

The cardinal symptom of a rectocele is difficulty in emptying the rectum. As a woman bears down to evacuate the rectum, stool is pushed into the rectocele, and the harder she strains, the bigger the rectocele becomes. Because constipation is common in older women, it is important to differentiate between infrequent bowel movements due to poor colonic motility or inadequate dietary fiber and difficulty due to a rectocele. Many women have found that if they press between the vagina and rectum to elevate the rectocele, this maneuver helps with defecation. This finding supports the fact that the rectocele is the source of the problem.

WHO SHOULD BE TREATED SURGICALLY

A decision about when an operation for prolapse should be performed is based on the individual woman's situation. It depends on the size of the prolapse, the presence or absence of symptoms, and whether or not physiologic complications have arisen because a prolapse is present. Conservative treatment with a pessary may be considered. There is little data on continuance rates with long-term pessary use. Contrary to prior recommendations that pessaries should be offered only to those women who are not operative candidates or to those awaiting surgery, a survey of urogynecologists found that 77% would offer a pessary for symptomatic patients as first-line treatment.

When the prolapse lies at or above the level of the hymenal ring, surgery should be performed only if definite symptoms are present and can be attributed reliably to the prolapse. Examples of this include:

- A patient with a cystourethrocele at the level of the hymen who has significant stress incontinence
- A woman with the cervix in the lower one third of the vagina, who has the characteristic dragging discomfort of a prolapse that resolves when she lies down or puts a supportive pessary in place
- A patient with a small rectocele in whom a definite pocket can be detected on rectal examination and elevation of the perineum relieves problems with defecation

It is unusual for women in whom the uterus has not yet descended to the level of the hymenal ring to have symptoms caused by descent of the uterus. Symptoms of pressure, back pain, or feelings that something is coming out should be studied to confirm that they are related to the prolapse, and not to other factors, before a decision to operate is made. If the symptoms go away when a pessary is placed or a patient notices prompt relief when she lies down, this helps to confirm that the prolapse is the source of the symptoms. A woman with low back pain whose discomfort persists after she is supine is more likely to have arthritic or musculoskeletal pain than pain caused by uterine prolapse, and the results of surgery are likely to disappoint her.

Among patients whose prolapse descends several centimeters below the hymenal ring, symptoms are usually present, and surgery will relieve this distress. Some women with a large prolapse will deny any symptoms, because they do not wish to undergo surgery or because they simply are not troubled by the prolapse. Their wishes should be respected. On the other hand, potential complications from the prolapse should be considered and discussed frankly.

A prolapse should be repaired, despite a lack of symptoms, if a patient has recurrent urinary tract infections associated with an increased postvoid residual urine volume. Ureteral dilation caused by the prolapse, which leads to an impairment of renal function, occurs in some patients with large prolapses and should be considered an indication for repair. An intravenous pyelogram and renal function testing can detect these abnormalities and indicate the need for treatment. The intravenous pyelogram should include films made with the patient standing and the prolapse present, because the supine position may mask significant dilation.

SURGICAL PROCEDURES

Vaginal Hysterectomy and Anteroposterior Colporrhaphy

Vaginal hysterectomy with appropriate anteroposterior colporrhaphy is the operation most often performed for the treatment of uterovaginal prolapse. Because simple removal of the uterus does nothing to correct the prolapse of the vaginal walls that accompanies descent of the cervix, it is necessary to consider how an operation works to cure these conditions properly.

Basic Principles Underlying the Surgical Repair of Prolapse

Removal of the uterus does not improve support of the genital tract. Successful repair depends on the way in which a surgeon resuspends the vagina and repairs other defects in pelvic organ support when performing a vaginal hysterectomy and anteroposterior repair. Once the uterus has been removed, the vaginal apex should be attached to a point that is higher in the pelvis than the vagina to elevate it to a normal position. During the vaginal hysterectomy, the cardinal and uterosacral ligaments can be shortened and used to resuspend the vagina. In addition, techniques such as McCall culdoplasty anchor a suture to a point on the uterosacral ligaments higher than the preoperative position of the vagina and use this suture to pull the vaginal apex to a point higher in the pelvis. It is the elevation of the vagina rather than removal of the uterus that is critical.

Preoperative Considerations

In addition to the usual thorough history, physical examination, and other medical measures necessary prior to any major operation, preoperative preparation for vaginal hysterectomy should include a pelvic examination, Pap smear, and urinalysis. Special care should be taken, as previously described, to determine the exact type and degree of prolapse and to detect any potential ovarian malignancy. A saline enema (e.g., Fleet enema) the night before surgery empties the rectum in the

event that a rectal examination is required during surgery and provides more room posteriorly, improving exposure. Patients should receive a prophylactic antibiotic to minimize the risk of postoperative infections (cefazolin sodium 1 g intramuscularly or intravenously, just before going to the operating room, is appropriate). Cervical cytologic examination results should be documented prior to hysterectomy, and if abnormal uterine bleeding is present, the endometrium should be sampled and tested preoperatively. Finally, special consideration should be given to assessing whether or not concomitant cystocele, stress incontinence, enterocele, or rectocele is present.

Before the hysterectomy is begun, a sterile preparation of the vulva and vagina is performed. An indwelling urinary catheter usually is not placed at this point, to allow the bladder to accumulate enough urine so that an inadvertent cystotomy may be recognized easily. Care should be taken in positioning and draping the patient to avoid compression of the femoral or peroneal nerve, but there should be adequate access to the operative site. An examination should be performed under anesthesia to, once again, assess whether or not any abnormalities exist that would make vaginal hysterectomy impossible and would indicate a switch to an abdominal approach.

Technique of Vaginal Hysterectomy

The elements of vaginal hysterectomy in the United States are derived from the operation described by Heaney (Fig. 45.18). A circumscribing incision is made through the vaginal wall at the cervicovaginal junction (see Fig. 45.18A). Anteriorly, the incision is placed at the lower edge of the bladder to allow entry into the vesicocervical space. The lower edge of the bladder can be palpated against the cervix to determine where this incision should be made. In addition, the junction of the vaginal rugae and the smooth surface of the cervix can be used as landmarks to identify the proper site of incision. Some operators inject saline into the tissues around the cervix to facilitate dissection. This injection should not contain epinephrine, because its use increases the incidence of postoperative pelvic infection. Several studies have documented decreased blood loss after infiltration of a dilute vasopressin solution at the cervical portio, without concomitant increased infection rates. The incision should be made through the full thickness of the vaginal wall. This can be determined by placing a retractor anteriorly while pulling forcefully on the cervix so that the vaginal wall is placed under tension. Once the vagina has been transected it separates, exposing the underlying cleavage plane. On the posterior aspect of the cervix, this exposes the area of the cul-de-sac. Blunt dissection here frees the peritoneum, which can then be grasped and entered (see Fig. 45.18B). Care should be taken not to dissect the peritoneum off the uterus, because that makes entry more difficult. Once the cul-de-sac incision has been extended laterally as far as the medial margins of the uterosacral ligaments, it can be sutured to the posterior vaginal cuff to minimize bleeding. At this point, it is appropriate to palpate the adnexal structures through the colpotomy to detect unsuspected tumors and to make a final decision concerning the feasibility of the vaginal approach, if any doubt existed. This is an easy time to acquire this valuable information, and if unsuspected disease is found, an abdominal approach can be taken.

FIG. 45.18. A: Vaginal hysterectomy is initiated by circumscribing the cervix at the cervicovaginal junction. **B:** The posterior cul-de-sac is opened. **C:** The peritoneum of the anterior cul-de-sac is incised. **D:** The base of the uterosacral and cardinal ligament usually is clamped in two bites. **E:** The upper cardinal ligament is clamped prior to its transection. **F:** The uterine fundus is delivered, and the connections between the adnexal structures and uterine corpus are clamped. **G:** Ligaments and vaginal cuff as they appear after hysterectomy. The posterior cuff is whip-stitched **(inset). H:** Technique for resuspension of the vaginal cuff and obliteration of the cul-de-sac: *1*, placement of suture through exteriorized ligaments and vaginal wall; *2*, reefing sutures placed in peritoneum; *3*, modified internal McCall suture; *4*, high purse-string suture to close the cul-de-sac. (From Mattingly RF, Thompson JD, eds. *Te Linde's operative gynecology*, sixth ed. Philadelphia: JB Lippincott Co, 1985:554, with permission.)

Next, the long blade of an Auvrard retractor is placed in the cul-de-sac, and attention is turned to entering the anterior cul-de-sac. Dissection along the vesicocervical plane is best performed by lifting the fascia anteriorly while cutting with Mayo scissors placed tip-down on the cervix. This avoids the problems that sometimes occur when a knife is used, because the scissors held in this orientation will not cut into the dense fibrous tissue of the cervix. Once the cleavage plane of the vesicocervical space is reached, gentle dissection with a gloved finger is all that is needed to elevate the bladder off of the cervix. If the bladder pillars are prominent, they can be clamped next to the cervix, transected, and ligated to provide better lateral exposure. The location of the peritoneum may be detected by moving a finger from side to side and feeling the way in which the two slippery mesothelial surfaces slide on one anther. The peritoneum can then be lifted, transilluminated, and incised (see Fig. 45.18C). After the incision is extended laterally, a suture is placed in its vesical edge and held with a hemostat to facilitate its identification at the time of reperitonealization.

Once the cul-de-sacs have been entered, the ureter should be palpated to determine its position prior to shortening and transecting the cardinal ligaments. This is a critical step, because only if the ligaments are shortened will the vagina be held at a level higher than that of the prolapsed cervix. A retractor is placed in the lateral fornix of the vagina and a finger in the anterior cul-de-sac. Because the ureter must pass under the uterine artery and end in the bladder anterior to the examining finger, it can be palpated against the retractor blade. The characteristic snap of the ureter permits its identification, and it can be followed for some distance by moving the retractor and examining finger anteriorly and posteriorly.

After the ureter is identified the uterosacral and cardinal ligaments are shortened by clamping them at a safe distance from the ureter, somewhat lateral to the cervix (see Fig. 45.18D, Fig. 45.18E). After the ligaments are cut and suture-ligated, the sutures are left long and marked for use in resuspending the vagina at the end of the procedure. The uterine arteries are similarly clamped, transected, and suture-ligated, but they are not tagged, to avoid dislodging the suture from this vascular pedicle.

At this point, the corpus of the uterus usually is brought through the posterior colpotomy by pulling on it with a tenaculum, to expose the connections between the adnexal structures and the uterus (see Fig. 45.18F). When this is not possible because of a small vagina or large uterus, the uterus can be divided along its sagittal plane, and one half can be pushed up into the peritoneal cavity. A long tenaculum is left attached to the elevated half of the uterus to allow its later retrieval, while the contralateral adnexal pedicles are dealt with. Clamps are placed across the adnexal structures, with care taken not to include bowel or adjacent structures, and the pedicles are transected.

Next, consideration should be given to removal of the ovaries. If the ovaries are to be removed, the mesovarium or infundibulopelvic ligament is clamped, the ovary is removed with or without the fallopian tube, and the remaining pedicle is suture-ligated.

Management of the Cul-de-sac and Suspension of the Vaginal Apex

Once the uterus has been removed and the ligaments have been prepared by shortening them, the reconstructive phase of the operation begins. These steps use the ligaments that were tagged during the hysterectomy (see Fig. 45.18G). The goals are to close the peritoneum and suspend the vaginal apex, while also correcting any existing enlargement of the cul-de-sac. The cul-de-sac peritoneum is attached to the uterus. Whenever the uterus prolapses, it pulls the cul-de-sac peritoneum with it. If this extension is not distended with bowel, it is referred to as a *traction enterocele*, and when the cul-de-sac is not only elongated but also distended with bowel, it is referred to as a *pulsion enterocele*, a true enterocele.

When little prolapse has been present (i.e., the cervix does not extend below the hymenal ring), simple closure of the cul-de-sac and attachment of the ligaments to the vaginal cuff suffice. An indwelling catheter usually is placed at this time to drain the bladder. This brings the anterior peritoneum closer to the surgeon and, thereby, facilitates its closure.

Closure of the vaginal cuff should accomplish two things: resuspension of the vaginal apex and closure of the cul-de-sac (see Fig. 45.18H). A suture is placed through the vaginal cuff and through the ends of the suspensory ligaments to reattach them to the vagina. Next, the cul-de-sac may be reefed and a suture placed through the uterosacral ligaments to bring them to the midline. Finally, the peritoneum is closed with a purse-string suture of 0 silk placed at the highest level possible, beginning on

the vesical peritoneum. A finger is placed in the peritoneum while this suture is tied, to avoid trapping intraabdominal contents in the suture, and is removed as the suture is snugged down.

Anterior Colporrhaphy

After the uterus has been removed and before the ligaments are reattached to the vaginal cuff, an anterior colporrhaphy is performed for patients with cystoceles (Fig. 45.19). Scissors are used to undermine and incise the mucosa of the anterior vaginal wall as far as the midurethra (see Fig. 45.19A). The vaginal fascia is then mobilized widely from the vaginal epithelium, with use of a combination of sharp and blunt dissection, until the superior lateral sulcus of the vagina is reached (see Fig. 45.19B). Care should be taken to remain superficial in this dissection to avoid transecting the fascia that is to be plicated in the midline. Special attention should be given to adequately developing the fascia that lies under the urethrovesical junction, because this is critical to improving urethral support. Once mobilization has been accomplished, a series of plication sutures are taken in the fascia, just medial to the junction of the anterior and lateral vaginal walls (see Fig. 45.19C).

FIG. 45.19. A: The vaginal epithelium is undermined when commencing anterior colporrhaphy. **B:** The fascia is separated from the mucosa. **C:** The ascia is sutured together in the midline. Special care should be taken to ensure adequate support at the urethrovesical junction. **D:** Excess epithelium is trimmed. **E:** The epithelium is closed. A bite of the underlying fascia is included to minimize dead space. (From Mattingly RF, Thompson JD, eds. *Te Linde's operative gynecology*, sixth ed. Philadelphia: JB Lippincott Co, 1985:612, with permission.)

Plication of the suburethral fascia deserves special attention. Once the first suburethral suture has been placed and tied, it pulls some of the more lateral fascia into view, and this offers an opportunity to place a second suture in this same region and improve the elevation that was possible with the first suture. Once the remainder of the fascia has been closed, the cranial edge of the fascia at the vaginal apex should be tagged so that it may be included in the sutures that reattach it to the cardinal and uterosacral ligaments. This step will help elevate the upper margin of the fascia and pull it higher in the pelvis. An appropriate amount of vaginal epithelium is then trimmed (see Fig. 45.19D), and the epithelium is closed with running or interrupted sutures (see Fig. 45.19E).

Posterior Colpoperineorrhaphy

Next, a rectocele, if present, must be corrected. Although often undertaken at the end of a tiring operation, this repair requires the most skill and judgment of all phases of surgery for prolapse. Overcorrection of the posterior wall may leave the patient unable to have satisfying intercourse, yet a failure to reinforce the supportive position of the posterior vaginal wall may increase the likelihood that prolapse will recur. The goal of this portion of the operation is to reinforce the rectovaginal septum and to return the size of the introitus to normal.

The posterior colporrhaphy is begun by establishing the size that the introitus should be at the end of the procedure. This is accomplished by estimating the amount of vaginal and perineal skin that must be removed to return the introitus to a normal diameter. Allis forceps are placed to grasp a solid bite of tissue at the hymenal ring bilaterally at the margins of the mucosa that is to be excised. These forceps are then approximated in the midline to bring the soon-to-be-united parts of the introitus together. This allows a preview of the degree to which the introitus will be narrowed. Adjustments may then be made in the placement of the forceps to obtain an optimal result before an irrevocable incision is made into the perineum. A patient with a normal introitus who has a rectocele above this level need not have any tissue excised, and a vertical incision can be made in the introitus.

After the skin of the introitus is incised, the mucosa is undermined (Fig. 45.20A). The vagina and perineal body are fused, so dissection in the 3 cm inside the hymenal ring must be done sharply. If the rectovaginal septum is thin, placing a finger in the rectum to guide dissection will minimize the likelihood of proctotomy.

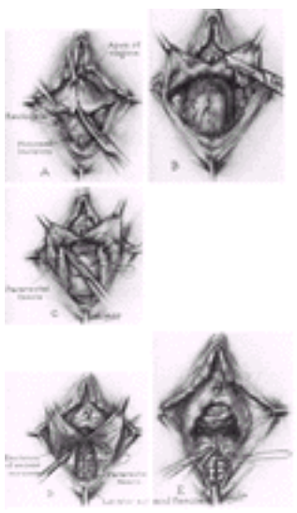

FIG. 45.20. A: To begin posterior colporrhaphy, a transverse incision is made in the perineal body, and a vertical incision is extended toward the vaginal apex. **B:** The perirectal fascia is mobilized from the mucosa. **C:** The perirectal fascia is sutured, beginning above the site of the rectocele. **D:** The inner surface of the levator ani muscles are approximated in the perineal body, and redundant mucosa is excised. **E:** The mucosa and perineal skin are closed. (From Mattingly RF, Thompson JD, eds. *Te Linde's operative gynecology*, sixth ed. Philadelphia: JB Lippincott Co, 1985:578, with permission.)

The rectovaginal space begins at the top of the perineal body and lies between the rectovaginal fascia and the rectum. It is a loose areolar plane and dissects easily. Once it is entered, it should be developed laterally (see Fig. 45.20B) until the inferior lateral sulcus of the vagina has been reached and the inner surfaces of the levator ani muscles can be felt. The upper limit of the dissection depends on the location of the rectocele and should extend, at least, to a point several centimeters above the upper limit of the bulge. When a posterior repair is used in a patient who previously had a hysterectomy, the upper vaginal dissection should include a search for an enterocele.

Once the rectovaginal space has been developed adequately, the repair may begin. With a finger depressing the rectum, the connective tissue lateral to the rectum is grasped with a needle and elevated, and the needle is retrieved (see Fig. 45.20C). A similar bite of the endopelvic fascia on the contralateral side is then taken. Successive sutures are then placed from that point to the introitus. After this is complete, it is prudent to make sure that no ridge has formed. If it has, the offending suture should be removed and replaced to avoid distortion. After this first layer has been placed, the space between the levator ani muscles may be narrowed by suturing their fascial covering, and the perineal body can be reconstructed (see Fig. 45.20D). This requires a second layer of sutures in the distal 3 cm of the vagina. After these sutures are placed, one final stitch usually is placed at the level of the hymenal ring to establish the triangular nature of the perineal body when seen in sagittal section. Finally, an appropriate amount of vaginal mucosa is trimmed, and the vaginal edges are reapproximated with interrupted or running absorbable sutures

(see Fig. 45.20E).

When the operation is finished, the adequacy of the vagina for intercourse should be assessed. Despite precautions to avoid vaginal stenosis, it sometimes is noted after the repair is complete. If so, relaxing incisions may be made in the vaginal wall to relieve the stricture, or part of the repair may be taken down and resutured. Time rarely improves a bad initial repair, and correction in the operating room is far superior to taking the patient back to the operating room later for revision.

Le Fort Partial Colpocleisis

In elderly patients who will no longer be engaging in intercourse, a colpocleisis may be used to cure the prolapse. This operation carries less operative and postoperative morbidity and may be performed under local anesthesia in the rare patient whose medical condition puts her at too great a risk to have a regional anesthetic. It consists of denuding a rectangle of anterior and posterior vagina and sewing them together (Fig. 45.21). This prevents the uterus and vagina from prolapsing. An adjunctive high perineorrhaphy at the time of the colpocleisis forms a shelf for the repair to rest on, so as to lessen the likelihood of prolapse recurring. Channels are left below the cervix and lateral to the closure to provide egress of cervical secretions and blood, should postmenopausal bleeding occur. Because the uterus is not removed and access to the cervix is blocked, care should be exercised in the preoperative evaluation to make sure that endometrial carcinoma is not present or likely to develop. Intraoperative dilation and curettage should be considered, as well, to exclude carcinoma.

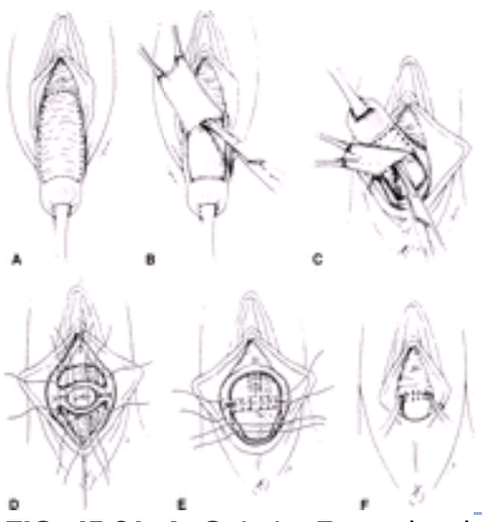

FIG. 45.21. A–C: In Le Fort colpocleisis, rectangles of vaginal mucosa are removed from the anterior and posterior vaginal walls. **D,E:** The denuded areas are then sutured together, leaving **(F)** channels on each side open. (From Mattingly RF, Thompson JD, eds. *Te Linde's operative gynecology*, sixth ed. Philadelphia: JB Lippincott Co, 1985:562, with permission.)

Stress incontinence may follow colpocleisis if there is poor urethral support associated with the prolapse. In this instance, steps should be taken during the operation to improve the situation. Preoperatively, occult stress incontinence may be detected by examining the patient with a full bladder and having her cough with the prolapse reduced. If stress incontinence is elicited, steps must be taken to improve urethral support by plicating the endopelvic fascia under the urethra or considering an incontinence procedure such as a postoperative collagen instillation, a pubovaginal sling, or a tension-free vaginal tape procedure.

Vaginal Repair of the Posthysterectomy Enterocele

The description earlier in this chapter concerning care of an enterocele and the cul-de-sac involves management of an enterocele encountered with the uterus in situ during vaginal hysterectomy. Because enterocele after hysterectomy is a significant problem in its own right, it will be considered separately here. Certain features of enterocele, such as its occurrence after high retropubic urethral suspension, warrant special consideration. Repair of an enterocele should not only obliterate the cul-de-sac but also should pull the vagina over the rectum by shortening the ligamentous suspension of the vagina, so that the normal closure of this space may be maintained. In addition, if the vaginal wall has been stretched because of its protrusion below the pelvic floor, the excess vaginal wall must be excised. Although transabdominal enterocele repairs (e.g., Moschcowitz, Halban) are useful as prophylaxis at the time of abdominal repair, an enterocele that appears after hysterectomy can almost always be repaired vaginally. This is the preferred method, because it avoids the morbidity of an abdominal incision and is much easier to perform.

The vaginal wall is opened over the enterocele sac. If a concomitant rectocele is present, this may be done by extending the incision made for the posterior repair up to the apex of the vagina. If a pure enterocele is present, the incision is made directly over the enterocele. In instances where the prolapsed vaginal wall has become stretched, a diamond-shaped incision may be made to excise the excess vaginal skin (Fig. 45.22A). Once identified, the peritoneum is separated from the vaginal wall (see Fig. 45.22B), and the excess peritoneum is excised. Next, the remnants of the uterosacral ligaments are brought together under the peritoneum and attached to the vaginal apex to improve its support (see Fig. 45.22C). At that point, any excess vaginal wall is trimmed, a posterior repair performed if needed, and the vaginal incision closed. Most enterocele repairs should be accompanied by a posterior colpoperineorrhaphy.

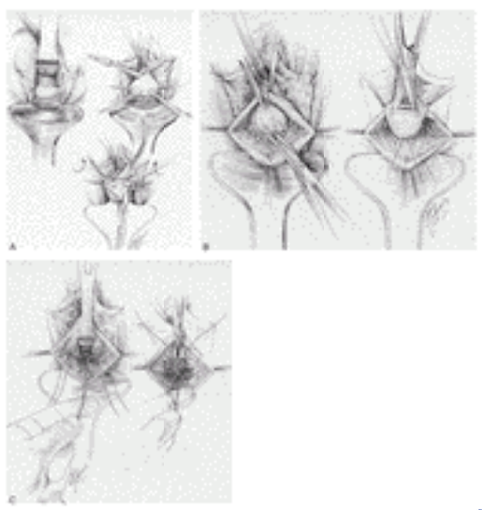

FIG. 45.22. A: The enterocele is exposed, and a diamond-shaped piece of vaginal wall is excised to reduce the size of the stretched upper vagina. **B:** The peritoneum is dissected from the surrounding structures, and it is closed with a purse-string suture. **C:** The uterosacral ligaments are defined by creating opposing traction with a retractor and suture to complete repair, after which the vaginal wall is closed. (From Segala CJ. New technique for the repair of vaginal vault prolapse following hysterectomy. *Int Surg* 1969;51:36, with permission.)

Posthysterectomy Prolapse

Prolapse subsequent to hysterectomy deserves special consideration. One third to one half of women will have had a hysterectomy by the age of 65, so prolapse in older women often will occur in the absence of a uterus. Although it might appear that these individuals would have only a cystocele or rectocele, because there could be no uterine prolapse, prolapse of the vaginal apex is often present. Apical prolapse must be recognized; otherwise, repair of a cystocele or a rectocele associated with prolapse of the vaginal apex is doomed to failure. Additionally, without recognition of the apical prolapse, the surgeon is likely to excise too much vaginal tissue with anterior and posterior colporrhaphy, leaving the patient with a very shortened, narrow vagina.

When the apex of the vagina, marked by the scar at the former location of the cervix, prolapses below the hymenal ring, vaginal prolapse is present. This usually is accompanied by an enterocele and often is seen in combination with a cystocele or a rectocele. To cure these patients, the apex of the vagina must be returned to and held in its normal position in the pelvis, and the cystocele or rectocele must be repaired. This may be accomplished by suturing the vaginal apex to the sacrospinous

ligament (Fig. 45.23A) or to the sacrum, using an interposing graft in an operation known as *abdominal sacral colpopexy* (Fig. 45.23B), or by performing a high uterosacral suspension. Each of these operations is accompanied by repair of the enterocele and whatever other prolapse must be addressed. In women who are no longer interested in preserving coital function, a complete colpocleisis obliterates the vagina and prevents prolapse from occurring, and this provides an easy, safe, and effective technique to relieve the symptoms.

FIG. 45.23. A: The vagina is fixed to the sacrospinous ligament. (From Morely GW, DeLancey JOL. Sacrospinous ligament fixation for eversion of the vagina. *Am J Obstet Gynecol* 1988;158:872, with permission.) **B:** The vaginal apex is attached to the sacrum with an intervening graft. (From Addison WA, Timmons MC, Wall LL, et al. Failed abdominal sacral colpopexy: observations and recommendations. Obstet Gynecol 1989;74:480, with permission.)

Paravaginal Repair

When a cystourethrocele persists or returns soon after anterior colporrhaphy, this often means that the loss of anterior vaginal wall support is due to a paravaginal separation of the pubocervical fascia from its normal lateral attachment to the arcus tendineus rather than to a midline defect in the fascia. In this instance, repeating the anterior colporrhaphy will not be effective, and repair of the separation will be required. Although the paravaginal repair usually is described as an operation to treat stress incontinence associated with cystourethrocele, it also is helpful in treating cystourethrocele in the absence of stress urinary incontinence, especially when an anterior colporrhaphy has failed. This retropubic operation reattaches the lateral margin of the pubocervical fascia to the pelvic sidewall along a line from the undersurface of the pubic symphysis to the ischial spine, along the line of the arcus tendineus. This reestablishes the normal lateral attachments of the pubocervical fascia and, therefore, prevents downward displacement of the bladder. It has not yet been established as a necessary procedure in the primary treatment of cystourethrocele without stress incontinence but, in instances of recurrent cystocele after anterior repair, simply repeating an operation that has not helped the patient is not desirable.

Conservative Measures

Vaginal pessaries are perhaps the oldest effective treatment for prolapse. Named after an oval stone (i.e., a *pessos*) used in certain Greek games, innumerable natural and man-made materials have been used to make pessaries. These objects are placed in the vagina. Because they are larger than the introitus, they are retained in the vagina above the pelvic floor musculature and thereby prevent the somewhat smaller uterine cervix from passing through the opening. When the pelvic muscles are relatively normal, these devices work well. When the pelvic floor opening is enlarged because of damage to the levator ani, a pessary may not be retained.

There are countless varieties of pessaries. The ones most commonly used for prolapse are the doughnut-shaped pessaries, either permanently inflated or inflatable. The largest pessary that the vagina will accommodate without undue pressure on the vaginal walls is inserted. Often, patients can be taught how to place and remove them. Having the patient remove the pessary at night minimizes the discharge inevitably associated with its use. Adjunctive treatment with topical or systemic estrogen helps the vaginal mucosa tolerate the foreign body. Because pessaries may cause erosion and ulceration, they should be checked periodically. If an ulcer is developing, pessary use should be discontinued or a smaller one fitted, and the ulcer should be monitored until it heals.

SUMMARY

Pelvic organ prolapse affects between 5% and 10% of women. It arises due to damage to the levator ani muscles and endopelvic fascia that occurs at the time of vaginal birth and the deterioration that occurs in these tissues with advancing age. Women who have these conditions express distress from the constant, unrelenting feelings of pressure and incontinence and from fear that this protrusion may lead to other problems.

The term *pelvic organ prolapse* encompasses a variety of related conditions that arise when the muscles and connective tissues of the pelvic floor can no longer hold the pelvic organs in their normal positions. The location and nature of the muscle injury and fascial ruptures determine which pelvic organ falls downward. The symptoms experienced by a woman come from this mechanical misalignment, along with the functional derangements of the pelvic viscera determined by neurologic injury and these prolapses. Identifying both the location of the abnormality and the symptoms experienced by the individual woman are critical to successful treatment.

Surgical treatment is aimed at resuspending the prolapsed pelvic organs and rearranging the damaged muscles to place them in the most favorable locations for function. This field is characterized by a great diversity of operative procedures used to correct individual elements of defective pelvic organ support. The particular operation that is chosen depends on the anatomic and functional abnormalities that a woman experiences, as well as the training of the surgeon. Individual surgeons become familiar with a subset of these techniques that allows them to address the problems they face. No two surgeons treat these problems in exactly the same way, and a good surgeon rarely will do two operations that are exactly alike.

SUMMARY POINTS

- Pelvic organ prolapse is a remarkably common and distressing condition.
- Vaginal delivery and advancing age are the most common factors causing pelvic organ prolapse.
- Pelvic organ prolapse arises due to a combination of neuromuscular and connective tissue injury and has variable symptoms associated with its development.
- Evaluating the status of each element of pelvic organ support is critical prior to instituting treatment.
- Surgical treatment of pelvic organ prolapse must be tailored to each woman's condition, so that all areas of pelvic support loss are corrected.

Introduction
Laparoscopy
Complications

In one sense, the historical perspective of endoscopic surgery begins in 1847, with Sir James Y. Simpson of Edinburgh, Scotland, introducing chloroform narcosis. This advance was followed by the first endoscopic evaluation of the abdominal cavity, using a dog model in 1901, by Kelling. Ten years later, Jacobaeus reported the first laparoscopic procedure in the human. Cold illumination fiberoptics followed, by Semm in 1963, and then the surgical area rapidly evolved. The first laparoscopic appendectomy was performed in 1980 and the first cholecystectomy in 1985.

This relatively new aspect of endoscopic surgery has far-reaching and ever increasing innovative aspects. Hysteroscopy has altered the approach to the myomatous uterus. Laparoscopy has blossomed to include radical hysterectomies and node sampling. This chapter provides the technical advances in a segment of gynecologic surgery that appears to be in a continuous state of evolution and ever more far-reaching new instrumentation.

LAPAROSCOPY

Patient Positioning

Proper patient positioning is paramount. The surgeon should position the patient so as to prevent any excessive pressure on the lower extremities. Nerve injuries can result from improper placement of the lower extremities in stirrups. Lithotomy position with access to steep Trendelenburg is appropriate. The physician should discuss with anesthesia personnel decisions regarding whether the arms should be extended or “tucked” along the sides of the patient. The latter requires particular attention to prevent any trauma to the hands and fingers when the table is maneuvered.

With the patient in the low lithotomy position and the legs supported in stirrups, the buttocks should protrude slightly from the lower edge of the table. The lateral aspect of the knee should be protected with padding in the stirrup to prevent peroneal nerve injury. The knees should be kept in slight flexion to minimize stretching of the sciatic nerves and to provide increased stability in the Trendelenburg position. With respect to positioning of the arms, care should be taken not to stretch or traumatize the brachial plexus.

It has been advocated that an angle of 145 degrees between the abdomen and the lower extremity (thigh) is ideal, providing the surgeon with adequate space for instrumentation. The typical patient positioning for endoscopic surgery is noted in Figure 46.1.

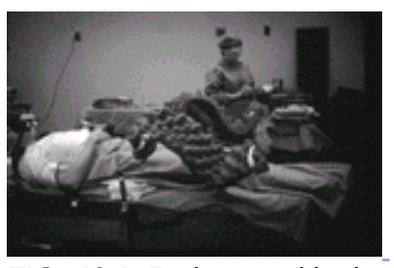

FIG. 46.1. Patient positioning for laparoscopic surgery.

Equipment

An array of instruments designed to facilitate operative laparoscopic procedures continues to evolve. This section describes a number of instruments.

Viewing System The video equipment should include a three-chip camera, a processor, a 300-watt xenon light source with fiberoptic cable, a high-resolution monitor, and a video recorder. The three-chip camera provides a sharper, brighter image with higher resolution than the older single-chip cameras (Fig. 46.2). Three-chip cameras can deliver over 600 lines of resolution; therefore, the video monitor's horizontal resolution should be greater to maximize image quality. Fiber light cables should be inspected for broken fibers, because damaged fibers will result in suboptimal light delivery.

FIG. 46.2. Autoclavable Goldtip videolaparoscope with camera processor and xenon light source (Olympus, Melville, NY).

Table An operating room table that allows 30 degrees of flexion (Trendelenburg position) is ideal for visualization of the deep pelvis. Shoulder braces (Stierlen-Maquet Shoulder Braces, Siemens Medical Systems, Englewood, CO) placed at the acromioclavicular joints and the arms placed at the patient's sides will minimize nerve injuries.
Insufflator For most procedures, the pneumoperitoneum may be maintained with an insufflator that flows at a rate of 2 to 7 L/min. High-flow insufflators that achieve up to 30 L/min are available and will maintain the pneumoperitoneum during procedures that allow escape of large amounts of CO_2, such as during tissue morcellation.
Carbon Dioxide Warmer There is evidence that warmed CO_2 is less irritating to the peritoneal surface and, therefore, may cause less adhesion formation. CO_2 warmers are commercially available.
Laparoscopes Laparoscopes are telescopes that vary in size from 2 to 10 mm. Zero-degree, 30-degree, 45-degree, and 70-degree viewing angles are available. Diagnostic laparoscopes do not contain an operating channel. Operative laparoscopes contain a channel through which instruments or laser may be passed, but they have a smaller number of optic fibers (Fig. 46.3 and Fig. 6.4).

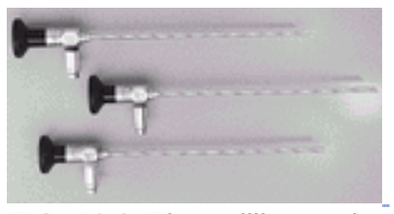

FIG. 46.3. Five-millimeter laparoscopes (Karl Storz Endoscopy-America, Culver City, CA).

FIG. 46.4. Ten-millimeter laparoscope (Karl Storz Endoscopy-America, Culver City, CA).

Trocars Trocars come in a variety of sizes, materials, and designs. Sizes range from 3 to 15 mm. Reusable metal trocars have the advantage of cost efficiency, but they may actually be more dangerous if the tips are not kept sharp (Fig. 46.5, Fig. 46.6 and Fig. 46.7). Disposable trocars are more expensive but are always sharp, which may decrease the risk of injury during insertion (Fig. 46.8). Some trocars are designed to stretch the fascia so that fascial closure is not necessary. Others have been designed to allow visualization of tissue layer separation with the laparoscope during insertion. Advocates assert that this type of trocar decreases bowel and vascular injuries. There are no objective data supportive of a reduction in risk for any trocar. The trocar chosen should be based on the surgeon's preference. Hasson-type trocars have a blunt end for placement in open laparoscopy (Fig. 46.9 and Fig. 46.10).

FIG. 46.5. Five- and ten-millimeter trocars (Karl Storz Endoscopy-America, Culver City, CA).

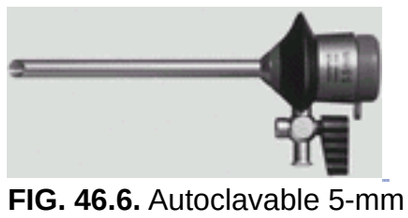

FIG. 46.6. Autoclavable 5-mm slim trocar with duckbill (Olympus, Melville NY).

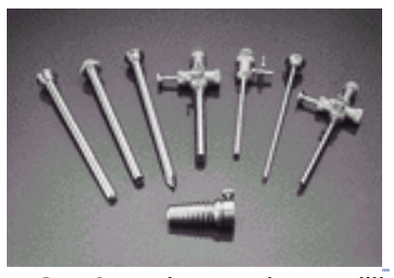

FIG. 46.7. Five- and ten-millimeter reusable trocars.

FIG. 46.8. Ten-millimeter disposable trocar (Olympus, Melville, NY).

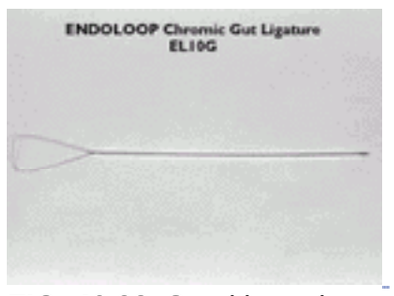

FIG. 46.32. Surgitie endoscopic suture ligature (U.S. Surgical, Norwalk, CT).

Microbipolar forceps
Morcellator
Rectal probe
Staplers Endoscopic staplers that simultaneously ligate and divide tissue are available. In gynecologic procedures, they are used most commonly on the infundibulopelvic ligament, round ligament, fallopian tubes, and uteroovarian ligaments in laparoscopically assisted vaginal hysterectomies. They also may be used when excising endometriosis from the bowel (Fig. 46.33).

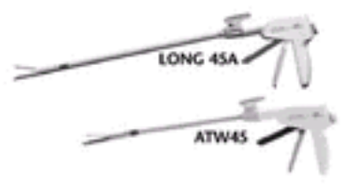

FIG. 46.33. Stapling device (U.S. Surgical, Norwalk, CT).

Harmonic Scalpel The active blade of the Harmonic Scalpel (Ethicon Endosurgery, Cincinnati, OH) vibrates at a rate of 55,000 cycles per second, resulting in coagulation and tissue separation. The scalpel is available as a 5- or 10-mm “hook,” “ball” dissector, spatula, or opposing jaws. Although electrical energy is not used, the tissue still becomes heated and a 2-mm lateral energy spread, which can cause thermal injury, may be seen.
Electrosurgery Unipolar electrosurgical instruments are used to cut and coagulate tissue. Cutting occurs when there is sufficient voltage (at least 200 volts) between the electrode and the tissue to produce an electric arc. This arc concentrates the current to points along the tissue, resulting in a cutting effect. In contrast to cutting current, coagulation is produced through instrument contact with the tissue. Contact allows heating of the tissue followed by irreversible cellular damage, evaporation of intracellular water, and contraction of blood vessels and surrounding tissue. Electrosurgical burns may occur due to insulation failure, direct coupling (activated electrode makes unintended contact with another metal object in the area of the surgical field), or capacitive coupling (induction of stray current to a surrounding conductor through the intact insulation of an active electrode). Bipolar electrosurgical instruments contain the electrical current between an active and return electrode, usually the two blades of forceps. The flow of alternating current is passed between the two electrodes rather than passing through the patient to a grounding pad. This eliminates the risk of capacitive coupling and stray current.
Laser Lasers offer an alternative method of cutting and vaporizing tissue. The CO_2 laser with a depth of penetration of 1 mm allows the surgeon some security when working around bowel, ureters, and large blood vessels. In addition, a CO_2 laser will not traverse through water, thus irrigation fluid may be used as a backstop. The Coherent 5000L (Coherent Laser, Palo Alto, CA) laser offers high-power density over a short period of time, minimizing thermal damage to surrounding tissue. This laser uses a ^{13}C isotope of CO_2 with an 11.1-mm–wavelength beam. The wavelength of the CO_2 purge gas in the operating channel of the laparoscope is 10.6 mm. Because the wavelengths are different, there is no absorption of the laser beam by the purge gas, keeping the power density 10 times more than at similar settings with other standard laser beams with 10.6-mm wavelengths. The 1.5-mm spot size is maintained at all power settings, offering precision, minimal surrounding tissue damage, and less charring. Fiber lasers (potassium-titanyl-phosphate [KTP], argon, and Nd:YAG [YAG]) are introduced through small channels of the operating laparoscope or through ancillary trocars. The KTP and argon lasers may be used for cutting and coagulating. As the tip of the fiber approaches the tissue, the power density increases and the laser is used for cutting. As the tip is moved away from the tissue, the spot size increases and power density decreases rapidly. The clinical applications for the YAG laser are more limited. The YAG laser coagulates well, but it doesn't cut well unless a sapphire tip is used to increase the power density.
Handoscopy Hand-assisted laparoscopy, or “handoscopy,” has become popular, mainly in the field of solid organ and bowel surgery. To date, the only gynecologic procedure where this device has been used is rectal resection for deep fibrotic endometriosis. The main advantage of handoscopy is that it allows the surgeon to regain the tactile feel of tissues lost in standard laparoscopies.

Physiologic Effects of the Pneumoperitoneum

The respiratory, hemodynamic, and renal consequences of the pneumoperitoneum are substantial but usually are well tolerated by the healthy patient. These changes may be severely problematic in the patient whose cardiopulmonary or renal system is compromised.

Respiratory Changes Ventilation during laparoscopic surgery is altered by the increased intraabdominal pressure (IAP) of the pneumoperitoneum. The airway pressure required for adequate ventilation consequently is increased. Thoracic compliance, diaphragmatic excursion, and functional residual capacity are all decreased. Studies have shown that the increase in IAP alone reduces compliance by 30%; this may be decreased by another 20% when the patient is placed in a Trendelenburg position. In addition to mechanical changes, the CO_2 pneumoperitoneum produces changes in acid–base balance. Because carbon dioxide is absorbed rapidly from the peritoneal cavity, the minute volume must be increased as indicated by the end-tidal CO_2 to prevent respiratory acidosis (Table 46.1).

1. Hypercapnia with subsequent acidosis
2. Increased airway pressure
3. Decreased functional residual capacity
4. Decreased thoracic compliance
5. Decreased diaphragmatic excursion

TABLE 46.1. *Ventilatory effects of carbon dioxide pneumoperitoneum*

Hemodynamic Changes Circulatory changes seen during laparoscopic surgery are the result of the mechanical compressive effects of the increased IAP and its associated hormonal changes (Table 46.2). Catecholamines, angiotensin, and vasopressin are all increased, resulting in increased systemic vascular resistance. An increase in systemic vascular resistance results in an increase in mean arterial pressure and a decrease in cardiac index. The increased IAP also causes increased intrathoracic pressure, with resultant increases in central venous pressure, pulmonary capillary wedge pressure, and pulmonary vascular resistance.

1. Increased systemic vascular resistance
2. Increased mean arterial pressure
3. Decreased cardiac index
4. Increased central venous pressure
5. Increased pulmonary vascular resistance
6. Increased pulmonary capillary wedge pressure

TABLE 46.2. *Hemodynamic effects of carbon dioxide pneumoperitoneum*

Renal Blood Flow Changes Animal studies have shown an increase in renal vascular resistance and a decrease in renal perfusion and glomerular filtration rate secondary to increased IAP. A subsequent decrease in urine output may be observed and may continue to remain low 1 hour after release of the pneumoperitoneum (Table 46.3).

1. Increased renal vascular resistance
2. Decreased renal blood flow
3. Decreased glomerular filtration rate
4. Decreased urine output

TABLE 46.3. *Renal effects of carbon dioxide pneumoperitoneum*

Compromised Patient The multiple cardiopulmonary and renal changes observed during CO_2 laparoscopy are well tolerated by the healthy patient. Extreme caution must be taken when performing gaseous laparoscopy in patients with compromised respiratory function, ischemic heart disease, congestive heart failure, and renal dysfunction. These compromised states may even be considered relative contraindications to gaseous laparoscopy. The lowest IAP that allows adequate visualization should be used to minimize increases in intrathoracic pressure. An alternative consideration would be to use an abdominal wall lift method (elevating the ventral abdominal wall by an inflatable balloon or fan retractor), eliminating the consequences of CO_2 in the peritoneum. The use of alternative gases such as argon, nitrous oxide, and helium for pneumoperitoneum has been considered. Carbon dioxide's advantages over these gases include higher solubility and, therefore, possibly fewer deleterious effects in event of gas embolism, ability to use cautery in its presence, and it is inexpensive. It is the surgeon's responsibility to take a careful history and perform appropriate preoperative diagnostic testing when determining a patient's candidacy for laparoscopic surgery. All of the advantages of laparoscopic surgery are inconsequential if the procedure is performed on an inappropriate patient.

Anatomy of the Anterior Abdominal Wall

Knowledge of the anterior abdominal wall vascular anatomy will reduce vascular complications associated with trocar placement. Of particular concern are the superior and inferior epigastric vessels. The superior epigastric artery, one of the terminal branches of the internal thoracic artery, enters first the rectus sheath and then the rectus muscle coursing near its lateral border. This artery and its adjacent vein often can be visualized by transillumination of the abdominal wall with the laparoscope.

Visualization of the ventral abdominal wall laparoscopically often will locate the deep inferior epigastric vessels. The artery, a branch of the external iliac, and its accompanying vein course along the abdominal wall peritoneum just lateral to the rectus muscle until midway between the symphysis pubis and umbilicus, where it blends into the body of the rectus muscle. These vessels may be seen medial to the insertion of the round ligament at the deep inguinal ring. Therefore, placement of the trocar lateral to the deep inguinal ring and lateral border of the rectus muscle will avoid injury to these vessels.

If placement of the trocar is too far laterally, branches of the superficial circumflex iliac vessels may be injured. Again, transillumination of the anterior abdominal wall using the laparoscope will assist in avoiding these vessels.

As a general guideline, the superficial and inferior epigastric vessels are located approximately 5.5 cm from the midline. The superficial circumflex iliac vessels are approximately 7 cm from the midline. Theoretically, a “safe area” would be 8 cm above the symphysis pubis and 8 cm from the midline. If transillumination is not effective due to a thick abdominal wall, the surgeon may consider insertion of a spinal needle through the abdominal wall at the selected trocar insertion site. If no bleeding is observed after removal of the needle, the location is likely safe for trocar placement.

Obtaining Intraabdominal Access

For most laparoscopic surgeons, obtaining access to the peritoneal cavity is the most anxiety-provoking step of the entire endoscopic procedure. There are a number of ways to obtain intraabdominal access for trocar placement and establishment of a pneumoperitoneum. None of the available methods precludes the possibility of complications from trocar or needle insertion. In general, these methods of entry can be classified as either open or closed.

An open entry uses the technique first described by Harry Hasson. An incision into the peritoneal cavity through all anterior abdominal wall layers at the umbilicus is made carefully. A blunt-tipped trocar is placed through the incision into the abdominal cavity. Insufflation is conducted through this trocar sleeve. This technique may reduce vascular injuries due to sharp trocar or needle placement, but the possibility of bowel injury still exits if there are abdominal wall adhesions.

The closed entry may be performed with or without the use of a Veress needle to insufflate CO_2. Placement of the sharp trocar through the umbilicus without prior insufflation has lost favor due to the higher risk of bowel and vascular injuries.

Insufflation of CO_2 through a Veress needle is the most common method of entry, although some would argue the open technique should become the method of choice. One technique of access using a Veress needle is performed in the following manner:

1. A vertical incision through the skin corresponding to the size of the trocar is made at the base of the umbilicus. Note that this incision ideally is made at the *base* of the umbilicus and not infraumbilically as is classically taught. This is because the distance between skin and peritoneum on the anterior abdominal wall is shortest at the base of the umbilicus. In addition, the peritoneum is firmly attached, which will prevent tracking through the subcutaneous tissue and subsequent retroperitoneal insufflation.
2. The Veress needle is inspected for sharpness and a functioning spring mechanism to extend the protective sheath in the absence of pressure.
3. The anterior abdominal wall inferior to the umbilicus is grasped with the nondominant hand and the umbilicus is moved in the caudad direction, further displacing it below the bifurcation of the aorta. Alternatively, the incision may be elevated by grasping the edges of the umbilical incision with two Alice clamps and lifting.
4. The tip of the Veress needle is held in the dominant hand between the thumb and forefinger while the ulnar palm rests on the patient's abdomen. The needle is inserted carefully at a 90-degree angle, through the base of the umbilicus, millimeter by millimeter, until a click is heard and resistance is no longer felt, identifying intraabdominal placement.
5. A saline-filled 10-cc syringe is attached to the Veress needle and aspirated, inspecting for blood or bowel contents. If only bubbles are visible, saline is injected and observed to fall from the trough on the needle into the peritoneal cavity.
6. The syringe is removed, the insufflation tubing (with CO_2 turned on low flow) is attached, and the initial IAP is observed. If the pressure is greater than 10 mm Hg, the needle should be removed quickly to avoid retroperitoneal insufflation, which further displaces the peritoneum from its attachment to the anterior abdominal wall. A second needle placement attempt is then made.
7. Once intraperitoneal placement is confirmed, a CO_2 pneumoperitoneum is obtained. Insufflation up to an IAP of 20 to 25 mm Hg, as initially described by Reich and others, remains one accepted method. This temporary increase in IAP increases the distance between abdominal viscera and the anterior abdominal wall (in the absence of adhesions) during primary sharp trocar placement through the umbilicus. It is also extremely beneficial for surgeons with small hands, who may find it difficult to grasp and further elevate the abdominal wall if the initial pressure is less than 20 mm Hg.
8. The end of the sharp trocar is held in the palm of the dominant hand, with the forefinger extended along the shaft as close to the sharp tip as possible. The tip is inserted through the umbilical incision until the fascia at the base of the umbilicus is felt. Insertion is carried through at a near-90-degree angle until the tip is felt to pass through the peritoneum. The trocar is then directed toward the pelvis to minimize risk of vascular or bowel injury.
9. After placement of the primary trocar, the intraabdominal placement is confirmed visually and the IAP is reduced to 12 to 15 mm Hg.

Alternative methods for obtaining pneumoperitoneum have been described and are useful in cases in which adhesions at or near the umbilicus are suspected. The most common method is insertion of the Veress needle in the left upper quadrant, followed by placement of a 5-mm trocar and laparoscope. Others have performed insufflation after inserting a Veress needle transfundally or through the posterior cul-de-sac into the intraabdominal cavity.

There are no prospective randomized studies comparing the safety and efficacy of open-entry with closed-entry techniques. The incidence of injuries is so low that a very large study population would be required to show any statistical difference. Randomized studies comparing the Veress needle with the direct trocar insertion technique favor the Veress needle. The vast majority of surgeons agree that the method used should be that with which the surgeon has the most experience and is, therefore, most comfortable.

Laparoscopic Procedures

Ectopic Pregnancy Through earlier diagnosis, ultrasonography has reduced significantly the morbidity and mortality associated with ectopic pregnancies. In 98% of cases after the fifth week of pregnancy (when HCG levels are greater than 1,000), transvaginal ultrasonography can reliably visualize a normal gestational sac. The absence of an intrauterine sac above this level should alert the physician of a high likelihood of ectopic pregnancy. With the advent of methotrexate use, the total number of ectopic pregnancies treated surgically has decreased. Laparoscopy remains a standard for surgical management in the stable patient. While obtaining

informed consent, the surgeon must discuss management alternatives. Should the pregnancy alone be removed leaving the fallopian tube in place, or should a salpingectomy be performed? Assuming the pregnancy can be aborted without significant bleeding from the fallopian tube, this decision should be based on the status of the contralateral ovary and tube. If the contralateral tube and ovary are normal in appearance, without adhesions, then a salpingectomy or salpingostomy may be performed with a subsequent intrauterine pregnancy rate of 85% and a repeat ectopic rate of 90%. If the contralateral tube is impaired, then the subsequent intrauterine pregnancy rate is 46% and repeat ectopic rate 52%. In this situation, the affected fallopian tube should be removed.

Technique for Salpingostomy or Salpingectomy Laparoscopic access is obtained as previously described. In addition to the umbilical port, two 5-mm lower abdominal ports are indicated, left and right. A suction-irrigator is used to aspirate the hemoperitoneum, if present. The pregnancy is identified within the fallopian tube, usually within the ampullary portion. The tube is stabilized with a Babcock or atraumatic grasper. There is considerable debate regarding the use of dilute vasopressin prior to making the incision on the antimesenteric side of the tube overlying the pregnancy. Clinicians must understand the use of vasopressin has the potential for delayed bleeding postoperatively. An incision parallel to the axis of the tube is now made on the antimesenteric side. This may be performed using a spoon, knife, or hook monopolar electrocautery, set at 50 to 80 watts to minimize bleeding. The suction-irrigator is used to “aquadissect” the attachments between the pregnancy and tube, thus aborting the pregnancy into the pelvis. Alternatively, the pregnancy may be grasped using atraumatic graspers and pulled from its attachment. It is then removed from the abdomen through the operating channel of a right-angle laparoscope or a 10-mm or larger port. If significant bleeding is encountered or the pregnancy does not dissect freely, a salpingectomy may need to be performed. Again, the fallopian tube is grasped with an atraumatic grasper and lifted. The tube is transected approximately 1 cm from its cornual end. Transection is performed after complete desiccation using bipolar cautery via Kleppinger forceps or may be performed after suture ligation (a window is created within the mesosalpinx inferior to the ligation site). The mesosalpinx, immediately inferior to the fallopian tube, is then desiccated using bipolar cautery and transected, freeing the tube and pregnancy from its anatomic attachments.

Adnexal Mass Laparoscopic management of adnexal masses is gaining acceptance but still conjures considerable debate. The patient's age, transvaginal sonographic findings, and CA-125 level (if indicated based on patient's age) will determine if a laparoscopic approach rather than laparotomy is acceptable. Ultrasonographic criteria for benign and malignant tumors are presented in Table 46.4 and Table 46.5. CA-125 levels are most useful in postmenopausal women. A level of 35 units in postmenopausal women carries a sensitivity of 81% and specificity of 91% for malignancy. If the level is greater than 50, then the sensitivity remains essentially the same and the specificity increases to 97%. In premenopausal women, sensitivity remains 60% as the level increases, but specificity increases from 73% at a level of 35 to 95% at a level of 100.

Size greater than 5 cm
High (solid) echogenicity
Internal septations
Irregular border
Papillary intracystic formations
Ascites

TABLE 46.4. *Ultrasonographic criteria for malignant ovarian tumors*

Size less than 10 cm
Unilateral border
Smooth border
Absence of excrescences
Absence of solid parts
Absence of fluid in the cul-de-sac

TABLE 46.5. *Ultrasonographic criteria for benign ovarian tumors*

A primary concern for those advocating laparotomy over laparoscopy for management of suspicious adnexal masses is the potential increased risk of rupture during laparoscopic surgery. Preoperative or intraoperative rupture changes a stage Ia ovarian carcinoma to a stage Ic. Studies have shown that intraoperative iatrogenic rupture of the tumor capsule does not adversely affect survival, but survival is negatively influenced by spontaneous or preoperative rupture. The American College of Obstetricians and Gynecologists guidelines for intraoperative management of adnexal masses are presented in Table 46.6. As a general rule, if malignancy is highly suspected, then a laparotomy and complete surgical staging procedure should be performed. If a laparoscopy is performed initially and malignancy subsequently is identified histologically, the staging procedure should be completed within 1 week.

Obtain peritoneal washings
Explore the upper abdomen
Obtain biopsy specimens from any abnormal areas
Look for external excrescences
Perform laparotomy for any question of malignancy or if mass is removed inadequately
Use frozen sections for cytologic analysis; perform laparotomy if malignant

ACOG, American College of Obstetricians and Gynecologists.

TABLE 46.6. *ACOG guidelines for laparoscopic intraoperative management of adnexal masses*

Technique for Ovarian Cystectomy After obtaining intraperitoneal access and placement of trocars, the uteroovarian ligament is grasped to stabilize the ovary. The ovarian cortex overlying the cyst is incised very superficially so as not to rupture the cyst. This may be performed using a CO_2 laser set at 5 to 10 watts, a monopolar electrode (knife, hook, spoon) set at 30 to 50 watts of cutting current, or scissors. The edge of the cut ovarian cortex is grasped with a biopsy forceps and elevated. The suction-irrigator is placed gently at the opening between cortex and cyst wall. Aquadissection is performed using Ringer's lactate. A blunt grasper is introduced within the space and the cyst is shelled out from its attachment to the cortex. The incision is made longer as necessary. The cyst is placed within an impermeable sac introduced through the umbilical port or through a culdotomy incision. For larger cysts, a zip-lock type sandwich bag may be gas sterilized and placed through the 10- to 12-mm umbilical port. The sac is then removed either through the umbilicus or transvaginally. A spinal needle may be used to aspirate the contents of the cyst within the sac prior to removal to decrease its volume.

Technique for Oophorectomy The first step in an oophorectomy procedure is always identification of the adjacent ureter. The ureter is most easily located at the pelvic brim near the bifurcation of the common iliac. Its retroperitoneal course may then be followed and location relative to the infundibulopelvic ligament noted. Once certain of the ureteral location, the infundibulopelvic ligament is grasped gently, elevated, and brought medially using a Babcock or other atraumatic grasper. The ligament is then desiccated at its attachment to the ovary using bipolar cautery. It is then transected. Alternatively, an opening through the peritoneum inferior to the ligament may be created using scissors. Suture ligatures may then be placed and tied. After transection of the infundibulopelvic ligament, the uteroovarian ligament is desiccated and transected. Desiccation of the mesovarium is followed by transection, completely freeing the ovary. The ovary is then placed in an impermeable sac and removed as described previously.

Tubal Sterilization Surgical occlusion of the fallopian tubes is the most common method of contraception in developing countries. The techniques have evolved from a laparotomy to minilaparotomy to a laparoscopic approach including excision, electrosurgical desiccation using bipolar cautery, and application of clips or rings. A Pomeroy tubal ligation is easily performed laparoscopically by grasping the fallopian tube at its isthmic portion and placing a chromic endoloop suture around a segment of tube. The knuckle of tube may then be excised. Two clips are approved by the U.S. Food and Drug Administration for tubal occlusion, the Hulka-Clemens clip and the Filshie clip. Both clips are placed properly at the proximal isthmus after the tube has been placed on stretch. The clip should be applied at 90 degrees to the long axis of the tube and advanced until the hinge reaches the tube, incorporating the mesosalpinx at its tip. The falope ring is placed on the ampullary portion of the fallopian tube by grasping the tube with the applicator and drawing the tube inside the applicator. A 1- to 2-cm segment of tube is drawn into the ring. Although sterilization failure rates are lowest with unipolar cautery, most are performed using bipolar cautery. Bipolar desiccation is performed correctly with an in-line ammeter (indicating complete desiccation), current set at 25 watts, and desiccation of three contiguous areas of the isthmus incorporating the blood supply from the mesosalpinx. The results of the U.S. Collaborative Review of Sterilization study found that all methods of tubal occlusion are very effective, although failure rates were higher than expected. The Hulka-Clemens clip and bipolar methods carry the highest failure rates, likely due to improper application technique.

Myomectomy Women with symptomatic leiomyomas who wish to retain their reproductive potential or who wish to retain their uteri are candidates for myomectomy. Most of these procedures are still performed abdominally, because laparoscopic myomectomy is one of the more difficult laparoscopic procedures. There is controversy as to whether a laparoscopic closure of the myometrium is comparable to a closure achieved in an open procedure. In general, a laparoscopic approach should not be selected if leiomyomas are larger than 5 to 8 cm, multiple, or embedded deep within the myometrium. If a laparoscopic approach is chosen, the patient should be informed of the potential increased risk of spontaneous uterine rupture prior to labor and of recurrence (33% after 27 months). Most myomectomies can be performed with three trocar sites. One 10-mm trocar is placed umbilically and 5-mm ones in the lower left and right abdomen. A vertical incision is made in the myometrium overlying the myoma using a spoon electrode (or other electrosurgical instrument) set at 80 watts of cutting current to minimize bleeding. The incision is continued through the myometrium to the surface of the myoma, identifying the plane between the pseudocapsule and fibroid. The myoma is grasped with a 5-mm single-toothed tenaculum or corkscrew, and traction is applied. The plane between the fibroid and pseudocapsule is entered and adhesions released with a combination of blunt and sharp dissection. The suction-irrigator works well here for blunt dissection. The adhesive attachments are desiccated using bipolar forceps prior to their transection to minimize bleeding. These adhesions may also be vaporized using the CO_2 laser. The process is continued until the base of the myoma is reached, where the remaining attachments are desiccated using bipolar cautery. The myoma is freed and placed in the posterior cul-de-sac for later retrieval. Hemostasis of the myometrium is achieved. A multilayer closure is now performed using single interrupted sutures placed and tied laparoscopically. Alternatively, if the operator is not skilled in laparoscopic suturing, or if there is a concern regarding obtaining a maximally tight closure, a small laparotomy incision may be made and the suturing performed abdominally. A uterine manipulator placed within the uterus can help to elevate the uterine incision to the laparotomy incision and make suturing through a smaller incision easier. The myoma is now removed from the abdomen. If a small laparotomy incision has been made, the myoma may be removed through this incision. Morcellation using a scalpel or scissors may be necessary if the myoma is larger than the incision. If the entire procedure has been performed laparoscopically, the myoma may be removed using a morcellator introduced through the umbilical incision and visualized with a 5-mm laparoscope placed in one of the lower trocar sleeves. Alternatively, a culdotomy incision can be made and the myoma removed vaginally. The culdotomy incision may then be closed vaginally or

laparoscopically.

Hysterectomy The advanced surgical skills required to perform a laparoscopic hysterectomy and the economic factors involved have limited the acceptance of this procedure in gynecologic practice. The laparoscopic hysterectomy or laparoscopically assisted vaginal hysterectomy was never intended to replace the vaginal hysterectomy. The primary role of this procedure is to reduce the number of abdominal hysterectomies performed. Seventy percent of hysterectomies in the United States are performed abdominally. A review of the data from the Health Insurance Commission Medicare in Australia showed a decrease in the incidence of abdominal hysterectomy from 70% in 1991-1992 to 57% in 1994-1995 after the introduction of laparoscopically assisted hysterectomies in private hospitals. The American College of Obstetricians and Gynecologists has agreed on the indications listed in Table 46.7 for laparoscopically assisted vaginal hysterectomy (there has been no comment on total laparoscopic hysterectomies, but the same indications inherently would apply).

Prior pelvic surgery requiring lysis of adhesions
Endometriosis requiring treatment or lysis of adhesions or both
Pelvic inflammatory disease requiring lysis of adhesions
Ligation of infundibulopelvic ligaments for ovarian removal allowing completion by vaginal hysterectomy
Pelvic mass
Limited uterine mobility
Narrow pubic arch
Constricted vagina with no prolapse

TABLE 46.7. *Indications for laparoscopically assisted vaginal hysterectomy*

Several randomized controlled trials comparing laparoscopically assisted vaginal hysterectomies with abdominal hysterectomies reported that the former are associated with significantly less postoperative pain, shorter hospital stays, faster return to work and normal activities, but possibly longer operative times.

Technique for Total Laparoscopic Hysterectomy A uterine manipulator (e.g., RUMI system), a vaginal extender (e.g., Koh Cup Vaginal Fornices Delineator), and a pneumooccluder (Colpo-Pneumo Occluder; all products from Cooper Surgical, Shelton, CT) or similar instruments are put in place at the beginning of the procedure. A 10-mm reusable trocar is introduced through the umbilicus after pneumoperitoneum is obtained as described previously. Five-millimeter trocars are introduced into the lower left and right abdomen under direct visualization. The course of the ureters is identified retroperitoneally. If the ovaries are to be removed, the infundibulopelvic ligament is isolated, desiccated, and transected as described previously for oophorectomy. If ovaries are to remain, then the round ligament, fallopian tube, and uteroovarian ligaments are desiccated using bipolar forceps and transected approximately 1 cm from their uterine attachments. The anterior leaves of the broad ligament are incised bilaterally to meet in the midline, releasing the bladder peritoneal attachment to the lower uterine segment. The harmonic scalpel with the hook attachment works well to minimize oozing. The bladder is gently pushed inferiorly over the vaginal metal colpodelineator. The posterior broad ligaments are incised downward using scissors to the insertion of the uterosacral ligaments, allowing lateral retraction of the ureters. The uterine arteries are identified within the broad ligament, and the surrounding loose, areolar tissue is skeletonized in a blunt fashion. The uterine arteries are then desiccated completely, as indicated by the ammeter, by placing the bipolar forceps at right angles to the lower uterine segment on either side, above the level of the vaginal metal colpodelineator. The uterus should take on a bluish hue if complete desiccation has been achieved. The desiccated arteries are transected, freeing the cardinal ligament attachment. The vaginal pneumooccluder balloon is then insufflated prior to the colpotomy incision. The vaginal metal colpodelineator is emphasized by pushing the uterus cranially. The harmonic scalpel with hook electrode is used to make a circumferential incision over the metal ring, releasing the cervicovaginal attachment. The occluder balloon is deflated, and the uterus is brought into the vagina and now serves as the pneumooccluder. Hemostasis of the vaginal cuff is achieved. The cuff is sutured and closed laparoscopically, incorporating the uterosacral ligaments for pelvic support. The uterus is then removed from the vagina.

Endometriosis Surgical treatment of endometriosis usually is performed for pain or infertility. There are no randomized controlled trials comparing excision, vaporization, fulguration, and desiccation of endometriotic lesions. Although each method of destruction has its proponents, the authors prefer excision of deep fibrotic endometriosis and vaporization of superficial implants. The only definitive cure for endometriosis is surgical resection or complete destruction of the endometriotic lesion. Surgical management does not include bilateral salpingo-oophorectomy. Removal of the ovaries will not necessarily ensure relief of symptoms. Estrogen, in addition to that produced by the ovaries, also is produced by peripheral conversion of androgens in the presence of aromatase. Aberrant aromatase expression has been identified in some endometriotic implants, causing local production of estradiol within them. This may explain the reason for failures or “recurrences” after bilateral salpingo-oophorectomy or only superficial destruction of the implant. Ovarian endometriomas should be treated by cystectomy rather than drainage and coagulation, as evidenced by the results of a randomized clinical trial. Often, these ovaries are adherent to the pelvic sidewall, adjacent bowel, or the opposing ovary. During adhesiolysis, the endometrioma often is ruptured, spilling its thick, chocolate-like fluid into the cul-de-sac. The thick fluid should be aspirated and opening to the endometrioma identified. If necessary, the opening is enlarged until the thick endometrioma cyst wall is identified. Using a biopsy forceps (single-toothed grasper), the cyst wall is grasped and peeled from its attachment to the ovarian cortex. Once hemostasis is achieved, the cortex usually does not require suture closure.

Complications

Information regarding entry access injuries is provided in a review reflecting the Physician Insurers Association of America (PIAA). They noted that entry access injuries occurred in between 5 per 10,000 and 3 per 1,000 patients undergoing laparoscopic surgery. Bowel, rectal, and retroperitoneal vascular injuries accounted for 76% of all injuries incurred in the process of establishing a primary port. The PIAA reported that approximately 50% of bowel injuries were unrecognized for 24 hours or longer following the laparoscopic surgical procedure. A delay in recognition, age over 59 years, and major vascular injuries were independent factors associated with death.

In a Canadian Task Force study, the overall complication rate for all laparoscopic procedures was 0.65%; for operative laparoscopy it was 0.80%. The American Association of Gynecologic Laparoscopists has noted similar results (1.45 complications per 1,000 procedures).

In a review of 32,205 gynecologic laparoscopic procedures in a Finnish study, 130 major complications were noted. The total complication rate was reported as 4 per 1,000 and, more specifically, 0.6 per 1,000 diagnostic laparoscopies, 0.5 per 1,000 sterilizations, and 12.6 per 1,000 operative laparoscopies. Intestinal injuries were reported in 0.7 per 1,000 procedures, incisional hernias in 0.3, urinary tract injuries in 2.5, major vascular injuries in 0.1. Overall, laparoscopically assisted vaginal hysterectomy was associated with the highest complication rate at 2.3%, with ureteral injuries occurring in 1% of women undergoing the procedure.

Gas and air emboli have been reported with both laparoscopic and hysteroscopic procedures. Oxygen saturation monitoring, as well as end-tidal carbon dioxide and, more recently, capnography and mass spectrometry, are designed to provide early diagnosis. If an embolus occurs, it frequently is accompanied by cardiac arrhythmia and cardiac arrest. It is beyond the scope of this chapter to provide detailed information regarding cardiopulmonary resuscitation.

Ureteral injury, as noted above, has been reported in association with minimally invasive surgery. Often times it is not recognized at the time of the initial procedure. The diagnosis should be considered when a patient exhibits postoperative fever, hematuria, flank pain, or evidence of peritonitis. Initial treatment with ureteral stenting on occasion is inadequate, resulting in subsequent ureteroneocystostomy. With respect to bladder injury, if one suspects such, distension of the bladder with methylene blue can identify a defect. If there is suspicion of ureteral injury, intravenous administration of indigo carmine frequently proves helpful in identifying the defect.

Other minimally invasive surgery–associated complications have included spleen laceration. The injury was reported in four patients, and predisposition included splenomegaly, with injury occurring primarily during trocar insertion. This was associated with a laparoscopic salpingoplasty. However, this complication is extremely rare.

Death, although extremely rare following minimally invasive surgical procedures, has been reported. It is more commonly associated with unrecognized trauma to the intestinal tract with ensuing sequelae. It also has been reported in association with major vascular trauma.

SUMMARY POINTS

- Endoscopic surgery has replaced open surgery for many commonly performed gynecologic procedures such as tubal sterilization, excision of unruptured tubal pregnancies, ablation of peritoneal endometriosis, and simple ovarian cystectomy.
- Endoscopically assisted vaginal hysterectomy with removal of the adnexal structures demonstrates the potential for this technology.
- Endoscopic procedures have several advantages. They can be performed on an ambulatory basis, require shorter recovery times, cause less postoperative pain, and improve the cosmetic impact of incisions.
- Endoscopic procedures require specialized equipment and a high degree of technical skill.

INTRODUCTION

Although hysteroscopy has been described since the early 1800s, widespread use by practicing gynecologists did not occur until the 1980s. With improvements in optics, video systems, and distension media, there has been an increased acceptance of hysteroscopy as the gold standard in the evaluation of the uterine cavity and treatment of intracavitary pathology.

Hysteroscopy is used most commonly for evaluation of abnormal uterine bleeding, but it also is used frequently for evaluation of the endometrial cavity in patients with recurrent pregnancy loss and infertility. Many studies have shown that blind dilation and curettage may miss up to 60% of endometrial pathology, such as endometrial polyps and submucous leiomyoma, although with increasing expertise in ultrasonographic techniques such as the saline sonohysterogram, endometrial pathology often can be suspected prior to performing definitive operative hysteroscopy. Alternatively, many practitioners perform office hysteroscopy with small-diameter hysteroscopes, which do not require significant dilation of the cervix, can provide direct visualization of the endometrial cavity, and facilitate a directed biopsy of suspected endometrial lesions.

Operative hysteroscopy requires larger diameter instrumentation and is best performed under anesthesia in the outpatient operating room because of the need for significant cervical dilation and more extensive instrumentation. Hysteroscopic surgery allows a variety of intrauterine surgical procedures such as myomectomy, polypectomy, resection of a uterine septum, endometrial ablation, correction of intrauterine synechiae, and cannulation of proximal tubal occlusion.

INSTRUMENTATION

Hysteroscopy can be used both as a primary diagnostic tool and as a more definitive operative technique. Diagnostic hysteroscopy can be performed either in an office setting or in the outpatient operating room and requires only small 3.6-mm to 5-mm hysteroscopes. These hysteroscopes may be either flexible or rigid. A small channel often is provided for a small biopsy instrument, but these are rather delicate, and significant surgical procedures will require larger hysteroscopes.

The flexible hysteroscope is used often for office hysteroscopy because it can be inserted through a narrow cervical os and can negotiate the cervical canal, using a deflecting lever to guide the instrument. The flexible hysteroscope is available in two diameters, 3.6 mm and 4.9 mm, both with a zero-degree optical view. The larger diameter endoscope also provides a 2.2-mm diameter instrument channel, which allows for directed biopsies of endometrial pathology. The larger instrument provides better optics than the smaller flexible hysteroscope but is still somewhat inferior optically to a 4-mm rigid scope.

Most small diagnostic hysteroscopes have only a single channel for installation of a distending medium. In an office setting, many physicians employ CO_2 as the distension medium, necessitating the use of a hysteroscopic insufflator to control intrauterine pressure. If blood or mucus is present within the endometrial cavity, a liquid medium will be required. If a low-viscosity liquid distension medium is used, then a continuous flow sheath, which allows for the continuous simultaneous inflow and outflow of the medium, thus flushing any blood or mucus from the cavity, will give the optimal view.

Rigid hysteroscopes are available with 0-, 12-, 15-, 30- and 70-degree optical view telescopes. Thirty-degree scopes are used primarily for diagnostic procedures in order to see easily the entire endometrial cavity by rotating the telescope 360 degrees. Operative procedures most commonly require the 12- or 15-degree telescopes, so that the operational component of the instrumentation can be visualized fully.

The operative hysteroscope uses a 4-mm rigid telescope within a 7- to 8-mm operative sheath, which can be configured to either provide a port for the insertion of accessory instruments (scissors, biopsy forceps, catheters) or use a resectoscope with a working element for resectoscope electrodes. Older models of operative hysteroscopes included only a single channel for installation of distension medium. Adequate egress of fluid usually is not possible with these hysteroscopes, because the only available exits are the fallopian tubes or around the hysteroscope through a patulous or over-dilated cervix. Use of these single-channel hysteroscopes should be limited to high-viscosity distension media. Most commonly, operative hysteroscopy is performed with a continuous flow sheath allowing for input of the distension medium through a middle channel and egress of the medium through an outer evacuation channel. This provides for constant washing of the uterine cavity, removing blood and debris and allowing the use of a low-viscosity distension medium.

Infusion of low-viscosity fluids can be accomplished either by the force of gravity or with infusion pumps. Suction tubing attached to the outflow port can be directed to wall suction or allowed to drain by gravity. Low-viscosity–fluid pumps have been designed to operate in pressure ranges of 0 to 80 mm Hg. They can deliver fluid at a rate necessary to maintain a preset pressure with a maximum flow rate of 300 mL/minute, although the upper limit of flow through the outflow ports for most hysteroscopes is 250 mL/minute. Outflow usually is adjusted to be significantly lower than the maximum to allow adequate visualization free from blood and debris, maintain adequate uterine distension, and minimize the amount of fluid needed to complete the procedure.

Alternatively, inflow of the distension medium can be controlled by gravity. The height of the bag of infusion medium above the patient controls the maximum intrauterine pressure. Every 1 foot of height above the patient that the bag of distension medium is placed will deliver approximately 25 mm Hg of pressure to the endometrial cavity. This system is then regulated by the amount of outflow, to maximize visualization while maintaining adequate uterine pressure. Because pressure of inflow is constant, changes in intrauterine pressure, and thus distension, are affected by alterations of the rate of the outflow. Use of standard suction containers to collect the outflow will make fluid measurement and calculation of any fluid deficit straightforward.

Modern operative hysteroscopy requires a video camera and video monitor for adequate operative visualization. A halogen or xenon light source providing 150 to 300 watts of incandescent light is used and attached to the hysteroscope by a fiber optic light cable. The light cable should be inspected frequently to ensure that a significant number of the internal fibers have not broken and that the light cable is capable of delivering an adequate amount of light through the hysteroscope. Most chip cameras have the capability to adjust gain and can be integrated with the light source for automatic light balance.

For documentation of findings and recording of procedures, video capture units may be used. Most commonly, VCRs are used to videotape pertinent portions of the procedure. Also available are video capture units for taking still pictures or storing digital images on a computer hard disk or CD.

Energy for operative hysteroscopy can be delivered either with the Nd:YAG laser or with electrosurgical generators delivering either unipolar or bipolar energy. Other

lasers, such as the CO_2 laser, are not used in hysteroscopy because of their failure to penetrate fluid and because of the generation of smoke if CO_2 is used as the distension medium. The Nd:YAG laser can be delivered through a flexible quartz fiber passed through the instrument channel of the operating hysteroscope, and its wavelength penetrates through the liquid distension medium used in hysteroscopy. The extent of tissue necrosis can be up to a depth of 4 to 5 mm. Varying the distance of the fiber tip and incident angle can regulate the extent of thermal damage. It is rendered ineffective at distances greater than 2 cm or as the incident angle deviates more than 90 degrees. This laser is used often to perform endometrial ablation, using power outputs of 50 watts by dragging the fiber over endometrial surfaces.

Electrosurgery through a standard resectoscope usually utilizes a monopolar technique, with the electrical probe serving as the source electrode and the return plate on the patient as the return electrode. The resectoscope can be used with either cut or coagulation output settings on the electrosurgical generator, or a blend of the two. When used in the cutting mode a high-frequency sine wave is delivered, which creates extremely high current density, instantly superheating cellular water to vaporization, causing cellular architecture to explode, resulting in tissue cutting. In the coagulation mode, delivery of high-frequency energy is interrupted by periods of modulation. This alternation of frequency and interruption results in wider zones of lateral tissue coagulation and damage, resulting in coagulation and sealing of blood vessels. A variety of electrode tips are available including a cutting loop for excision of tissue, a roller ball or bar for coagulation and ablation, and a knife electrode for incision.

A new family of bipolar electrical generators (Versapoint, Gynecare of Ethicon, Somerville, New Jersey) has been developed. Electrodes have been designed in several configurations producing variable tissue effects. A ball tip can be used for vaporization with limited tissue desiccation, a spring tip for vaporizing larger amounts of tissue, and a twizzle tip for resecting and morcellating tissue. These tips have both active and return electrodes and require an electrolyte-containing medium such as saline. In contrast, if one is using a monopolar resectoscope, a nonelectrolyte distension medium such as glycine must be used.

Distension Media

Four basic types of distension media are used for hysteroscopy. The first type, CO_2, is used primarily for diagnostic hysteroscopy in an office setting. Secondly, a high-viscosity medium such as Hyskon is used primarily with inflow only–type hysteroscopes. The third and fourth types are both low-viscosity solutions that are used with continuous flow hysteroscopes, electrolyte solutions and nonelectrolyte solutions. The choice between an electrolyte and nonelectrolyte solution will depend on the use of monopolar versus bipolar electrocautery.

For diagnostic procedures in the office, many physicians choose CO_2 as the distension medium. CO_2 use requires a hysteroflator that delivers the gas at preset intrauterine pressures and has regulated flow rates. CO_2 may be used with either a small diagnostic rigid hysteroscope or a flexible hysteroscope and does not require a return channel for continuous flow, because the CO_2 gas will escape from the cervix or through patent fallopian tubes into the peritoneal cavity where it is absorbed. Starting pressures for CO_2 are usually between 50 and 75 mm Hg. If adequate distension is not achieved, it may be necessary to increase the intrauterine pressure to a maximum of 100 mg Hg or a maximal flow of 100 mL/minute. Higher pressures or flow rates may produce a gas embolus and fatalities have been reported. CO_2 will give an ideal view of a uterus that is not bleeding, because light reflection is identical to that of room air. However, any blood or mucus within the endometrial cavity will require changing to a liquid medium.

Thirty-two percent high-molecular-weight Dextran-70, Hyskon, was used commonly as a liquid distension medium for operative hysteroscopy for many years prior to the evolution of hysteroscopes that accommodate continuous flow. Its nonmiscibility with blood allowed its use when either blood or mucus was present in the endometrial cavity or bleeding is anticipated. Hyskon is compatible with either the Nd:YAG laser or electric cautery devices. When using Hyskon as the distension medium, its delivery requires significant constant pressure to overcome the resistance of a high-viscosity fluid flowing through a standard diagnostic sheath. The major disadvantage of Hyskon is the difficulty in cleaning the solution from the instruments and stopcocks. If the instrumentation is not thoroughly cleaned, the dextran crystallizes and results in clouding of the hysteroscope lens and freezing of stopcocks. Rarely, patients may have an anaphylactic reaction to the dextran. Intravascular absorption of Hyskon will also result in a ten-fold increase of intravascular volume, with accompanying cardiovascular overload and pulmonary edema. Careful monitoring of the amount of Hyskon intravasated during the procedure is mandatory, and absorption of 100 to 200 mL of Hyskon should warrant terminating the procedure. Because the molecular weight of Hyskon exceeds that which can pass into the circulation from the peritoneal cavity, spill through the fallopian tubes is inconsequential.

Operative hysteroscopy most commonly now uses low-viscosity solutions, which can be either electrolyte solutions or nonelectrolyte solutions. If monopolar resectoscopes are used, this equipment requires nonelectrolyte solutions, so that the flow of energy will be directed from the electrode tip into the tissue and not allowed to “short circuit” through an electrolyte-containing medium throughout the entire uterus. Nonelectrolyte solutions that have been used commonly for operative hysteroscopy include 1.5% glycine, sorbitol, 5% mannitol, and dextrose in water. Significant intravasation of distension medium may occur with resectoscope use. As tissue is resected, venous channels within the endometrium and myometrium are opened, and the pressure of the distension medium will result in the absorption of these solutions. The primary complications associated with nonelectrolyte low-viscosity solutions include fluid overload and hyponatremia. Fluid overload may result in pulmonary edema, and severe hyponatremia may result in neurologic sequela such as confusion, seizures, and even death. Intraoperative monitoring of inflow and outflow must be performed every 5 to 10 minutes throughout the procedure, and a discrepancy between 500 and 1,000 mL with nonelectrolyte solutions should warrant termination of the procedure. Glycine use has also been reported to cause hyperammonemia because of its conversion from glycine to ammonia by the liver.

Electrolyte solutions, such as normal saline or lactated Ringer solution, are used with bipolar electrical devices or for continuous flow diagnostic hysteroscopy. Because bipolar devices contain both the active and return electrodes at the electrode tip, electrolytes are needed to complete the electrical circuit. The primary complication associated with electrolyte solutions is fluid overload, and a discrepancy of 1,500 to 2,000 mL during the procedure warrants termination of the procedure.

During operative hysteroscopy with significant operating time and use of large amounts of distension medium, the anesthesiologist should keep intravascular fluid replacement to a minimum to avoid fluid overload. Anesthesia personnel should also monitor the patient carefully for electrolyte abnormalities when using nonelectrolyte solutions and anaphylactic shock when using Hyskon.

General Technique

Hysteroscopy can be difficult to perform during the luteal phase because of the abundance of endometrial tissue. Performing hysteroscopy during the early to middle follicular phase should ensure adequate visualization of the uterine cavity. Alternatively, the endometrium can be suppressed with 2 to 4 weeks of progestin therapy, or hysteroscopy may be performed at any time in a patient taking oral contraceptives because of the dominant atrophy effect of progestin. Gonadotropin-releasing hormone (GnRH) analogs have most commonly been used to prepare the endometrium for endometrial ablation. At least 4 weeks of preoperative treatment are required for GnRH analogs such as leuprolide acetate (Depo-Lupron), because these medications are initially agonists and will actually increase estrogen output for the first 7 to 10 days before subsequent down-regulation of the pituitary ovarian axis and subsequent endometrial atrophy.

The cervix should be dilated no larger than the outer diameter of the hysteroscope that will be used. With many larger operative hysteroscopes, this will require dilation of the cervix to at least the diameter of a 20-French Hank dilator or a 9/10-French Hegar dilator. Care should be taken to avoid cervical lacerations and uterine perforation during cervical dilation.

With insertion of the hysteroscope, the cervical canal can be visualized and the hysteroscope guided into the endometrial cavity under direct vision. If over-dilation of the cervix has occurred and the distension medium cannot be kept within the endometrial cavity, an additional tenaculum may be placed on the posterior lip of the cervix, or a special four-pronged tenaculum can be used to compress the cervix around the hysteroscope. The cervical canal and internal os will appear off-center within the field of view when using offset-angle lenses. When the angle of the lens is oriented to look downward, the internal os will appear at the 12 o'clock position. If the telescope is inverted and the lens pointed upward, the os will appear in the 6 o'clock position. The latter position is useful for viewing a retroverted uterus. The surgeon always should maintain the camera position in a straight-up-and-down configuration so that the view on the screen corresponds anatomically to the patient's position. As the hysteroscope is rotated to visualize the entire endometrial cavity, one hand should be kept on the camera to prevent its rotation, or the view on the monitor will be oriented improperly.

With insertion of the hysteroscope, the cervical canal should be visualized and the endometrial cavity entered carefully through the internal os. If adequate visualization is prevented by blood and mucus, continuous flow of the distension medium should be maintained for 30 to 60 seconds to wash out blood and debris. If the field of view still appears red, the hysteroscope should be pulled back 1 to 2 centimeters, because it is a common mistake to insert the hysteroscope too far and the lens may be abutting the uterine fundus. Visualization can also be compromised by inadequate distension of the uterine cavity because of insufficient intrauterine pressure. The fluid delivery devices should be checked to ensure adequate pressure, or if a gravity system is being used, the height of the bag above the patient should be extended. Careful adjustment of the outflow should be made to clear any ongoing bleeding and debris without decreasing intrauterine pressure or using extremely large volumes of distension medium.

The entire endometrial cavity should be inspected carefully, including the identification of both tubal ostia, the fundus, and the anterior and posterior portions of the

uterine wall. Video documentation of the intraoperative findings is useful. If operative techniques are to be used during the hysteroscopy, inflow and outflow should be measured carefully and reported to the surgeon every 5 to 10 minutes. If significant bleeding or a long operative time is anticipated, vascular constriction through the paracervical injection of a dilute pitressin solution may be used. Care should be taken that pitressin is not injected intravascularly, because reports of fatalities with inadvertent intravenous administration have been reported.

ENDOMETRIAL ABLATION

Approximately 35% of gynecologic complaints concern menorrhagia, and it is estimated that 60% of these women ultimately will be treated with hysterectomy. Endometrial ablation originally was developed as an alternative treatment for patients who are medically too unstable for the surgical stress of hysterectomy. Since its original development in the 1980s, however, patient selection criteria have now expanded and hysteroscopic endometrial ablation is viewed by many as an alternative to hysterectomy, even in healthy patients. Prior to consideration of hysteroscopic endometrial ablation, endometrial pathology needs to be excluded with either a combination of endometrial biopsy to rule out hyperplasia or carcinoma and transvaginal ultrasonography with saline infusion to rule out polyps or submucous myomas or, alternatively, office diagnostic hysteroscopy could be performed with directed biopsies.

Because the goal of an endometrial ablation is the artificial creation of intrauterine synechiae, many experts feel that preoperative preparation of the endometrium with an GnRH agonist or continuous progestin will maximize the chance of adequate scar formation within the endometrial cavity postoperatively. Alternatively, some authors perform a mechanical preparation of the endometrium using a sharp curette or suction curettage immediately prior to endometrial ablation. This technique has the advantage of being able to immediately perform the procedure without a lengthy preoperative medical suppression of the endometrium. The disadvantage of a mechanical preparation, however, is the possibility of inadequate visualization during the procedure because of bleeding and the possibility of a compromised outcome secondary to inadequate destruction of the endometrial basalis.

Endometrial ablation can be done either with the Nd:YAG laser or the hysteroscopic resectoscope, using either a wire lube or roller ball technique. The Nd:YAG laser system uses a 600-μ bare fiber with power settings of 55 to 70 watts. The Nd:YAG laser penetrates 4 to 5 mm into the endometrium, destroying not only the superficial endometrial layers but also the endometrial basalis and superficial myometrium. A touching technique was described originally, dragging the fiber against the endometrium, thus destroying the endometrium and superficial myometrium by vaporization and necrosis. Alternatively, a nontouch technique with the higher power setting has been described in which the fiber is held perpendicular to the endometrium without touching the surface, achieving a deep coagulation effect. Many practitioners use a combination of the two techniques, and results of the two techniques appear comparable.

Due to the expense of laser ablation, electrosurgical ablation is performed more commonly. Most resectoscopes use monopolar electrodes, necessitating a nonelectrolyte low-viscosity medium. Hysteroscopic resection of the endometrium has been described using a loop electrode to excise strips of endometrium, although the incidence of uterine perforation is reportedly higher with this technique when compared with a roller ball or laser ablation. Most commonly, a roller ball technique is used. With a roller electrode, a blend 1 setting with 70 to 140 watts of power is used, depending on the width and thickness of the electrode. This current will allow consistent penetration and destruction of the uterine tissue. Care must be taken to ensure adequate ablation of the uterine cornu and to avoid destruction of the endocervical canal to prevent cervical stenosis.

Extensive studies of the outcome following endometrial ablation have been published. Approximately 80% to 90% of women will have a significant reduction of their menorrhagia and will be satisfied with the outcome, including approximately 25% to 40% of women experiencing amenorrhea postoperatively.

Complications of endometrial ablation include a 10% hysterectomy rate because of dissatisfaction with the outcome of surgery. In addition to the immediate postoperative complications previously discussed, there also have been reports of isolated endometrial carcinoma in areas of the uterus not adequately ablated and symptomatic hematometra developing in loculated areas of inadequate ablation. Although most women are sterile after this procedure, intrauterine pregnancies can occur and patients should be counseled to use adequate contraception.

HYSTEROSCOPIC SEPTUM RESECTION

The septate uterus is the most common congenital uterine malformation associated with recurrent reproductive failure and obstetric complications. The appearances of a septate uterus and bicornuate uterus are extremely similar on hysterosalpingogram, and the distinction must be made by demonstrating a normal external fundal contour with a uterine septum, as opposed to the presence of two uterine horns in a bicornuate uterus. The uterine septum may be thin or broad and may be of varying length, from an exaggerated arcuate appearance to total division of the uterine corpus, possibly including the cervix (Fig. 47.1). Indications for hysteroscopic resection of a uterine septum include repeated first- or second-trimester losses, a history of premature labor and delivery and, possibly, concurrent infertility.

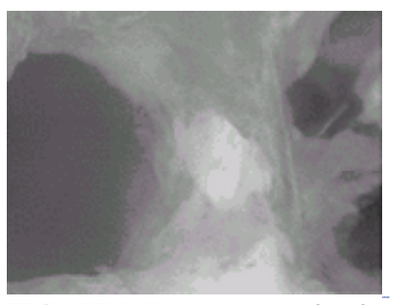

FIG. 47.1. Hysteroscopic view of a uterine septum extending down to the lower uterine segment before division.

The hysteroscopic approach to the division of the uterine septum is performed almost exclusively today rather than the classic transabdominal resection or incision of the septum performed prior to the 1970s. The hysteroscopic approach allows for ambulatory treatment of this disorder and, because the uterine wall has not been invaded, cesarean delivery is not indicated postoperatively.

After adequate documentation of the diagnosis of a septate uterus and the exclusion of concurrent causes of pregnancy wastage, the surgery should be scheduled during the early follicular phase to allow adequate visualization of the septum. The use of GnRH analogs or other drugs to induce endometrial suppression may result in the iatrogenic formation of postoperative intrauterine scar formation unless postoperative estrogen replacement is given. Semi-rigid scissors are most commonly used to divide uterine septa (Fig. 47.2). The uterine septum is usually avascular and cautery is typically unnecessary. Under direct visualization, the septum is incised at its midpoint. As the incision is carried toward the fundus, the septal tissue normally retracts anteriorly and posteriorly into the myometrial wall, and resection of tissue usually is not needed. When the uterine cavity is symmetric, or when normal myometrial tissue is observed because of bleeding, the dissection should stop (Fig. 47.3). It is also useful to perform concurrent laparoscopy to both visualize the normal fundal contour before dividing the septum, as well as to guide the direction and extent of the dissection hysteroscopically.

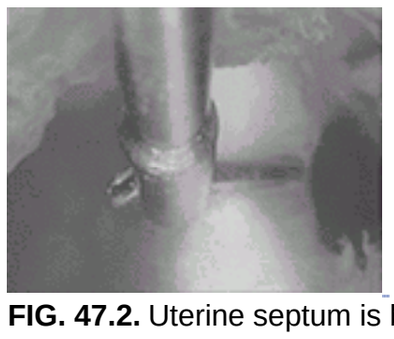

FIG. 47.2. Uterine septum is being divided by hysteroscopic rigid scissors.

FIG. 47.3. The uterine septum has been resected completely and a contour of the fundus is normal, with normal myometrial tissue visible.

The septum also can be divided with either fiberoptic lasers or cutting loop resectoscopes. The disadvantages of these techniques include additional instrumentation and further complications should uterine perforation occur. When perforation occurs with hysteroscopic scissors, bleeding is unlikely and damage to surrounding structures is rare. When uterine perforation has occurred using an electrical cutting loop or laser fiber, damage to the surrounding bowel is possible. There is also concern that these modalities may damage surrounding normal myometrial and endometrial tissue.

Although some surgeons routinely administer high-dose estrogen therapy for 30 days postoperatively, randomized studies have shown no benefit when used in normally cycling women. Similarly, an intrauterine splinting device such as a pediatric Foley catheter has been advocated by some authors but usually is not needed because of the rapid reepithelialization of the endometrial cavity postoperatively.

Normal reproductive outcome following the division of a uterine septum is reported to be between 70% and 85% term delivery rate in patients with prior recurrent spontaneous abortions. Pregnancy outcome is equal with all three methods of septum division.

HYSTEROSCOPIC MYOMECTOMY

Uterine leiomyomas are the most common benign tumors of the uterus, and submucous myomas are common causes of menorrhagia and abnormal uterine bleeding. Submucous myomas also are associated with recurrent pregnancy loss and infertility. The evaluation of abnormal uterine bleeding and menorrhagia should include either a diagnostic hysteroscopy or a saline infusion sonohysterography to diagnose submucous myomas. Blind procedures, such as endometrial biopsy and dilation and curettage, will commonly miss these tumors. Most submucous myomas do not have a pedicle but project into the endometrial cavity with a broad base. Myomas that have greater than 50% of their volume projecting into the cavity and are less than 3 to 4 cm in size can be approached adequately for resection hysteroscopically. It is often useful to pretreat patients with a GnRH analog prior to a hysteroscopic myomectomy to shrink the myoma, as well as thin the endometrium. If the patient is anemic from menorrhagia, GnRH-agonist pretreatment also will allow her a period of amenorrhea and permit her hemoglobin level to normalize.

The resectoscope with a loop electrode is used commonly to shave the myoma until it is flush with the endometrial cavity. Power settings of 100 to 120 watts are used. With unipolar devices, a nonelectrolyte solution must to be used as the distension medium. The loop should be advanced past the myoma, and resection of strips of tissue is accomplished by pulling the loop toward the operator (Fig. 47.4). This technique will minimize the risk of uterine perforation. It is frequently necessary to remove the chips of tissue when they become so numerous as to obscure the surgical view. After removal of the resectoscope, a uterine polyp forceps can be used to blindly remove the chips. Even if all the tissue fragments are not removed, they will be expelled from the uterus with the next menstrual period.

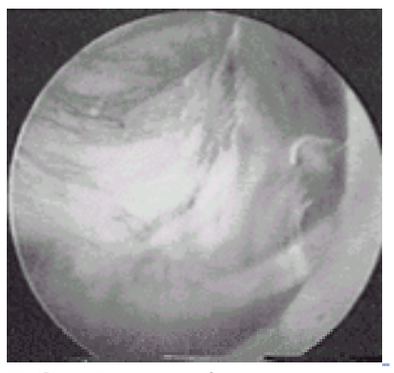

FIG. 47.4. A submucous myoma is being resected with a resectoscope loop electrode.

It may be useful to reduce intraoperative bleeding and reduce intravasation of distension medium by injecting a dilute solution of pitressin, 20 units per 100 cc injectable saline, paracervically prior to the endometrial resection to achieve vascular constriction. Care should be taken not to inject this solution intravascularly, because deaths have been reported. A total of 5 to 10 cc is usually sufficient. Intraoperatively, small bleeding vessels may be coagulated with the loop electrode using 40 watts of coagulation current.

Bipolar systems have been developed (Versapoint, Gynecare, a division of Ethicon), which cause vaporization of tissue. Because these devices use a bipolar electrode, an electrolyte solution is needed as the distension medium. This system requires its own generator and will not work with other electrical generators such as Valley Lab's product. The advantage of these systems is the prevention of multiple tissue fragment generation as the technique vaporizes tissue. If pathologic diagnosis is desired, the tips can be used to isolate and remove a portion of tissue to be sent to the pathology department.

When performed for menorrhagia, success rates of hysteroscopic myomectomy have been reported in approximately 80% of patients. Conception rates have been reported between 43% and 63% following hysteroscopic myomectomy in previously infertile women.

HYSTEROSCOPIC POLYPECTOMY

Endometrial polyps are diagnosed in approximately 20% of women with abnormal uterine bleeding. This diagnosis usually requires either direct visualization of the polyp with a diagnostic hysteroscope or the visualization of a polyp using saline infusion sonohysterography. Hysteroscopically, endometrial polyps generally are more often pedunculated than submucous myomas and have a softer, fleshier appearance (Fig. 47.5).

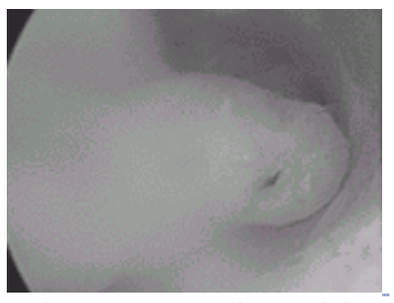

FIG. 47.5. An endometrial polyp is seen hysteroscopically as a soft fleshy growth.

Depending on the size of the endometrial polyp, it may be removed by one of several techniques. With a small pedunculated polyp, grasping the polyp stalk with a hysteroscopic grasper and rotating of the grasper to remove the polyp can be performed easily (Fig. 47.6). With larger polyps or polyps with a larger base, a cutting loop resectoscope should be used. By resecting the base of the polyp with the loop electrode, the polyp subsequently can be removed intact with grasping forceps. If a small portion of the base remains, it can be destroyed with the loop electrode. Care should be taken not to destroy adjacent normal endometrial tissue to prevent postoperative adhesion formation.

FIG. 47.6. A rigid grasper is placed through the hysteroscope to grasp the base of an endometrial polyp for removal.

ASHERMAN SYNDROME

Intrauterine adhesions or synechiae, Asherman syndrome, may develop when opposing endometrial surfaces are damaged and heal as a coalescing adhesion. This typically occurs when inflammation or infection persists after spontaneous first-trimester abortion and when estrogen production is low. Patients who have had late postpartum curettages for retained placental fragments are at high risk for the development of Asherman syndrome (Fig. 47.7). Postpartum, estrogens of placental origin are metabolized rapidly and ovarian suppression continues for several weeks. With the absence of estrogen, the endometrium will fail to proliferate and reepithelialize damaged areas of endometrium following a curettage. Any concurrent inflammation or infection will increase the risk of intrauterine synechiae. Patients who have had elective abortions or postabortal curettages for any reason are also at risk for the development of intrauterine adhesions. The patient with Asherman syndrome may have amenorrhea if the extent of the adhesions is severe, but more commonly it manifests with normal menses or mild hypomenorrhea with recurrent spontaneous abortion or with infertility. The diagnosis of Asherman syndrome can be made by hysterosalpingogram, saline infusion sonohysterography, or direct visualization with diagnostic hysteroscopy.

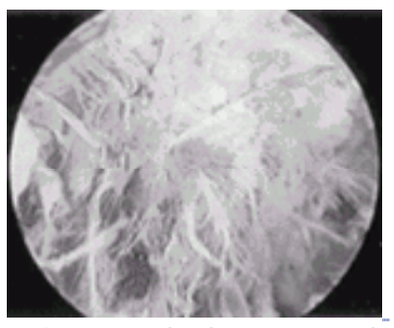

FIG. 47.7. The hysteroscopic appearance of a retained placental fragment 1 month postpartum.

Intrauterine adhesions should be lysed with hysteroscopic scissors under direct visualization. This procedure is straightforward with mild to moderate cases of Asherman syndrome but can be very complicated in severe cases with complete obliteration of the endometrial cavity. In difficult cases, concurrent laparoscopy can be useful to guide the hysteroscope. Pockets of normal endometrium are used as guides to the lysis of thick adhesion bands. Both cornu of the uterus ultimately should be visualized, and the uterine contour should be relatively normal at the end of the procedure.

Postoperatively, most practitioners will place patients with Asherman syndrome on high-dose estrogen replacement, Premarin (conjugated estrogens) 2.5 mg twice daily, or its equivalent, for 30 days to help induce proliferation of any remaining endometrium to reepithelialize the previous site of adhesions. Stenting of the uterus with a pediatric Foley catheter balloon filled with approximately 3 cc of saline for 1 week postoperatively also will prevent the damaged endometrial surfaces from coming immediately into contact with one another. With this foreign body in place, antibiotics should be used to prevent infection.

PROXIMAL TUBAL CANNULATION

Approximately 20% of tubal occlusion occurs in the intramural portion of the fallopian tube at the uterotubal junction. Pathologically, proximal occlusion may be caused by debris plugs or fibrosis from inflammation, intraluminal endometriosis, or salpingitis isthmica nodosa. The diagnosis of proximal tubal occlusion often is made by hysterosalpingography. However, a definitive diagnosis cannot be made with this technique, because uterine muscle spasm falsely suggesting proximal tubal occlusion may be a consequence of the procedure itself. If pathologic proximal tubal occlusion is suspected, selective injection of contrast medium into the fallopian tubes may be performed either fluoroscopically or via hysteroscopy with concurrent laparoscopy. The latter technique has the advantage of simultaneously inspecting the distal portion of fallopian tube for damage. If the patient has both a proximal and a distal occlusion, the tubes are not candidates for surgical correction, and in vitro fertilization should be recommended. If selective injection of one or both of the fallopian tubes does demonstrate proximal tubal occlusion, then hysteroscopic cannulation of the fallopian tube can be performed immediately.

Hysteroscopically, a flexible guidewire, 0.3 to 0.8 mm in outer diameter, is guided into the uterine cornu. The softness of this guidewire usually allows it to penetrate the occlusion while staying within the tubal lumen. When the guidewire is seen in the proximal portion of the fallopian tube laparoscopically, a soft Teflon catheter of 1.3-mm outer diameter is pressed over the guidewire until this is also within the proximal portion of fallopian tube. The guidewire can then be removed and methylene blue injected through the Teflon catheter to confirm tubal patency.

Approximately 80% of proximal tubal occlusions can be cannulated successfully. Complications include perforation of the guidewire through the proximal portion of fallopian tube, but this rarely results in troublesome bleeding or infection. Intrauterine pregnancy rates have been reported as approximately 30% to 40% following proximal tubal cannulation.

SUMMARY POINTS

- The development of good hysteroscopy skills is important to gynecologists so that they may use the diagnostic and operative advantages these techniques offer.
- Careful attention to the surgical technique and particularly the distension medium employed is important in order to perform hysteroscopy safely.
- Diagnostic hysteroscopy is the gold standard for evaluation of the endometrial cavity.
- Operative hysteroscopy offers an outpatient surgical approach to many uterine problems including submucous and intracavitary leiomyomata, endometrial polyps, intrauterine synechiae, uterine septa, and proximal tubal occlusion.
- Endometrial ablation offers women an alternative to hysterectomy for the management of abnormal uterine bleeding or menorrhagia.

Surgical Management of Urinary Incontinence

Urinary incontinence is a medical condition affecting 15% to 50% of adult women depending on the age and risk factors of the population studied. As we live longer and enjoy more active lives, increasing numbers of women will be affected. Costing approximately $12.4 billion dollars to treat women alone in 1995, urinary incontinence ranks in the top ten in expenditures for treatment of illnesses.

While once considered a “natural” consequence of aging, further investigations have shown that urinary incontinence is seen in women of all ages, with varying degrees of severity and different etiologies. Unfortunately, incontinence often goes undetected and only half of the women suffering from this condition seek treatment. This is unfortunate because there are many types of effective therapies available including bladder retraining, pelvic floor exercises, and surgery.

As health care providers for women, we are obligated to ask the question “Do you have difficulty controlling your bladder?” Once the condition is identified, specific questions targeted at identifying the type of incontinence, the frequency of loss, and the social impact for the woman can be addressed. Many times with the use of voiding diaries, detailed physical examinations, and simple bladder testing, the cause of incontinence can be determined and treated.

DEFINITIONS OF TERMS AND DIFFERENTIAL DIAGNOSIS OF URINARY INCONTINENCE

Maintenance of urinary incontinence requires that many anatomic, neurologic, and psychological functions and relationships be intact. Therefore, it is not surprising that many conditions may affect urinary continence (Table 48.1, Table 48.2).

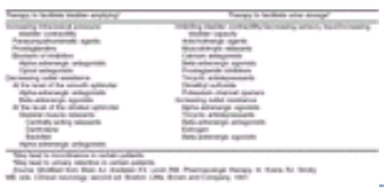

TABLE 48.1. *Drug effects on lower urinary tract function*

TABLE 48.2. *Causes of urinary incontinence*

In order to communicate with the patient and other practitioners that evaluate, diagnose, and treat the various causes of urinary incontinence, a standardization of terms and description of conditions is required. A committee on terminology as part of the International Continence Society (ICS) has provided standardized terms and definitions for the classifications of functions of the lower urinary tract. The ICS definitions of terms and conditions of urinary incontinence are listed in Table 48.2 and Table 48.3.

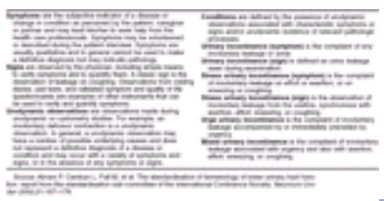

TABLE 48.3. *International Continence Society terms and definitions*

Patients with symptoms of urinary incontinence are generally not concerned about the strict definition of their condition but are rightly focused on the cause and

foremost the treatment of their incontinence. As clinicians, we may or may not agree with the patient on the severity of her symptoms. Generally, when the symptoms are mild, the patient and practitioner are nearer in agreement than when the patient perceives her symptoms as severe. Therefore, it is useful to use standardized criteria or a validated quality-of-life measure to determine the impact of the incontinence condition on the patient's ability to perform her daily activities. Several such questionnaires exist and can be beneficial in the initial assessment as well as determining the benefit of therapy. An example of such a validated questionnaire is seen in Table 48.4.

TABLE 48.4. *Urogenital distress inventory (UDI-6)*

A patient complaining of stress symptoms may actually have cough-induced detrusor overactivity or mixed incontinence. Therefore the clinician must not only listen to the symptoms of the patient, but also document some sign of urinary incontinence. Signs of urinary incontinence are objective measures of urine loss evaluated in conjunction with the bladder state (empty or full) and conditions of leakage. Signs include urine loss documented by a voiding diary noting physical activity or bladder urgency linked to incontinence, a pad test, a cough stress test, or urine leakage at the time of urodynamic testing.

EPIDEMIOLOGY

Prevalence and Social Impact

Urinary incontinence is a common problem among women. The estimated prevalence ranges from 3% to 40% depending on the population studied and how the condition is defined. Approximately 10% to 30% of community-dwelling women between the ages of 15 and 64 years of age and 25% of women older than 65 years experience urinary incontinence. Approximately 50% of nursing home patients have urinary incontinence. One in five women with urinary incontinence will also suffer from fecal incontinence or “dual incontinence.” Urinary incontinence is two to three times more likely in women than in men. This is especially true for women under the age of 60, when stress incontinence is more likely the dominant type. As men and women age, the likelihood of urge incontinence or voiding dysfunction increases in both sexes.

How urinary incontinence is defined determines the prevalence of the condition in the population or the incidence of the condition at any given time. Clinicians generally use the ICS definition of urinary incontinence that is “the involuntary loss of urine sufficient to be a social or hygienic problem for the patient.” For some women this may mean leaking urine once a day, while for others urinary incontinence occurring only periodically with exercise may be unacceptable. Survey studies of community-dwelling women using “daily,” “weekly,” or “most of the time” criteria for diagnosing urinary incontinence report prevalence ranges of 3% to 14%. This amount of leakage corresponds with the frequency of leakage found in women seeking treatment. Higher estimates of incontinence are based on broader definitions, such as “any incontinence in the prior year” or “leakage more than twice a month.”

Many etiologies and factors contribute to urinary incontinence and many of the factors are variable over time and affect the presence and severity of urine loss. The strength of the pelvic floor muscles and urethral sphincter, the level of physical activity or high-impact exercise, the amount of fluid intake, or the level of bacteria are just of few of the variables that relate to urinary incontinence. While little information is known about the natural progression of incontinence severity, for women surveyed over a 2-year span, there was an 11% remission rate or resumption of continence.

Risk Factors

Many risks factors, conditions, or causes have been linked to the development of urinary incontinence. Unfortunately, few longitudinal and well-designed studies have been performed to separate the cause and effect for many of the risk factors. Why certain conditions and events such as childbirth and aging affect some women and not others is still unknown. Bump has developed a model (Fig. 48.1) combining many of the known risk factors for the development of urinary incontinence. Which of these factors are most important and how they interact for a particular patient is not known but are areas of current investigation.

FIG. 48.1. Factors related to the development of urinary incontinence. (From Bump RC, Norton PA. Epidemiology and natural history of pelvic floor dysfunction. Obstet Gynecol Clin North Am 1998;25:723.)

Gender and Age

Urinary incontinence is two to three times more likely to occur in women than in men. This is especially true regarding community-dwelling adults under 60 years of age. Compared to urge incontinence, stress incontinence is more common in younger women and rarely occurs in men. Since childbirth is considered a major risk factor for the development of stress urinary incontinence, it is not surprising that this condition occurs more often in women than in men. But as men and women age, they both have more symptoms of bladder overactivity, urge incontinence, and voiding dysfunction. These symptoms develop such that the gender gap narrows as men and women approach the age of 70.

Brown and colleagues have shown that 12.5% of women under 80 years of age reported daily incontinence and that for every 5-year increment in age beginning at age 80, there was a 30% increase in the prevalence of incontinence. While increasing age is consistently seen as a risk factor for urinary incontinence, the idea that urinary incontinence is a “natural” part of aging is not true. Like other conditions, such as heart disease, hypertension, and arthritis, incontinence is more prevalent as we get older. Like these other conditions, not all older people suffer from incontinence and those who do should be offered treatment and care and not left to “suffer this malady of old age.”

Why urinary incontinence increases with age is not fully understood. With aging, approximately 1% of striated muscle mass is lost each year. Since the sphincter urethra muscle, as well as pelvic floor muscles play important roles in the maintenance of incontinence, it is not surprising that incontinence increases with aging. How aging, menopause, and decreasing hormone levels relate to urinary incontinence and other pelvic floor dysfunctions is poorly understood. Studies evaluating the use of oral combined estrogen replacement therapy have not shown improvement in or prevention of the development of urinary incontinence. Yet clinicians and some patients note improvement in function of the lower urinary tract, especially in decreasing nocturia, when using transvaginal estrogen replacement therapy. Further studies on the effect of estrogen on the blood supply, smooth muscle of the urethra and vaginal submucosa, and collagen content of the anterior vaginal wall are needed to determine the usefulness, correct route and preparation, and dosage of hormone replacement therapy that could be beneficial.

Race

Racial differences in the prevalence and type of urinary incontinence have been reported but remain poorly understood. Fultz and associates reported a urinary incontinence prevalence of 23% in Caucasian women and 16% in African-American women in a national survey of 4,040 community-dwelling individuals over the age of 70. Smaller studies evaluating younger women do not include large enough numbers of African-American, Hispanic, or Asian women to make any conclusions about the prevalence or type of incontinence. In women seeking treatment for incontinence, African-American women appear to have more urge incontinence and detrusor overactivity on urodynamic testing than pure stress incontinence. Whether these differences are related to treatment patterns or true biologic differences is yet undetermined. It does appear, however, that there are racial differences in urethral muscle mass, urethral closure pressures, and urethral hypermobility between continent nulliparous African-American women and Caucasian women. These findings suggest morphologic and physiologic reasons for racial differences in the type of urinary incontinence.

Childbirth

Vaginal childbirth has been seen as the leading inciting factor in the development of urinary incontinence and pelvic floor dysfunction. Yet vaginal delivery does not lead to urinary incontinence in all women and women who have never delivered vaginally or have even been pregnant can develop urinary incontinence and pelvic floor dysfunction. Strong associations have been made between vaginal delivery and stress urinary incontinence. Large population studies have also shown vaginal childbirth is also a risk factor for developing urge incontinence.

Women who deliver by elective cesarean section without ever laboring have a reduced risk of developing urinary incontinence compared to women who deliver vaginally, but a cesarean section is not 100% protective. In addition, the protective benefits appear to decrease after three pregnancies and repeat cesarean sections. Episiotomies, once thought to be protective, have not been shown to decrease or increase the risk of urinary incontinence, either immediately after birth or after several years.

The majority of the damage to the pelvic tissues appears to occur with the first delivery. Other factors associated with increased risk from vaginal delivery include forceps deliveries, prolonged second stage, large-for-gestational-age birth weight, and large head circumferences. Not all of these obstetric factors have been found to be statistically or clinically significant in the literature and their etiologic role in the development of urinary incontinence remains to be determined.

Vaginal childbirth causes damage to the pelvic floor tissues by stretching, tearing, and pressing the soft tissues against the bony pelvis causing anoxia and tissue necrosis. The muscles, nerves, and connective tissues of the pelvis can all be affected and damaged. Studies have shown damage to all of the tissues as measured by prolonged pudendal nerve motor latencies, decreased levator muscle strength, and decreased urethral pressures. Fortunately, with healing and muscle strengthening with Kegel exercises, the majority of the damage can be repaired, and continence regained in the first 6 months after delivery. Long-term pelvic floor trauma secondary to vaginal delivery and aging appear to combine as the major risk factors for urinary incontinence and pelvic floor dysfunction.

Smoking, Exercise, and Obesity

Women who are cigarette smokers or ex-smokers are two to three times more likely to have urinary incontinence than nonsmokers. Whether this association is related to chronic cough and increased abdominal pressure or tissue damage from tobacco toxins is not known.

Physiologically, exercise has many positive and negative effects that may alter the balance between continence and incontinence. Increased abdominal pressure with high-impact exercise may overcome the continence mechanism in some women briefly causing situational episodes of leakage, but does not appear to increase their long-term risks for developing stress incontinence. Exercise that strengthens the lower extremities also strengthens the pelvic floor and enhances the continence mechanism. For the many health benefits, including strengthening the pelvic floor, women should be encouraged to exercise or take daily walks.

Obesity has been shown to be more common in women with both stress and urge incontinence than in continent women. In addition, morbidly obese women who lose weight have shown objective as well as subjective cure of their incontinence. Consideration should be given to surgically managing their morbid obesity over surgically attempting to correct their stress incontinence.

EVALUATION OF URINARY INCONTINENCE

History

The first step in evaluating a patient with urinary incontinence is to pose the question to the patient. Often a brief, directed review of bladder and bowel function can elicit symptoms. Open-ended questions such as “Could you please tell me about problems you are having controlling your bladder?” can be a useful initial approach. If the answer is affirmative for incontinence symptoms then an incontinence evaluation in initiated.

The evaluation begins with more direct questioning concerning the patient's symptoms, timing, and severity of incontinence. Frequently asked questions listed in Table 48.5 can help distinguish the type and severity of a patient's incontinence. Questions aimed at type of protection or pad used and number of pads used in a 24-hour period can indicate the severity of the problem. In addition, questions regarding lifestyle changes such as decreasing fluid intake or avoiding physical activities reflect the impact of incontinence on the patient's quality of life.

If you are having problems with urinary incontinence, please answer the following questions:

1. How long have you had incontinence?
2. How would you describe the severity of your incontinence?
3. Do you lose urine when coughing, sneezing, or laughing?
4. Is your urine leakage associated with a strong urge to go to the bathroom?
5. When you lose urine, is it a small amount, a moderate amount, or a large amount?
6. Do you ever lose urine at night while sleeping?
7. In the last month, how many times did you lose urine?
8. After the episodes of urine leakage do you usually need to change your underpants?
9. What do you usually wear for protection?

TABLE 48.5. *Frequently asked questions*

The presence of symptoms associated with both the storage and the emptying phases of the bladder cycle should be determined. Specific questions should ask about irritative symptoms (urgency or frequency), incontinence (stress or urge), and voiding dysfunction (urinary retention or postvoid fullness). A detailed history of any prior treatment of the genital or urinary tract, including surgeries should be obtained. The surgical history should contain details of any prior procedures for incontinence, including indications, technique, and type of suture used. Any complications (i.e., prolonged catheter use after surgery) or the development of new symptoms (i.e., urinary frequency and urgency following surgery) should be noted.

An obstetric history including route of delivery, episiotomy, lacerations, the use of forceps or vacuum, birth weights, and the length of the second stage of labor can determine the patient's risks associated with childbirth. A history of pelvic cancer therapy should include the dates and findings of any cystoscopic examinations. Other comorbid conditions affecting the lower urinary tract, including cigarette smoking, neurologic and endocrine diseases, as well as family history of urinary incontinence and pelvic organ prolapse may direct the clinician toward one type of urinary incontinence or need for further diagnostic evaluation. Any functional components such as difficult ambulation, declining cognition, or severe fecal impaction or constipation should be addressed prior to further evaluation or treatment.

Medications currently used should be reviewed in detail as many medications have adverse effects on the lower urinary tract (see Table 48.1). Unfamiliar medications should be verified. Diuretics and a-antagonists, two classes of medication commonly used to treat hypertension, may cause incontinence in some women. When incontinence is temporarily related to onset of use or dosage increase, it may be reasonable to use alternative medications that have less effect on the lower urinary tract.

Office evaluation should follow a stepwise progression (Fig. 48.2). Initial evaluation should focus on the severity of urinary leakage and the patient's goals for resolution of the problem. Some women may simply wish to regain sufficient bladder control to participate in certain social or athletic activities, while others desire complete continence under all circumstances. The extent of the evaluation and the proposed therapy should match the patient or her caregiver's expectations and goals.

FIG. 48.2. Evaluation algorithm. (From Fantyl JA, Newman DK, Colling J, et al. Urinary incontinence in adults: acute and chronic management. Clinical Practice Guidelines Number 2, 1996 Update. Rockville, MD: Agency for Health Care Policy and Research, US Dept of Health and Human Services; 1996. AHCPR publication 96-0682.)

Physical Examination

Beyond the standard speculum and bimanual examination, the specific goal of a urogynecologic physical examination is to assess vaginal supports, strength of the pelvic floor, the anatomic position of the anterior vaginal wall, and the stability of the urethrovesical junction (UVJ). The examination for pelvic organ prolapse and the use of the standardized Pelvic Organ Prolapse Quantitative System (POP-Q) can be found in Chapter 45. In addition to noting any prolapse of the vaginal walls, uterus, or vaginal apex, the resting location and mobility of the UVJ with cough or strain is noted. In most cases, the urethral hypermobility can be documented by having the patient strain and the clinician noting prolapse of the distal anterior vaginal wall. If uncertain, and deemed important by the clinician, then a sterile Q-tip may be placed in the urethra or transperineal ultrasound used to document mobility. Not all women with a hypermobile urethra have stress incontinence and not all women with stress incontinence have a hypermobile urethra. African-American women appear to have more urethral hypermobility than Caucasian women, yet they have less stress incontinence because of higher urethral pressures. The importance of noting a hypermobile urethra is useful when considering certain treatment options. Both surgical and nonsurgical techniques that work by stabilizing or supporting the UVJ work best when the urethra is hypermobile allowing for repositioning or stabilization.

Neurologic evaluation of the incontinent female includes assessing intact perineal sensation that primarily represents the S2 dermatome. The bulbocavernosus reflex or anal wink is used to assess the sacral reflexes. A Q-tip swab is gently used to touch the skin overlying the bulbocavernosus muscles in the labia majora or perianally. A positive reflex indicates an intact pudendal nerve and L5-S5 motor neurons causing spontaneous contraction of the external anal sphincter. As with other reflexes, the sign is positive or negative. Hyperreflexia may be seen in upper motor lesions. Unlike the corresponding cremaster reflex in men, approximately 10% of normal, neurologically intact women will not demonstrate this reflex or the response is too weak to see. If, however, in the context of urinary or fecal incontinence or with other neuromuscular abnormalities of the buttocks or lower extremities, the absence of the bulbocavernosus reflex should alert the clinician to possible pathology in the sacral or cauda equina regions of the spinal cord.

A cough stress test should be performed, noting the position of the patient as supine or standing and whether her bladder is full or empty. Documentation of the sign of stress incontinence is adequate for diagnosis in most patients and avoids performing further, more complex and expensive testing.

Other conditions that can be detected during physical exam include hypoestrogenism, levator atrophy, and fecal impaction, which can all affect bladder control. If comorbid conditions such as edema or declining cognitive function are contributing to the patient's incontinence, then an expanded physical examination including mental status assessment, manual dexterity, and ability to ambulate is warranted.

Urinary Diary or Bladder Record

While not always available at the time of the initial history and physical, the urinary diary is an essential part of the of incontinence evaluation (Fig. 48.3). This tool allows the patient to record voided volumes, leakage episodes including amounts and associated activities, and the type and volume of fluid intake. Although a 3- to 7-day diary is optimal, evaluation of the events of a typical 24-hour period can be very helpful clinically. By simply keeping the diary, patients can notice how the amount and types of fluid they drink, as well as when they drink impact incontinence. In addition, the clinician can assess the severity of the leakage and begin to formulate an opinion of the type and etiology of the patient's incontinence and need for further evaluation. Upon review of the diary, the practitioner can suggest simple behavioral interventions such as fluid intake and medication adjustments.

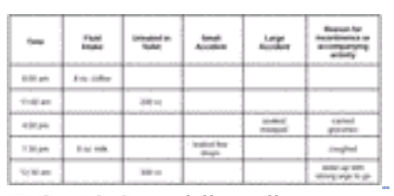

FIG. 48.3. Voiding diary.

Urinalysis and Postvoid Residual Volume

Sterile urine and a normal postvoid residual volume should be documented in all women. This assessment can be performed using a small-gauge catheter within 20 minutes after voiding. While there is no strict definition of a normal postvoid residual, the volume should generally be less than 100 mL. The catheterized urine specimen can then be used to rule out infection. While dipstick methods are available to detect bacteriuria and pyuria, the diagnostic accuracy is variable and dependent on the prevalence of urinary tract infections in that population. Therefore if the dipstick is positive or the patient's symptoms are consistent with a urinary tract infection, obtaining a urine culture is recommended.

Alternatively, an approximation of postvoid residual volume may be obtained with the use of an ultrasound specifically designed for determining bladder volume and using a clean catch urine sample to rule out infection. Infection should be treated and sterile urine should be demonstrated before further incontinence evaluation. If the residual volume is elevated, the test should be repeated on a separate visit. Persistently high residual volume should be evaluated. Conditions affecting bladder emptying such as peripheral neuropathies or pelvic organ prolapse outside the hymen are common etiologies for elevated postvoid residuals. Unlike men who frequently suffer urinary retention due to obstruction by an enlarged prostate gland, women rarely have obstruction unless they have undergone prior surgery for urinary incontinence that is obstructing urine flow.

Stress Test

The stress test is used to observe urinary leakage associated with straining or coughing, and is best performed with a full bladder in the standing position. Often a series of coughs is required to demonstrate incontinence. The patient should be positioned over a pad or paper towel, wrapped with a sheet or gown, and reassured that the physician wants to see urine leakage. Many times patients are embarrassed and reluctant to leak urine in the office setting in front of ther people. Putting the patient at ease and respecting her privacy helps to obtain a positive test and preserves patient dignity. A positive test confirms the sign of stress incontinence. A negative test does not completely rule out stress incontinence, but when performed with a full bladder and in the standing position the diagnosis of stress incontinence is less likely. If the patient also suffers from pelvic organ prolapse, then the prolapse should be repositioned to a “normal” anatomic position with a pessary or large vaginal swabs during the stress test.

Pad Test

A pad test is an objective test used to document the presence and amount of urinary incontinence. The test requires that the patient wear a preweighed pad while she performs activities usually associated with her incontinence. A 1-hour pad test is typically conducted. Generally, the test begins with the patient emptying her bladder and then drinking a known amount of water, typically 500 cc. Alternatively, the bladder can be filled with a set amount or to maximum capacity. The pad is weighed after 1 hour of activity. While pad testing has been found to be reproducible, in terms of objective documentation of incontinence and ability to evaluate pre- and post-treatment incontinence, its use in routine clinical evaluation is limited. A specific use for the pad test is when the clinician is unsure if the symptoms of incontinence

are due to urine loss or secondary to vaginal secretions or sweating. By giving the patient phenazopyridine hydrochloride (Pyridium) to turn her urine orange, a pad test can confirm urine loss.

After taking a careful history, performing a directed pelvic examination including a postvoid residual, ruling out infection, and performing a stress test, an accurate diagnosis can be made on the type of urinary incontinence for approximately 80% of women. Initial management can begin as outlined in Table 48.6.

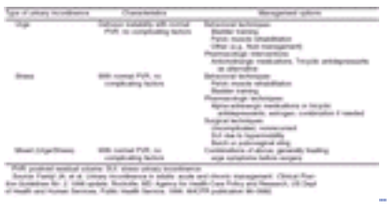

TABLE 48.6. *Management options after basic evaluation*

Specialized Tests

The need and use of specialized tests for the diagnosis and management of patients with urinary incontinence is far from standardized in clinical practice. While some clinicians feel advanced testing is useful, the reproducibility of certain tests such as multichannel urodynamics, leak point pressures, and voiding studies have led many clinicians and expert panels to use specialized testing in selected cases. The Agency of Health Care Policy and Research under the jurisdiction of the United States Department of Health and Human Services has recommended the use of specialized testing according to the guidelines listed in Table 48.7. Clinicians caring for patients with urinary incontinence recognize the difficulties in trying to determine the exact cause of leakage in all patients. When therapies can be used which effectively treat both urge and stress incontinence or there is acceptable cost and morbidity for the individual patient, determining the exact etiology is less critical. However, prior to surgical interventions, because of cost and morbidity, cystometry is recommended to document stress incontinence.

Uncertain diagnosis and inability to develop a reasonable treatment plan based on the basic diagnostic evaluation. Uncertainty in diagnosis may occur when there is lack of correlation between symptoms and clinical findings.
Failure to respond to the patient's satisfaction to an adequate therapeutic trial, and the patient is interested in pursuing further therapy.
Consideration of surgical intervention, particularly if previous surgery failed or the patient is a high surgical risk.
Hematuria without infection.
The presence of other comorbid conditions, such as:
incontinence associated with recurrent symptomatic urinary tract infection
persistent symptoms of difficult bladder emptying
history of previous anti-incontinence surgery or radical pelvic surgery
beyond hymen and symptomatic pelvic prolapse
prostatic nodule, asymmetry, or other suspicion of prostate cancer
abnormal postvoid residual volume
neurologic condition such as multiple sclerosis and spinal cord lesions or injury.

[a]Some patients who meet the criteria may not be appropriate for further evaluation and treatment if such evaluation and/or treatment is not desired by or feasible for the patient.

TABLE 48.7. *Criteria for Further Evaluation of Urinary Incontinence* [a]

If a patient presents with moderate to severe pelvic organ prolapse outside the hymen and has no subjective urinary incontinence, she should be tested for occult or potential stress incontinence. Studies have shown that with the prolapse reduced and straightening of the urethra, incontinence can “occur” in 30% to 50% of patients with prolapse. If urinary incontinence is found, then an antiincontinence surgery should be performed at the time of surgical correction for the patient's pelvic organ prolapse. Which antiincontinence surgery is best for occult incontinence is not known.

Consultation should be considered for cystometric testing and surgical management for patients who have not responded to initial treatments or have failed prior incontinence procedures.

Cystometry Cystometry is the test used to measure the pressure–volume relationship during bladder filling. The main purpose of cystometry is to diagnose or rule out detrusor contractions. A catheter attached to a vertical fluid column, a pressure transducer, or a microtip catheter measures the bladder pressure. Single channel or simple cystometry implies that only the bladder pressure is being monitored during the study. A multichannel or complex cystometry includes a second catheter for monitoring intraabdominal pressure. During a multichannel study, true detrusor pressures are calculated by subtracting the intraabdominal pressure from the bladder pressure. While filling the bladder, the compliance (bladder pressure divided by the infused volume), the first desire to void, maximum bladder capacity, and the presence of detrusor contractions are documented. Stress incontinence is diagnosed with the patient coughing or by performing a Valsalva maneuver and noting urine loss in the absence of a detrusor contraction.
Simple Cystometry or Single Channel Cystometry Performing simple cystometry can easily be done in the office of most gynecologists using a red rubber catheter, a three-way stopcock, intravenous tubing, and sterile water or saline. The patient is placed supine or if possible seated at a 45-degree angle. The sterile catheter is inserted and a postvoid residual volume is obtained. By attaching a three-way stopcock to the end of the catheter, a tube for filling and a tube for measuring detrusor pressures can be used. By taping the pressure tubing vertically to a 100-cm measuring stick taped to an intravenous pole, and then having the zero mark at the level of the bladder, the bladder is filled in 50- to 100-cc increments. After filling, the stopcock is turned off to the filling catheter. The pressure in the tubing represents the pressure in the bladder, including the intraabdominal pressure. The patient is instructed not to talk or perform any maneuvers that will increase her intraabdominal pressure. A rise in the fluid column should then represent a rise in bladder pressure secondary to abnormal compliance or a bladder contraction (Fig. 48.4).

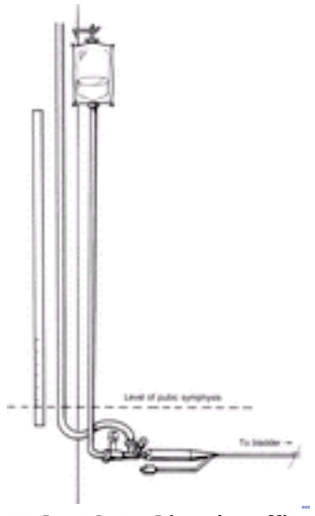

FIG. 48.4. Simple office cystometrogram. The zero mark of a meter stick is aligned with the upper margin of the patient's symphysis pubis, and a Foley catheter is in place for infusion of fluid. (Adapted from the American College of Obstetricians and Gynecologists, Bent AE, ed. *Urogynecologic evaluation, endoscopy, and urodynamic testing in the symptomatic female.* Washington, DC: ACOG Audiovisual Library, 1990.)

An alternative method for simple cystometry uses a specialized filling catheter with a pressure transducer that relays the bladder pressure to a recording device. Several types are commercially available.
Multichannel Urodynamics Approximately 10% of patients require multichannel urodynamic studies for diagnosis and treatment of urinary incontinence. Like all diagnostic tests, the clinician must understand the information gained from the procedure, the accuracy of the measurements, and how the information obtained will alter diagnosis, prognosis, or management of the condition. Multichannel urodynamics, once considered the gold standard for the diagnosis of detrusor overactivity and

stress incontinence, have been questioned regarding their reproducibility and cost-effectiveness in the routine evaluation of urinary incontinence. As outlined in Table 48.7, if initial assessment and treatment are not successful, further evaluation with multichannel urodynamic studies is indicated. Table 48.8 lists the common terms and definitions for urodynamic studies. Multichannel urodynamics are performed using a specialized machine or unit that records the bladder and intraabdominal pressures, subtracts the intraabdominal pressure from the bladder pressure to determine true detrusor pressure, and provides a report. Most units also have the ability to record urethral pressures and electromyography of the pelvic floor or urethra during the multichannel study. When reporting a multichannel cytometric study, the filling medium, rate of bladder fill, and position of the patient during the study should be noted. A typical tracing for a patient with detrusor overactivity is seen in Fig. 48.5. Note the rise in detrusor pressure without a rise in the abdominal pressure that is seen with a cough.

Intravesical pressure is the pressure within the bladder.
Abdominal pressure is the pressure surrounding the bladder and can be estimated from vaginal or rectal pressure.
Detrusor pressure is intravesical pressure that is created by forces in the bladder wall. It is estimated by subtracting the intraabdominal pressure from intravesical pressure.
First desire to void is the feeling during cystometry that would lead the patient to pass urine at the next convenient moment, but voiding can be delayed.
Maximum cystometric capacity is the volume at which the patient feels she can no longer delay micturition.
Detrusor overactivity is a urodynamic observation characterized by involuntary detrusor contractions during the filling phase which may be spontaneous or provoked.
Maximum urethral closure pressure (MUCP) is the maximum difference between the urethral pressure and the intravesical pressure.
Abdominal leak point pressure (ALPP) is the intravesical pressure at which urine leakage occurs due to increased abdominal pressure in the absence of a detrusor contraction.
Intrinsic sphincter deficiency (ISD) refers to urodynamic measures. MUCP ≤20 cm H_2O or ALPP of <60 cm of H_2O, that may indicate poor urethral function. For some surgeons, a diagnosis of ISD may alter the anti-incontinence surgical procedure that is performed.

TABLE 48.8. *Cystometric definitions*

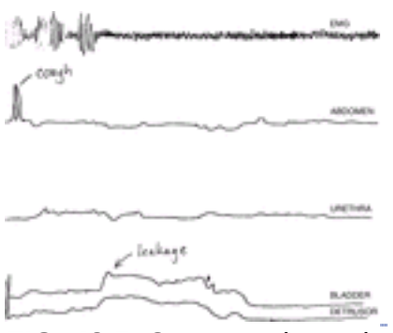

FIG. 48.5. Cystometric tracing.

Uroflow Studies and Voiding Cystogram Uroflowmetry measures the flow rate visually, electronically, or with the use of a disposable unit and is measured in mL per second. An electronically generated flow curve is considered helpful in identifying abnormal flow patterns such as Valsalva voiding (increasing vesicle pressure by pushing rather than having a detrusor contraction). Uroflowmetry does not help diagnose the type of urinary incontinence and is not a routine part of the evaluation of urinary incontinence. A voiding cystometrogram is a uroflow performed with a catheter in the bladder to record bladder pressures. For a patient with urinary retention, a voiding cystogram may help distinguish obstruction from detrusor weakness. A voiding cystometrogram may be useful in the evaluation of patients with elevated postvoid residuals, neurologic conditions such as diabetes that may affect bladder emptying or inability to void after extensive pelvic surgeries, or antiincontinence procedures.
Urethral Pressure Profilometry Urethral pressure profilometry (UPP), a urethral function test, measures resting and dynamic (with cough) pressures in the urethra. Clinically, UPP is used by some clinicians to assess the patient for a weak sphincter or intrinsic sphincter deficiency (ISD). Patients with ISD have been found to have less success with antiincontinence surgeries aimed at repositioning or elevation of the bladder neck and therefore the diagnosis of ISD would determine which surgical procedure was used. Sphincteric function can also be assessed by measuring abdominal or vesical pressure needed to overcome urethral resistance or abdominal or vesical leak point pressure. Clinically, the usefulness of the UPP versus abdominal leak point pressure has not been adequately studied.
Electromyography Both surface and needle electrodes have been used to record urethral sphincter and pelvic floor muscle activity during urodynamic studies. Technically difficult to reproduce, except in a few urodynamic laboratories which have expertise in electromyography (EMG), the clinical usefulness is questionable. The goal of EMG is to evaluate relaxation of the pelvic floor and urethra at the time of voiding. Many patients, while seated in the urodynamics chair with catheters in place and persons in the room, will have difficulty relaxing their pelvic floor and may give a false-positive test for EMG activity and poor relaxation during voiding. Pathologically, patients with detrusor sphincter dyssynergia (DSD) have a detrusor contraction to void but the urethra and periurethral striated muscle contract preventing or decreasing urine flow. DSD is caused by an upper motor neuron injury, most commonly multiple sclerosis.
Cystourethroscopy Cystourethroscopy is not recommended in the basic evaluation of urinary incontinence. For patients with bladder pain, sterile microscopic or gross hematuria, new-onset irritative symptoms without infection, or suspected intravesical foreign body, a cystoscopy is warranted to rule out neoplasia.

TREATMENT OPTIONS

Three major categories of treatment for urinary incontinence include behavioral, pharmacologic, and surgical. Treatment options are often used in combination, such as behavior modification with timed voiding in conjunction with pelvic floor exercises for strengthening the pelvic floor. Realistic expectations for success and any risks of the therapy must be reviewed with the patient before initiating treatment. In choosing treatment for one condition, the potential for exacerbating another condition must be considered. For example, surgery performed to cure minor stress incontinence may dramatically worsen urge incontinence.

Behavioral Techniques

When taught or provided by knowledgeable health care providers, behavioral techniques decrease the frequency of urinary incontinence in most individuals, have no reported side effects, and do not limit future treatment options. Behavioral therapies are most successful when persons can actively participate in their training program, but they can be provided effectively by caregivers for patients with cognitive and motor deficits.

Bladder Retraining Behavioral modification is defined as the analysis and alteration of the relationship between the patient's symptoms and her environment for the treatment of maladaptive voiding patterns. Because most women either decrease their fluid intake or urinate more frequently in order to avoid leakage, behavior modification is helpful in virtually every patient with urinary incontinence. By inquiring about self-directed modifications the patient has made in her diet, fluid intake, or activity level, the practitioner can gain insight not only into the patient's diagnosis, but save time and have a more direct impact by not recommending modifications that the patient has already tried. Simple techniques may be discussed after review of the urinary diary, including adjustments in the type and volume of fluid intake. Older patients frequently have nocturnal diuresis. The diaries of these patients reflect several episodes of nighttime voiding, possibly with urinary loss while en route to the toilet. However, the important diary clue is a large bladder volume—sometimes larger than the patient's first morning voided volume. Rather than adding a nighttime bladder medication, a late afternoon supine rest or leg elevation can help the diuresis. Consuming large volumes of fluid intake, often in an attempt to aid weight loss, is a problem and should be addressed. Women should be counseled to drink and titrate their fluids according to urine color and number of voids. Generally the urine should be a light yellow. Women should aim for six to seven voids in a 24-hour time period. Inadequate hydration may be found in women who restrict intake as a method of controlling their incontinence symptoms. For some women, this may contribute to urgency and frequency as the concentrated urine is more irritative to the bladder than dilute urine. Also, caffeinated beverages increase urinary urgency and frequency and may exacerbate incontinence episodes. Timed voiding is effective for approximately 60% of women with detrusor overactivity. The patient is instructed to void at a specific interval by the clock during waking hours. By examining the voiding diary, a voiding interval that is slightly longer than the current interval that results in leakage is used as a starting time. For example, if a patient is voiding every 30 minutes to avoid leakage, she is encouraged to try and hold her urine for 1 hour and to use the clock to monitor her frequency. Over a period of 6 to 8 weeks, the intervals are gradually lengthened until the patient is able to urinate without leakage at 3- to 4-hour intervals. An alternative technique for women who are going to the bathroom every 30 minutes to 1 hour to avoid incontinence is to add 15 minutes of waiting time to when they feel the first desire to void. By asking the woman to sit and squeeze her pelvic floor when she feels the urge to void and to try and wait 15 minutes before voiding, she can again increase her times between voids to 3- to 4-hour intervals within 6 to 8 weeks. These techniques have significant advantages, including the lack of systemic adverse effects and the minimal cost. It is an ideal initial intervention for many women. Written materials are helpful for optimal understanding and compliance. For women with cognitive impairment or decreased mobility, timed-voiding prompted by a caregiver can also be effective in decreasing the number of incontinent episodes and the amount of leakage. A bedside commode can facilitate voiding and help the patient avoid falls. These behavior modification techniques are often done in conjunction with pelvic floor exercises and have been found to be equal to or more effective than pharmacotherapy for some women with urinary incontinence.
Pelvic Floor Muscle Training Pelvic floor muscle training is defined as “repetitive selective voluntary contraction and relaxation of specific pelvic floor muscles.” Most

women are familiar with the concept of pelvic floor exercises often termed “Kegels” after the gynecologist who first introduced the concept in the 1950s. Women with weakened pelvic floor muscles may benefit from muscle-training protocols. These protocols are helpful for patients with detrusor overactivity or stress incontinence. Muscle rehabilitation aims not only to strengthen but to activate the muscle contraction at the appropriate time. Miller and colleagues have shown that with proper instruction as to the timing of the pelvic floor contraction with a cough or urge to void, women can have immediate success in decreasing their incontinence before any strengthening of the pelvic floor muscles takes place. Like exercises aimed at strengthening other striated muscles, measurable improvements in strength occur after 4 to 6 weeks of training. Patients frequently have difficulty identifying muscles used in pelvic floor contractions and are unaware if they are contracting the right muscles and how to perform the exercises. Assessment as part of the exam for pelvic floor dysfunction can help the patient isolate the right muscles. The examiner places an index finger with light pressure on the posterior fourchette and asks the patient to Kegel, or squeeze her pelvic floor as if she is trying to hold urine or not pass flatus. Another method is to have the patient try to stop her urine flow. This method should only be used as a test and not for performing the exercises. If the patient is able to stop or slow the urine flow then she is squeezing the correct muscles and a strengthening program can be initiated. Women with profound weakness or apparent paralysis generally require a supervised exercise program and biofeedback or electrical stimulation therapy. Biofeedback uses a pressure balloon, surface electrodes that record pelvic floor muscle activity, or another measuring device that, visually or by sound, alerts the patient that she is squeezing the proper muscles. Over time, the patient is able to isolate and contract the muscles without the auditory or visual cue and a formal exercise program can be initiated. Strength can be gained through a variety of exercise programs. There is little scientific evidence to suggest the superiority of any specific muscle-training regimen; however, it is likely that general principles of muscle strengthening apply. Physical therapists and nurses may be helpful in initiating and supervising the rehabilitation program. Simple written or verbal instructions may be sufficient to teach patients how to perform pelvic muscle exercises properly. Performing these exercises supine decreases the gravitational forces and may make the exercise easier for the patient to perform. With improved strength, she may advance to exercising in the upright position. Patients should be instructed to perform 10 to 20 ten-second pelvic floor contractions three or more times per day. A minimum of 30 contractions per day for at least 6 weeks is usually required to achieve a detectable beneficial effect. Too vigorous a program should be discouraged as muscle soreness could result in dyspareunia and abandonment of the exercise program. Older women may need a longer training period. These exercises should be performed indefinitely to prevent recurrence of incontinence. An adjunct to biofeedback and standard pelvic floor exercises is the use of weighted vaginal cones. The cones, weighted 20 to 100 g, are used as part of a structured, progressive, resistive exercise program. Women insert the plastic coated cone into the vagina much like a tampon, and attempt to keep the cone from falling out by squeezing the pelvic floor. The exercise is performed for 15 to 20 minutes once a day. Once a weight has been successfully held for 3 days, the next higher weight is used. For women with stress incontinence, weighted cones have been found to be equal to other pelvic floor exercise programs where patients are monitored closely by nurses or physical therapists. Cones may be preferred by some women because they are done at home, do not require nursing or physical therapy visits, and they are relatively inexpensive. Regardless of the exercise method used, as the muscles are strengthened, the patient must also learn to use her muscles correctly to inhibit urinary urge and reduce stress incontinence episodes. She must learn to contract these muscles firmly in advance of a cough, sneeze, or similar anticipated stress. Strength without timing or timing without strength will result in clinically unsatisfactory results. Once the muscles are strengthened and the patient has learned to squeeze at the appropriate time, the extent of exercise needed to maintain the effect is not fully known. Like many exercise programs, the patient's dedication to the activity likely will diminish with time.

Electrical Stimulation Therapy

Transvaginal electrical stimulation produces a contraction of the levator ani, external urethral sphincter, and anal sphincters, accompanied by a reflex inhibition of the detrusor and is dependent on a preserved reflex arc through the sacral micturition center in order to work. Electrical stimulation with a transvaginal probe reduces detrusor overactivity and stress urinary incontinence in approximately 50% to 70% of affected women. Two randomized trials comparing electrical stimulation to placebo or sham device have been performed. Sand and colleagues, using high frequency probes, reported objective “cure” or improvement in 48% of patients with stress urinary incontinence versus 13% improvement in the control group. Brubaker and co-workers reported on 121 women with urge, stress, and mixed incontinence. Participants used either a sham device or underwent electrical stimulation using a low-frequency, 20-Hz, 2-second to 4-second work–rest cycle for 20 minutes twice daily for 8 weeks. Detrusor overactivity was cured in 49% of women receiving electrical stimulation, but there was no statistically significant change in the percentage with detrusor overactivity in the sham device group. There was no statistical improvement in the women with stress urinary incontinence.

Typically, a transvaginal probe is used once or twice daily for 15 to 20 minutes. Symptom relief generally occurs within 6 to 8 weeks and continues with reduced stimulation (e.g., three times weekly). Like timed voiding and muscle training, this treatment is free of systemic adverse effects. The main drawback is the cost of rental or purchase, which may be out-of-pocket expense for many patients. Many third-party providers and Health Care Financing Administration (HCFA) have approved the use of electrical stimulation therapy for urinary incontinence making the treatment more affordable. Several devices approved by the U.S. Food and Drug Administration are available, and treatment can be home-based or, less commonly, office-based. Women with pacemakers should avoid this therapy unless other options are not available.

Implantable electrostimulators, such as InterStim, are now being used for patients with refractory urge incontinence. Before considering InterStim, all other treatment options should have been used properly, including transvaginal electrostimulation. InterStim requires insertion of a wire electrode, through an incision in the back and placement of a permanent stimulator, to the nerve root of S2, S3, or S4. The nerve root is stimulated and theoretically aberrant afferent signals to the spinal cord are blocked, decreasing bladder overactivity. Improvement of urgency and frequency symptoms ranges from 60% to 83%.

Vaginal and Urethral Devices An increasing selection of vaginal and urethral devices is available and appears to be the fastest-growing type of incontinence therapy. Pessaries modified for use in incontinence provide additional suburethral pressure and are safe and reasonably effective. For some women, the placement of a vaginal tampon may provide adequate urethral support to prevent leakage during physical activities such as playing golf or tennis. Both external and internal urethral barriers are becoming increasingly available. While not optimal for all patients, these devices can provide effective treatment for patients who leak only under known circumstances or perhaps to improve their quality of life while awaiting surgery. External barriers range from patches that fit over the urethral meatus to small suction cups that limit urine loss. Internal urethral barriers are available, but they have the distinct disadvantage of causing urinary tract infections and hematuria. Although effective in preventing urine loss, the devices are less than ideal because of these adverse effects. In addition, many women are not comfortable with the idea of placing something into or over their urethra or are not physically able to do so. The efficacy, cost, comfort, and adverse effects including urinary tract infection and skin irritation for each of these barriers must be considered. More experience is needed before recommendations can be made.

Pharmacotherapy

Detrusor Overactivity or Urge Incontinence No ideal medication for the treatment of incontinence is available, primarily because of the unwanted side effects. In general, drug treatment is used for detrusor overactivity and is aimed at reducing inappropriate detrusor contractions (Table 48.9).

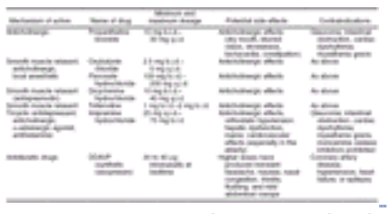

TABLE 48.9. *Pharmacologic therapy for detrusor instability*

Drugs for detrusor overactivity are typically anticholinergic agents. Thus, the adverse effects include xerostomia or dry mouth, blurred vision, drowsiness, and constipation. Narrow-angle glaucoma is an absolute contraindication to the use of this class of medications, and they should be used cautiously in women with cardiovascular disease. While other anticholinergic medications have been used clinically, oxybutynin chloride, propantheline, and tolterodine are the only medications in this class with scientific evidence of efficacy for treating detrusor overactivity. Oxybutynin chloride is available in generic formulations and in a longer-acting, once-a-day nongeneric formulation. Tolterodine, available in a once- or twice-a-day dosing form, may have fewer adverse effects when compared to generic oxybutynin chloride. Because of the high side-effect profiles, the medications should be started at very low doses and increased according to the patient's symptoms of incontinence and adverse reactions. The medications can be self-titrated over a period of 6 to 8 weeks with written instructions. Since constipation is a common comorbid condition in the elderly, recommending a stool softener when initiating therapy should be considered. Long-term compliance with incontinence medications is poor and usually ranges from 40% to 50%. This low compliance should be considered when selecting this mode of therapy and follow-up should be scheduled. The effectiveness of pharmacotherapy is poor in women whose incontinence is related to insensible loss (leakage that occurs without the patient's knowledge).
Stress Incontinence Medications that stimulate a-receptors are used to increase urethral tone in an effort to reduce stress incontinence episodes. These medications stimulate a-receptors throughout the body (e.g., in the cardiovascular system) and may cause hypertension. Phenylpropanolamine and pseudoephedrine are the first-line pharmacologic therapy for women with stress incontinence. Women with mixed urinary incontinence may benefit from imipramine hydrochloride, a tricyclic antidepressant. This medication offers a combination of anticholinergic medication for detrusor suppression and a-receptor sympathomimetic activity to increase urethral pressure.
Estrogen The role of oral or vaginal estrogens in the management of overactive bladder or stress incontinence remains unclear. Prospective studies have shown little effect of oral combined estrogen/progestin therapy on lower urinary tract function, including prevention or improvement in urinary incontinence. Meta-analysis of prior studies has shown some improvement in nocturia secondary to estrogen therapy in postmenopausal women. While many clinicians feel strongly that preoperative transvaginal estrogen therapy improves surgical outcome and tissue healing, further evaluation is needed.

Surgical Management

Surgical management of urinary incontinence has been reported since the early 1900s. With an aging United States population, there will be greater demand for surgical and nonsurgical treatment of incontinence. Estimates indicate the demand for services will increase 10.9% for women between the ages of 30 to 58 years and 80.7% for those between 60 to 89 years by 2020. Although hundreds of operations have been described, today there are basically three types of procedures used: a suburethral plication, a shelf or repositioning type of procedure, or a pubovaginal sling. The large number of reported procedures indicates that no single type of operation will cure all patients. Table 48.10 presents the studies that have included objective testing and highlights the handful of studies that have been prospective, randomized, controlled trials. Based on the clinical findings in each individual patient, the surgeon must select the procedure or combination of procedures that will most likely alleviate the condition. Selection of the antiincontinence procedure is determined by many factors including need for other concomitant abdominal or vaginal procedures to correct pelvic organ prolapse, history of prior repairs, urethral hypermobility, and overall health and surgical risks for the patient.

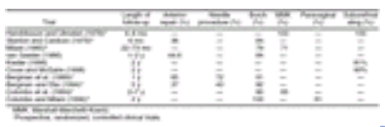

TABLE 48.10. *Urinary incontinence procedures: objective cure rates*

Significant limitations in reviewing data on the surgical treatment of stress incontinence have been encountered. There is no standardized pre- or postoperative evaluation for the surgical treatment of stress incontinence. Variable lengths of follow-up, inconsistent outcome criteria, and reporting biases of operating surgeons make comparison of many clinical series nearly impossible. The 1996 revision of the Agency for Health Care Policy and Research Urinary Incontinence Clinical Practice Guidelines summarized that “the surgical literature is deficient in standards for describing the patient population, the type of incontinence, the method for accurate diagnosis, the techniques of the surgical procedure, or the outcome in different domains.” In 1997, the American Urologic Association completed a comprehensive, evidence-based review of the surgical literature on the treatment of stress incontinence. Minimal criteria for follow-up interval and reporting outcomes resulted in the elimination of over half the reported clinical series from the database. There were no standardized pre- and postoperative evaluations and uniformity in the terminology describing the surgical procedures. Limited, poorly defined outcome measures (e.g., “dry”, subjective vs. objective variables, “improved”—1 pad/day vs. 3 pads/day) with little accuracy in morbidity rates made comparison of the surgical literature impossible.

Although our understanding of the pathophysiology of stress incontinence is incomplete, most accept the current concepts of urethral hypermobility and intrinsic sphincter dysfunction as causes, whether alone or in combination. Einhorning believed that the proximal urethra descended beyond the pelvic diaphragm and thus beyond the sphere of influence of the abdominal cavity, and restoration of continence required the urethra be drawn back within the abdominal cavity. Reexamination of the anatomy of the female pelvis from both a structural and functional perspective has led to the current concept that poor support of the proximal urethra as a result of relaxation or detachment of the anterior vaginal wall is responsible for the hypermobility associated with stress incontinence. It is recognized that this is an incomplete explanation since the majority of women with hypermobility do not have stress incontinence. Thus, there must also be some abnormality in the function of the urethra in women with stress incontinence. Whether this dysfunction is a primary neurologic defect or muscular defect is not yet determined, but there is strong evidence that denervation plays an important role. Snooks and co-workers demonstrated that the denervation effects of vaginal birth and subsequent pudendal neuropathy are significantly associated with GSI.

A subset of women develop stress incontinence despite excellent support of the UVJ. The term “intrinsic sphincter deficiency” (ISD) was created to describe this condition. ISD is a weakness or defect in the intrinsic urethral sphincter, resulting in stress incontinence, and is generally considered a more severe type of stress incontinence which emphasizes decreased urethral sphincter function rather than urethra position or mobility. Whether there is an actual physiologic difference in these “types” of stress incontinence or their underlying pathophysiology is unknown. This distinction may be artificial, looking at the same problem of neuromuscular dysfunction along one continuous spectrum.

Traditionally, from a surgical standpoint, the distinction between the two types of stress incontinence has been used to determine the type of surgical procedure performed—colposuspension or pubovaginal sling. Hypermobile stress incontinence has generally been managed with the “urethral hammock” support using a colposuspension such as a Marshall-Marchetti-Krantz (MMK), Burch, or paravaginal repair. The surgical procedure's goal is to elevate and stabilize the UVJ.

Patients with ISD have been found to have lower success rates following retropubic urethropexies when compared to patients with urethral hypermobility and a better functioning urethra. Thus pubovaginal sling procedures employed to treat ISD are designed to restore compression and coaptation of the damaged urethral sphincteric mechanism.

While some surgeons continue to surgically treat these “types” of stress incontinence differently, many surgeons, both urologists and gynecologists, are increasingly using a pubovaginal sling for all patients with stress urinary incontinence. Because of the reported durability, the pubovaginal sling, in increasing numbers of practices, is being performed for patients with hypermobile stress incontinence without ISD. Cross and associates performed pubovaginal slings on such patients with a cure rate of 93% reported at 22 months.

In 1996, a review by Black found four prospective studies done to compare colposuspension with sling procedures. None reported a difference in cure rate although all had substantially less than 50% power to detect a significant difference and all defined surgical success differently. Only one study analyzed complication rates and found a statistically significant higher risk of complications after a sling operation including elevated postvoid residual urine, entry into the bladder, and uterine prolapse. One large retrospective trial suggested that colposuspension may be more effective than sling procedures (95% vs. 79%). Marinkovic and colleagues, in a retrospective review of 18 women having a Burch colposuspension and 18 women undergoing a pubovaginal sling, found that the Burch group had twice the number of postoperative complications, with comparable success. In contrast, Enzelsberger showed significant increases in postoperative voiding dysfunction in patients after pubovaginal sling (13%) that was not observed in Burch patients. Thus, there is no convincing evidence that the effectiveness of colposuspension and sling procedures differ. The differences may be in the complication rates for the two procedures. However, less than 150 patients have ever been included in prospective studies concerning these two surgeries. Two large, prospective trials comparing Burch colposuspension and pubovaginal sling are underway and should help determine the best procedure.

Suburethral Plication/Anterior Colporrhaphy While most surgeons have abandoned the suburethral plication as an antiincontinence procedure, for a select group of patients, the Kelly-Kennedy plication is appropriate. Dr. Howard Kelly from Johns Hopkins University was the first to describe this operation in 1913. The technique has changed very little from his original description. Through an anterior vaginal incision, the vesicovaginal space is dissected bilaterally to the pubic rami. A series of plicating mattress sutures of either permanent or delayed-absorbable material are then placed beneath the UVJ and then subsequently, in any significant pubocervical fascial defect, below the urethra and bladder. Although Dr. Kelly reported a more than 90% subjective success rate with his anterior vaginal repair, subsequent success rates in the literature have ranged from 31% to 69% with 1- to 5-year follow-up. One noteworthy exception to these figures, however, is two studies from Dr. R. Peter Beck of Canada. In his original series of 105 patients reported on in 1982, a 90% subjective cure rate was described. In a follow-up paper published in 1991, similar outcome numbers were provided for over 500 patients. Dr. Beck attributed much of his success to the use of delayed absorbable polyglycolic suture instead of chromic cat gut suture. Anterior vaginal repair remains indicated in the treatment of a cystocele caused by a central fascial defect. Concomitant suburethral plication may be a reasonable choice in the prevention of potential or occult stress incontinence for patients having vaginal reconstruction for pelvic organ prolapse. The most appropriate indication for a suburethral plication is in conjunction with an obliterative procedure, such as when complete or LaForte colpocleisis is performed. These patients, generally older with poorly functioning detrusor muscles or detrusor overactivity, are at risk for urinary retention or worsening of incontinence from detrusor contractions if a more durable antiincontinence surgery is performed. A suburethral plication may be the best antiincontinence surgery for these patients. Their incontinence may not be “cured”, but the low morbidity balances the higher risks of urinary retention or overactive bladder. Success in these cases is defined by improved quality of life from prolapse surgery and hopefully a reduction in urinary incontinence and avoidance of self-catheterization. Complications include hemorrhage, vaginal foreshortening, and suture misplacement in the bladder, urethra, or ureter. Thus, follow-up cystoscopic evaluation is recommended to assess for potential injury to the lower urinary tract.

Retropubic Urethropexy Retropubic urethropexy (RPU) is used by many surgeons as their primary repair for stress incontinence. The first RPU, described in 1949, the Marshall-Marchetti-Krantz (MMK) procedure has had success rates ranging from 70% to 90%. After entry to the retropubic space is achieved, the urethra is identified along its course to the bladder neck. One to three pairs of sutures, usually nonabsorbable, are placed on each side and close to the urethra through the pubocervical fascia. These are then fixed to the fibrocartilage of the symphysis pubis. Because the angle of elevation is more acute and centrally placed than with a Burch procedure, the potential exists for the patient to have an increased risk of bladder neck obstruction. Voiding dysfunction occurs in 5% to 20% of cases. The rate of subsequent osteitis pubis is approximately 2%. In 1961, Dr. John Burch of Nashville, Tennessee described a new fixation point for the RPU sutures, namely Cooper's ligament. Through a Pfannenstiel incision, the retropubic space is entered. With the surgeon's nondominant hand in the patient's vagina, the Foley catheter is pulled down to the UVJ. While gently retracting the bladder medially, the paravaginal tissues are identified and, if necessary, gently cleaned off at the UVJ and midurethra extending approximately 2 cm lateral to the urethra. Seeing the white surface of the vaginal submucosal layer in contrast to the yellow bladder helps identify

the vagina. A full thickness figure-of-eight of permanent suture is placed at the UVJ and midurethra on both sides. Cooper's ligament is identified, and both arms of the sutures are brought through the ligament, with the midurethral sutures most caudad (Fig. 48.6). The sutures are tied while elevating the vagina so that the urethra is repositioned parallel to the floor. Overcorrection should be avoided; suture bridges are the norm. Cystoscopy, transurethrally or through the bladder dome, teloscopy, is then performed to assess the integrity of the lower urinary tract. Consideration for placement of a suprapubic catheter is reasonable, especially if the patient is predisposed to postoperative voiding dysfunction.

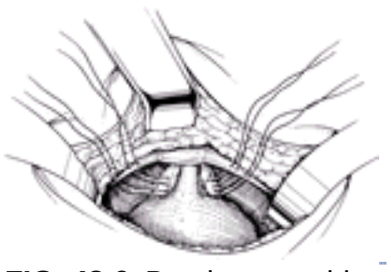

FIG. 48.6. Burch retropubic urethropexy. Sutures are placed lateral to the urethrovesical junction and lateral to the midurethra and brought to the Cooper ligament bilaterally. (Adapted from Tanagho EA. Colpocystourethropexy: the way we do it. *J Urol* 1976;116:751.)

Objective cure rates for the Burch RPU range from 70% to 90%. Complications include ureteral damage (usually from overcorrection or kinking, not direct trauma) and bleeding from the adjacent large veins of Santorini. Enterocele formation following colposuspension has been reported in 3% to 17% of patients, leading most surgeons to perform a uterosacral ligament plication or cul-de-sac obliteration for patients predisposed to pelvic organ prolapse. The prevalence of postoperative detrusor overactivity is 5% to 18%. Postoperative management is similar to that for other abdominal surgical procedures. It is usually possible to allow patients to have oral intake soon after the operation, because the peritoneal cavity was not entered. The bladder is drained continuously for the first 1 or 2 postoperative days. If used, the suprapubic catheter is occluded and patients are asked to indicate when they feel that the bladder is full. They are then allowed to void, and the amount of urine remaining inside the bladder is measured by the nursing personnel. If transurethral catheter drainage has been used, the bladder can be filled retrograde until the patient feels full. The catheter is then removed and the patient is asked to void. The voided amount is measured using a hat placed in the toilet. By subtracting the voided amount from the amount instilled in the bladder, the postvoid residual can be determined. The catheter should be replaced or the suprapubic catheter should be left in until the patient is able to void adequately with small amounts of residual urine (<100 mL or <25% of the total volume in the bladder) consistently for three voids. The patient can also be taught clean, intermittent self-catheterization to perform until her postvoid residuals are adequate. Most patients can void adequately within 72 hours. Some literature suggests that the Burch procedure has fewer complication rates than the MMK. Columbo and colleagues randomized 80 patients with stress incontinence to receive either a Burch or an MMK. Although the cure rates were equal, patients who underwent an MMK were more likely to have detrusor overactivity and voiding dysfunction postoperatively.

Laparoscopic Bladder Neck Suspension The laparoscopic approach to correcting stress incontinence has been described with increasing frequency since the early 1990s. Reports by expert laparoscopic surgeons who perform the Burch procedure identical to the open technique report similar success rates to the open procedure. Reports where techniques are altered, such as one suture used on each side rather than two, or only one arm of the suture being brought through Cooper's ligament have shown significantly more failures. The applicability of this technique demands that the procedure be performed in exactly the same way as an open Burch. Complications with the laparoscopic technique include injuries to nearby structures at the time of surgery and are more frequent than with open dissection. This is most likely due to the learning curve. Most skilled laparoscopists cite a learning curve of 10 to 20 procedures.

Paravaginal Repair Paravaginal repair is another retropubic procedure used for the correction of stress incontinence. The abdominal paravaginal repair was first described by Burch, in his initial attempts to surgically support the UVJ. Due to poor results, Burch modified his procedure, elevating the sutures from the endopelvic fascia to Cooper's ligament rather than the arcus tendineus fasciae pelvis (ATFP). Cullin Richardson reintroduced paravaginal repair as a procedure to correct paravaginal (lateral) defects in anterior vaginal wall support. Although others have suggested that the procedure may also be used as an antiincontinence surgery, closer examination of the procedure performed indicates that the investigators combined Burch stitches to the Cooper ligament with paravaginal stitches to the ATFP. The only randomized, prospective study comparing the Burch procedure to a pure paravaginal repair, with pre- and postoperative objective follow-up, indicates that the paravaginal repair yields inferior cure rates, 75% versus 100%, in treating stress incontinence. The paravaginal repair should be considered a procedure for correcting anterior lateral vaginal wall defects and not as an antiincontinence procedure.

Suburethral Slings Suburethral sling procedures have been described since the early 1900s. In 1942, Aldridge was the first surgeon to use strips of autologous rectus fascia, placing it under the bladder neck and affixing it to the anterior abdominal wall. Traditionally, suburethral slings have been performed for recurrent stress incontinence, for patients with risk factors for surgical failure such as chronic pulmonary conditions like asthma, or for patients who perform physically demanding activities that cannot be modified. The more common indication is for ISD with or without urethral hypermobility. There has also been a trend in performing primary sling procedures in patients with hypermobile stress incontinence based on the high failure rates of other procedures, particularly, anterior repair and needle suspensions. Suburethral sling procedures may use autologous materials or foreign materials to support the UVJ. Autologous materials such as fascia lata may be obtained from the leg, or rectus fascia from the anterior abdominal wall has also been used. Synthetic materials such as Marlex and Mersilene have been used for suburethral slings with success. Allograft fascia has been used with varying success rates depending on tissue source and processing. Surgeons continue to search for the ideal sling material. While autologous materials have fewer long-term complications such as erosion or infection, the harvesting of grafts increases operative time and potential for morbidity. The technique of a suburethral sling procedure basically involves placement of either a tissue or synthetic graft under the bladder neck and fixation of the material to an abdominal site. A graft measuring approximately 8- to 10-cm long by 2-cm wide is either harvested or cut from the synthetic material and tagged at the corners with permanent suture. The vaginal portion of the procedure begins with a vertical or U-shaped incision made along the anterior vaginal wall, and entry into the retropubic space is accomplished. The UVJ is identified by gently pulling on an indwelling Foley catheter. The sling itself will be sutured such that two-thirds of the 2-cm–wide sling are under the urethra and one-third is under the trigone (Fig. 48.7).

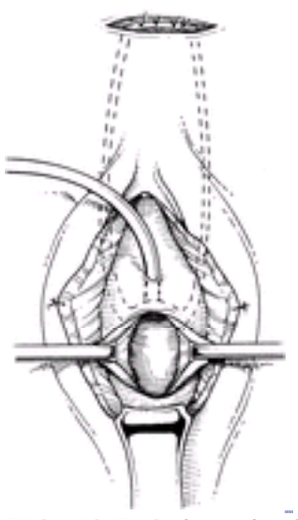

FIG. 48.7. Suburethral sling procedure. After dissection of the anterior vaginal wall, the sling is anchored underneath the urethrovesical junction, and the arms are brought to the anterior rectus fascia, where they are similarly anchored. (Adapted from Horbach N, Blanco J, Ostergard DR, et al. A suburethral sling procedure with polytetrafluoroethylene for the therapy of genuine stress incontinence in patients with low urethral closure pressure. *Obstet Gynecol* 1988;71:648.)

A short suprapubic incision is made to the level of the anterior rectus fascia. A stab wound is made through the rectus fascia 2.5 cm lateral to the midline just above the symphysis. A uterine packing forceps or suture carrier is passed through this incision down into the vagina, guided by the surgeon's index finger. The arm of the sling is grasped and withdrawn up to the anterior rectus fascia. The procedure is repeated on the opposite side. At this point, a cystoscope is introduced into the bladder to ascertain whether or not perforation of the bladder has occurred and urethral function remains normal. The sling is then secured at the UVJ using fine absorbable suture. The sling is then gently elevated until there is no slack. The most important step in the procedure is paying careful attention to not to pull the sling too tight. The sling functions as a backstop, not by occluding the urethra. Experienced surgeons know that loose is better than tight. While various techniques including Q-tip angles and cystoscopy have been used to try and “standardize” sling tension, none have proven useful. The sling is sutured first to the rectus fascia. The anterior vaginal wall is approximated and the anterior abdominal wall incision is closed. Postoperative care and bladder management is the same as described for colposuspension. Complications of the suburethral sling procedure include the possibility of erosion of the sling material into the vagina or the anterior abdominal wall with sinus tract formation. Occasionally, slings must be removed because of this problem. Slings may also be removed from patients who develop marked obstruction and who do not want to use self-catheterization on a permanent basis. Success rates for sling procedures range from 85% to 90%. Reasons for failure include inaccurate placement at the bladder neck, inadequate sling tension, poor tissue graft, or inadequate fascial attachment. The most common complication and the reason many surgeons avoid sling procedures is postoperative voiding dysfunction. Failure to void after the procedure occurs in up to 20% of patients. Although there are procedures designed to remedy this situation (i.e., sling release or modification), the best method is prevention by assuring that the sling is not placed too tightly in the first place. Some patients may be able to modify their urination by changing positions such as leaning forward or standing. As long as the patient is not having serious sequelae such as pain or urinary tract infections, treatment may remain conservative. The patient may very well be willing to accept some voiding difficulty in exchange for being dry. If however, the patient cannot spontaneously void by 6 weeks after surgery, sling revision should be offered. In most cases, the sling can be cut transvaginally and the patient does not develop recurrent incontinence.

Tension-free Vaginal Tape In 1995, a modification of the pubovaginal sling, the tension-free vaginal tape (TVT), was introduced. Developed by Petros and Ulmsten in

Sweden, the TVT differs from the traditional pubovaginal sling in that the sling is placed at the midurethra and not the UVJ, and the sling material is a 1-cm–wide mesh of Prolene that is held in place by friction and not sutures. The procedure, designed to be performed under local or regional anesthesia, allows the patient to cough with a full bladder during sling adjustment. The sling is elevated to the level where urine leakage stops and is not made any tighter. For women with hypermobility and a normal functioning urethra, an objective cure rate of 90% has been reported after a 5-year follow-up. For a small group of women with ISD, cure rates of 74% with additional improvement in 12% with a 4-year follow-up have been reported. Immediate complications, including bleeding and bladder perforation, are similar to other series for pubovaginal slings. Voiding dysfunction appears to be less than for traditional pubovaginal slings, but is probably related to having a looser sling. As more surgeons have adapted the loose sling technique to traditional sling placement, the voiding dysfunction in more recent series is also decreasing. Long-term complications, including graft erosion, are unknown. While Prolene appears to have properties that are more favorable for vaginal placement than other meshes, it is likely that there will be a 1% to 3% erosion rate. Longer follow-up and careful reporting of outcomes will determine the use of TVT in the management of stress urinary incontinence.

Transurethral Collagen Injections Although initially thought to be a significant breakthrough in treating patients with severe incontinence, periurethral bulking agents have a less than 50% long-term success rate. However, for some patients this is a reasonable surgical alternative to more invasive procedures. The patient best suited for a bulking agent is one who has ISD, an immobile bladder neck, excessive surgical risk, and who has undergone multiple antiincontinence procedures. Short-term cure rates approach 70% to 90%. Periurethral collagen injections are not indicated in women with urethral hypermobility, because cure rates are only 20% to 25% in this group of women. The most commonly used substance for bulking is gluteraldehyde cross-linked bovine collagen. Because of potential allergies, a patient must have a negative reaction to a collagen skin test weeks before surgery. The procedure can be done in the physician's office or in an outpatient setting with local anesthesia. A zero-degree operative cystoscope with a spring-mounted injection needle is employed. Once the bladder neck is visualized, a site approximately 1 to 2 cm distal to it is selected for needle insertion. Injections are performed at the 3 o'clock and 9 o'clock positions in an attempt to close the bladder neck. Usually, 5 to 7 cc of material will be sufficient. The patient is asked to cough to observe for leakage. Injections can last 3 months to several years. Most patients require multiple injections given 2 to 3 months apart, followed by a general improvement lasting 6 months to 1 year. This method is probably best used by obstetrician–gynecologists who specialize in the treatment of incontinence.

Artificial Urinary Sphincters Few treatment centers implant artificial urinary sphincters in women, mostly because of the high complication rates. The ideal patient has ISD but no scarring at the bladder neck. Failure of a sling procedure or collagen injections may prompt the surgeon to consider this surgery. The sphincter is placed using a combined abdominal/vaginal approach. The sphincter is placed around the urethra, with the reservoir in the retropubic space and the pump in the labia majora. The active sphincter mechanism is not activated for 6 weeks until healing has taken place. The device maintains closure of the bladder neck until patient activation of the device evacuates the cuff for several minutes to allow voiding. Complications include infection, device erosion, or pump failure.

SELECTING THE APPROPRIATE SURGICAL PROCEDURE FOR STRESS INCONTINENCE

Selection of a surgical procedure for a given patient is based on the operating surgeon's impression of the clinical complaints, the physical examination findings, and cystometric values. Objective urodynamic assessment of the patient is only required if the surgeon is going to base the choice of surgical procedure on specific objective findings such as the urethral closure pressure or the bladder pressure needed to overcome the urethra. If however, the surgeon will perform a pubovaginal sling, for all patients with stress incontinence regardless of urethral function, then urodynamic testing in not indicated.

Traditionally, if a patient's urethral pressure has been considered normal, greater than 20 cm H_2O, a retropubic urethropexy of the Burch type is preferred. If the urethral pressure is less than 20 cm H_2O, a suburethral sling procedure should be considered. In both circumstances, it is assumed that inadequate support of the UVJ is present, as indicated by a Q-tip test that is greater than 30 degrees from the horizontal during straining. If the UVJ is well supported, as indicated by a Q-tip deflection on straining of less than 30 degrees from the horizontal, the patient is less likely to respond to either of the aforementioned procedures, and other surgical means may be indicated for treatment. Options for treatment of intrinsic sphincter deficiency and a supported bladder neck include an artificial sphincter, periurethral injection, or an obstructive sling. With the latter choice, the patient needs to be informed of the extremely high probability that lifelong self-catheterization may be required to empty the bladder.

Much discussion has taken place regarding the different procedures used to manage stress incontinence in regard to efficacy and long-term success. Unfortunately, most studies in the literature have lacked objective pre- and postoperative assessment and therefore an objective measurement of cure. Table 48.10 shows the studies that have included objective testing and highlights the handful of studies that have been prospective, randomized, controlled trials.

SUMMARY

Many women of all ages have urinary incontinence. Unfortunately, many women still do not seek treatment. All clinicians who care for women should ask about bladder function and reassure patients that many successful treatments are available. After asking the question, the clinician should work with the patient to determine the type and severity of her incontinence and the impact her urine leakage is having on her life. Evaluation should be directed at ruling out treatable causes such as urinary tract infections, fluid overload, or medications that affect fluid balance or lower urinary tract function. Bladder testing with cystometry should be considered before surgical treatment to be sure the patient suffers from stress incontinence and not detrusor overactivity that may be made worse or have no improvement after surgery. Treatment should be based on the patient's expectations, ability to use behavioral techniques, side effects of therapies, cost, and success for treating her condition.

SUMMARY POINTS

- Urinary incontinence is a common condition affecting women. Many successful treatment options are available.
- Diagnosis of lower urinary tract conditions, particularly urinary incontinence, cannot be made based on symptoms alone. A systematic approach including history, physical examination, voiding diary, assessment of postvoid residual, and ruling out infection begin the assessment.
- A positive stress test demonstrates the sign of stress urinary incontinence.
- Multichannel urodynamic studies are indicated for approximately 10% of women to help make the diagnosis of the type of urinary incontinence. Clinicians who specialize in urinary incontinence use multichannel urodynamics to test more patients because of the complexity and prior failed treatments in women referred for subspecialty care.
- Selection of the appropriate surgical procedure for the correction of stress incontinence should be based on urethral function, the presence or absence of urethrovesical junction (UVJ), hypermobility, and the need for other surgical procedures for pelvic organ prolapse.
- Retropubic urethropexy procedures, specifically the modified Burch procedure, offer the best long-term support of the UVJ and cure of incontinence with the least morbidity.
- Intrinsic sphincter deficiency should be considered in patients with severe leakage with minimal activity or those with recurrent incontinence, a history of radical pelvic surgery, or radiation. Options for therapy include periurethral injection of bulking agents or artificial sphincter in patients with a well-supported UVJ, or a suburethral sling when UVJ hypermobility is present.
- Detrusor overactivity should be looked for in every patient with urinary incontinence, most importantly prior to any surgical antiincontinence procedure. It is best treated with bladder retraining, electrical stimulation therapy, or anticholinergic medications.

Leiomyomata represent the most common gynecologic tumors and are responsible for approximately 300,000 hysterectomies per year. They can cause a variety of symptoms, including menometrorrhagia, dysmenorrhea, pelvic pain, infertility, preterm birth, and compression of adjacent pelvic viscera. Paradoxically, large subserosal leiomyomata may be totally asymptomatic. These tumors are often multiple, are almost always benign, and represent gonadal steroid–responsive aberrant clonal expansions of individual myometrial cells. Leiomyomata are more common in African-American women and have a nonmendelian inheritance pattern with up to a 50% recurrence rate after myomectomy. Treatment of patients with leiomyomata should be undertaken only to address a specific clinical problem and the therapy choice depends on the goal of therapy, with hysterectomy most often used for definitive management and myomectomy when preservation of childbearing potential is desired. Intracavitary and selected submucous leiomyomata can be removed by hysteroscopic resection and, although laparoscopic myomectomy is technically feasible, the risk of uterine rupture during subsequent pregnancy is potentially greater with the endoscopic removal of intramural leiomyomata. Although gonadotropin-releasing hormone (GnRH) agonist–induced hypogonadism can reduce the volume of leiomyomata by up to 50%, the severe side effects and prompt reenlargement after discontinuance make this approach useful only for short-term goals such as: (a) shrinking an intracavitary tumor prior to hysteroscopic resection, (b) preoperatively correcting anemia, or (c) reducing the overall size of the uterus to facilitate surgery. Nonextirpative approaches, such as myolysis and uterine artery embolization (UAE), are being evaluated and may prove useful options for carefully selected women if proven safe and efficacious in long-term follow-up studies. The impact of these nonextirpative options on fertility and pregnancy has not been determined. Ultimately, if the genetic basis for fibroid development or the molecular mechanism(s) of myometrial proliferation are better understood, additional nonsurgical therapeutic interventions may be forthcoming.

INTRODUCTION

Uterine leiomyomata are by far the most common benign tumors of the female genital tract and likely the most common soft tissue tumors of all. Approximately 300,000 hysterectomies and 20,000 myomectomies are performed annually in the United States because of symptoms caused by leiomyomata. These tumors can attain very large size with few if any symptoms and, alternatively, small leiomyomata may cause massive uterine bleeding, marked abdominal distension, and disabling dysmenorrhea. Although representing one of the most frequent indications for gynecologic surgery, the incidence of leiomyomata far exceeds the frequency of clinical problems, with estimates of as high as 50% of women having at least one identifiable fibroid at menopause. Understanding what is known regarding the pathophysiology, genetic risk predisposition, and natural history of leiomyomata is invaluable for the practicing clinician.

CLINICAL PICTURE

Leiomyomata come to clinical attention for a variety of reasons, and the symptoms (Table 49.1) depend upon tumor size and location (Fig. 49.1). It is unusual but not rare for fibroids to become symptomatic before a woman reaches age 30. Excessive menstrual bleeding (menorrhagia) leading to anemia, debilitating dysmenorrhea, generalized pelvic pain, or symptoms of pressure on the adjacent pelvic viscera my occur, but pain other than dysmenorrhea is typically a late symptom. Vaginal bleeding apart from the expected menses, despite being heavy, is not typically a sign of uterine fibroids and usually indicates an underlying endocrine abnormality such as anovulation. Furthermore, the typical scenario is not a sudden heavy bleeding episode, but rather a gradual increase in menstrual bleeding that parallels the growth of the fibroids. Leiomyomata occasionally undergo rapid enlargement during pregnancy with central avascular necrosis, the so-called *red degeneration*, resulting in extreme pain requiring hospitalization and narcotics. As the size and number of the leiomyoma increase, particularly with single large subserosal leiomyomata, the adjacent pelvic viscera may become compressed, resulting in urinary frequency, constipation and, occasionally, dyspareunia. Rarely, when the fibroids are large and fill the pelvis or grow laterally from the midportion of the uterine body, they can compress the ureters and cause hydronephrosis (Fig. 49.2). Intracavitary fibroids often are on a vascular pedicle and may be extruded through the cervix, appearing as a necrotic mass. Rarely, large uterine leiomyomata will become entrapped in the pelvis when the expanding tumors are juxtaposed against the promontory of the sacrum and cause the cervix to descend in the vagina and occasionally appear at the introitus. This is particularly true when a woman with large serosal leiomyomata conceives and the tumors, as well as the gravid uterus, enlarge rapidly and can become incarcerated in the pelvis. Although fibroids can be present and cause symptoms at any age after puberty, they typically do not become a clinical problem until the early to mid-30s. With a rising age at which women first attempt pregnancy, this increasingly represents a difficult management problem which did not exist a generation ago when simple hysterectomy was the frequent curative choice. Preserving reproductive potential while relieving symptoms is the challenge today, with the rising age at first pregnancy increasing the likelihood that leiomyomata will develop prior to completing childbearing.

TABLE 49.1. *Symptoms of leiomyomata*

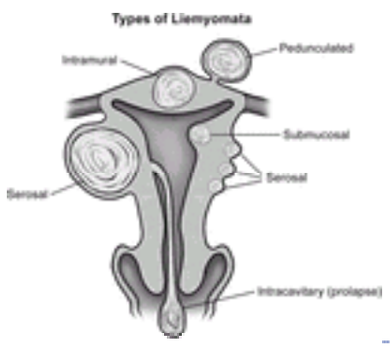

FIG. 49.1. Possible locations of leiomyomata. This schematic diagram illustrates the many locations at which leiomyomata may develop. Symptoms related to heavy vaginal bleeding generally are greater when the leiomyomata are in close proximity to the endometrial cavity, with serosal tumors that can attain large size with virtually no change in menstrual bleeding. Fibroids can develop anywhere in the uterus, with the cervix having proportionally fewer because of its lower complement of myometrial cells.

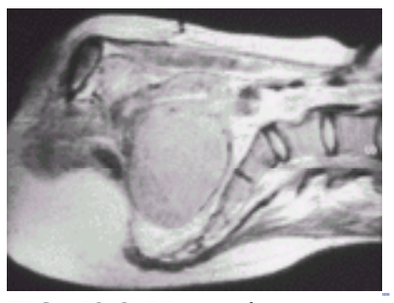

FIG. 49.2. Magnetic resonance imaging of leiomyomata. This magnetic resonance image demonstrates a large leiomyoma arising from the posterior aspect of the uterus and filling the entire pelvis. It directly contacts the promontory of the sacrum.

Anatomic Features

Leiomyomata represent benign sex steroid–responsive smooth uterine muscle tumors originating as clonal expansions of individual myometrial cells. The histology is virtually indistinguishable from normal myometrium, except for a circular whorling pattern with the cellularity and mitotic activity being highly variable. The number of mitoses per high-power field is usually low, and increased numbers are critical to the risk of malignancy. Assessing the number of mitoses is typically part of the pathologic evaluation when fibroids are removed. There are often interspersed areas of fibrosis and occasional calcification, especially after pregnancy-induced degeneration and in postmenopausal women. Leiomyomata typically grow in a spheric or nodular fashion with a relatively distinct demarcation from the surrounding normal myometrium, reflecting their clonal origin.

Leiomyomata can arise from anywhere in the myometrium (see Fig. 49.1) and may be single or multiple, with occasional women having very large numbers of fibroids. When the cell of origin is near the serosal surface, the path of least resistance to expansion is to bulge outward into the peritoneal cavity, termed a *serosal* or *subserosal fibroid.* Serosal tumors can grow very large without symptoms, because they virtually represent external appendages to the uterus. When a tumor is very superficial, this can result in a pedunculated fibroid, with a pedicle narrower than the tumor diameter containing the vascular supply. Occasionally, a pedunculated tumor will become detached from the uterus completely and derive its blood supply from an adjacent site. This is likely the result of pressure necrosis of the interface between the tumor and the adjacent viscera, or torsion of the pedicle and attachment at the new site during healing. When the myometrial cell of origin is deep within the myometrium, an intramural fibroid develops. These are associated more commonly with menorrhagia and dysmenorrhea, with the normal prostaglandin-mediated uterine contractions resulting in higher intrauterine pressures and failing to constrict the vessels feeding the endometrium during menses. If the myometrial cell of origin is near the endometrium, a submucosal tumor will develop and these are very likely to be associated with menorrhagia and dysmenorrhea, even at a relatively small size. When clonal expansion occurs in a cell immediately under the endometrial layer, the tumor may protrude into the endometrial cavity, and an intracavitary tumor on a pedicle may develop. Intracavitary tumors can cause severe symptoms despite their small size. With uterine contractions, the fibroid's stalk may elongate, extruding the fibroid through the cervix, typically associated with significant cramps and sanguineous vaginal discharge. Compression of the vascular pedicle may cause aseptic necrosis and the degenerating tumor becomes secondarily infected, making it appear similar to a necrotic cervical cancer. Although cervical fibroids can occur, they are infrequent, paralleling the small number of myometrial cells within the cervix. However, because of their proximity to the bladder, urinary symptoms typically can be very distressing.

There is virtually no neovascularity within fibroids, and individual leiomyomas derive their vascular supply from the vessels on the periphery of the tumor at the interface with the normally vascularized myometrium. Although fibroids are stimulated by sex steroids, the vascular supply is more likely to be the limiting factor for the growth of individual tumors. Often the uterine blood vessels are visibly enlarged because of the increased metabolic requirements of the uterus containing leiomyomata. However, the anatomic relationship of the vessels to the surrounding viscera is not altered, despite enlarged vascular pedicles. Collateral vascular channels are comparably engorged and represent a challenge to the surgeon if they are not considered in the surgical approach. Not surprisingly, this increased vascularity may increase the blood loss with any extirpative surgery, even if performed by the most experienced surgeon. When rapid fibroid growth does occur, such as is observed occasionally during pregnancy, the vascular demands of the tumor may exceed the capability of the vasculature. The leiomyoma then undergoes aseptic necrosis and, reflecting the peripheral nature of the vascular supply, the center of individual tumors undergoes degeneration with the outer layers relatively spared. This is initially described as *red degeneration* and later, as the devitalized central tissue is replaced by fibrosis, described as *hyalinized degeneration*, and ultimately may become calcified. It is not unusual to find marked calcium deposits in leiomyomata which have long ago undergone degeneration and were never symptomatic.

Influence of Sex Steroids

There is little doubt that the growth of leiomyomata is related to exposure to sex steroids, because they (a) are not noted prior to puberty, (b) typically regress after menopause, (c) possess sex steroid receptors (estrogen and progesterone), (d) often enlarge dramatically during pregnancy when estrogen and progesterone levels are very high, and (e) can be made to shrink with medically induced hypogonadism. Clearly, the uterus, like other secondary sex organs such as the breasts, enlarge with exposure to the higher levels of ovarian steroids produced at puberty. However, this growth is programmed and should cease once reaching the appropriate development, despite continued exposure to sex steroids throughout the reproductive lifespan.

There is no evidence that higher or aberrant patterns of ovarian steroid secretion of estrogens, progestins, or androgens contribute to the development of leiomyomata. However, myomatous tissue has the same number of estrogen receptors but a higher number of progesterone receptors than the adjacent normal myometrium. This, coupled with the observations that mitoses within myomas are more frequent in the luteal phase of the cycle and that progesterone up-regulates several growth factors, suggests that progesterone is causally involved somehow in either myomatous development or growth. Because estrogen stimulates the synthesis of progesterone receptors in other reproductive tissues, a more complex relationship among the two dominant female sex steroids and leiomyomata is likely present. Additionally, some data indicate that the development of fibroids may be related to postpubertal weight gain, which may relate to endogenous nonovarian estrogen production. Despite these observations, there is no consensus on the specific roles of the various sex steroids aside from a general positive relationship with development of leiomyomata.

Oral contraceptive use has not been associated with an increased incidence of leiomyomata or more rapid recurrence or progression. Treatment of postmenopausal women with hormonal replacement therapy occasionally, but not consistently, allows continued growth of existing leiomyomata. There is no evidence, however, that if leiomyomata are not present, they will develop in response to hormone replacement therapy after menopause. For clinical purposes, withholding hormone replacement therapy for fear of stimulating leiomyomata in otherwise appropriate candidates is not appropriate, given its well-documented benefits. Special note should be made of postmenopausal women with breast cancer treated with tamoxifen, because this compound has both estrogen agonist and antagonist activity, which has the potential

to influence the pattern of fibroid growth. Undoubtedly, gonadal steroids are important in the development or growth of leiomyomata and, as more selective estrogen, progestin, and androgen response modulators become available for clinical use, their impact on the development or growth of leiomyomata will become apparent. Potentially, some of these agents will be found therapeutically useful.

GENETIC INHERITANCE PATTERN

It has been estimated that more than 40% of first-degree female relatives of women with leiomyomata will develop fibroids sometime during their lifetime. These will not necessarily be symptomatic, and the number and location are not predictable. Although leiomyomata are common in all races, African-Americans appear to have a somewhat higher incidence than women of other ethnicities, despite being a common disease in women of all ethnicities. African-American women undergoing hysterectomies have increased numbers of and larger fibroids, and it has been estimated that nearly 90% of uteri removed from these women for clinical symptoms contain leiomyomata. Regardless of ethnicity, leiomyomata are, by far, the commonest genital tract tumors and remain the most frequent indication for gynecologic surgery. This familial pattern seems most consistent with a multifactorial genetic inheritance pattern, rather than simple mendelian genetics, which is modified by confounding cofactors, such as the impact of gonadal steroids. Aside from the disease's apparent familial, age, and ethnic associations, there is little clinical predictability for an individual woman. Given the high prevalence of leiomyomata, virtually all women are at risk for developing them in their latter reproductive years.

Molecular Mechanisms and Genetic Dysregulation

Leiomyomas represent monoclonal neoplasms, in which etiologic genetic mutations in individual tumors are highly likely. Cytogenetic studies of individual leiomyomas reveal that approximately one third have some type of chromosomal aberration, but these are not consistent among individual leiomyomata, even among fibroids in the same woman, further supporting the clonal nature of leiomyomata. The most common aberrant patterns are translocations between chromosomes 12 and 14, deletions of the short arm of chromosome 7, and rearrangements of the long arm of chromosome 6. It is not clear whether there is real clinical relevance to these differences in the rate of tumor growth, recurrence rates, and responses to various therapies. Interestingly, when tumors have translocations between chromosomes 12 and 14, they are more likely to be larger myomas, whereas deletions of the long arm of chromosome 7 are found more often in smaller myomas. Although there are no consistent alterations in gene expression noted in leiomyomata, the transcription-factor high-motility group A2 is up-regulated in leiomyomata with expression of the 12;14 chromosome translocation. These observations imply that, despite similar histologic appearance and benign growth characteristics, there may be several molecular mechanisms by which these tumors develop, with correspondingly different clinical implications.

Undoubtedly, individual myometrial cells become neoplastic as a result of a complex interaction of factors including genetic mutations, endogenous sex steroid production–stimulating growth, reproductive patterns and, potentially, medicinal hormonal exposure after menopause. Molecular geneticists have noted abnormal expression of a variety of genes leading to altered growth factors and steroid receptors in individual leiomyomata, but there remains no single predominant molecular mechanism or group of mechanisms underlying their development and growth. Although this molecular dysregulation may explain the propensity to grow disproportionately to the normal pattern of myometrial growth throughout life, the molecular evidence does not suggest a progression from benign leiomyomata to leiomyosarcoma. Undoubtedly, the mechanism of clonal expansion of individual myometrial cells involves the interplay of gonadal steroids and aberrant expression of autocrine, paracrine, and endocrine growth factors. During the coming years, this molecular puzzle undoubtedly will be better understood but will just as likely prove to be very complex, without a single abnormality responsible for most leiomyomata. Clarifying the pathophysiologic mechanism(s) of growth of this most common of neoplasias should provide opportunities for better predicting the clinical course, genetic inheritance, as well as optimal prevention and therapeutic strategies for individual women.

Impact of Leiomyomata on Reproduction

The impact of leiomyomata on the ability to reproduce remains difficult to define in clinical terms useful for individual patients (Table 49.2). Clearly, the most logical approach for women with leiomyomata is to attempt to conceive and elect treatment only if they encounter difficulty. There is general agreement that intracavitary and submucosal leiomyomata are likely to cause infertility by preventing implantation, comparable to the effect of an intrauterine device. Fibroids within the endometrial cavity or impinging on the cavity contour can be detected by hysterosalpingography, sonohysterography, or hysteroscopy, and their removal can be expected to improve fertility. With intramural leiomyomata, a relationship to infertility is less certain and all other potential causes should be considered before concluding that the leiomyomata are causal. Intramural leiomyomata have been associated with a reduced pregnancy rate following assisted reproductive technology (in vitro fertilization and gamete intrafallopian transfer, known collectively as *ART*), indicating they may interfere with implantation. Given the time, expense, and complicated nature of ART, it is prudent to remove intramural fibroids in carefully selected infertile women before they undergo ART, when other therapeutic options have failed and no other cause is identified. Whether postoperative adhesions form after myomectomy is of lesser importance under these circumstances, because the oocytes will be retrieved transvaginally, regardless of whether adhesions involving the adnexae are present. The most important issue is that the couple be given the highest chance of success with ART, given the stress, expense, and time involved.

Impaired Implantation
Submucous
Intracavitary
Enlarged uterine cavity volume
Impaired Tubal Transport
Obstruction
Distension

TABLE 49.2. *Mechanisms of infertility with leiomyomata*

Although fibroids can be found anywhere in the myometrium, when they arise adjacent to the entry of the fallopian tubes into the uterus there is concern about occluding a tube or altering its function. This rarely occurs, likely due to the relatively slow growth of leiomyomata and the distensibility of soft tissues such as the fallopian tubes. However, because oocyte capture by the ciliated epithelium of the fimbria is necessary for fertilization, growth of fibroids near the distal end of the oviduct, which increases the distance between the surface of the ovary and the tubal ostia, theoretically can reduce the chance of conception. For this to be considered a problem, however, both fallopian tubes would need to be affected similarly. This is an infrequent circumstance, and a myomectomy should be performed to improve tubal function only when the uterine fibroids visibly distort the ovarian tubal anatomy bilaterally and after all other possible infertility factors have been excluded.

Whether leiomyomata are associated with a higher risk of first-trimester pregnancy loss, preterm labor, or intrauterine growth restriction is much more controversial. The impact of fibroids in each patient is critically dependent on location, not simply size or number. Clearly, many women with large myomatous uteri deliver infants without difficulty, while in others, fibroids may compromise the ability of the endometrial cavity to accommodate a growing fetus or the maternal vascular adaptation necessary for normal placental function. Complicating this picture is our inability to predict which women with leiomyomata will experience rapid enlargement of their fibroids during pregnancy. An abruption may occur rarely when the placental bed overlies an enlarging fibroid. Lower segment fibroids have the potential to obstruct labor, and a classic cesarean section occasionally is required when the presenting part cannot be applied directly to the cervix. If the leiomyomata are extremely large and intramural in location, preconception removal or other management of the fibroids may be considered, but the potential benefit must be weighed carefully against the complications of the procedure. There simply is no predicting which women will encounter problems and which will not. Clinical judgment will be sorely taxed to make correct decisions in the absence of a previous adverse clinical outcome. Overall, term delivery rates following myomectomy for symptomatic leiomyomata in an unselected patient population vary from 40% to 50%. The need to perform a cesarean section following myomectomy needs to be considered in any risk–benefit analysis.

LEIOMYOSARCOMA

Rarely, a leiomyosarcoma is encountered that is clinically indistinguishable from simple leiomyomata, but these are typically in older postmenopausal women, with the average age well over 60. The diagnosis often is suggested by enlargement of the uterus after menopause in the absence of any hormone replacement therapy. Uterine fibroids present prior to menopause may enlarge when the gonadal steroids are replaced, but this is not common and does not represent a frequent enough problem to preclude the use of any type of hormone replacement therapy. A leiomyosarcoma is not thought to develop from a preexisting leiomyoma, rather it arises de novo, with the factors leading to this rare cancer obscure. Rapid growth is not a very ominous sign of malignancy, because this is a common occurrence in women with leiomyomata before menopause. No physical findings or unique imaging differences can reliably distinguish leiomyomata from leiomyosarcoma. The diagnosis of a leiomyosarcoma typically is based on histology, not gross appearance. Degenerating leiomyomata may have unusual and varied features, including necrosis and central liquefaction. The histologic changes suggesting malignancy include increased numbers of mitoses, cellular pleomorphism, and thrombotic degeneration within the tumor. Many fibroids are very cellular but without other characteristics suggestive of malignant potential. Typically, more than 10 mitoses per high-power field suggests a risk that the tumor is malignant, between 5 and 10 represents a “cellular” or actively growing fibroid, and below 5 is usual for the typical myoma. Because of the difficulty accurately characterizing the number of mitoses by frozen section microscopy, the intraoperative diagnosis of a leiomyosarcoma is difficult to make with confidence and permanent sections usually are required. When a leiomyosarcoma is diagnosed following surgery, a second procedure for extirpation of any remaining pelvic organs and lymph node sampling for staging usually is required to plan optimal management. Leiomyosarcomas are estimated to account for 0.1% of all uterine tumors, but 1.7% of women undergo hysterectomy for leiomyomata during their seventh decade of life. For practical purposes, leiomyomata always should be

considered benign in premenopausal women and rarely malignant in elderly women, but with the caveat that all excised specimens should undergo careful pathologic examination.

DIAGNOSTIC STUDIES

The vast majority of leiomyomata are detected on pelvic examination performed for routine health maintenance or because of a gynecologic symptom, such as increasing dysmenorrhea, menorrhagia, or pelvic pressure. The uterus typically is enlarged and irregular on bimanual examination. It is important to distinguish leiomyomata from other pelvic masses such as ovarian tumors. This is done most easily with an endovaginal or abdominal ultrasonographic examination, because the leiomyomata appear solid by sonography, with acoustic impedance similar to that of the normal myometrium. Other imaging techniques, such as computerized tomography or magnetic resonance imaging, can prove useful in selected circumstances (see Fig. 49.2, Table 49.3). Indeed, it must be appreciated that detecting an unrelated but clinically important adnexal mass may be difficult when there is a large leiomyoma. Unless the tumor has been stable on pelvic examination for many years in women in the latter reproductive years and beyond, some diagnostic imaging modality is warranted to ensure that the abnormal physical examination findings reflect leiomyomata and not another type of pathology with a greater potential for malignancy. Other imaging modalities, such as computerized tomography or magnetic resonance imaging, can distinguish leiomyomata from adnexal pathology, but they are much more expensive and time consuming and yield no more useful information than simple office sonography.

Endovaginal ultrasonography
Sonohysterography
Hysterosalpingography
Hysteroscopy
Computerized tomography
Magnetic resonance imaging

TABLE 49.3. *Diagnostic techniques*

The proximity of the leiomyomata to the endometrial cavity usually can be demonstrated by taking advantage of the acoustic differences between normal myometrium, fibroid tumors, and the endometrial cavity. The endometrial stripe is a reliable marker of the endometrial cavity, and a smooth continuous endometrial stripe with normal underlying myometrium between the cavity and any fibroids suggests that palpably detectable fibroids are primarily in a subserosal location. Simultaneously injecting saline into the endometrial cavity while performing an endovaginal ultrasonographic examination (sonohysterography) improves the delineation of submucous and intracavitary leiomyomata. However, it is not possible to distinguish an endometrial polyp from an intracavitary myoma with any imaging technology.

The closer the fibroid is to the endometrial cavity, the greater the likelihood and severity of dysmenorrhea and menorrhagia. Additionally, distortion of the endometrial cavity increases the probability of difficulty in achieving and maintaining a pregnancy. Hysterosalpingography often is undertaken if infertility is present concurrently, because this technique can identify intracavitary tumors or an otherwise normal endometrial cavity enlarged by stretching of the normal myometrium around leiomyomata (Fig. 49.3). This radiographic technique has the added advantage of determining tubal patency. Removal of leiomyomata will not improve the likelihood of conception unless an enlarged endometrial cavity, an irregular endometrial ontour, or an intracavitary defect is present. Increasingly, office hysteroscopy is being used when tubal patency is not an issue, because this technique allows clear differentiation between leiomyomata and other intracavitary pathology, such as endometrial adhesions, uterine septae, and endometrial polyps.

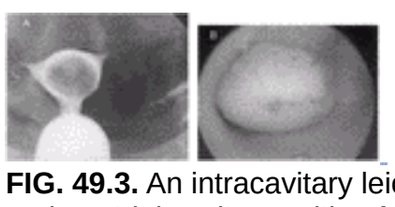

FIG. 49.3. An intracavitary leiomyoma. **A:** A hysterosalpingogram using a water-soluble contrast medium demonstrates a large, smooth filling defect within the endometrial cavity resulting from an intracavitary fibroid. The mass effect on the study is nonspecific, and only direct visualization can confirm that it is caused by a fibroid. **B:** The hysteroscopic view of this intracavitary leiomyoma.

Another disease involving the myometrium, adenomyosis, occasionally can be difficult to distinguish clinically from leiomyomata, and imaging studies may not be helpful. This disease process represents functional endometrial glands and stroma within myometrium, with these cells presumably infiltrating into the underlying myometrium from the endometrium. This is an infiltrative process, which is found immediately adjacent to the endometrial cavity and parallels the contours of the endometrial cavity. It is always continuous with the endometrium but not necessarily present in all subendometrial areas. Frequently, a marked fibrotic reaction is present around the isolated endometrial cells within the myometrium, presumably because of the irritation caused by menstrual shedding in the midst of the muscle. When the process is localized, these fibrotic areas may be difficult to distinguish on palpation from leiomyomata and the true diagnosis made only with surgery. Leiomyomata typically have a clear demarcation from the underlying myometrium, whereas a nodule of adenomyosis has a very indistinct infiltrating border which makes complete surgical removal virtually impossible. Adenomyosis tends to have more variability in shape, but the two pathologic entities occasionally may be indistinguishable by any of the available imaging techniques and the diagnosis made only after excision of the lesion. Magnetic resonance imaging is useful in differentiating adenomyosis from leiomyomata, because it better delineates the borders of the intramyometrial pathology; however, this is not used routinely preoperatively because of the expense involved. Like endometriosis, adenomyosis may be associated with an elevation in serum CA-125, but this is a nonspecific serum marker and cannot be used alone to diagnose adenomyosis.

Because most leiomyomata are identified only after symptoms are present and treatment carries considerable risk and expense, development of an inexpensive screening tool with reasonable sensitivity and specificity would be a major clinical advance. There are no laboratory markers which detect leiomyomata which are too small to cause symptoms or be palpated on pelvic examination. Detecting small leiomyomata in women with a familial risk would be very helpful, because it would assist in determining their true prevalence, better define the natural history, identify risk factors, and lead to earlier medical intervention, potentially reducing the need for surgical excision.

PREVENTING DEVELOPMENT, PROGRESSION, AND RECURRENCE

The ultimate goal of understanding the pathophysiology of leiomyomata is to prevent their occurrence in both genetically susceptible women and those without a family history. With further insight regarding the molecular mechanism(s) of growth, it may be possible to identify medicinal approaches to interfere with the molecular pathway(s) and reduce the risk of development, progression, and recurrence of leiomyomata. This will be particularly useful for women at risk of leiomyomata because of a strong family history, those with previous myomectomy, and women with leiomyomata approaching menopause who can anticipate spontaneous regression once ovarian function ceases. Additionally, understanding the impacts of childbearing, lactation, the various forms of steroidal contraception, and estrogen and hormone replacement therapy on the development, progression, and recurrence of leiomyomata should help optimize clinical recommendations. There are few, if any, predictors of the development of leiomyomata, aside from a family history. Endocrine markers such as early puberty, late menopause, parity, oral contraceptive use, and hormone replacement therapy of any kind are not correlated with either the development or the recurrence of fibroids after myomectomy.

TREATMENT

When to Treat

Although fibroids are responsible for a large number of gynecologic surgeries, management of these benign tumors requires the same risk–benefit analysis as any other therapeutic decision. Often, a prostaglandin synthetase inhibitor or oral contraceptives will relieve the symptoms. Although an increasing variety of options exist, it is important that the management be goal directed to alleviate specific symptoms. Simply identifying leiomyomata does not imply that they will continue to grow, become symptomatic, or require management. Occasionally, however, it may be appropriate to remove asymptomatic large leiomyomata in an effort to prevent anticipated problems before attempting pregnancy. Similarly, when a woman has intracavitary or large submucous myomas but has not attempted to conceive, it is likely, but not unequivocal, that removal of her fibroids will improve her chances. Removing myomas which cause significant distortion of the endometrial cavity in an infertile population will improve the likelihood of pregnancy and the maintenance of early pregnancy. Large tumors which fill the pelvis can impinge on the pelvic sidewalls, causing hydronephrosis, and their removal is critical. However, therapeutic intervention generally should be focused on the alleviation of symptoms, and observation is all that is necessary in the vast majority of asymptomatic women.

The growth characteristics of individual leiomyomata remain highly unpredictable, because many leiomyomata have limited growth potential and, thus, may remain static in size until the sex steroid levels decline at menopause, when they shrink. Paradoxically, some leiomyomas have already undergone rapid growth, aseptic necrosis, or replacement by fibrosis without symptoms and will not shrink after menopause. Although many fibroids may enlarge gradually, causing symptoms well before the anticipated regression at menopause, the growth pattern is so varied that there are simply no predictive characteristics helpful in identifying which women will need intervention and which will not.

The symptoms caused by leiomyomata vary, depending on the size, number, and location of the tumors, and can include dysmenorrhea, menorrhagia, increased abdominal girth, pelvic pressure (frequent urination or constipation), and pelvic pain with physical activity or intercourse. Dysmenorrhea and menorrhagia are more frequently linked than other symptoms. When the dysmenorrhea or menorrhagia is mild, nonsteroidal antiinflammatory agents and oral contraceptives are often useful, and the symptoms may improve sufficiently to avoid further intervention. In most cases, a therapeutic medical trial is indicated before proceeding to more aggressive medical or surgical options. When dysmenorrhea and menorrhagia are caused by leiomyomata, they are typically of secondary onset and worsen gradually in severity paralleling the enlargement of the tumors.

Location of the fibroids is critically important; the closer they are to the endometrial cavity, the greater and earlier the symptoms. Intramural, submucosal, and intracavitary fibroids are far more likely to cause dysmenorrhea and menorrhagia than intramural or subserosal myomas. Severe symptoms may warrant intervention at a relatively small size, particularly for an intracavitary or submucosal fibroid. Typically, the closer to the serosal surface the fibroids are located, the larger the size will be attained before symptoms occur. Indeed, some extremely large leiomyomata will not be associated with any symptoms aside from increased abdominal girth. This explains why many patients with extremely large leiomyomata are either minimally symptomatic or asymptomatic, while those with small submucosal or intracavitary fibroids may have dramatic bleeding and pain. Because of the proximity of the bladder, the most frequent symptom associated with a large subserosal or pedunculated myoma is frequent urination, comparable to what women experience during pregnancy. Rarely, compression of the colon against the sacrum may cause difficulty with defecation, although this is infrequent and, more often than not, feelings of constipation are not relieved completely by removing or shrinking the leiomyomata. As the tumors enlarge, these pressure symptoms intensify and ultimately may require medical or surgical intervention.

Selecting the Appropriate Therapy

When clear indications for therapy are present, the most critical questions which must precede a decision are as follows: (a) Is future reproduction is desired? and (b) How soon can menopause be anticipated? Because a simple hysterectomy represents a definitive cure, this is an attractive option for many symptomatic women when maintenance of reproduction is not desired, menopause is not imminent, and more conservative measures have failed to alleviate the symptoms (Fig. 49.4). This also requires an assessment of the woman's individual preferences, as well as her surgical and anesthetic risks. Clearly, women view extirpation of the uterus in their own social, cultural, and religious contexts, and removal of any genital structure cannot be viewed as inconsequential, even if there is no wish to preserve reproductive capacity. As a result, many women wish to preserve the uterus independent of reproduction, and they should be provided with all the therapeutic options and their choices respected. When the preservation of reproductive capacity is desired, a myomectomy is the primary choice. However, because the recurrence risk of symptomatic leiomyomata is high, myomectomy should be viewed as providing a disease-free interval and the women encouraged to attempt to reproduce as soon as is reasonable. As a result, many women without reproductive desires are interested in other, less well-established options such as UAE or myolysis, which may reduce the symptoms and retain the uterus.

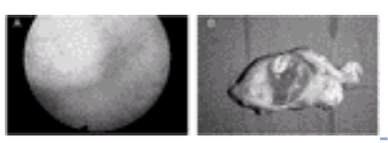

FIG. 49.4. Submucous leiomyoma. **A:** A submucous fibroid visualized at hysteroscopy is from a woman with a history of menometrorrhagia unresponsive to medical management with NSAIDs and oral contraceptives. Although the tumor protrudes into the endometrial cavity, most of it is still within the underlying myometrium. **B:** The hysterectomy specimen which demonstrates the submucous myoma responsible for the excessive vaginal bleeding.

Extirpative Surgery for Leiomyomata

The mainstay of management for symptomatic leiomyomata is surgical, either hysterectomy or myomectomy, depending on the woman's desires regarding childbearing (Table 49.4). Given the risks inherent with all surgical procedures, the decision to proceed with any surgery should be based on a personalized clinical risk–benefit assessment, with the pivotal issue being future reproduction. Virtually no woman with leiomyomata need be faced with the painful choice of having to endure the symptoms in order to maintain reproductive potential versus relieving symptoms at the price of terminating reproductive options. A myomectomy is virtually always an option, even if a large number of fibroids are present or the tumors are very large or both. The uterus functions well in pregnancy after a myomectomy, despite the impact of multiple incisions. Although improvements in surgical technique, particularly minimally invasive surgery, have the potential to improve the benefits for women with symptomatic leiomyomata, comparative clinical trials of the various surgical approaches are urgently needed.

Endoscopic Techniques
Laparoscopically assisted supracervical hysterectomy
Laparoscopically assisted total hysterectomy
Myomectomy
Abdominal Approach
Supracervical hysterectomy
Total hysterectomy
Myomectomy
Vaginal Approach
Hysterectomy
Myomectomy

TABLE 49.4. *Extirpative options*

Hysterectomy

When childbearing is not desired and the symptoms are severe enough to warrant treatment, a simple hysterectomy often is chosen, because it relieves the symptoms permanently, prevents recurrence, provides permanent contraception, and improves the quality of life as measured by questionnaires, presumably by eliminating further vaginal bleeding. An infrequently considered and poorly appreciated additional benefit is making hormone replacement therapy after menopause much simpler, with estrogen replacement without progestin the favored option. The decision to proceed with removal of the uterus should be based on a risk–benefit decision weighing the severity of the symptoms with the personalized surgical risk, and not on a concern that the leiomyomata might be malignant. The surgical approach, either abdominal or vaginal, should be individualized, based on the size and location of the fibroids, the degree of uterine descensus, the woman's habitus, and whether or not an oophorectomy is being considered or other pathology is present. The available techniques are an abdominal hysterectomy, vaginal hysterectomy, or a laparoscopically assisted hysterectomy.

Preservation of the cervix in appropriately selected women is an increasingly popular option. The myometrium is the portion of the uterus at risk for growth of leiomyomata and, because the cervix is composed primarily of fibrous tissue, the potential for the development of leiomyomata in a retained cervix is extremely low. The structural ligamentous support for the cervix and vaginal apex remains intact when the cervix is retained with, at least theoretically, lower rates of vaginal prolapse. Additionally, a major portion of the surgical morbidity associated with hysterectomy by any technique relates to the surgical dissection necessary for removal of the cervix. This morbidity is avoided when choosing a supracervical hysterectomy, without risk of recurrence or the need to add a progestin to a hormone replacement regimen. The risk of subsequent cervical dysplasia is very low in this age group, and it is managed easily on an outpatient basis if it occurs, with the same methods used if the fundus is still in place. However, when choosing to retain the cervix, the continued need for screening cervical cytology should be emphasized.

The risks of complications with a hysterectomy are significant and, when prospectively documented, are approximately 17% with abdominal hysterectomy, 23% for vaginal hysterectomy, and 19% for laparoscopically assisted hysterectomy. The risk of complications is apparently higher when the hysterectomy is done for fibroids. The complications include the usual problems associated with abdominal operations but, specifically, hemorrhage and injuries to the bladder and ureters. The risk of ureteral injury is 7 times greater with the vaginal approach, likely secondary to the limitations in visualization of the anatomy when operating through the vagina. Despite these concerns, hysterectomy is associated with a high level of patient satisfaction, even if there are surgical complications.

Hysteroscopic Myomectomy

With improvements in endoscopic surgical technology, most intracavitary and a substantial number of submucous leiomyomata can be resected via surgical hysteroscopy in an ambulatory setting. If the tumor protrudes completely into the endometrial cavity via a stalk, such as a completely intracavitary myoma, a hysteroscopic resection is by far the most cost-effective method of removal. This does require an experienced hysteroscopic surgeon and should not be attempted unless the requisite skill is available. When a submucosal leiomyoma is predominately within the endometrial cavity, most are similarly amenable to removal via hysteroscopic resection. However, if despite protruding into the endometrial cavity, the bulk of the tumor is still contained within the underlying myometrium, a hysteroscopic approach will likely not prove successful and, indeed, can prove hazardous if the surgeon does not recognize the depth of the myoma. In this circumstance, extreme caution should be exercised when resecting a submucous fibroid, and resorting to an abdominal procedure should not be perceived as a failure but rather should be considered the safest option.

A hysteroscopic myomectomy typically is performed using a hysteroscopic resectoscope comparable to that used for transurethral prostate resection. It is inserted through the cervix, the endometrial cavity distended with a nonconductive media, and the leiomyoma resected by electrical loop excision. The fragments are removed with the effluent of the distending media through an inflow–outflow system. Careful preoperative selection of patients is required to ensure safe, effective removal in an ambulatory setting. Preoperative shrinkage of the leiomyoma with a gonadotropin hormone–releasing hormone agonist often may be helpful and affords a reduction in the height of the surrounding endometrium. Preoperative atrophy of the endometrium, to provide a clear operative field without resorting to complete pituitary down-regulation, can be accomplished with a 10-day preoperative course of a progestin (20 mg/day of medroxyprogesterone acetate) or an androgen (danazol 800 mg/day). Care must also be taken to avoid excessive intravascular absorption of the distending medium, which can result in fluid overload, electrolyte imbalance, or a bleeding diathesis, depending upon the type of medium.

Abdominal Myomectomy

When symptomatic leiomyomata are not completely within the endometrial cavity but in an intramural location, an abdominal surgical approach usually is required. With infrequent exceptions, a low transverse incision yields adequate surgical exposure. Rarely, a vaginal myomectomy can be performed with proper patient selection, but this clinical situation is rare and requires a high degree of surgical skill. The goal of a myomectomy is to remove all the identifiable leiomyomata with the least possible alteration of the reproductive tract. There are numerous surgical techniques but, in general, the myometrium is incised, the myoma dissected from the surrounding myometrium, and the incision closed in layers with absorbable suture to ensure hemostasis and myometrial integrity (Fig. 49.5). Entry into the endometrial cavity is not associated with any significant morbidity, but it is essential not to place sutures though the endometrial cavity wall as if it is a layer to close. Because the distance to the opposite endometrial surface is small, approximating the myometrium underlying the endometrium to the corresponding opposite side is all that is necessary. Cervical fibroids can represent a significant surgical challenge because of their proximity to the bladder and ureters, as well as the difficulty attaining hemostasis. Similarly, parasitic fibroids can be difficult to remove depending on their vascular supply (Fig. 49.6).

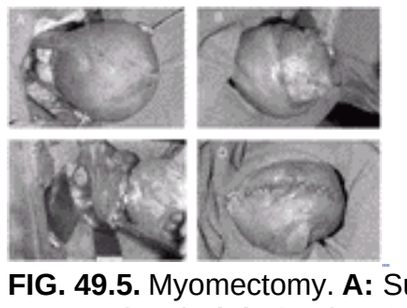

FIG. 49.5. Myomectomy. **A:** Surgical exposure of a large uterus containing an intramural leiomyoma is depicted. The fibroid is dissected from the underlying myometrium in **(B). C:** The uterine incision is extended down into the cavity and the fibroid is removed. The myometrium is reapproximated in layers **(D)** and the uterine muscle wall closed.

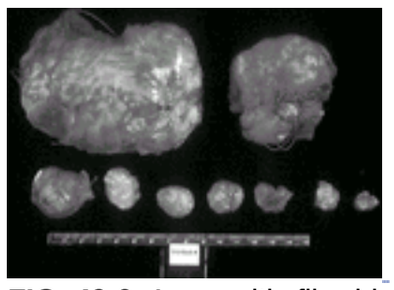

FIG. 49.6. A parasitic fibroid. A large tumor has become parasitic to a loop of small bowel, deriving its blood supply from the new vascular source. This typically happens only with large posterior or fundal tumors and is more common when they are pedunculated. The mechanism is felt to be pressure necrosis and revascularization during healing of the necrosis of the bowel wall.

Because myometrium is extremely well supplied with vasculature, significant intraoperative blood loss is encountered frequently. Myomectomy at the time of an operative delivery is particularly hazardous because of the increased vascularity of the myometrium associated with pregnancy. Careful surgical technique, applying a tourniquet around the lower uterine segment to compress the uterine arteries, intramyometrial injection of vasospastic agents such as vasopressin, and employing an intraoperative blood scavenger system can reduce the net blood loss. These steps, coupled with the preoperative correction of anemia, storage of autologous blood, and mild overhydration to reduce the amount of red blood cell loss per unit of blood lost, have reduced dramatically the need for homologous transfusion. Rarely, if ever, is a hysterectomy necessary because of intraoperative blood loss when a myomectomy is undertaken. Caution should be exercised when using the injection of intramyometrial vasopressin, because uterine incisional bleeding after the metabolism of the vasopressin may result in unappreciated blood loss which, even if it does not put the patient at a hemodynamic risk, increases the time required for resolution of the postoperative anemia and may complicate efforts to reduce adhesion formation. During the immediate postoperative interval, it is common that women with multiple uterine incisions experience febrile morbidity unrelated to any demonstrable infection. Whether this is related to a tissue reaction from the relatively large surgical area of the uterine incision(s) or a response to hemorrhage within the myometrium is not clear, but it is a benign occurrence, and antibiotic therapy should be reserved for women with clinical findings suggesting infection.

Once the myometrium has sustained a surgical incision involving a significant portion of the uterine wall, an elective cesarean section generally is recommended as the route of delivery. When a myomectomy incision is repaired properly, the likelihood of a dehiscence during pregnancy is very remote, estimated to be approximately 0.002%. The incisions required for myomectomy are not similar to the low transverse uterine incisions used for most cesarean sections; rather, it is more comparable to the fundal incision used in a classic cesarean section. Furthermore, the endometrial cavity does not need to be entered for there to be concern regarding the integrity of the uterine wall during labor. Following a myomectomy, the couple should wait 2 to 3 months before attempting pregnancy, to allow complete healing of the uterine incisions and to minimize the potential for myometrial scar disruption before labor. This recommendation is based on the clinical experience with the rate of dehiscence of classic cesarean section scars which involve the contractile part of the uterus. Because the myomectomy incision is comparable in location, it has an impaired ability to withstand the force of a prolonged labor without rupture, a catastrophic occurrence for both the mother and fetus. The selection of women for an operative delivery should be based on the depth and extent of the myomectomy incision and the adequacy of the incisional repair, because the risk of uterine rupture is not well defined in the modern era but appears to be lower than when a cesarean section has been performed. Further data regarding circumstances following an abdominal myomectomy under which a vaginal delivery does not represent an increased the risk to the mother and fetus will likely not be forthcoming. As a result, an elective cesarean section is usually the preferred route of delivery for most women with a previous abdominal myomectomy.

Laparoscopic Myomectomy

Improvements in endoscopic surgery allow myomectomy to be accomplished via the laparoscope. It is clear that pedunculated, serosal, and superficial intramural leiomyomas can be removed via laparoscopy, but the surgery is lengthy, technically difficult, and should be undertaken by only the most experienced endoscopic surgeons. Furthermore, because only clearly obvious leiomyomata can be removed via laparoscopy, this therapy should be undertaken only when removal of a specific tumor can be anticipated to relieve the symptoms. Many smaller intramural fibroids will not be identified by this technique, so it is anticipated that a higher rate of subsequent symptomatic leiomyomata can be anticipated. Endoscopic closure of the uterine incisions is also technically difficult, and there have been several reports of spontaneous uterine rupture after laparoscopic myomectomy. This is additionally disconcerting, because this may occur during pregnancy prior to the onset of labor, as

early as 33 weeks of gestation. This is distinct from that observed with abdominal myomectomy, when the risk of uterine rupture is felt to be limited primarily to the labor process. This suggests that even with careful attention to incision closure by skilled endoscopic surgeons, uterine rupture should be major risk factor considered in choosing the endoscopic approach. In the absence of long-term safety studies, selection of laparoscopic myomectomy for patients desirous of pregnancy should be done very carefully. By contrast, when the symptoms can be attributed to an isolated fibroid in a woman not desirous of childbearing, a laparoscopic myomectomy performed by an experienced surgeon can be a reasonable option.

Recurrence of Leiomyomata Following Myomectomy

There appears to be a genetic basis for the development of leiomyomata. Even when all of the palpable leiomyomata have been removed by myomectomy, the rate of recurrence and persistence with continued growth has been variably reported as high as 30%, depending on the number of tumors present and the length of follow-up. Indeed, between 10% and 25% of women undergoing myomectomies require another surgical procedure within the next decade. There is a suggestion that a delivery after a myomectomy may reduce the likelihood of recurrence, but this has a relatively small impact. Virtually all the data regarding *recurrence* or, more properly termed, *development of new leiomyomata* has been derived from women undergoing myomectomy with all the palpable fibroids removed. Obviously, small tumors may remain, and this will be impossible to separate from new clonal expansion of isolated myometrial cells or from persistence of small nonpalpable tumors not identified during surgery.

Some women who have symptoms but lack absolute evidence of existence of fibroids have undergone one of the newer nonextirpative therapies such as myolysis or UAE. The “recurrence” of fibroids has not been assessed in these women. Obviously, if leiomyomata are felt responsible for symptoms following a therapeutic procedure during which they are not removed, it will be impossible to distinguish persistence from the development of entirely new fibroids. It may be more appropriate to consider the frequency and time to recurrence of symptoms rather than simply when and at what interval fibroids are again present. If the newer techniques are applied mainly to women close to menopause, this may be a nonissue considering the natural loss of the stimulation by gonadal hormones. However, if younger women elect the nonextirpative therapies, only long-term comparative trials will yield useful discriminating information. Given the climate favoring broader nonextirpative options, such studies are needed urgently to assist women with therapeutic decision making.

In general, the size, location, or histologic pattern of the myomas have limited predictive ability for recurrence rates. The size of individual myomas may be of greater predictive value, because it appears that extremely large fibroids have a lower recurrence rate after myomectomy than do smaller tumors, despite an overall smaller volume of leiomyomata. It is not clear if the cytogenetic abnormalities have any predictive value for recurrence. The number of leiomyomata may be important in predicting recurrence, with women having single large tumors less likely to have subsequent fibroids detected than women with multiple, particularly smaller diameter, fibroids (Fig. 49.7).

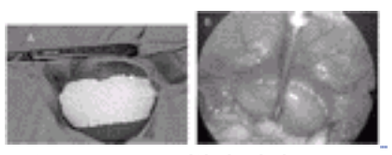

FIG. 49.7. Multiple leiomyomata excised at myomectomy. Many individual fibroids of different sizes and shapes can be encountered within the same patient. Some are very large and obvious, while others may be small and difficult to palpate.

The time of follow-up affects the risk of a clinical recurrence, with the longer the interval of observation correlated with the greater the apparent recurrence risk. It is no surprise that the younger the woman is when fibroids are detected, the greater the likelihood of recurrence after myomectomy. When leiomyomata do recur, it is typically 3 to 5 years following the myomectomy, giving most women an opportunity to reproduce before fibroids are again present. When fibroids are noted in a shorter time frame, it is more likely that not all the myomas were removed. Although too few endoscopic myomectomies are available to reach a meaningful conclusion, it can be anticipated that higher recurrence rates will be observed, because it is difficult to identify all the tumors present without direct palpation of the uterus. Similarly, when a GnRH agonist is used preoperatively, the leiomyomata usually shrink and some smaller tumors might become too small to be detected at surgery, only to reemerge as symptomatic or palpable fibroids relatively quickly. As with the myolysis procedures, these “recurrences” may simply represent the persistence of tumors. Many small leiomyomata with the potential to enlarge simply will not be identified visually because they are intramural and deep within the myometrium. Undoubtedly, the technical skill to remove all the leiomyomata by any procedure is critically important and will influence the rate of apparent persistence or recurrence.

The methodology used to identify recurrent myomas will undoubtedly influence the recurrence rates. If clinical symptoms lead to evaluation, palpation will detect a larger tumor than will routine surveillance by transvaginal ultrasonographic examination. Other imaging techniques such as magnetic resonance imaging or computerized tomography, although rarely used for routine monitoring, would probably detect small fibroids before clinical symptoms develop and thus influence the apparent recurrence rate. If a clinically significant recurrence does occur, the typical time frame for the return of symptomatic fibroids after abdominal myomectomy is 3 to 5 years. Women with a single large leiomyoma appear to have lower recurrence rates than those with multiple intramural tumors. Women clearly should be counseled that when all the palpable myomas are removed during abdominal myomectomy, an interval free of symptoms and the opportunity to reproduce is provided, but it does not “cure” an inherited predisposition to the their development. No long-term data are available regarding the recurrence or persistence risks with experimental myolysis procedures or UAE, but when such data are available, clinical decision making will need to incorporate these findings.

Postoperative Pelvic Adhesions

A major complication of any myomectomy is postoperative adhesions. These can involve viscera adherent to the uterine incision sites, as well as de novo adhesions at nonsurgical sites, generally attributable to the unavoidable peritoneal trauma associated with surgery. The frequency of postoperative adhesions following myomectomy exceeds 50% and can result in reduced fertility, pain, or bowel obstruction. Interestingly, endoscopic surgery has not reduced the rate of postoperative adhesions at the site of the surgery, but it does appear to reduce the de novo adhesion rate. Careful surgical technique to minimize the degree of surgical trauma, confining the incisions to the anterior uterine surface so as to prevent contact with the bowel and adnexal structures, and covering the posterior uterine incisions with surgical barriers have been advocated to minimize the rate of postoperative adhesions. The materials used as adhesion prevention barriers are quite varied and include oxidized regenerated cellulose that is degraded by leukocytes; polytetrafluoroethylene, a nonreactive permanent material which is typically removed several weeks following surgery after the peritoneum has reconstituted itself (Fig. 49.8); and a hydrolyzable barrier composed of a combination of hyaluronic acid and carboxymethylcellulose. All of these materials have their advantages and disadvantages, and few comparative studies are available. In the only direct comparative study, fewer postoperative adhesions were associated with the use of the barrier composed of polytetrafluoroethylene versus oxidized regenerated cellulose. Improvements in surgical barrier technology, other systemic or intraperitoneal medicaments, and alternative surgical strategies will undoubtedly be forthcoming to help reduce the rate of postoperative adhesions.

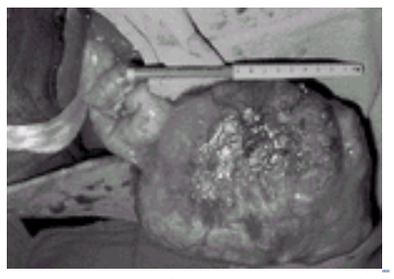

FIG. 49.8. Placement of a barrier of polytetrafluoroethylene at the time of myomectomy. To reduce the risk of adhesion formation between the visceral peritoneum of the uterus and the tubes and ovaries, a permanent barrier composed of polytetrafluoroethylene is anchored over the uterine incision with permanent sutures **(A).** The barrier is removed several weeks later via laparoscopy. **B:** The appearance of the uterine incision a year after the barrier was retrieved at a laparoscopy done for unrelated reasons. Note the healed uterine incision does not have any adhesion and represents an optimal surgical result.

Nonextirpative Management of Leiomyomata

When removing fibroids is not appropriate, either because of patient choice or when confounding medical problems exist, a nonextirpative approach should be taken. A variety of options exist (Table 49.5) including medical suppression, in situ destruction of the myomas, or depriving them of their vascular supply. These approaches all suffer because long-term data are lacking and because the fibroids themselves, although regressed, are not removed. However, with the onset of menopause, the

tumors can be anticipated to regress spontaneously, so a temporizing measure may suffice to relieve symptoms permanently.

GnRH, gonadotropin-releasing hormone.

TABLE 49.5. *Nonextirpative options*

Medical Suppression

Many medicinal agents have been considered for the management of leiomyomata including estrogen antagonists, progesterone antagonists (RU-486), androgens (danazol), and pituitary down-regulation with GnRH agonists. However, only suppressing ovarian steroid production and creating a state of hypogonadism with GnRH agonists has been demonstrated to reduce the size of leiomyomata and relieve symptoms to such a degree as to be clinically useful. Although the volume of the leiomyomata typically decreases by 35% to 50%, this is somewhat misleading. Physicians consider a reduction in the diameter of a fibroid to be the most clinically useful measure of shrinkage, and the diameter decreases far less than the total volume as determined using imaging measurements. Unfortunately, most leiomyomata rapidly return to the pretreatment size upon discontinuance of GnRH agonist therapy, and the return of symptoms parallels the enlargement. Prolonged hypogonadism may cause central necrosis of large cellular tumors and permanently reduce the size of individual fibroids. However, few data address this possibility or the circumstances under which it might occur. As a result, the reexpansion of the fibroids to their pretreatment size is the most likely clinical outcome, when ovarian function resumes after discontinuing the GnRH agonist.

Hypogonadism cannot be sustained for a prolonged interval because of the significant side effects, such as vasomotor hot flashes, accelerated bone loss, genital tract atrophy, and loss of the cardiovascular benefits of estrogen. Approximately 1% of the bone mass is lost per month after the onset of hypoestrogenism, and the hot flashes and genital tract atrophy can be very debilitating. Although most of the bone mass is regained if the therapy is limited to 6 months in young women, longer intervals or use in women closer to menopause may result in a permanent loss of age-adjusted bone mineral density. In an attempt to alleviate the severity of the hypogonadal symptoms, the simultaneous administration of low doses of estrogen and progestin simultaneously with GnRH agonists, the so-called *add-back regimens*, have been advocated. Although these regimens certainly relieve the hypoestrogenic symptoms and prevent bone loss, they have yet to be demonstrated to be as efficacious as GnRH-agonist therapy alone and do not offer any other objective benefit. The GnRH agonist with add-back approach will require a substantial amount of long-term data demonstrating a meaningful clinical benefit before it is considered a viable therapeutic option.

The important question to ask is "What is the goal of medical suppression?" The most important reason for using a GnRH agonist is to stop excessive vaginal bleeding and improve the hemogram prior to surgery, or to temporarily stop the bleeding and delay surgery in order to correct other medical problems posing an increased surgical risk. It is important to recognize that there is an initial action of the GnRH agonist that lasts 2 to 3 weeks before attaining the hypogonadal state. Hence, the bleeding may worsen transiently before stopping, and GnRH agonists are of little use for acute management of bleeding problems. Although reduced surgical blood loss and shortened operative time by preoperative use of a GnRH agonist often are espoused as benefits, scant data support these contentions. Indeed, the softening of small intramural leiomyomata by the hypogonadism may be a detriment. It may be virtually impossible to palpate them during a myomectomy and perhaps even make those identified more difficult to remove by reducing the surgeon's ability to demarcate clearly the boundary between normal myometrium and the fibroid. Given the variation in blood loss with surgery, it will be very difficult to demonstrate reduced intraoperative blood loss with GnRH-agonist pretreatment. Until convincing clinical data are available, the use of GnRH agonists for other than for preoperative correction of anemia will remain controversial.

Myolysis

There have been many attempts to induce therapeutic necrosis of cells within the center of a fibroid, such as myolysis, and thereby to shrink the tumor size, relieve symptoms, and prevent progressive growth of the tumors. These strategies typically involve repeatedly inserting a surgical probe of some sort into the tumor, typically at laparoscopy, and then causing tissue injury by the means of the following: (a) monopolar or bipolar electrocautery, (b) laser hyperthermia, (c) fiber laser vaporization, (d) diathermy (heat-generating ultrasonography), or (e) cryotherapy. All of these techniques require substantial operative time, result in a variable amount of cellular injury within the fibroid, and occasionally injure a portion of the normal myometrium, as well. Aseptic necrosis may cause significant pain during the immediate posttreatment interval, comparable to that observed with degeneration of leiomyomata seen in pregnancy. Long-term data for the efficacy of the various myolysis techniques are lacking, particularly with respect to the normalcy of subsequent pregnancy, safety, and persistence or recurrence rates. As a result, myolysis should be considered experimental until these issues are clarified by well-designed, long-term comparative trials.

Uterine Artery Embolization

When menorrhagia is the primary clinical symptom and either the surgical risk is judged unacceptable or the patient declines extirpative surgery, therapeutic UAE has been advocated to deprive leiomyomata of blood supply, induce necrosis, and reduce the volume of blood loss (Fig. 49.9). Importantly, there is no dominant vascular pedicle to individual fibroids, so bilateral embolization of both uterine arteries is required to reduce the blood supply to the leiomyomata. The procedure involves cauterizing the femoral artery on one or both sides and identifying the uterine arteries. An embolic agent is then infused to induce clotting and to obstruct blood flow to the uterus. This approach has been used in women with otherwise uncontrollable postpartum hemorrhage and palliatively for women exsanguinating from locally eroding advanced cervical cancer. In those clinical situations, the uterine arteries are the primary vascular supply to the bleeding sites involved, and occluding them reduces this vascular supply. UAE has been employed successfully under these circumstances with comparatively little morbidity relative to the other available options, such as emergency surgery. Based on its success for acute genital tract bleeding, UAE has been promoted actively by interventional radiologists as a primary therapy for virtually any symptoms attributable to fibroids.

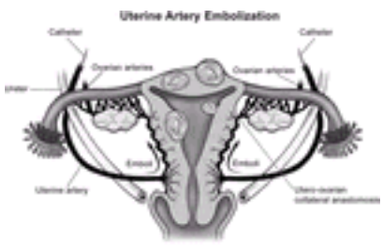

FIG. 49.9. The technique of uterine artery embolization. This schematic diagram demonstrates the technique used to inject emboli into the uterine arteries and deprive the normal myometrium as well as the leiomyomata of blood supply. Note that the uterine arteries have collateral connections with the ovarian arteries and provide a pathway for potential embolization to the ovarian vasculature.

With leiomyomata, the situation is nonemergent and significantly different from postpartum hemorrhage or an eroding cervical cancer. The vascular supply to the myomatous uterus varies significantly from woman to woman, with a large aberrant blood supply developing from normally minor collateral vasculature. UAE, by the nature of the technique, deprives the normal myometrium, as well the tumors enclosed within the uterus, of its blood supply. The technique's success depends on a large differential requirement of blood supply to the fibroids compared with that to the surrounding myometrium. Several case series of carefully selected women with leiomyomata have demonstrated a resolution of the menorrhagia ranging from 65 to 90%, but virtually no data are available for the efficacy for other symptoms attributable to leiomyomata, such as dysmenorrhea, pressure on adjacent viscera, and pelvic pain. The impact of UAE on the size of fibroids is not as well documented, with estimates ranging from 30% to 50%, comparable to the reduction seen with GnRH-agonist management. The leiomyomata typically shrink but, because they are not removed, not always enough to eliminate symptoms such as dysmenorrhea, pelvic pain, and pressure on adjacent viscera.

Although the benefits of UAE for stopping massive bleeding in women with postpartum hemorrhage and with eroding cervical cancer are obviously lifesaving, the long-term safety and efficacy in women with fibroids remain to be demonstrated. This is particularly true for women wishing to retain fertility, whose increased uterine blood flow during pregnancy is a normal physiologic adaptation, critically important to the survival and normal development of the fetus. Few pregnancies have been reported, because most women undergoing UAE are over 40 years of age and not desirous of further childbearing. No information is available regarding intrauterine growth restriction, abnormal placentation, or the value of a cesarean section to prevent uterine rupture during pregnancy or labor. As with an abdominal myomectomy,

the risks involved are likely to be related to the number, size, and location of the fibroids being treated.

Another concern for women wishing to retain their fertility is ovarian function. Because there are substantial anatomic collateral connections between the uterine and ovarian vasculature, it is possible for the embolic agents to enter the ovarian vasculature, reduce blood supply to the ovary, and cause premature ovarian failure. The overall rate of ovarian failure is between 5% and 10%, with most of these women being over age 40 at the time of the UAE. However, because the surgical removal of one ovary does not result in earlier menopause, many oocytes may be lost without causing premature menopause. Women may also experience postprocedure amenorrhea when ovarian function is normal, indicating loss of the integrity of the endometrium, which is also of concern regarding fertility. It is imperative that controlled trials with long-term follow-up be performed in order to counsel accurately women with childbearing desires as to the results to be attained with UAE.

UAE has been widely touted as avoiding the risks of abdominal surgery, causing less pain, and requiring less recovery time than surgical extirpation. However, the aseptic necrosis often causes such intense abdominal pain that women undergoing UAE are hospitalized routinely for parenteral narcotic administration for 24 to 48 hours. If intracavitary or submucous myomas are present, the avascular necrosis following UAE may result in prolapse of the degenerating myoma through the cervix, necessitating surgical removal. A postembolization syndrome can develop, similar to that observed after a myocardial infarction, manifested by a flulike syndrome with general malaise, elevated temperature, and leukocytosis. This is difficult to distinguish from an infection and usually is treated with antibiotics. Sepsis can occur, but whether is secondary to an ascending infection or from another source is not clear.

As the number of women undergoing UAE increases, serious acute complications necessitating hysterectomy, and even including death, are being reported. Until randomized comparative trials with long-term follow-up are available demonstrating a benefit of UAE over surgery in a defined clinical setting, this technique will remain a controversial addition to our therapeutic armamentarium. UAE should be considered primarily for women with unacceptably high surgical risks or those women without reproductive desires who do not want surgery. It should be undertaken with the understanding that, although UAE may relieve symptoms, it is not without the risk of serious complications, including death, and that no data are available regarding recurrence rates and long-term complications such as premature ovarian failure.

Another nonextirpative option is the laparoscopic cauterization of both uterine arteries to reduce the flow of blood to the myomatous uterus. As with UAE, the theoretic value is to reduce the vascular supply to both the normal myometrium and the leiomyomata and, thus, cause tissue schemia, with the uterus tolerating this to a greater degree than the myomas. Also like UAE, this therapy has not been assessed adequately in large long-term trials, but in a few highly selected patients it has reduced the symptoms attributable to the leiomyomata. This must be considered an experimental therapy, and its clinical application should await the results of randomized clinical trials with long-term follow-up.

SUMMARY POINTS

- Leiomyomata represent the most common gynecologic tumors and can grow to impressive size, despite being almost invariably benign in the reproductive age group.
- Fibroids cause a variety of gynecologic symptoms and account for a substantial proportion of gynecologic surgery.
- Although some insights into the molecular mechanisms responsible for growth of leiomyomata have been gained, much remains to be learned about this gynecologic tumor, because no consistent molecular mechanism of tumor growth has been identified.
- The therapeutic choices focus on extirpation, with hysterectomy most often used for definitive treatment and myomectomy when preservation of reproductive potential is desired, albeit with a significant recurrence risk.
- Medical therapy focused on hypogonadism is successful for temporarily treating symptoms, but the leiomyomata rapidly return to the pretreatment size upon discontinuance, and this approach does not represent a long-term treatment nor eliminate the risk of recurrent symptoms.
- Newer techniques of UAE and myolysis have not yet been evaluated adequately in comparative clinical trials to establish accurately their risks and long-term recurrence rates, particularly their impact on future reproduction.
- Until a better understanding of the factors involved in initiating leiomyomata growth is achieved, management will remain focused primarily on the surgical relief of symptoms.

Breast cancer remains the most common cancer in women, and is second only to lung cancer as the leading cause of cancer-related death in the United States. It is estimated that in 2003 there will be 211,300 new cases of breast cancer diagnosed. The lifetime risk among women of developing breast cancer is 12.5% (1 in 8); the lifetime risk of dying from breast cancer is 3.6% (1 in 28). Although breast cancer remains a serious health concern in the United States as well as in other countries, breast cancer mortality is declining in the U.S. and in other industrialized countries. This decline is thought to be secondary to increased use of mammographic screening and early detection of breast cancer.

Obstetricians and gynecologists are commonly the primary care physicians for many women. According to the American College of Obstetricians and Gynecologists (ACOG), the diagnosis of breast disease, as well as the education of women on breast self-examination, and their referral for mammographic screening, is central to the obstetrician/gynecologist's role in women's health care.

This chapter presents an overview of breast cancer screening, benign and malignant conditions of the breast, and the role of the obstetrician/gynecologist in the diagnosis of and education of women about breast disease.

ANATOMY OF THE BREAST

The adult breast lies between the second and sixth ribs in the vertical plane and between the sternal edge (medially) and midaxillary line (laterally). The average breast measures 10 to 12 cm in diameter and is 5 to 7 cm in thickness. It is concentric, with a lateral projection into the axilla named the *axillary tail of Spence*.

The breast consists of three major structures: skin, subcutaneous fatty tissue, and breast tissue (parenchyma and stroma). The skin contains hair follicles, sebaceous glands, and eccrine sweat glands. The glandular breast is divided into 15 to 20 segments (lobes) that are separated by connective tissue and converge at the nipple in a radial arrangement. These lobes are made up of 20 to 40 lobules, which in turn consist of 10 to 100 alveoli (tubulosaccular secretory units). Five to ten major

collecting milk ducts drain each segment and open at the nipple into subareolar lactiferous sinuses.

A superficial pectoral fascia envelops the breast; the undersurface of the breast lies on the deep pectoral fascia. Between these two fascial layers are fibrous bands, Cooper suspensory ligaments, which provide support for the breast. The space between the deep layers of the superficial fascia of the breast and the deep investing fascia of the pectoralis is the retromammary bursa.

The epidermis of the nipple (mammary papilla) and areola is pigmented and wrinkled and consists of keratinized, stratified squamous epithelium that contains smooth muscle fibers in dense connective tissue. These fibers are responsible for the erection of the nipple. Two receptor-type nerve endings (Ruffini-like bodies and end bulb of Krause) are present on the nipple and are associated with the tactile reception of stretch and pressure.

The areola has no hair follicles; it has sebaceous glands (at its margin), apocrine sweat glands, and accessory areolar glands (Montgomery glands) that open on the surface of the areola as small elevations called Morgagni tubercles.

The blood supply of the breast is mostly from superficial vessels. The principal blood supply is derived from the internal thoracic (mammary) and lateral thoracic artery and their tributaries. The posterior intercostal arteries of the second to fourth intercostal spaces also give off tributaries, the mammary branches.

The superficial veins follow the arteries and drain through perforating branches of the internal thoracic vein, tributaries of the axillary vein, and perforating branches of posterior intercostal veins. The veins anastomose circumferentially around the nipple, which is named the circulus venosus.

EPIDEMIOLOGY OF BREAST CANCER

Risk Factors and Assessment

Age The incidence of breast cancer increases with age. Age is the most significant risk factor for breast cancer.
Family History Hereditary breast cancers account for 5% to 10% of all breast cancers and are thought to be attributable to highly penetrant mutations in breast cancer–susceptibility genes. Two such tumor-suppressor genes, *BRCA1* and *BRCA2*, have been well characterized. Breast cancer has also been noted to occur in association with other cancers such as in the Li-Fraumeni syndrome and Cowden syndrome.
Personal History A patient's history of prior breast biopsy is important. Although the number of breast biopsies undergone does not increase a woman's risk of breast cancer, certain pathologic entities do play a role. Atypical ductal or lobular hyperplasia and lobular carcinoma in situ are considered markers of increased risk of developing invasive breast cancer. A personal history of breast cancer increases the risk for development of another breast cancer. Women treated for breast cancer are at risk for the development of a contralateral breast cancer. Various studies have shown this risk to be between 0.5% and 1% per year. In addition, patients treated with breast conservation (lumpectomy and radiation therapy) are at risk for an ipsilateral recurrence. In these women, this risk could be 10% or higher at 10 years post-treatment.
Reproductive History Early menarche, late menopause, and nulliparity are thought to be risk factors for breast cancer. Age at first pregnancy is also thought to be a relative risk (RR) factor for breast cancer. Early age at first pregnancy is often associated with a lower risk for breast cancer; pregnancy by the age of 30 may reduce risk by up to 30%, and a full-term pregnancy by the age of 20 reduces risk by 50%. Breast-feeding has been reported to reduce risk of breast cancer, and the greatest effect is seen when cumulative times exceed 24 months. The effect of menopause as it relates to breast cancer risk has been examined. Late menopause poses an increase in risk of breast cancer. Bilateral oophorectomy before natural menopause has been reported to reduce risk of breast cancer.
Exogenous Hormone Use The role of exogenous estrogens in the promotion of breast cancer is still controversial. Studies of oral contraceptives (OCP) and hormone replacement therapy (HRT) have yielded conflicting results. Studies of HRT and breast cancer risk indicate that women who are currently using HRT are at increased risk for breast cancer development. A meta-analysis of the largest studies, however, suggests that the increased risk is only about 10%. Women who have taken HRT in the past but are not currently using HRT are not at increased risk. Long-term use of HRT (>10 years) has been associated with relative increase in breast cancer risk, and the highest risk was noted in those patients using HRT with progestins (RR =1.41). Of note, multiple studies have shown that patients who develop breast cancer while on HRT have smaller, less aggressive cancers and a lower risk of death from breast cancer. Recently, results from the Women's Health Initiative randomized controlled trial were reported. Between 1993 and 1998, 16,609 women with an intact uterus were randomized to receive combination HRT (0.625 mg/day conjugated equine estrogens and 2.5 mg/day medroxyprogesterone acetate) versus placebo. The planned duration of the trial was 8.5 years; however, the data and safety monitoring board of the committee recommended halting the trial because the incidence of invasive breast cancer had exceeded the stopping boundary that had been set at the initiation of the trial. This occurred after a mean of 5.2 years of follow-up. The increased risk of breast cancer reported hazard ratio was 1.25 (95% confidence interval [CI], 1.00-1.59). There was also a reported increased risk of coronary heart disease (HR 1.29; 95% CI, 1.02-1.63), stroke (HR, 1.41; 95% CI, 1.39-3.25). Beneficial effects included decreased risk in colorectal cancer (HR, 0.63; 95% CI, 0.43-0.92) and hip fracture (HR 0.66; 95% CI, 0.45-0.98). Based on the data and safety monitoring board did not recommend stopping the estrogen-alone arm in women who had had a hysterectomy. Results of this part of the study are anticipated in 2005. The annual increased risk for an individual woman is still relatively small. The increased risk for breast cancer is apparent after four years of HRT use. The American College of Obstetricians and Gynecologists (ACOG) stresses the importance of addressing the reasons for initiating or continuing on HRT. It is no longer recommended to prevent heart disease in healthy women (primary prevention) or to protect women with preexisting heart disease (secondary prevention). In addition, it is no longer recommended solely for prevention of osteoporosis. HRT is highly effective in treating vasomotor symptoms with limited effective alternative therapies. In this setting, short-term use (<5 years) can be considered as data on short-term use does not show an increased association with breast cancer. In the past, most studies addressing OCP use and breast cancer risk concluded that there was a significant increase in risk associated with OCP use. However, the majority of studies regarding OCP use and breast cancer risk have demonstrated little association with breast cancer incidence rates. In women who have used OCP for extended periods of time (>10 years), a minimal, nonsignificant increase in breast cancer cases has been reported, seen most commonly in the group of women who began using OCP at a young age (<20 years). Past or present use of OCP at the time of diagnosis of breast cancer does not affect mortality from breast cancer. The presence of a family history of breast cancer does not appear to further increase the risk of breast cancer associated with either OCP or HRT use.
Prior Exposure to Radiation Therapy Exposure to ionizing radiation such as occurs in treatment with mantle radiation for Hodgkin's disease poses a risk for breast cancer. This is noted 7 to 10 years after completion of radiation therapy. The cumulative probability of breast cancer at age 40 approaches 35% in these women. The risk of breast cancer associated with radiation exposure decreases with increasing age at exposure.
Other Factors Breast cancer is more frequent in Jewish women than in non-Jewish women and in black women than in white women. Asian women have a low incidence of breast cancer. Japanese women show lower rates of breast cancer than white women. Although postmenopausal breast cancer is less common in Japanese women who have migrated to Western countries than among the general populations of these countries, after two or three generations, the incidences of breast cancer in these women approaches that of white women. The Western diet, with the increased intake of animal fat, has been implicated in these studies. Alcohol consumption has been reported to increase breast cancer risk in a dose-related manner. Women who drink approximately one drink per day have slightly elevated risk of breast cancer over nondrinkers. This risk is significantly higher with moderate to high alcohol consumption (two to five drinks per day).

Relative Risk

Relative risk (RR) is a ratio that depicts the likelihood over time of an event's occurrence in a study population relative to that in a reference population. It is often used to quantify risk factors for breast cancer. Absolute risk is a percentage that depicts the likelihood over time of the occurrence of an event. For rare events, these two are the same, but for common events they are not. It is best to discuss risk with patients in terms of absolute rather than relative risk.

Several models exist to estimate a woman's risk of breast cancer. The Gail model, developed for use in the National Surgical Adjuvant Breast and Bowel Project (NSABP P-1) Breast Cancer Prevention Trial, is available from the National Cancer Institute and provides a measurement of absolute risk over time for breast cancer. However, in familial-type hereditary cases, it underestimates the risk of breast cancer by overlooking age at onset, bilaterality of disease among affected family members, and breast cancer in nonfirst-degree relatives (Table 50.1).

Factor	Relative risk
Family history of breast cancer	
First-degree relative	1.8
Premenopausal first-degree relative	3.0
Postmenopausal first-degree relative	1.5
Premenopausal first-degree relative (bilateral breast cancer)	9.0
Postmenopausal first-degree relative (bilateral breast cancer)	4.0–5.4
Menstrual history (age in years)	
Menarche before age 12	1.7–3.4
Menarche after age 17	0.3
Menopause before age 45	0.5–0.7
Menopause from age 45–54	1.0
Menopause after age 55	1.5
Menopause after age 55 with >40 menstrual years	2.5–5.0
Oophorectomy before age 35	0.4
Anovulatory menstrual cycles	2.0–4.0
Pregnancy history	
Term pregnancy before age 20	0.4
First term pregnancy at age 20–34	1.0
First term pregnancy after age 35	1.5–4.0
Nulliparous patient	1.3–4.0
Noninvasive breast disease	
Atypical lobular hyperplasia	4.0
Lobular carcinoma in situ	7.2
Other neoplasm	
Contralateral breast cancer	2.0–10.0
Cancer of the major salivary gland	4.0
Cancer of the uterus	2.0

TABLE 50.1. *Risk factors for breast cancer*

BRCA1 and BRCA2 *BRCA1* and *BRCA2* are breast cancer–susceptibility genes that have expanded our knowledge of familial breast cancer. Linkage studies done in 1990 in early-onset breast cancer families led to cloning of the *BRCA1* gene at the University of Utah in Salt Lake City in 1994. The *BRCA1* gene consists of 22 coding exons distributed over approximately 100 kb of genomic DNA on chromosome 17q21. It is thought to be responsible for approximately 45% of early-onset hereditary breast cancers, and nearly 90% of hereditary ovarian cancers in families with a high incidence of breast and ovarian cancers. Two specific mutations, *185delAG* and *5382insC*, are present in approximately 1% and 0.25% of the Ashkenazi Jewish population, respectively. They are thought to be founder mutations (i.e., an altered gene or genes seen with a high frequency in a population originating from a small ancestral group, one or more of the founders of which were carriers of the mutant gene). *BRCA2* was isolated on chromosome 13q12-13 in 1995. The *BRCA2* gene is composed of 26 coding exons distributed over approximately 70 kb of genomic DNA. This gene appears to account for 35% of families with early-onset breast cancer. It confers a lower risk of ovarian cancer compared with breast cancer. A single mutation, *6174delT*, is found in approximately 1.4% of the Ashkenazi Jewish population. Together, both *BRCA1* and *BRCA2* mutations are found in approximately 1 in 40 Ashkenazi Jewish individuals. For both genes, the estimated penetrance is 70% to 90% for breast cancer by age 70, but the risk of breast cancer by age 50 may be lower for *BRCA2* mutations. The likelihood of a patient having a *BRCA1* or *BRCA2* mutation is dependent on certain factors such as age at the time of diagnosis of breast or ovarian cancer and the number and age of first- and second-degree relatives in the same parental lineage and ethnicity with breast or ovarian cancer. The parental lineage can be either maternal or paternal. The American Society of Clinical Oncology issued guidelines for recommending genetic testing for families with high probability (>10%) of having a mutation for *BRCA1* (Table 50.2).

Three or more kindred with breast cancer < age 50
Two or more breast cancers and one or more ovarian cancer diagnosed at any age
Sister pairs with two breast cancers, two ovarian cancers, or a breast and an ovarian cancer, all diagnosed < age 50

TABLE 50.2. *American Society of Clinical Oncology (ASCO) guidelines for recommending genetic testing for families with high probablility (>10%) of having BRCA1 mutation*

Identification of patients with a high-risk family history should be referred for genetic counseling and testing. The decision to undergo genetic testing is a complex one, as it can affect an individual's personal, psychological, social, financial, and ethical well-being. Women who have a negative genetic test should still be considered at risk on the basis of age, environment, or other genetic factors or unknown mutations.

HISTORY AND PHYSICAL EXAMINATION

Obtaining a thorough history, including a family history and information on menstrual status, pregnancies and lactation, hormone use, prior breast surgeries and trauma, is essential. In addition, ascertaining whether the patient performs breast self-examinations, as well as the presence and characterization of nipple discharge or a breast mass is important.

Bilateral breast examination is best performed right after menstruation and prior to ovulation. At this time, breast engorgement and tenderness is less likely to be present. A multipositional breast examination should be performed, including examination in the upright and supine positions (Fig. 50.1 and Fig. 50.2). Breast retraction and subtle changes in the skin and nipple may be missed if the patient is examined in only one position. Examination should be performed with hands at sides, elevated above the head, and finally, with the arms tensed at the waist (contracting the pectoralis muscles). Attention is directed toward the supraclavicular area and axilla. Digital palpation is performed beneath the lateral pectoralis muscles into the axilla itself.

FIG. 50.1. A: Inspection of patient with arms at sides. **B:** Inspection of patient with both arms raised. **C:** Inspection of patient with hands at waist, pectoral muscles contracted.

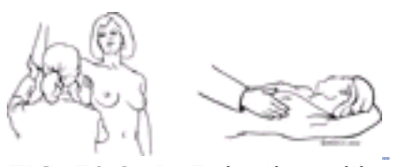

FIG. 50.2. A: Palpation with patient upright, with support of ipsilateral elbow; axillary nodes and also supraclavicular nodes examined. **B:** Palpation of breast with patient in supine position.

The second phase of the breast examination is conducted with the patient in the supine position. Digital palpation is carried out using the index and middle fingers and applying varying amounts of pressure with the flats or pads of the fingers. A thorough examination systemically covers the entire breast and chest wall. The examination can be done in a clockwise direction or by rows (stripwise). It is important to carefully examine beneath the nipple–areolar complex and within the axilla.

An inflammatory appearance of the breast should raise suspicion of an inflammatory carcinoma. The classic appearance of inflammatory breast cancer includes a red, swollen breast with skin edema (“peau d'orange”). The breast is generally not tender. If the inflammation persists following a short course of antibiotics to rule out cellulitis, biopsy of the breast and skin is warranted. Inflammatory breast cancer is often a clinical diagnosis, and a benign skin biopsy should not dissuade the clinician from undertaking further evaluation and treatment. Any asymmetric skin changes or changes of the nipple–areolar complex should arouse suspicion. Paget disease of the nipple is the presence of intraductal or invasive cancer involving the nipple and should be excluded by a nipple biopsy of the abnormal area following a mammogram.

It is important to instruct patients in the technique of breast self-examination. Physician-directed discussion on breast self-examination is the most effective approach. Physicians have the opportunity to reinforce what is normal versus abnormal to patients during the examination.

If no abnormal findings are noted on examination, it is critical to document negative findings. The date of the last mammogram, discussion of cancer screening, and plans for follow-up should also be recorded.

Hormones (HRT or OCP) should not be renewed without a documented annual breast examination or mammography if indicated. A great deal of litigation results from failure to diagnose breast cancer. The Physician Insurers Association of America's breast cancer claims study, conducted in 1988, determined that 75% of successful malpractice lawsuits involved primary care physicians with practices in family medicine, internal medicine, or obstetrics and gynecology. It is important that the medical

chart include careful documentation, since approximately one third of the cases reported in the Physician Insurers Association of America's study resulted from inadequate documentation.

MAMMOGRAPHY

The primary goal of mammography is to screen asymptomatic women to help in detection of breast cancer at an early stage. In general, a routine screening mammogram consists of a mediolateral oblique (MLO) view and a craniocaudal (CC) view of each breast. With modern low-dose screening, the dose is less than 0.1 rad per study (for comparison, a chest x-ray delivers 0.025 rad per study). The effectiveness of screening also varies depending on the density of the breast.

Breast composition may be one of four patterns of increasing density:

1. almost entirely fat
2. scattered fibroglandular densities
3. heterogeneously dense
4. extremely dense.

The greater the breast density, the lower the sensitivity of the mammogram. Because some palpable cancers are invisible on mammography, a negative study cannot always exclude cancer. It is important to note that the false-negative rate for mammograms is 10% to 15% and that a normal mammogram does not eliminate the need for further evaluation of a dominant mass in the breast. If the clinical examination is suspicious, a negative mammogram should not delay further investigation.

Mammographic screening in women 40 years or older has reduced mortality by 20% to 30%. The efficacy of screening mammography in decreasing breast cancer mortality has been demonstrated in numerous studies. In the 1960s, the Health Insurance Plan of Greater New York performed a study of physical examination and mammography in a study group of 30,756 women and a control group of 30,239 women between the ages of 40 to 64 years. At 10-year follow-up, the study group had a 30% decrease in breast cancer mortality compared with the control group.

A total of eight large randomized trials on mammographic screening have been conducted. Six of the eight trials revealed a statistically significant reduction in mortality with mammographic screening. The reduction in mortality was not as evident among women between the ages of 40 and 49 compared with women over 50 years of age. The relative mortality reduction appears later in women between the ages of 40 and 49 at randomization compared with women 50 years of or older. It is also likely that the small numbers of women between 40 and 49 years of age in the existing randomized trials may have contributed to this difference.

In a meta-analysis of eight randomized, controlled trials of mammographic screening, a statistically significant 18% reduction in mortality in women aged 40 to 49 was noted. Combined data from five Swedish trials yielded a statistically significant mortality decrease of 29% (Table 50.3).

Trial	Relative risk (95% CI)
Malmö	0.96 (0.68–1.35)
Canada	1.08 (0.84–1.40)
Göteborg	0.55 (0.31–0.95)
Stockholm	0.73 (0.50–1.06)
Kopperberg	0.58 (0.45–0.76)
Östergötland	0.76 (0.61–0.95)
New York	0.79 (0.64–0.98)
Edinburgh	0.87 (0.70–1.08)

CI, confidence interval.

TABLE 50.3. *Randomized population-based mammography trials*

A re-analysis of the meta-analysis excluded six of the eight studies because of issues related to randomization methods used and other factors in these trials. This re-analysis questioned the risk reduction offered by mammography and resulted in much controversy. The risk reduction associated with mammography continues to be an area of debate within the medical community.

Screening Interval

For several years, there has been a significant debate about the appropriate age at which to commence mammographic screening. In 1997, the American Cancer Society (ACS) and the National Cancer Institute (NCI) modified the guidelines for mammographic screening for women between the ages of 40 and 49, recommending regular mammograms for women in this age group. The recommended intervals differ: the ACS recommends a yearly mammogram starting at age 40, while the NCI recommends a mammogram every 1 or 2 years. The ACOG recommendations on mammography are similar to the NCI guidelines.

Annual screening mammography may commence earlier than age 40 in a few special circumstances (Table 50.4).

TABLE 50.4. *Screening guidelines for women under age 40*

BI-RADS

In the past, a lack of uniformity in mammography terminology and reporting often led to confusion as to the malignant nature of a lesion. In 1994, the Mammography Quality Standards Act was passed by Congress and is administered by the Food and Drug Administration (FDA). It requires that mammography facilities monitor the results of their breast cancer–detection programs, including the number of recommended biopsies, and the size, number, and stage of cancers detected. The American College of Radiology (ACR) Breast Imaging Reporting and Data System uses a terminology and lexicon system called *BI-RADS* for reporting abnormalities seen on mammography (Table 50.5). This standardized reporting system—the Breast Imaging Reporting and Data System—was developed in 1995. Each category leads to a fixed assessment and specific management recommendations.

BI-RADS categories	Assessment
0	Need additional imaging evaluation—assessment is incomplete
1	Negative
2	Benign finding
3	Probably benign finding—short interval follow-up suggested
4	Suspicious abnormality—biopsy should be considered
5	Highly suggestive of malignancy—appropriate action should be taken

Source: American College of Radiology. *Illustrated breast imaging reporting and data system (BI-RADS)*, third ed. Reston, VA: American College of Radiology; 1998.

TABLE 50.5. *American College of Radiology (ACR) BI-RADS assessment categories*

In addition, associated findings such as skin or nipple retraction, skin thickening, skin lesions, axillary adenopathy, and the presence of architectural distortion should also be reported.

The predictors of malignancy for the BI-RADS categories are 0% to 2% for category 3 and approximately 98% or greater for category 5.

Category 4 is less predictable. Liberman and colleagues and Orel and colleagues have placed the risk of malignancy for this category around 30%.

The ACR is working on a new edition of the BI-RADS classification system that, in particular, will attempt to provide data on category 4 in terms of risk of malignancy. According to the ACR, in the forthcoming edition of BI-RADS, category 4 will be divided into three subdivisions—low, medium, and high—in an effort to better guide clinicians and to get meaningful data about this category (personal communication, July 2002).

Diagnostic Mammography

Abnormalities found on mammographic screening may need further evaluation with additional mammography views or other imaging modalities such as ultrasound or magnetic resonance imaging (MRI). In some screening programs, the mammograms are reviewed by the radiologist as they are performed, and if additional views are needed, they are performed on the same day. In other programs, if additional studies are required, the patient is called back for them at a later date. In several studies, the frequency of “call-backs” has ranged from 5% to 11%.

Mammographic Lesions

A “mass” is defined as a space-occupying lesion seen in two different projections. If a possible mass is seen on only one view, it is called a “density” until its three-dimensionality is confirmed. A description of the shape and the margins of the lesion are also necessary. The highest frequency of carcinoma is noted in masses that have an irregular shape or spiculated borders. These lesions are associated with pleomorphic calcifications that appear discontinuous and linear in distribution. This discontinuous linear pattern suggests irregular filling of a duct with abnormal cells.

Microcalcifications

The BI-RADS lexicon describes calcification morphology (shape) and distribution. Calcifications may be scattered or clustered, coarse or fine, old or new. Comparison with prior mammograms is often necessary (Table 50.6).

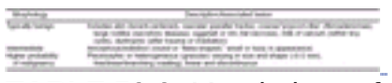

TABLE 50.6. *Morphology of microcalcifications and associated lesions*

Breast Ultrasound and MRI

Breast ultrasonography can be used to distinguish between solid and cystic masses in the breast. It can be used to evaluate a focal mass identified on a mammogram or a palpable mass. It is also used as an adjuvant for biopsy. Because of its low specificity, it is not thought to be a good modality for screening. It cannot replace mammography, as it has no ability to detect microcalcifications. Ultrasound can complement mammography in young women with dense breasts (which limits the accuracy of the mammogram).

Presently, MRI has no role in breast cancer screening. MRI has a high sensitivity in the diagnosis of breast cancer, ranging from 86% to 100%, but a low specificity 37% to 97%. Because of this low specificity it is of limited value in screening. It is an expensive test that requires intravenous contrast and the technology for performing biopsy under MRI guidance is not widely available. Current uses include evaluation of breast implants for rupture, evaluation of pectoralis involvement with extensive breast cancer, and evaluation of post-lumpectomy bed fibrosis. Research into the use of MRI for screening of patients with dense breasts is under investigation. Future uses may include evaluation of occult breast cancers and evaluation of multifocal disease in those patients who are considering breast conservation.

DIAGNOSTIC EVALUATION

Palpable Mass

The workup of a patient with a dominant mass should include a bilateral mammogram. In addition to gaining valuable information about the characteristics of the mass, a secondary purpose in this setting is to screen the normal surrounding breast and the contralateral breast for nonpalpable mammographic abnormalities (densities or calcifications). Evaluation of a palpable mass is important to determine whether the mass is cancerous even if the mammogram is negative.

Fine-Needle Aspiration or Biopsy

Fine-needle aspiration (FNA) can be extremely useful in providing a cytologic analysis of a palpable breast mass. Many palpable thickenings and all dominant masses should be considered for FNA as it can differentiate between solid and cystic masses. In addition, FNA can diagnose and treat simple cysts and provide cellular material for cytologic analysis. The FNA should be performed after radiologic examination because the resultant hematoma could mask an underlying abnormality.

The breast is prepped with alcohol; with the physician facing the patient, the lesion is stabilized with the physician's opposite hand. Usually, a 21-gauge or 25-gauge needle on a 10-cc syringe is used. Approximately 3 cc of air is aspirated into the syringe to facilitate expulsion of the contents onto the slide following the procedure. The needle is introduced into the lesion, and suction is applied on the syringe (Fig. 50.3A, Fig. 50.3B and Fig. 50.3C). If the mass is cystic, the fluid is completely evacuated and the lesion should completely disappear. The syringe is withdrawn and the fluid is discarded if it is serous and nonbloody. The patient should return in 4 to 6 weeks for reexamination.

FIG. 50.3. Aspiration biopsy. **A:** Mass. **B:** Stabilizing the lesion. **C:** Aspirating.

If the lesion encountered is not cystic or suspected to be solid, an FNA biopsy can be performed in the same manner. After insertion into the lesion, multiple passes (10–15) through the lesion with changes in direction allow extensive sampling and create a “feel” for the mass (carcinomas are usually hard and gritty). The goal of sampling is to obtain material in the hub of the needle, not to fill the syringe. Care should be taken to release the suction before withdrawing the needle to prevent aspiration into the syringe. The sample is then ejected onto a glass slide, gently smeared with another slide and placed in sterile jars containing 95% ethanol for transport to the cytology lab. Alternatively, it can be placed in a specimen jar containing cytofixative. The needle should be removed from the syringe, the medium

aspirated into the syringe, the needle replaced, and the medium then ejected into the jar.

An FNA requires a cytopathologist experienced in breast pathology. The false-negative rate can range from 3% to 35% depending on the expertise of the aspirator and the cytopathologist, the size of the lesion, the location within the breast and the cellular composition of the lesion. Negative findings of an FNA in the presence of a suspicious mass should not preclude further diagnostic evaluation. A diagnosis of atypical cells following an FNA warrants a surgical biopsy. Any mass remaining after aspiration of a cyst should be excised. Similarly, a cyst that recurs in the same location after one or two aspirations should be excised.

The false-positive rate of an FNA is less than 1%, but in the United States most surgeons will not perform definitive surgery (i.e., a mastectomy or axillary dissection) without a prior surgical biopsy, core-needle biopsy, or frozen-section diagnosis at the time of surgery. An FNA that is positive for adenocarcinoma could, however, provide a preliminary diagnosis and guide subsequent management.

Patients with palpable solid masses can have a biopsy of the mass in the office with use of a Tru-cut 14-gauge biopsy device. The breast is prepped sterilely and a local anesthetic is used to infiltrate the skin. A small nick is made in the skin with a scalpel to accommodate the biopsy instrument. A core biopsy of the solid mass is obtained. The instrument has a “firing” range and therefore should be kept parallel to the chest wall to avoid penetrating trauma. The specimen is placed in formalin and sent to pathology. It is believed that if the specimen “floats” in the solution, it is likely nondiagnostic fat. Tumor specimens will have a grayish appearance and will typically “sink” in the solution.

Needle-Localization and Excision

Needle localization is a technique that allows surgical excision of a lesion that is nonpalpable. The technique uses a hook-wire system to target the lesion, and image guidance can be provided by mammogram, ultrasound, and in some cases MRI. In mammography-guided needle localization, coordinates of the lesion are obtained by placing the breast in an alphanumeric grid. The needle is inserted and, when adequate placement is noted, the hook wire is deployed and the needle removed. Two mammographic views are then obtained.

The mammography films are available intraoperatively and show the relationship between the lesion and localizing hook. Excision with needle localization allows the surgeon to minimize the amount of breast tissue removed by following the needle to the targeted lesion. After removal, a specimen radiograph is obtained to ensure that successful removal of the lesion has been performed. Radiologists and surgeons experienced in needle localization and excisions report only 0.2% to 0.3% of lesions missed with this approach. The specimen radiograph helps to ascertain the lesion was not missed.

Image-Guided Percutaneous Breast Biopsy

With the current advancements available in breast imaging, percutaneous image-guided breast biopsy is increasingly being used as an alternative to surgical biopsy. Percutaneous biopsy methods differ with respect to the method of imaging guidance and the tissue-acquisition device used. The use of image-guided percutaneous biopsy has advantages over surgical excision for the diagnosis of breast lesions. It is less invasive and because less tissue is removed, it will result in less scarring on subsequent mammograms. Regardless of whether the diagnosis is benign or malignant, the patients who have percutaneous biopsies will undergo fewer operations. In addition, in cases of malignancy, the discussion and surgical treatment plan can be streamlined. The choice of which image-guided modality to use depends on the lesion. Stereotactic biopsy is best for calcifications. If a lesion is seen on ultrasound, it is best to use that modality, since it is easier to use and has been reported to be less costly.

Stereotactic Biopsy

Stereotactic biopsy uses specialized mammography equipment to calculate the location of a lesion in three dimensions. Stereotactic biopsy can be performed with the patient prone on a dedicated table or with the patient sitting in an upright unit. An automated core needle or directional vacuum-assisted biopsy probe is used to obtain the tissue specimens. Multiple tissue specimens are obtained for pathologic analysis. Many reports in the medical literature state the procedure has a sensitivity of 70% to 100% and a specificity of 85% to 100%. The greatest success is noted in reports using 14-gauge core needles, as well as in those with increased numbers of specimens obtained. In mass lesions, it is likely that five core samples may be adequate for accurate diagnosis; however, ten or more core specimens may be required in cases of calcifications.

Ultrasound-Guided Biopsy

The use of ultrasound imaging for percutaneous biopsy of lesions seen on ultrasound has certain advantages. For example, it requires no specialized equipment, no radiation exposure, and has the ability to sample areas that may be inaccessible with stereotactic biopsy (such as the axilla). A 14-gauge automated needle is used, and real-time imaging allows accurate positioning. Multiple tissue core samples are sent for pathologic analysis.

Tissue-Acquisition Devices

Available tissue-acquisition devices include fine needles, automated core needles, directional vacuum-assisted probes, and biopsy cannulas. Excellent results have been obtained using the 14-gauge automated needle for biopsy of masses under ultrasound or stereotactic guidance. Most centers use larger tissue-acquisition devices instead of fine needles, because of accuracy of tissue diagnosis when a larger volume of tissue is obtained. Compared with the automated needle, the vacuum device acquires larger samples of tissue, has a higher frequency of retrieval of calcifications, and may provide more accurate lesion characterization. Accurate placement of a localizing clip through the biopsy probe is necessary to facilitate subsequent localization if needed.

Surgical Excision/Breast Biopsy

The ACOG has stopped short of recommending that open biopsy be performed by every obstetrician and gynecologist.

A biopsy can be performed on an outpatient basis under local anesthesia in the majority of patients. It is important to choose the appropriate incision and location (Fig. 50.4). Unless the lesion is close to the nipple or suspected to be a fibroadenoma, the incision should be made in close proximity to the mass and not circumareolar. The surgeon should keep in mind the possibility of subsequent mastectomy when placing the incision. Many times, the biopsy is part of the treatment. The specimen should be adequately oriented for margin analysis by the pathologist and also sent for the appropriate markers such as estrogen-receptor (ER) and progesterone-receptor (PR) status and HER2/ *neu*. Orientation of the specimen is important, as a reexcision of a close or involved margin may need to be performed.

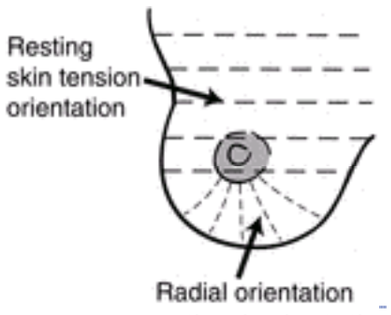

FIG. 50.4. Optimal orientation of biopsy incisions.

The incision should be closed with fine suture material, with a subcuticular closure. Hemostasis needs to be ascertained prior to closing and is usually achieved with electrocautery. Weck clips can be placed in the cavity bed if a diagnosis of breast cancer is known and breast conservation is planned. No particular immobilization is required but a good support bra is recommended to minimize hematoma and induration.

BENIGN BREAST CONDITIONS

Fibrocystic Changes

Fibrocystic change is the most common benign breast condition in women. It is a result of fluctuating hormone levels, and most common in premenopausal women between the ages of 20 and 50. It is often associated with pain and tenderness (mastodynia) and tends to be bilateral. Most women will report symptoms during the premenstrual phase of the cycle.

Pain is due to breast stromal edema, ductal dilation, and associated inflammatory response. An increase in breast size is also frequently reported. The differential diagnosis for breast pain includes other conditions affecting the anterior chest wall such as intercostal neuralgia, myalgia, and chronic costochondritis. Women with large pendulous breasts will have associated stretching of Cooper ligaments and associated breast pain.

Etiologic factors are still inconclusive. The ingestion of foods and medications containing methylxanthines has been implicated through an inhibition of 3'5'-cyclic adenosine monophosphate (cAMP) phosphodiesterase and 3'5'-cyclic guanosine monophosphate (cGMP) phosphodiesterase. This inhibition will lead to accumulation of increased amounts of cAMP and cGMP. High levels of cAMP and cGMP have been detected in patients with fibrocystic change. In some studies, reduction of dietary methylxanthines has been associated with symptomatic subjective reduction in pain, tenderness, and palpable nodularity. Other studies, however, have failed to show an effect from decreased consumption of dietary methylxanthines.

Fibrocystic change is not a risk factor for cancer in the majority of women. Histologically, there are two changes noted with fibrocystic change: nonproliferative changes and proliferative changes. The nonproliferative changes include cystic changes with formation of microcysts (2 mm or less in size), macrocysts, and fibrosis.

Proliferative Changes

Proliferative changes include hyperplasia and adenosis. Hyperplasia is proliferation of ductal epithelium, which results in layering of the cells. Atypia may be associated with this proliferation. If atypia is noted, this confers a five fold increase in breast cancer risk for the patient. Hyperplasia with atypia is the only fibrocystic change associated with an increased risk factor for breast cancer. If atypia is noted on a core biopsy, a surgical excision of the area is recommended, as it is thought that there is a 50% chance of finding a coexistent carcinoma.

Adenosis is also a proliferative lesion, caused by changes in the acini in the distal mammary lobule. Sclerosing adenosis refers to the dense, fibrotic tissue surrounding these small ducts. These lesions may present as a palpable mass in women in their 30s and 40s.

A papilloma can result from this ductal proliferation. Papillomas are papillary lesions with a branching fibrovascular core surrounded by epithelium. These lesions are associated with serosanguineous nipple discharge in 25% to 50% of presentations. Ninety percent of the time, there is a small palpable mass adjacent to the areola. Intraductal papillomas are rarely associated with carcinoma, but require surgical excision to rule out the possibility of misdiagnosis of a malignancy.

Management of fibrocystic changes includes regular physical examinations, appropriate imaging, and supportive measures. Recommendations for use of a good support bra may be helpful, especially in physically active women. Dietary restrictions of methylxanthines may produce subjective improvement in 65% of patients. The use of vitamins A and E has been reported in some studies to be helpful. Diuretic therapy during the premenstrual period has been reported to provide temporary relief, and requires cyclical use. Fluid retention is a result of cyclical hormonal stimulation.

Oral contraceptives suppress symptoms of fibrocystic changes in the majority of patients (70%–90%). Symptoms often recur after discontinuation. Other medications such as danazol (17a-norethisterone) in doses of 100 to 400 mg per day should be reserved for patients in whom other agents have been ineffective. Their side-effect profile can lead to poor compliance. A 3- to 6-month course can provide significant reduction in symptoms, and its effect can last several months after its discontinuation.

Fibroadenoma

Fibroadenomas are benign fibroepithelial tumors and are the second most common benign lesion of the breast. They are the most common lesion found in women under the age of 25. They will persist during the menstrual years of a woman's life, but regression after menopause has been reported. Patients typically present with a mobile, smooth, painless, palpable mass. Ultrasound examination, along with physical examination, can help in making the diagnosis. Mammographically, fibroadenomas may appear as round, oval, or lobulated masses with circumscribed margins. In older women, they can have a rim of coarse calcifications. FNA will reveal benign ductal epithelial cells and elongated dense stromal cells. Microscopically fibrous tissue composes most of the fibroadenoma. Carcinoma arising in fibroadenomas is rare.

Fibroadenomas can be followed without the need for complete surgical excision. This can be achieved with physical examination or ultrasound examination if they are not palpable. However, surgical excision should be performed if:

- the mass continues to enlarge
- the results of FNA or core biopsy are inconclusive or yield atypia
- the patient desires surgical excision.

Phyllodes Tumor

Phyllodes tumors are uncommon, slow-growing fibroepithelial tumors. Previously referred to as cystosarcoma phyllodes, this name contributed to confusion in understanding this entity. Although very similar to a fibroadenoma, the stromal component is hypercellular with increased pleomorphism and mitotic activity. Phyllodes tumors can occur in women of any age, but more commonly occur in premenopausal women.

Malignant behavior in phyllodes tumors is rare in premenopausal women. Malignant phyllodes tumors are noted when there is a combination of increased mitotic activity, invasive borders, or marked pleomorphism. Incomplete excision is a major determinant for local recurrence. Treatment is total surgical excision with a wide margin of healthy tissue.

Superficial Thrombophlebitis

Superficial thrombophlebitis is also known as Mondor disease of the breast. It is an uncommon benign inflammatory process. It can occur spontaneously, but usually is associated with breast trauma, breast surgery, or pregnancy. It is a thrombophlebitis of the thoracoepigastric vein, which drains the upper-outer quadrant of the breast. Patients present with acute pain and a linear, tender fibrotic band with skin retraction over the distribution of the thoracoepigastric vein.

Treatment is conservative, with analgesics and application of heat. The condition resolves in 1 to 3 weeks. Skin retraction superficial to the area of inflammation can remain if the inflammation is extensive. Biopsy is not necessary.

Mastitis

Mastitis usually occurs in relation to lactation. It can occur in nonpuerperal periods in association with galac-torrhea. Skin organisms, *Staphylococcus aureus*, and *Streptococcus* species may cause infection of the nipple and breast ducts. Presence of milk in the ducts is an excellent medium for infection.

Women with mastitis may continue to breast-feed. Antibiotic therapy with dicloxacillin sodium (250 mg q.i.d.) or penicillin G is indicated. If there is no response, an abscess that may require surgical drainage must be excluded. Inflammatory carcinomas can mimic mastitis, and if no resolution of infection is noted despite continued antibiotics, a skin biopsy may be indicated.

Galactoceles are milk-filled cysts. They are usually tender and present after the abrupt termination of breast-feeding. Aspiration of the cyst is often necessary for symptomatic relief. If reaccumulation occurs, however, surgical excision may be required to avoid infection.

Duct Ectasia

Duct ectasia is a condition usually occurring in perimenopausal or postmenopausal women. Patients present with a tender, hard erythematous mass adjacent to the

areola in association with burning, itching, or a sensation of pulling in the nipple area. A thick greenish-black discharge may be present. Histologic evaluation of the area shows dilate, distended terminal collecting ducts obstructed with inspissated lipid-containing epithelial cells and phagocytic histiocytes. This process tends to occur in a segmental fashion extending from the involved nipple area to adjacent ducts. Occasionally, as a result of this infection, a small abscess forms at the base of the nipple. Treatment is excisional biopsy.

Younger women can present with inflammation of the ducts in the region of the nipple, which may produce fissures and fistulae with connection from the nipple ducts to the skin at the edges of the areola. Prior periductal mastitis leads to the squamous epithelium of the terminal dilated portion of the collecting ducts to undergo squamous metaplasia. Keratin is formed in the duct, accumulates, and can cause an abscess at the base of the nipple. Excision of the area usually is necessary.

Fat Necrosis

Fat necrosis is a relatively uncommon benign condition occurring as a response to breast trauma. Patients present with a hard mass that can mimic a carcinoma. The irregular mass is palpable and may involve skin retraction. Multiple calcifications can be seen on mammography.

The histology is active chronic inflammatory cells, with lymphocytes and histiocytes predominating. In the later stages, a collagenous scar is noted, with “oil cysts” or free lipid material released by lipocyte necrosis. Fat necrosis does not increase the risk of carcinoma, and its clinical importance is in the differential diagnosis of a carcinoma.

Nipple Discharge

Nipple discharge has been reported in 10% to 15% of women with benign breast disease and in 2.5% to 3.0% of those with carcinoma. The discharge is classified according to its appearance as milky, green, bloody, serous, cloudy, or purulent. The drainage should be classified according to whether it is unilateral, bilateral, or spontaneous, or recurrent. This information is obtained at the time of a thorough history and physical examination. For example, if the drainage first appeared in the patient's bra or nightgown on awakening, this finding is significant. The presence of a mass should also be investigated. The risk of cancer is increased when the discharge is unilateral from a single duct, occurs in a postmenopausal patient, or when a mass is present.

Unilateral, Spontaneous Nipple Discharge In cases of unilateral, spontaneous nipple discharge, several causes are included in the differential. The most common cause of nipple discharge is mammary-duct ectasia, which produces a multicolored (green, yellow, white, brown, gray, or reddish brown) nipple discharge. The reddish-brown discharge is often mistaken for a blood discharge. It is thought to be due to an increase in glandular secretions, with the production of an irritating lipid fluid that can produce a nipple discharge. Guaiac of the discharge can help to diagnose whether it is bloody. The next most common cause of a multicolored, sticky nipple discharge is nonpuerperal mastitis. The persistent type involves inflammation in deeper portions of the breast; the transient types are associated with periareolar inflammation. If the inflammation develops into an inflammatory mass, surgical excision and drainage are necessary. Medical management with local care, avoidance of all nipple manipulation, and nonsteroidal antiinflammatory agents and an antistaphylococcal antibiotic is often successful when infection is suspected. Bloody nipple discharge warrants surgical evaluation. Intraductal papillomas are the most common cause of bloody nipple discharge. During the breast examination, physicians should look for an associated periareolar mass. The examination consists of gently and carefully palpating the subareolar region to identify the pressure point that produces the discharge. It is important to reproduce the discharge and demonstrate the breast quadrant from which it emanates. All significant nipple discharges warrant referral for tissue biopsy. Although a mass is usually present when the discharge is due to cancer, there is no palpable mass in 13% of cancers with nipple secretions. Bloody discharge occurring in the third trimester of pregnancy however may be regarded as physiologic and does not require intervention unless persistent for several months after delivery. There are no contraindications to breast-feeding in these patients. In addition, physicians should not rely solely on the cytology of the discharge because there is an 18% false-negative rate and a 2.6% false-positive rate with standard cytology alone. Galactography (injecting radiopaque contrast into the discharging duct and then performing mammography) offers better visualization of small intraductal papillomas but cannot differentiate between benign and malignant lesions. A surgical procedure is still necessary. Mammography has a 9.5% false-negative rate and a 1.6% false-positive rate for detecting cancer in patients with a nipple discharge.

BREAST CANCER

Natural History

The most common site of origin of breast cancer is the upper-outer quadrant (38.5%), central area (29%), upper-inner quadrant (14.2%), lower-outer quadrant (8.8%), and the lower-inner quadrant (5%). These percentages correlate with the amount of tissue that is present in these quadrants. Metachronous bilateral carcinoma of the breast has been observed in 5% to 8% of patients.

Metastasis to the ipsilateral axilla is the most common route of spread. Metastasis to the internal mammary nodes is more frequent with inner-quadrant lesions and is more likely to occur when involvement of the axillary nodes is also present.

Pathology

Ductal Carcinoma in Situ Ductal carcinoma in situ (DCIS) is an abnormal proliferation of malignant epithelial cells within the mammary ductal–lobular system without invasion into the surrounding stroma. It is classified as a heterogenous group of lesions with different growth patterns and cytologic features. Classification of DCIS has traditionally been based on architectural pattern. The most common types are comedo, cribriform, micropapillary, papillary, and solid.
Paget's Disease Paget's disease is involvement of the nipple with intraductal carcinoma. In absence of a palpable mass, invasive carcinoma occurs in less than 40% of cases. The malignant cells are large and pale-staining and are seen in the basal layer and upper portions of the epidermis. Diagnosis is made through a nipple biopsy.
Lobular Carcinoma in Situ Foote and Stewart initially described lobular carcinoma in situ (LCIS) in 1941 as a noninvasive lesion arising from the lobules and terminal ducts of the breast. LCIS is characterized by a solid proliferation of small cells with round to oval nuclei that distort the involved spaces in the terminal duct–lobular units. Three important features of LCIS are:

1. It is usually an incidental microscopic finding that is not detected clinically or by gross pathologic examination.
2. It is multicentric, and the associated cancer may be ductal or lobular.
3. The risk for subsequent cancer is the same for both breasts.

It is unfortunate that Foote and Stewart chose the name they did, as it has led to a great deal of confusion over the past several decades. LCIS is a marker for breast cancer risk and is not a malignant finding.
Invasive Duct Carcinoma Invasive duct carcinoma is the most common group of malignant mammary tumors and comprises 65% to 80% of all mammary carcinomas. Included in this group are special subtypes: Tubular, medullary, metaplastic, mucinous (colloid) papillary, and adenoid cystic carcinoma. Each subtype constitutes only 1% to 2% of all invasive breast cancers, except medullary carcinoma, which constitutes 7%, and the rare adenoid cystic carcinomas, at less than 0.1%. Many of these subtypes, such as tubular and medullary carcinomas, carry an excellent prognosis. Metaplastic carcinomas, however, often have an aggressive behavior. These tumors are characterized by the presence of homologous (epithelial) or heterologous (mesenchymal) elements. Two types have been described: Squamous and pseudosarcomatous metaplasia. Invasive duct carcinoma not otherwise specified (NOS) is a generic term that includes tumors that may express more than one element of the specific forms of duct carcinoma.
Infiltrating Lobular Carcinoma Infiltrating lobular carcinoma has been reported to constitute 10% to 14% of invasive carcinomas. These carcinomas are characterized by uniform cells with small, round nuclei and limited cytoplasm. The presence of intracytoplasmic mucin vacuoles often gives the cells the appearance of signet-ring cells. The cells tend to grow circumferentially around ducts and lobules with a linear arrangement. This pattern is referred to as “Indian-file” or targetoid growth. There is often an associated desmoplastic stromal reaction.

Inflammatory Carcinoma

Inflammatory carcinoma is characterized by cutaneous findings present with an underlying invasive carcinoma. Usually the invasive tumor is a poorly differentiated infiltrating duct carcinoma. Upon microscopic evaluation, skin involvement often reveals tumor emboli in dermal lymphatics with an associated lymphocytic reaction in the dermis.

Metastases from Extramammary Tumors

The most common primary site of an occult extramammary tumor is the lung. Other primary sites include the ovaries, uterus, kidneys, and stomach. In those previously diagnosed, melanoma, prostate, cervix, uterus, and urinary bladder are the most common sites. Metastatic ovarian cancer may simulate papillary or mucinous

carcinoma of the breast. A workup and history are often helpful in difficult cases. Often, identification of an in situ component helps to provide definitive evidence of a mammary origin.

Biologic Markers/Prognostic Factors

Axillary Lymph Node Status The most important prognostic factor is nodal status. The presence of metastasis, as well as the number of lymph nodes involved, is significant and correlates with local failure and distant metastases. It is predictive of overall survival.
Tumor Size Tumor size correlates with the incidence of lymph node metastases. The size of the tumor is also important, even in the absence of lymph node involvement. Patients with tumors less than 1 cm in size, or with good histologic types measuring less than 3 cm, do very well.
Histologic Grade Histologic grade also correlates with breast cancer outcome. Poorly differentiated tumors have been associated with more aggressive behavior.
Estrogen Receptors/Progesterone Receptors The hormone receptors can be measured by immunohistochemical (IHC) studies using monoclonal antibodies directed against the receptors. Positivity correlates with response to antihormonal agents as well as better prognosis.
HER2/neu HER2/ *neu* is an oncogene whose protein product may function as a growth factor receptor. It can be detected by IHC demonstration of the protein product or by gene amplifications. Overexpression or amplification has been shown to correlate with a poor prognosis; however, the studies differ with regard to the method of detection used, as well as the interpretation of results. HER2/ *neu* has been used as a predictor of response to certain chemotherapeutic agents. Particularly, increased-response, doxorubicin-based therapy has been reported in the treatment of patients with positive nodes and overexpression of HER2/ *neu*. Herceptin (trastuzumab) is a humanized anti-HER2 antibody against the extracellular domain of the 2-neu oncoprotein. Its use in the metastatic setting has been reported to demonstrate an increase in response rate and prolongation of disease-free and overall survival.
p53 A tumor-suppressor gene, *p53* has a protein product that is a nuclear transcription factor with many functions, including regulation of the cell cycle and apoptosis. Most clinical studies have used IHC to study protein expression. Accumulation of p53 protein has been reported to correlate with reduced survival in some studies.

STAGING OF BREAST CANCER

Staging of Breast Cancer Using the Tumor–Node–Metastasis (TNM) System

The American Joint Committee on Cancer (AJCC) determines staging of breast cancer. The AJCC staging system is a clinical and pathologic staging system based on the tumor–node–metastasis (TNM) system. The new updated AJCC staging system (2002) incorporates sentinel node staging. It distinguishes micrometastasis from isolated tumor cells on the basis of size and histologic evidence of malignant activity. In the current AJCC staging system, supraclavicular lymph node metastasis is now classified as N3 disease, rather than M1 disease, as in the old system (Table 50.7, Table 50.8).

TABLE 50.7. *American Joint Committee on Cancer Staging for breast cancer*

Stage 0	Tis	N0	M0
Stage I	T1*	N0	M0
Stage IIA	T0	N1	M0
	T1*	N1	M0
	T2	N0	M0
Stage IIB	T2	N1	M0
	T3	N0	M0
Stage IIIA	T0	N2	M0
	T1*	N2	M0
	T2	N2	M0
	T3	N1	M0
	T3	N2	M0
Stage IIIB	T4	N0	M0
	T4	N1	M0
	T4	N2	M0
Stage IIIC	Any T	N3	M0
Stage IV	Any T	Any N	M1

*T1 includes T1mic.
Note: Stage designation may be changed if post-surgical imaging studies reveal the presence of distant metastases, provided that the studies are carried out within four months of diagnosis in the absence of disease progression and provided that the patient has not received neoadjuvant therapy.

TABLE 50.8. *Stage by tumor, node, metastasis (TNM)*

TREATMENT OF BREAST CANCER

Mastectomy

William Halsted performed a radical mastectomy in 1894. The guiding principle at this time was centered on the belief that cancer originates in the breast and spreads in a stepwise fashion first to the regional lymph nodes, and then to distant sites. Removal of all the breast tissue, pectoral muscles, and axillary contents was the standard surgical treatment. Over the next several decades, two simultaneous trends existed. One involved less-radical surgery, which included removal of the breast and axillary contents, but preserved the pectoral muscles and more skin. This was described by Patey and Dyson in 1948, and is the modern-day modified radical mastectomy. The other trend involved more extensive surgery, the extended radical mastectomy, which included en-bloc removal of the internal mammary chain at the time of radical mastectomy. Subsequent randomized trials failed to show a survival advantage with the extended radical mastectomy when compared with the radical mastectomy.

Breast-Conservation Therapy

The shift toward less radical surgery at the time of mastectomy occurred for several reasons. As earlier diagnosis of breast cancer with smaller tumors and less involvement of pectoral muscles occurred, the need for radical procedures decreased. In addition, even with radical mastectomy not all patients were cured, and although regional recurrences were low, patients died of distant disease. The morbidity of the radical mastectomy was well documented, including lymphedema, immobility of the shoulder, and disfigurement. A shift to breast conservation followed the same trends. The initial trials with radiation therapy using radium implants at the Princess Margaret Hospital in Toronto had promising results.

This led to randomization studies comparing breast-conservation therapy with mastectomy. Table 50.9 lists randomized trials that compared radical and modified radical mastectomy in stage I and stage II carcinoma of the breast.

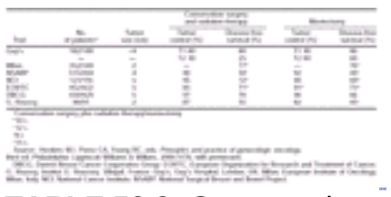

TABLE 50.9. *Conservation surgery and irradiation in Stage I and II carcinoma of the breast: Results of randomized comparisons with radical or modified mastectomy*

In breast-conserving surgery, a wide local excision is performed with excision of the tumor and a 1- to 2-cm rim of normal tissue. This excision is referred to as “lumpectomy” or a “tumorectomy.” This differs from a quadrantectomy, in which a resection of the tumor with the overlying skin and the involved quadrant of the breast is performed. The six randomized trials differed with respect to the type of wide local excision performed as well as tumor size in the patients who were randomized. In the Milan trial, a quadrantectomy was performed. In the Insitut Gustave Roussy trial, the “tumorectomy” performed was removal of the tumor and a 2-cm margin of normal tissue. In the United States, the NSABP B-06 trial did not specify the margins on the lumpectomy specimen, providing they were grossly free of tumor.

In all trials, the authors noted comparable disease-free survival in both arms. The only difference noted was in local recurrence. In addition to the randomized trials, there are many nonrandomized reports published with similar results in survival between breast conservation and mastectomy.

Radiation therapy is an important component of breast conservation. Adequate surgical margins are required to be negative on pathologic inspection. After healing, the radiation therapy is planned. Treatment to the entire breast should be at a dose of 1.8 to 2.0 Gy per day for a total of 45 to 50 Gy. A 10- to 15-Gy electron-therapy boost is often given to the lumpectomy bed.

Breast conservation depends on the use of radiation. The question of whether lumpectomy alone would yield similar results has been addressed through randomized trials. Local recurrence rates of 18% to 40% with lumpectomy alone have been reported compared with 2% to 14% with lumpectomy and radiation. In these studies, a significant reduction in relapse was noted in the lumpectomy-and-radiation arm.

The NSABP B-17 trial is the only randomized trial of lumpectomy alone versus lumpectomy and radiation in patients with DCIS. Ipsilateral relapse was 7% in the radiation arm versus 16.4% in the lumpectomy-alone arm. Actuarial 5-year survival showed an ipsilateral recurrence rate of 7.5% for noninvasive and 2.9% for invasive recurrence in the lumpectomy-plus-radiation arm. By comparison, the rates were 10.4% and 10.5%, respectively, in the lumpectomy-alone arm. The overall survival was excellent and comparable to that seen with mastectomy. In cases of invasive recurrence, patients in the lumpectomy-plus-radiation arm can be salvaged with mastectomy.

Patient Selection

Possible contraindications can interfere with offering a patient breast-conservation therapy. Cosmetic result should be considered when deciding whether to offer breast-conserving surgery; tumor size in relation to breast size is an important consideration. In addition, other factors that may affect the ability to receive irradiation must be considered (i.e., history of prior breast or chest irradiation, concurrent pregnancy, autoimmune connective-tissue disease). Particularly with a history of systemic lupus erythematosis, radiation may not be a possibility. Women with multiple cancers in the breast are not candidates for this approach and require a mastectomy. In addition, in patients with extensive calcifications on a mammogram suggesting a diffuse process may be better treated with mastectomy.

An area of controversy remains over the status of negative margins at the time of lumpectomy. Generally a reexcision should be performed. Extensive intraductal component (EIC) is a condition that exists when greater than 25% of the tumor is associated with DCIS. In these cases, the invasive component may be outside the area of the intraductal carcinoma. This has been reported to have a higher relapse rate with breast conservation; however, it is thought to be secondary to margin status, since margin involvement may be an indication of residual intraductal carcinoma. In DCIS, Silverstein and associates developed the Van Nuys prognostic index (VNPI). The system combines the scores for histologic grade, tumor size, and margin status of a lesion in order to obtain an overall score. It considers margins of 1 cm to indicate a decreased rate of local relapse, even with no radiation.

Management of the Axilla

The axilla is a pyramidal space between the arm and thoracic wall. It contains the axillary vessels and their branches, the brachial plexus and its branches, and lymph nodes embedded in fatty tissue. The primary route of lymphatic drainage of the breast is through the axillary lymph nodes. The lymph nodes are also divided into levels based on location relative to the pectoralis minor. Level 1 lymph nodes lie lateral to the lateral border of the pectoralis minor muscle. Level 2 nodes lie behind the pectoralis minor muscle, and level 3 nodes are medial to the medial border of this muscle.

In an axillary dissection, nerve branches of the brachial plexus are encountered. The lateral and medial pectoral nerves supply the pectoralis muscles. The thoracodorsal nerve runs downward, and innervates the latissimus dorsi. The long thoracic nerve is located on the medial wall of the axilla on the serratus anterior. It arises from the C5 to C7 roots, and injury to these nerves results in paralysis to part or all of the serratus anterior. The functional deficit is inability to raise the arm above the level of the shoulder.

At the time of Halsted's radical mastectomy procedure, a complete axillary dissection was performed. The status of the axilla is the most important prognostic factor for breast cancer. The use of axillary dissection has, in the past, been demonstrated to significantly decrease local recurrence, which may ultimately translate to a survival advantage.

Clinical examination of the axilla is inaccurate, since even in patients with a T1 lesion, there is a 10% risk of lymph node metastasis. Prior to the use of sentinel lymph node biopsy, there was no accurate method to adequately stage the axilla without an axillary dissection. Axillary lymph node sampling (i.e., removal of only a few lymph nodes) was inadequate.

Metastatic involvement of lymph nodes usually occurs in a stepwise manner. Rosen and co-workers demonstrated the incidence of ?skip metastasis? to be less than 2%. A complete level 1 and 2 lymph node dissection provides excellent local control, and local recurrence after this procedure has been shown to be less than 1%. The NSABP B-04 trial randomized patients with clinically negative nodes to one of three groups: radical mastectomy, total mastectomy with nodal irradiation, or total mastectomy alone. The patients who had no axillary nodal therapy had an overall worse survival if recurrence occurred.

The morbidity associated with axillary lymphadenectomy is not inconsequential. About 10% to 15% of patients will develop lymphedema. In addition, numbness, pain, or weakness contribute to a significant decrease in the quality of life in these patients.

Sentinel Lymph Node Biopsy Sentinel lymph node (SLN) biopsy in breast cancer evolved out of efforts to minimize the morbidity associated with axillary lymph node dissection while still providing important staging information. Initial studies in melanoma, by Morton and colleagues in 1992, demonstrated the feasibility of the concept. Methods employed include use of blue dye or radioisotope (Fig. 50.5).

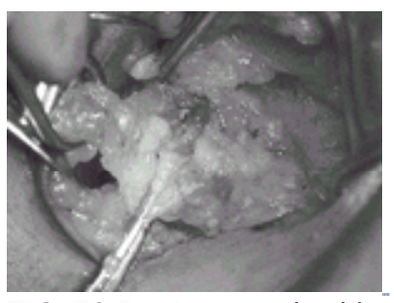

FIG. 50.5. Intraoperative identification of the sentinel lymph node.

Several studies have confirmed the accuracy of SLN biopsy. In the majority of the studies, successful identification of the SLN occurs between 92% and 98% of the time. The combination of blue dye and isotope has been reported to be better for identification of the SLN; when used in combination, the positive predictive value of the technique approaches 100%, with a negative predictive value close to 95%. The false-negative rate is about 5% to 10% in most studies. The validity of the SLN concept lies in the ability of the SLN to predict the status of the regional lymphatic basin. Turner and colleagues performed IHC staining of all lymph nodes, sentinel and nonsentinel, in a series of patients undergoing standard axillary dissection with negative nodes. Of 157 SLNs, 10 (6%) demonstrated IHC positivity compared with 1 of 1,087 (0.09%) of the non-SLNs. This provided validity of the SLN concept. Overall, greater scrutiny is paid to SLNs through serial sectioning and IHC stains. This is

possible because only a few SLNs are obtained at the time of the procedure, and would not be cost-effective in a standard axillary dissection that yields an average of 20 nodes. The use of the SLN biopsy procedure is widely employed in invasive breast cancer. In certain situations, however, a standard axillary dissection should still be considered. These include:

- in cases of palpable suspicious nodes
- in cases of large lesions (the majority of reports indicate that the procedure is reliable if there are no suspicious nodes in the axilla)
- in cases of prior radiation, of a large excisional cavity close to the axilla, or any condition in which disruption of the lymphatics is suspected.

Systemic Treatment

Adjuvant treatment in breast cancer was first used over 100 years ago. In 1894, Beatson reported on the results of oophorectomy and response rate in the metastatic breast cancer setting. Initially, the use of systemic therapy involved the use of single-agent chemotherapy; later, multi-agent chemotherapy was employed. As in most breast cancer trials, the initial reports were of patients with metastatic disease.

Multiple randomized studies have demonstrated that the addition of chemotherapy improves overall survival in patients with breast cancer. The decision to use adjuvant chemotherapy or hormonal therapy depends on certain factors such as the size of the primary tumor, lymph node status, and the presence or absence of metastatic disease. In addition, the expression or lack of expression of ER or PR (ER/PR status) is also an important factor.

Adjuvant chemotherapy is standard treatment for patients with positive nodes or large tumors. The combination of CMF (cyclophosphamide, methotrexate, and 5-fluorouracil [5-FU]) has been used for many years in the treatment of patients with breast cancer. An anthracycline-based regimen such as FAC (5-FU, adriamycin, and cyclophosphamide) has been used in patients with high risk factors for recurrence. The use of paclitaxel is also considered in this setting. For patients with intermediate risk factors, such as ER-negative tumors (>1 cm in size) and negative nodes, chemotherapy is considered.

The Early Breast Cancer Trialists' Collaborative Group was formed in 1985 to analyze all available, properly conducted, randomized trials. A second overview was done in 1990, and a third in 1995. In women under the age of 50, administration of multi-agent chemotherapy decreased the annual risk of relapse by 35% and mortality by 27%. With 10 years of follow-up, this translates into absolute gains of 7% in patients with node-negative tumors and 11% in those with node-positive tumors. For women over the age of 50 years, the benefits of chemotherapy were smaller but still significant. Annual risk reduction was 20% for recurrence and 11% for mortality. At 10 years of follow-up, this risk reduction translated into absolute gains of 2% in patients with node-negative tumors and 3% in patients with node-positive tumors. It is important to note that in the overview, different regimens of CMF were used; but the greatest benefit was seen in those using CMF for 6 months or longer.

The question of whether to use CMF or FAC in high-risk patients (tumors = 2 cm in size or ER/PR-negative with negative nodes) has been addressed. While the anthracycline regimen is more toxic than CMF, trials have shown superiority with this regimen. Presently, other factors are used to determine which regimen to recommend in this subgroup. The most promising candidate factor is HER2/ *neu* overexpression because increased response rates with an anthracycline-based therapy have been reported in cases where there is overexpression of HER2/ *neu*.

The use of taxanes such as docetaxel and paclitaxel as adjuvant treatment in combination with anthracycline-based chemotherapy is being investigated. Postmenopausal women with negative nodes and ER-negative tumors greater than 1 cm in size are also considered for chemotherapy. In these patients, CMF is usually the treatment of choice.

Metastatic Disease

The goal of therapy in metastatic disease is palliation of symptoms, as cure is unlikely. The majority of patients with metastatic disease receive antihormonal therapy. First-line agents include tamoxifen, or aromatase inhibitors such as letrozole or anastrozole. These agents offer a 20% response with in ER/PR-positive tumors. Disease stabilization is the goal of therapy, and because these therapies are less toxic than chemotherapy, most patients will remain on them for prolonged periods of time. Upon failure of these agents, however, chemotherapy is the next step.

High-Dose Chemotherapy

Five large randomized trials have been conducted addressing the use of high-dose chemotherapy with bone-marrow or stem-cell rescue in metastatic breast cancer. Only one trial, conducted in South Africa, showed a lower rate of relapse. The other four trials showed no increase in overall survival. The investigators of the trial conducted in South Africa subsequently admitted to fraud. Thus, it is felt that high-dose chemotherapy offers no survival advantage over conventional treatment approaches.

Neoadjuvant Chemotherapy

Preoperative or neoadjuvant chemotherapy is attractive, as it may reduce the amount of disease present and thereby facilitate in obtaining clean surgical margins when the disease is still confined to the breast. This is often the case in inflammatory breast cancer, or in N2 disease, in which neoadjuvant chemotherapy may improve surgical resectability. A significant response of 50% to 90% has been seen with this approach.

Down-staging of the tumor, as well as the axillary lymph nodes, has been reported.

The NSABP B-18 trial randomized patients with operable breast cancer to receive adjuvant chemotherapy preoperatively for four cycles followed by reevaluation for surgical treatment. Results for this group were compared with those for patients who received surgery followed by adjuvant chemotherapy. Preoperative chemotherapy was associated with a higher incidence of breast conservation. Also, a significant reduction in the number of positive axillary nodes was noted in the preoperative chemotherapy group. There was, however, no difference in overall survival between those patients who received preoperative chemotherapy and those who received postoperative chemotherapy. Several subsequent trials have reported a higher local recurrence rate for patients treated with neoadjuvant chemotherapy and breast-conservation therapy.

Radiation Therapy

Radiation therapy is used in conjunction with lumpectomy for patients opting for breast conservation. The dose used is 1.8 to 2.0 Gy per day for a total of 45 to 50 Gy to the entire breast. A 10- to 15-Gy electron-therapy boost is often given to the lumpectomy bed.

Postmastectomy chest-wall irradiation is used with increasing frequency. Patients with large tumors (T3 lesions) and more than four positive nodes are offered chest-wall radiation because they are at risk for local–regional failure. Chest-wall radiation is 50 Gy over 5 weeks, with a 10-Gy boost to the mastectomy scar. For patients with a chest-wall recurrence, the option of surgical debulking followed by chest-wall irradiation is employed.

Radiation therapy can also be used in the palliative setting. It can be used for metastatic lesions to the bone or brain and can help to alleviate the patient's symptoms.

Stage-Directed Therapy

Patients with intraductal carcinoma and stage I and stage II breast cancer have the options of breast-conservation therapy and mastectomy.

For patients with invasive breast cancer, the axillary nodes can be addressed with an SLN biopsy and, possibly, an axillary dissection.

In intraductal carcinoma, an SLN biopsy or axillary dissection is generally not indicated. There are special circumstances of intraductal carcinoma such as high-grade DCIS or extensive DCIS in which a microinvasive component may be associated with the intraductal carcinoma. In these circumstances, particularly if a mastectomy is being performed, an SLN biopsy may be considered.

For patients with more extensive disease, a mastectomy may be necessary. The use of postmastectomy chest-wall irradiation in these patients may also be considered.

Breast Reconstruction

Breast reconstruction represents a major advance in cancer rehabilitation for patients undergoing a mastectomy. Previously, a 2-year surveillance period was recommended prior to reconstruction for detection of local disease recurrence. Immediate reconstruction has not interfered with disease detection, however, and it has the advantage of combining the two procedures into one. In addition, a greater amount of skin can be saved with planned immediate reconstruction, and the scar tissue that would be encountered with delayed procedure can be avoided.

A delayed reconstruction can be performed if the patient is ambiguous about the reconstruction, or if operative risk is increased with prolonged anesthesia. It is also considered in those patients with locally advanced disease if a delay in adjuvant irradiation or chemotherapy is anticipated because of the reconstruction.

Reconstruction options include expandable breast prosthesis (implant) and autologous tissue transfer. Tissue-transfer operations may yield the greatest symmetry between breasts, especially with larger breasts; however, they take longer, require greater surgical expertise, involve a longer recovery, and result in another scar at the donor site. The donor site may be the latissimus dorsi, transverse rectus abdominus, or gluteal muscle.

SPECIAL ISSUES

Hereditary Breast Cancer

One of the most characteristic features of hereditary breast cancer is its tendency to manifest at a young age. In the Breast Cancer Consortium's study of *BRCA1*-linked families that transmit *BRCA1* mutations, more than 80% of breast cancers occurred in women under 50 years of age.

Pathologic Features Most *BRCA1*-associated breast cancers have been reported to be of an infiltrating ductal type with an over-representation of poorly differentiated high-grade types. The tumors tend to be ER/PR-negative. Less than 20% of these cancers are ER/PR-positive, even when age matched with non– *BRCA1*-associated controls. In *BRCA2* there is less of this over-representation of aggressive histology. Overall, *BRCA2*-associated breast cancers tend to be ER/PR-positive.
Stage Most studies demonstrate that *BRCA*-associated breast cancers are seen at a stage comparable to non– *BRCA*-associated breast cancers. The incidence of axillary metastasis does not appear to be significantly different in patients with *BRCA*-associated breast cancers. In the literature, conflicting study data exist regarding the prognosis of patients with *BRCA*-associated breast cancer. Some studies have conferred a worse prognosis in patients with certain mutations in *BRCA1*. Some of these reports have been of highly selected groups of women, and thus further study is necessary in larger series of women with *BRCA1* and *BRCA2* mutations.
Treatment Although some researchers have questioned the role of breast-conservation therapy in women with hereditary predisposition, there is no reason to suspect a unique survival advantage for mastectomy in these women. Studies that have examined the outcomes of breast-conservation therapy in women with *BRCA* mutations are small with variable follow-up. Local ipsilateral recurrence appears to be about 15% at 5 years. Although this is higher than would be expected for patients treated with breast-conservation therapy, it is within the range observed for treatment of young women with breast cancer. It is likely to be an influence of the age at diagnosis and not because of radiation resistance. After breast-conservation therapy, however, the breast tissue remains at risk for developing a second primary. Women with *BRCA* mutations may be at risk for a late ipsilateral recurrence because of the development of a second primary breast cancer. The degree of contralateral risk needs to also be addressed with patients. Some studies have reported an estimated average risk of 2.5% to 5% per year in *BRCA1* mutation carriers, and this risk may be higher with younger age at diagnosis. In patients with *BRCA2*, the risk appears lower, estimated at 1.8% per year. Unlike the *BRCA1*-associated risk, in *BRCA2* the age dependence is unknown.

Chemoprevention

Chemoprevention is the principle that cancer prevention can be achieved through pharmacologic intervention. It refers to the use of a medication in a healthy patient to reduce the risk of a particular cancer. It is an option for all women with significant risk for future breast cancer development. Currently, the only FDA-approved medication for prevention of breast cancer is tamoxifen. Tamoxifen is a selective estrogen-receptor modulator that acts as an antiestrogen in breast tissue. It has been used in the adjuvant setting in breast cancer since 1972 for both metastatic and early breast cancers. A reduction of 40% to 50% in contralateral breast cancer was seen in the adjuvant setting; thus, it was thought to be an ideal agent to use in a chemopreventive setting.

The trial to determine the role of tamoxifen in chemoprevention was performed by the NSABP. In this randomized, double-blinded trial, women with a projected risk of breast cancer of greater than 1.66% over a 5-year period received either tamoxifen or a placebo for a period of 5 years. The Gail model was used to assess the risk. When an independent reviewing agency verified a 50% reduction in both invasive and noninvasive breast cancer cases in the population taking tamoxifen, the trial results were unblinded earlier than expected. Shortly thereafter, the use of tamoxifen was approved for chemoprevention.

Two other chemoprevention trials using tamoxifen have been reported: the Italian tamoxifen-prevention study and the Royal Marsden Hospital tamoxifen trial in the United Kingdom. These two trials did not reveal a statistically significant reduction in breast cancer risk in women randomized to tamoxifen. However, the studies differed in respect to subject numbers, median age, eligibility criteria, risk, and use of HRT.

Raloxifene is also a selective estrogen-receptor modulator (SERM) and is FDA-approved for use in osteoporosis. In studies in which raloxifene was used for treatment of osteoporosis, a secondary finding was a noted reduction of breast cancer risk of 50% to 70% in the population taking the medication. The women in those trials were at fairly low risk of breast cancer development. A randomized, double-blinded trial to compare raloxifene with tamoxifen in a population of postmenopausal women at increased risk for breast cancer development is currently open, the Study of Tamoxifen and Raloxifene (STAR) trial/P-2 study. In the NASBP P-1 study there was an increased risk of developing endometrial cancer with tamoxifen use (annual risk 2.3/1,000 women vs. 0.9/1,000 women in the placebo group). All cases of endometrial cancer in the patients taking tamoxifen were early stage. Another important side effect noted was a higher incidence of thromboembolic phenomena. Raloxifene does not increase the risk of endometrial cancer and thus may prove to be an alternative to tamoxifen in a chemopreventive role. An ideal SERM would have an antiestrogenic activity on breast and uterine tissues, but estrogenic effects on bone and the cardiovascular system among others. Current investigations into other SERMs are being conducted.

CONCLUSIONS

Screening for breast cancer is clearly indicated for all women at the appropriate age. Determining a woman's unique risk factors will help to determine both the age at which that screening should begin and also the intensity of that screening. It will also help to identify those women who need to be counseled regarding options for prevention of breast cancer. The hope is that, by correctly identifying high-risk populations and then applying appropriate screening schedules and chemopreventive agents, many cases of breast cancers will be averted completely and that those that still occur will be found at the earliest stages. The role of the obstetrician and gynecologist in providing information on breast cancer diagnosis and screening is very important.

In addition, the understanding of breast disease, benign and malignant, is crucial not only in the diagnosis of disease, but also in helping to guide women in their treatment and follow-up.

Vaginal Cancer

Vulvar and vaginal cancer represent uncommon gynecologic cancers that occur most often in older women. Squamous lesions are the most frequent histology and risk factors are similar for both disease sites. This chapter describes the epidemiology, clinical presentation, patterns of spread, and treatment of squamous cell carcinomas of the vulva and vagina. Less common histologic subtypes including Paget disease, melanoma, adenocarcinomas, and sarcomas are also reviewed.

VULVAR CARCINOMA IN SITU

Vulvar carcinoma theoretically results from malignant transformation of a vulvar carcinoma in situ as is seen with cervical squamous lesions. Unlike squamous lesions of the cervix, the natural history of vulvar intraepithelial neoplasia (VIN) is less well understood. The incidence of vulvar dysplasia has increased over the last 20 years, particularly among younger women. A report from Austria demonstrated a 307% increase in the overall incidence of high-grade VIN and a 394% increase among women under 50 years of age between 1985 and 1998. In a review of Surveillance, Epidemiology, and End Results (SEER) data, Sturgeon found that the incidence of VIN III nearly doubled between 1973 and 1976 and 1985 and 1987, from 1.1 to 2.1 per 100,000 woman years. Factors implicated in this increase include increased human papillomavirus (HPV) infection, increased surveillance, tobacco use, and immunosuppression, either with human immunodeficiency virus (HIV), organ transplant, or diabetes.

Patients with VIN most commonly present with pruritis and vulvar lesions. These lesions may appear scaly, white, red, or hyperpigmented (Fig. 51.1, Fig. 51.2, Fig. 51.3 and Fig. 51.4). Careful inspection with 5% acetic acid and liberal use of punch biopsy are the cornerstones of diagnosis. An underlying malignancy may be present in 7% to 22% of patients who undergo surgical excision for vulvar carcinoma in situ. Wide local excision with at least a 5-mm margin is the preferred management option as it allows pathologic confirmation and is associated with less morbidity than skinning vulvectomy. Skinning vulvectomy with split thickness skin graft may be an option in patients with widespread disease. Laser ablation is also an effective nonmutilating option in patients with multifocal or clitoral disease. Recurrences are frequent (10%–50%) despite negative surgical margins and therapy should be tailored to symptom control and ruling out underlying malignancy. Patients should be followed every few months with careful visual inspection of the vulva and taught self-exam skills as well.

Epidemiology

Vulvar carcinoma is the fourth most common genital tract malignancy in women, representing 3% to 5% of gynecologic malignancies and affecting an estimated 3,600 women in the United States in 2001. The majority of cancers are squamous in origin with occasional cases of basal cell carcinoma, melanoma, adenocarcinoma, and Paget disease.

Vulvar cancer tends to be a disease of older women with a mean age at diagnosis of approximately 65 years. As the population ages, more older women will be at risk for vulvar carcinoma. Evidence exists that there are two distinct types of vulvar carcinoma with different etiologies. Tumors in older women are often unifocal and may be associated with chronic vulvar inflammation of long-standing duration such as lichen sclerosus or hyperplastic dystrophy. These keratinizing squamous cell carcinomas have associated HPV changes in only 6% of cases. While retrospective studies indicate that up to 50% of vulvar carcinomas are related to hyperplastic dystrophies and lichen sclerosus, prospective studies have demonstrated only 5% of women with vulvar dystrophies develop invasive carcinoma. Cancers found in younger women tend to be multifocal with adjacent VIN and have a basaloid or warty histology. Nearly 90% are associated with HPV infection, particularly HPV 16. Thirty-eight percent of women with HPV-associated lesions in a series by Trimble and colleagues were under age 55, compared with only 17% of those with classic keratinizing squamous cancers. Other associated risk factors include immunosuppression from chronic steroid use, diabetes or HIV, smoking, and a history of other lower genital tract dysplasia or neoplasia.

Presentation

Most women present with pruritis and an identifiable lesion (Fig. 51.5, Fig. 51.6). Less common symptoms include pain and bleeding. Unfortunately, there is often a delay of many years between onset of symptoms and diagnosis. This is in part because patients self-medicate with a variety of over-the-counter preparations rather than seeking care and also because physicians may not biopsy liberally. The cornerstone for diagnosis of vulvar malignancy is a low threshold for a punch biopsy as it may be extremely difficult to distinguish between dysplasia, chronic vulvar dystrophy, and carcinoma. Any patient with symptoms lasting for longer than 2 weeks deserves a thorough exam and a biopsy. In order to adequately evaluate a patient with a vulvar lesion, 5% acetic acid is applied to the vulva for 5 minutes and then the area is examined either with the naked eye or a handheld magnifying glass. The entire vulva including the hair-bearing, perianal, and periclitoral regions should be examined for suspicious ulcerations and hyperpigmented, acetowhite, or gross warty lesions. Up to 5% of patients will have multifocal disease and may require multiple punch biopsies.

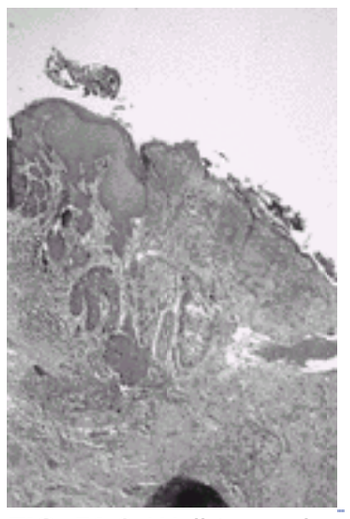

FIG. 51.6. Well-to-moderately differentiated invasive squamous cell carcinoma of the vulva.

Staging/Spread Patterns

An International Federation of Gynecologists and Obstetricians (FIGO) surgical classification system replaced clinical staging for vulvar cancer in 1989 (Table 51.1). By relying on histopathologic classification of the lymph nodes, the new system more accurately reflects prognosis since the previous system provided an inaccurate assessment of groin node involvement in one-fourth of cases.

Stage 0	Carcinoma in situ, intraepithelial neoplasia grade III
Stage I	Lesions ≤ 2 cm in size (T1), confined to the vulva or perineum, no nodal metastasis
Ia	Lesions ≤ 2 cm in size, confined to the vulva or perineum and with stromal invasion ≤ 1.0 mm, no nodal metastasis
Ib	Lesions ≤ 2 cm in size, confined to the vulva or perineum and with stromal invasion >1.0 mm, no nodal metastasis
Stage II	Tumor confined to the vulva or perineum; >2 cm in greatest dimension (T2); no nodal metastasis
Stage III	Tumor of any size with adjacent spread to the lower urethra or vagina, the anus, or unilateral regional lymph node metastasis
Stage IVa	Tumor invades any of the following: upper urethra, bladder mucosa, rectal mucosa, pelvic bone, or bilateral regional node metastases
Stage IVb	Any distant metastasis including pelvic lymph nodes

FIGO, International Federation of Gynecology and Obstetrics.

TABLE 51.1. *Vulvar carcinoma: FIGO staging 1994*

Local spread occurs to contiguous structures such as the vagina, urethra, and rectum. Metastatic spread via lymphatics is common and has been well characterized by anatomic studies. Ipsilateral lesions tend to be characterized by spread to the ipsilateral groin nodes first, followed by contralateral groin, and then pelvic nodes. Lesions that cross the midline may have lymphatic drainage to both groins. Metastasis to the contralateral groin or pelvic nodes is highly unusual in the absence of ipsilateral groin node involvement. The superficial inguinal nodes above the cribriform fascia are believed to be involved prior to the deep femoral nodes below the cribriform fascia. Risk of lymphatic spread is related to tumor size, tumor thickness, older patient age, tumor grade, presence of lymphovascular space invasion, and clinically suspicious groin nodes. Groin node metastasis was found in 19% of patients with lesions =2 cm and in 42% of patients with lesions greater than 2 cm. The Gynecologic Oncology Group (GOG) surgicopathologic staging analysis demonstrated that lymph node dissection could be safely omitted in patients with less than 1 mm of stromal invasion. Hematogenous metastasis to distant organs such as bone, liver, and lungs is rare as a primary event but may be seen in patients with recurrent disease.

Treatment

Historically vulvar cancer has been treated with en-bloc radical vulvectomy and bilateral inguinofemoral lymphadenectomy or “longhorn incision” (Fig. 51.7, Fig. 51.8 and Fig. 51.9). This technique resulted in a median hospitalization of 30 days, 70% to 90% wound breakdown, and chronic debilitating lymphedema in nearly 9% of women. Significant disruption in self-image and sexual function also occurred. Attempts to decrease morbidity first led to the use of separate incisions for groin node dissection while continuing to use radical vulvectomy. In 1981, Hacker and colleagues reported a series of 100 patients who underwent radical vulvectomy and lymphadenectomy through three separate incisions. The incidence of major wound breakdown was only 14% with a mean hospitalization shortened to 19 days. This procedure lead to the shortest length of hospitalization reported at that time and produced a dramatic decrease in complications. The majority of local recurrences were salvaged with repeat excision. Overall survival was not compromised by deviating from en-bloc dissection and the authors concluded that this technique is appropriate for patients with stage I and II vulvar carcinoma.

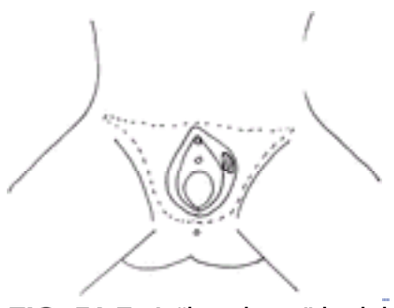

FIG. 51.7. A “longhorn” incision. Radical excision of the vulva from genitocrural fold to genitocrural fold, deep to the inferior fascia of the urogenital diaphragm along with en-bloc lymphadenectomy.

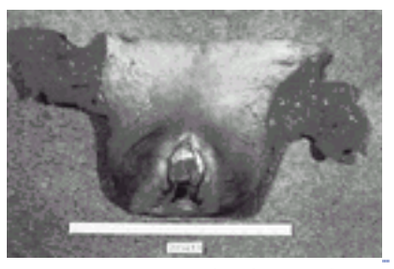

FIG. 51.8. Surgical specimen after en-bloc radical vulvectomy and inguinofemoral lymphadenectomy via longhorn incision.

FIG. 51.9. Healed vulva after en-bloc resection via longhorn incision.

DiSaia and associates first proposed conservative vulvar surgery in 1979 as a way of preserving sexual function in young patients. Requirements for conservative surgery were an invasive cancer 1 cm or less in diameter confined to the vulva with less than a 5-mm depth of invasion. Patients were treated with radical wide excision ensuring a 3-cm margin and lymphadenectomy was performed through separate groin incisions. There were no recurrences at a mean follow-up of 32 months and sexual function was deemed preserved. The authors concluded that there existed a subset of patients with vulvar cancer who could be treated with less radical vulvar procedures.

Berman and co-workers expanded the experience with conservative surgery in 1989 with a report of 50 patients with T1 lesions treated with radical local excision, again providing a 3-cm margin and superficial lymphadenectomy. No patient had a resection margin positive for carcinoma. Median hospital stay was shortened to 7 days and only 12% required wound debridement compared to 50% or more with historical controls. There were five recurrences (10%), four of them local. All local recurrences were salvaged with a second local resection.

In 1990, Burke and colleagues provided the first report of a conservative vulvar surgery in patients with both T1 and T2 lesions. Thirty-two patients (15 with T2 lesions) underwent radical wide excision removing a 1- to 2-cm margin of normal tissue in addition to selective inguinal dissection. The mean lesion diameter was 23 mm with a mean depth of invasion of 4.1 mm. No patients had invasive cancer at the surgical margins but 19% were positive for VIN. The authors reported only 15.5% wound separation with a mean hospital stay of 10 days. Three patients (10%) developed local recurrence and two were salvaged with repeat excision. The authors concluded that radical wide excision appears to be an acceptable surgical option for patients with resectable vulvar carcinomas.

As these retrospective trials used differing criteria to identify patients suitable for less radical approaches, the GOG conducted a prospective trial beginning in 1983 which evaluated modified radical hemivulvectomy and ipsilateral superficial inguinal lymphadenectomy in 155 patients with clinical stage I vulva carcinoma limited to a depth of invasion of less than 5 mm. A 2-cm margin of normal skin around the lesion was excised. There were 19 recurrences and 7 deaths among 122 patients available for evaluation. Recurrences were evenly distributed between local and distant failures. Acute and long-term morbidity was decreased significantly compared to historical controls, but at the cost of increased risk of local recurrence. The authors concluded that although there was no consensus regarding the characteristics that would make a patient with early vulvar carcinoma a candidate for a limited surgical approach, this approach appeared to be an alternative to traditional radical surgery for a highly selected group of patients with stage I vulvar carcinoma (Fig. 51.10, Fig. 51.11).

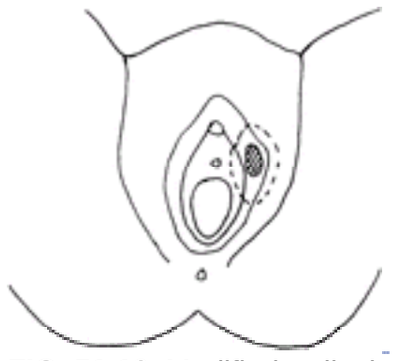

FIG. 51.10. Modified radical vulvectomy. Radical excision of the vulva deep to the inferior fascia of the urogenital diaphragm with a 2-cm margin around the lesion.

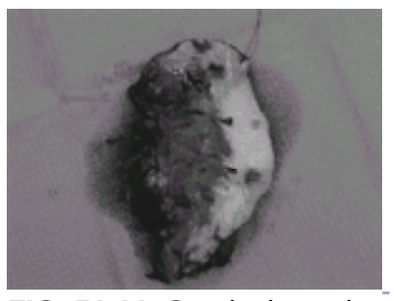

FIG. 51.11. Surgical specimen after modified radical vulvectomy. Lymphadenectomy is performed through separate incisions.

A need for establishing a clear margin for treatment of patients with vulvar cancer may be more important than the particular treatments. Heaps and colleagues reviewed surgicopathologic factors predictive of local recurrence in 135 patients treated with radical vulvectomy or radical local excision. Twenty-one developed local recurrence after radical resection. No patient with a surgical tumor-free margin = 8 mm suffered from local recurrence but 48% with less than an 8-mm margin recurred locally. As an 8-mm margin on fixed tissue corresponds to 10-mm margin with fresh tissue, the authors concluded that use of a 1-cm margin should successfully prevent local recurrence and reduce the currently used standard margin by over 50%. This would allow further modification of the procedure in order to decrease morbidity and avoid disfigurement and loss of organ function without sacrificing survival.

Other modifications in the surgical management of vulvar carcinoma over the last 30 years include the elimination of routine pelvic lymphadenectomy and elimination of contralateral groin node dissection in patients with lateral T1 lesions and negative ipsilateral nodes.

Overall survival in vulvar carcinoma is related to groin node status and lesion diameter with nodal status being the most important factor. Five-year survival is 98% for patients with negative nodes and a T1 lesion. Patients with one to two positive ipsilateral nodes have over 70% to 80% 5-year survival while those with three or more positive nodes or bilaterally positive nodes have survival in the range of 12% to 36% (Table 51.2). Postoperative adjuvant groin radiotherapy is indicated in patients with more than one positive node or clinically evident groin nodes.

Node status	Lesion size	Relative 5-y survival (%)
Negative	≤ 2 cm	98
Negative	2.1–8.0 cm	87
One positive	≤ 2 cm	87
Negative	>8 cm	75
One positive	>2 cm	75
Two unilaterally positive	≤ 8 cm	75
Two unilaterally positive	>8 cm	29
Three or more positive	Any	29
Bilaterally positive	Any	29

TABLE 51.2. *Survival by groin node status and lesion size in vulvar carcinoma*

Radiotherapy for vulvar carcinomas is indicated in patients with unresectable vulvar tumors or unresectable groin nodes. Boronow popularized treatment of locally advanced tumors with radiotherapy followed by resection of the primary tumor in order to preserve urethral, bladder, or rectal function and to avoid the morbidity of pelvic exenteration. In recent years, concurrent radiotherapy and chemotherapy has been shown to improve both local control and overall survival. The GOG has demonstrated high rates of resectability and local control of the lymph nodes in patients with clinically suspicious, fixed, or ulcerated nodes treated preoperatively with radiotherapy, concurrent cisplatin/5-fluorouracil (5-FU) chemotherapy, and followed by tailored surgery.

New approaches to decrease morbidity of groin node dissection include the use of lymphatic mapping and sentinel lymph node biopsy. Intraoperative mapping with vital dye with or without lymphoscintigraphy may identify 56% to 100% of sentinel nodes. While this technique is widely used for breast cancer and melanoma, it is being prospectively evaluated by the GOG and other investigators. If the sentinel node can predict lymph node involvement with sufficiently high negative predictive value, then more extensive lymphadenectomy may be avoided. This may decrease one of the major morbidities of vulvar cancer surgery.

Recurrence after definitive therapy for vulvar carcinoma may occur locally in the vulva or in the groin. The risk of local recurrence depends on prior surgical technique with higher rates of recurrence seen with less aggressive vulvar approaches. Vulvar recurrences may be characterized as new primaries due to field effect or recurrence at the prior site of excision. They are usually salvageable with radical excision though patients who have had prior radiotherapy to the groin will require some type of reconstructive flap to ensure adequate vascular supply and healing. Groin recurrences are much more difficult to treat. If the patient has not been irradiated, surgical excision of the nodes with postoperative radiotherapy is the treatment of choice. If radiotherapy has already been administered, no satisfactory therapy exists and survival is dismal.

Other Histologic Subtypes

Rare histologic types of vulvar carcinoma exist, representing about 10% of vulvar malignancies. These include melanoma, invasive Paget disease, basal cell carcinoma, verrucous carcinoma, Merkel cell carcinoma, adenocarcinoma, adenosquamous carcinoma, transitional cell carcinoma, sarcomas, and metastatic disease from other sites.

Melanoma Melanoma is the second most common vulvar malignancy, accounting for about 6% of vulvar lesions and 1.3% of all melanomas among women. It is highly aggressive and characterized by both local recurrence and distant metastasis through hematogenous spread. The median age at presentation is 66 years, several decades older than for cutaneous melanomas. It is more common in white women with a relative risk of 2.6 compared to other races. Overall 5-year survival ranges from 35% to 50%. Patients frequently present with pruritis and visible lesions but many may be asymptomatic. The differential diagnosis of a pigmented lesion includes melanoma, lentigo, vulvar melanosis, squamous dysplasia, hemangioma, Paget disease, various nevi, and acanthosis nigricans. Biopsy should be considered of any pigmented lesion, particularly if the borders are indistinct r spreading or the lesion is raised. Excisional biopsy is preferred to better delineate depth of invasion. A punch biopsy of the most nodular area is the next best option. Three histologic subtypes of vulvar melanoma have been described. The most common is superficial spreading melanoma followed by nodular and acral lentiginous melanoma. Immunohistochemical testing may be necessary to distinguish between melanoma and Paget disease. Paget disease is typically positive for carcinoembryonic antigen (CEA) and melanoma is positive for S-100. Unlike squamous lesions, vulvar melanoma is staged using classification systems for cutaneous melanomas. The Clark system is based on level of invasion, while the Breslow system is based on vertical thickness of the lesion from the surface of intact epithelium to the deepest point of invasion. Other staging systems include Chung's modification of the Clark's system and the American Joint Committee on Cancer (AJCC) staging system (Table 51.3). While the Breslow and Chung microstaging systems are more accurate than the Clark system, prospective evaluation by the GOG found that the AJCC staging system is most predictive of survival (Table 51.4).

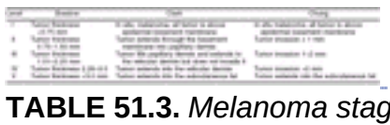

TABLE 51.3. *Melanoma staging: Breslow, Clark, and Chung microstaging levels*

Stage	Description
IA	Primary melanoma <0.75 mm thick or Clark's level II
IB	Primary melanoma 0.75–1.50 mm thick or Clark's level III
IIA	Primary melanoma 1.51–4.0 mm thick or Clark's level IV
IIB	Primary melanoma >4.0 mm thick or Clark's level V
III	Regional lymph node or in-transit metastases
IV	Systemic metastases

TABLE 51.4. *American Joint Committee on Cancer staging for vulvar melanoma*

As with squamous lesions, more conservative vulvar surgery is now being advocated for melanoma. Excision should include a 1- to 2-cm lateral margin and at least a one centimeter deep margin. The presence of capillary lymphatic space involvement and central tumor location has been correlated with positive groin node status. The role of lymphadenectomy in vulvar melanoma remains unresolved. Prospective evaluations have failed to show a survival benefit with lymphadenectomy. Adjuvant therapy for advanced disease includes the use of chemotherapy, immune modulators, and tumor vaccines. Given the small number of patients, no trials specific to vulvar melanoma have evaluated the role of adjuvant therapy.

Paget Disease Paget disease accounts for 1% to 2% of vulvar malignancies. It occurs most frequently in postmenopausal white women and is characterized by red eczematous lesions with a superficial white coating and intense pruritis. As with other vulvar malignancies, there may be a long delay between initial symptoms and diagnosis. Histologic disease may spread well beyond the visible lesion. Biopsy reveals characteristic large eosinophilic cells in the basal layer of the epithelium (Fig. 51.12). Paget disease of the vulva may exist as four clinical entities, the first of which is noninvasive or intraepithelial Paget disease. This represents 60% of cases and is cured with local excision. In invasive Paget disease, the Paget cells penetrate the basement membrane and invade the dermis. Intraepithelial Paget disease may also be associated with an underlying adenocarcinoma of sweat gland origin or a coexistent cancer. Underlying malignancy is seen in approximately 20% to 30% of patients, a rate lower than that seen with mammary Paget disease. Parker and co-workers reported poor survival in patients with invasive Paget disease and in patients with underlying malignancy. Patients with clitoral disease also had a poorer prognosis. Therapy for Paget disease involves wide excision. A skinning vulvectomy with split thickness skin graft is often needed to remove large areas of involved skin. Recurrences tend to be local and range from 7% to 58% with an average of about 30%. Some authors recommend sending margins for frozen section to ensure complete resection while others have not demonstrated a benefit to this approach with respect to recurrence. Radical surgery is reserved for patients with underlying malignancy.

FIG. 51.12. Paget disease of the vulva. Large eosinophilic cells with large nuclei and prominent cytoplasm in basal cells represent Paget cells.

Basal Cell Carcinoma Basal cell carcinoma accounts for 2% to 4% of vulvar malignancies. It is typically seen in older women and tends to be well circumscribed, firm, and typically less than 2 cm in diameter. Metastasis is extremely rare and wide local excision is the preferred therapy.

Verrucous Carcinoma Verrucous carcinoma is a variant of squamous cell carcinoma with distinctive pathologic and clinical characteristics. It is characterized by a large condylomatous or cauliflower-like lesion with minimal cellular atypia, a pushing border, and rare metastasis. Unless biopsies are deep enough, it may be confused with benign condyloma or papilloma. Wide local excision is the preferred therapy. Radiotherapy is contraindicated given the potential for anaplastic transformation.

Merkel Cell Carcinoma Merkel cell tumors are neuroendocrine tumors of the skin and resemble small cell carcinomas. They are associated with lymphatic and distant metastases and have a very poor prognosis.

Adenocarcinoma Adenocarcinoma of the vulva tends to arise in the Bartholin gland, although it may also arise from the sweat glands or Skene glands of the vulva (Fig. 51.13). Adenoid cystic carcinoma also arises from the Bartholin gland and is characterized by slow growth and a tendency for local and perineural invasion (Fig. 51.14). Distant metastasis is most commonly seen in the lung. Therapy involves radical excision, ipsilateral lymphadenectomy, and postoperative radiotherapy.

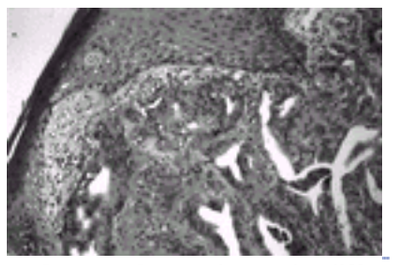

FIG. 51.13. Moderately differentiated adenocarcinoma arising from vulva.

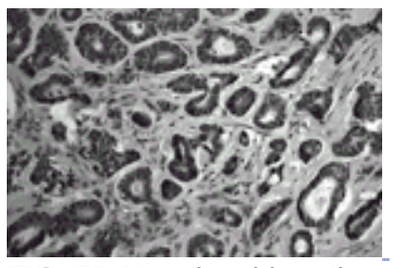

FIG. 51.14. Adenoid cystic carcinoma arising from Bartholin gland.

Adenosquamous Carcinoma Adenosquamous carcinoma is a rare cause of Bartholin gland carcinoma and is composed of both malignant squamous and glandular components.
Transitional Cell Carcinoma Transitional cell carcinoma may arise within the Bartholin gland but is more commonly seen as metastatic spread from a urethral or bladder carcinoma.

Sarcoma

Sarcomas of the vulva are extremely rare, representing only 1% to 3% of vulvar malignancies. While leiomyosarcoma is the most common histologic subtype, malignant fibrous histiocytoma, and various other sarcomas have been reported. Radical surgery is the primary therapy, although the behavior of these neoplasms is not well understood.

Metastatic Disease Metastatic disease to the vulva usually occurs from other lower genital tract malignancies, most commonly cervix. Rare causes include malignancies arising from the vagina, endometrium, ovary, breast, kidney, stomach, or lung.

VAGINAL CARCINOMA

Primary vaginal cancer is the fifth most common gynecologic malignancy, with an expected 2,000 new cases in the United States in 2001. Only fallopian tube carcinomas are a less common gynecologic malignancy than vaginal carcinoma. The vast majority of vaginal neoplasms are metastatic from other sites, particularly direct extension from the cervix or endometrium. Lymphatic or hematogenous spread to the vagina is also possible. Primary vaginal neoplasms are typically squamous in origin and occur in postmenopausal women. Risk factors for vaginal dysplasia or carcinoma include a history of prior lower genital tract dysplasia or carcinoma, tobacco use, low socioeconomic status, history of genital warts or HPV infection, prior abnormal Pap smear, prior radiotherapy of the genital tract, immunosuppression, vaginal discharge or irritation, and early hysterectomy. History of diethylstilbestrol (DES) exposure is associated with development of clear cell adenocarcinoma of the vagina.

Vaginal Intraepithelial Neoplasia

The vagina is the least common site for lower genital tract dysplasia, occurring 100 times less frequently than cervical dysplasia. A review by Dodge and associates of 121 patients with biopsy-proven vaginal intraepithelial neoplasia (VAIN) showed that 65% of women with a uterus in place had associated cervical intraepithelial neoplasia and 10% had associated VIN. The upper third of the vagina is the most common site of involvement and over 60% of these women will have multifocal disease. The mean age for patients with VAIN III is approximately 40 years.

Diagnosis is through careful colposcopic inspection after application of 5% acetic acid and directed biopsy (Fig. 51.15, Fig. 51.16). Due to the rugated nature of the vagina, colposcopic evaluation may be a challenge. It is important to remember to colposcopically evaluate the vagina in patients with cytologic abnormalities, particularly those with normal appearing cervices. Acetowhite epithelium is the most common colposcopic feature. Application of half-strength Lugol solution allows for identification of nonstaining areas, which may represent dysplasia. Most patients with vaginal dysplasia are completely asymptomatic, fewer than 5% will present with bleeding or abnormal vaginal discharge. Postmenopausal patients with atrophy may benefit from a course of vaginal estrogen prior to undergoing colposcopy and directed biopsies.

FIG. 51.15. Vaginal intraepithelial neoplasia III after application of acetic acid. Note acetowhite lesions. See color figure 51.15.

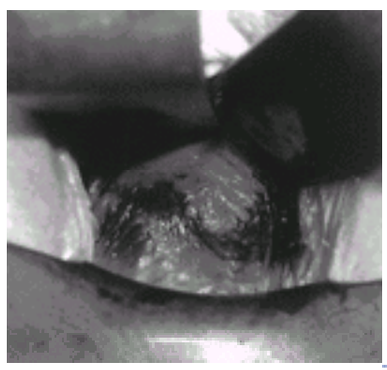

FIG. 51.16. Vaginal intraepithelial neoplasia III after application of Lugol solution. Note nonstaining lesions.

Various treatment options have been employed for therapy of VAIN. These include laser ablation, partial or total vaginectomy, topical 5% 5-FU cream, cavitron ultrasonic aspiration, and loop electrosurgical excision procedure (LEEP). Choice of therapy for VAIN depends on the number and severity of lesions and their location, whether the patient is sexually active, and prior radiotherapy, as well as physician and patient preference. Hoffman and associates found invasive carcinoma in 28% of patients undergoing upper vaginectomy for VAIN III. Overall recurrence rates after therapy range from 10% to 42%. While partial vaginectomy is well suited to unifocal lesions and those involving the upper aspect of the vagina, it may lead to vaginal shortening and sexual dysfunction. Total vaginectomy with split thickness skin graft is reserved for patients who have failed more conservative approaches. Laser ablation to a depth of 2 to 3 mm is associated with minimal blood loss and is well suited for multifocal lesions. The challenge with laser therapy is ensuring that no lesions have been missed among the vaginal rugae. While 5-FU allows patients to treat themselves medically, it may be associated with significant skin desquamation, chronic ulceration, and be poorly tolerated. Dodge and colleagues found that recurrence is highest after laser ablation (38%) and 5-FU (59%) as well among those patients with multifocal disease (45%). Recurrence is lowest after partial vaginectomy (0%). Overall 2% to 12% of patients progress to vaginal cancer after therapy for vaginal dysplasia so careful cytologic and colposcopic surveillance is critical.

Squamous Carcinoma

Squamous carcinoma accounts for 80% to 90% of vaginal carcinomas with a mean age at presentation of 60 to 65 years. As with vaginal dysplasia, the most common location will be the posterior upper third of the vagina but the entire vaginal cylinder is at risk for malignant transformation. Abnormal vaginal bleeding occurs in over half of patients. Less common symptoms include abnormal vaginal discharge, pain, and dysuria (Fig. 51.17).

FIG. 51.17. Vaginal carcinoma located in upper third of the vagina.

Vaginal carcinoma may spread by local extension, lymphatic spread to pelvic or inguinal nodes, and hematogenously. Lesions involving the upper two-thirds of the vagina tend to spread to pelvic nodes while lesions involving the lower third of the vagina tend to spread to inguinal nodes as would be seen with vulvar malignancies. To be considered primary vaginal carcinoma, a patient must have no evidence of disease in either the vulva or cervix. Staging of vaginal cancers is clinical and based on either the FIGO or AJCC systems (Table 51.5).

TABLE 51.5. *Vaginal carcinoma: FIGO and AJCC clinical staging*

Therapy for vaginal carcinoma typically involves both external irradiation and brachytherapy. Surgical resection is typically reserved for small stage I tumors confined to the posterior aspect of the vaginal apex. Complications from therapy include fistula formation and stenosis. Overall prognosis is poorer than for cancer of the cervix. Recurrent disease tends to occur locally within 2 years of primary therapy. Extenterative procedures are required to adequately treat locally recurrent or persistent disease but are associated with considerable morbidity. Chemotherapy does not yet have a significant role in treatment of vaginal carcinoma.

Clear Cell Adenocarcinoma

Clear cell adenocarcinoma of the vagina is a rare malignancy most commonly seen in young women whose mothers received DES during pregnancy for prevention of miscarriage (Fig. 51.18). This association was first noted in 1970, leading to removal of the drug from the U.S. market in 1971. Approximately 60% of patients with clear cell carcinoma are known to have been exposed to DES or other synthetic estrogens. The risk of developing clear cell adenocarcinoma of the cervix or vagina has been estimated at 1 per 1,000 to 1 per 1,500, with DES exposure in the first trimester conveying the greatest risk. The median age at diagnosis for DES-exposed patients is 19 years. DES-exposed daughters do not appear to have an increased risk of developing any other malignancies but do have an increased risk of cervical dysplasia. This may be due to increased surveillance or congenital abnormalities in the lower genital tract. No increased risk in squamous cancers of the cervix or vagina has been reported in DES-exposed women.

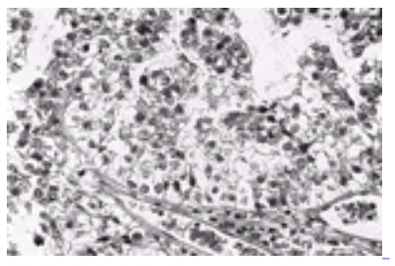

FIG. 51.18. Clear cell adenocarcinoma of the vagina associated with diethylstilbestrol exposure.

Most patients present with early stage disease, located in the exocervix or upper third of the vagina. Therapy is typically surgical and involves radical hysterectomy with removal of the upper vagina and pelvic lymphadenectomy. While this results in sterility, it may allow ovarian preservation and improved vaginal function over treatment with radiotherapy. Overall 5-year survival for stage I disease is more than 90% and approximately 80% for patients with stage II disease. Favorable factors in survival include early stage disease, older age, a tubulocystic histology, superficial invasion, small tumor diameter, and negative nodal status. Adenocarcinoma unrelated to DES exposure is a rare entity seen in postmenopausal women.

Melanoma

Melanoma is the second most common cancer of the vagina, accounting for less than 5% of vaginal malignancies and 0.3% of all melanomas among women. Nodular lesions are the most frequent histologic subtype. While vulvar melanoma is more common among white women, no association with race is seen for vaginal melanoma. It is a disease of older women and overall 5-year survival is poor at only 19%.

Sarcoma Botryoides

Sarcoma botryoides, or embryonal rhabdomyosarcoma, is a rare sarcoma found in young girls. It presents with vaginal bleeding and a polypoid “grapelike” mass. Historically this was treated with radical surgery, but now multimodality chemotherapy with VAC (vincristine, dactinomycin, and cyclophosphamide) and limited surgery can allow for a cure while preserving reproductive function. Radiotherapy may also be used in conjunction with multi-agent chemotherapy.

Endodermal Sinus Tumor

This is an extremely rare germ cell tumor arising in the vagina. It is seen in infants and is treated with combination chemotherapy as is used for germ cell tumors of the

ovary.

Lymphoma

Vaginal involvement with lymphoma may be secondary to systemic disease or may be localized to the vagina. This rare entity presents with bleeding and a vaginal mass. Primary vaginal lymphomas are typically diffuse, large, B-cell type.

Metastatic Disease

Although primary vaginal malignancy is quite rare, metastatic spread to the vagina is common and occurs through direct extension of vulvar, cervical, endometrial, and rectal malignancies. A thorough search for another primary site should be undertaken before concluding that a patient has a primary vaginal malignancy.

SUMMARY POINTS

- The incidence of vulvar intraepithelial neoplasia (VIN) is increasing with younger patients more likely to have human papillomavirus (HPV)-related lesions. The underlying risk for cancer in a field of VINIII is 7% to 22%.
- Vulvar carcinoma in older women tends to be unifocal and is associated with chronic vulvar irritation rather than HPV changes. Carcinomas in younger women tend to be multifocal and HPV changes are seen in 90% of cases (HPV 16 is most common).
- The risk of groin node metastasis with vulvar carcinoma increases with increasing tumor size, depth of invasion, and presence of lymphovascular space involvement.
- Modifications in surgery to reduce the radical nature of vulvar and groin surgery are possible in select patients. Vulvar resection margins should be at least 1 cm. The use of sentinel node biopsy to modify groin node dissections remains investigational.
- Squamous cell carcinoma of the vagina is a rare entity best treated with combined external beam radiation therapy and brachytherapy.

Cervical Cancer in Pregnancy

In the United States, cancer of the uterine cervix is the sixth most common solid cancer in women after carcinoma of the breast, lung, colorectum, endometrium, and ovary. The American Cancer Society has estimated that in 2002 there will be 13,000 new cases of invasive carcinoma of the cervix in the United States, over 50,000 cases of carcinoma in situ, and 4,100 deaths from the disease. The average age of diagnosis for cervical cancer is 52 years, and the distribution of cases is bimodal with peaks at 35 to 39 years and 60 to 64 years. Worldwide, cervical cancer continues to be a leading cause of death due to cancer among women, with approximately 500,000 cases occurring annually. Lifetime risks for cervical cancer show significant geographic variation, ranging from 0.4% in Israel to 5.3% in Cali, Colombia, where cervical cancer is the most common malignancy in women.

RISK FACTORS

Screening

Cytologic evaluation of cells obtained from the cervix and vagina was first proposed by Papanicolaou and Traut in the 1940s as a method for detecting cervical cancer and its precursors. Since that time, cervical cytology has proved to be the most efficacious and cost-effective method for cancer screening. By increasing detection of preinvasive and early invasive disease, cervical cancer screening with the Pap smear has decreased both the incidence and mortality from cervical cancer in communities with active screening programs. A single negative Pap smear may decrease the risk for cervical cancer by 45%, and nine negative smears during a lifetime decreases the risk by as much as 99%. Eddy, using a mathematical model, indicated that in women 35 to 64 years of age, screening intervals of 10, 5, and 3 years would reduce the incidence of invasive cervical cancer by 64%, 84%, and 91%, respectively. Despite the recognized benefits of cytologic screening, substantial subgroups of women in the United States have not been screened or are not screened at regular intervals. One-half of women with newly diagnosed invasive cervical carcinoma have never had a Pap smear, and another 10% have not had a Pap smear in the 5 years preceding diagnosis. The absence of prior regular Pap smear screening is associated with a two- to six-fold increase in the risk of developing cervical cancer. Unscreened populations include older women, the uninsured, ethnic minorities, and women of lower socioeconomic status, particularly those in rural areas. Women over age 65 years should continue to be screened, as 25% of all cases of cervical cancer and 41% of deaths from the disease occur in women in this age group.

Race

Although the incidence of cervical cancer in the United States has declined significantly over the past 50 years, the rates among African Americans remain about twice as high as those among whites. The incidence is also approximately two times higher for Hispanic Americans and even higher for Native Americans, while most Asian-American groups experience rates similar to whites. These differences are at least partially accounted for by the strong inverse association between cervical cancer incidence and socioeconomic factors. When socioeconomic differences are controlled for, the excess risk of cervical cancer among African Americans is substantially reduced, from over 70% to less than 30%. Racial differences are also apparent in survival, with 59% of African Americans with cervical cancer surviving 5 years, compared to 67% of whites with the disease.

Sexual and Reproductive Factors

First intercourse before 16 years of age is associated with a two-fold increased risk of cervical cancer compared with that for women whose first intercourse occurred after age 20 years. Cervical cancer risk is also directly proportional to the number of lifetime sexual partners. Although difficult to separate epidemiologically, there is evidence to indicate that both early age at first coitus and the number of lifetime sexual partners have independent effects on cervical cancer risk. Increasing parity also appears to be a separate risk factor for cervical cancer, even after controlling for socioeconomic and reproductive characteristics. There is little evidence to support an association between age of menarche, age at menopause, or character of menses with carcinoma of the cervix.

Smoking

Cigarette smoking has emerged as an important etiologic factor in squamous cell carcinoma (SCC) of the cervix. The increased risk for smokers is approximately two-fold, with the highest risk observed for long-term or high-intensity smokers. Proposed mechanisms include genotoxic or immunosuppressive effects of smoke-derived nicotine and cotinine, which can be detected in high levels in the cervical mucus of smokers.

Contraceptive Use

Numerous confounding factors—time interval since last cervical smear, sexual behavior, and role of the male partner, among others—complicate the interpretation of the data on oral contraceptive use and cervical cancer. After controlling for these and other variables, it appears that long-term oral contraceptive users (5 years or more) have about a two-fold increased risk of cervical cancer, compared to nonusers. Use of barrier methods of contraception, especially those that combine both mechanical and chemical protection, have been shown to lower the risk of cervical cancer, presumably because of reduced exposure to infectious agents.

Immunosuppression

Cell-mediated immunity appears to be a factor in the development of cervical cancer. Immunocompromised women (e.g., from renal transplantation or human immunodeficiency virus [HIV] infection) may not only be at higher risk for the disease but also demonstrate more rapid progression from preinvasive to invasive lesions and an accelerated course once invasive disease has been diagnosed. Maiman and colleagues report that HIV-positive women with cervical cancer may have a higher recurrence risk and cancer-related death rate compared to HIV-negative control subjects.

Human Papillomavirus Infection

During the past decade, epidemiologic evidence has accumulated, implicating infection with human papillomavirus (HPV) as a likely etiologic agent in cervical SCC. All known types of HPV have a similar structural and genomic organization. They are non-enveloped virions with a double-stranded circular DNA genome of 7,800 to 7,900 base pairs and an icosahedral capsid. HPV DNA is present in virtually all cases (93%) of cervical cancer and its precursor lesions. While HPV infection is thought to be a component of neoplastic transformation, it is unlikely to be entirely sufficient in and of itself.

HPV colonizes mucosal or cutaneous epithelium and may induce hyperproliferation, resulting in the formation of warts at the site of infection. Based on differences in DNA sequencing, over 70 different types of HPV have been identified, 23 of which are known to infect the anogenital tract. Low oncogenic risk–type viruses include types 6, 11, 42, 43, and 44 and are associated with condyloma acuminatum and some cases of low-grade squamous intraepithelial lesions, but rarely with invasive cancer. High oncogenic risk–type viruses include types 16, 18, 31, 45, and 56 and are commonly detected in women with high-grade squamous intraepithelial lesions (HGSIL) and invasive cancer. HPV types 33, 35, 39, 51, and 52 can be considered as being of intermediate oncogenic risk, as they are associated with HGSIL but are uncommonly detected in invasive carcinomas.

Following acute HPV infection, three clinical sequelae are possible:

1. Latent viral infection occurs when the HPV genome becomes stabilized as a nonintegrated episome and remains in the host cell without clinical or morphologic changes in the squamous epithelium. Clinically, patients may display no gross or morphologic evidence of infection but still harbor virus as demonstrated by DNA detection techniques.
2. Active infection, manifested by proliferation of squamous epithelium into benign tumors (warts), is present when HPV undergoes vegetative replication.
3. Highly oncogenic HPV viruses associated with high-grade lesions can become integrated into the host genome, interrupting control of proliferation by certain oncoproteins.

Initiation of cervical dysplasia and carcinoma may involve interactions between HPV and specific genes that regulate cell growth. The E6 and E7 open reading frames of the HPV genome are particularly important in the immortalization and transformation of infected cells. In HPV types 16 and 18, the protein products synthesized from the E6 and E7 open reading frames can bind to the gene products of the *p53* and retinoblastoma (*Rb*) tumor suppressor genes, respectively. Viral integration results in the overexpression of the E6 and E7 viral protein products with increased binding and inactivation of their respective tumor suppressor proteins. Removal of these two inhibitory influences on cellular proliferation is thought to provide HPV-infected cells with a growth advantage, ultimately leading to neoplastic transformation.

CLINICAL FEATURES

Presenting Symptoms

The most common symptom of cervical cancer is abnormal vaginal bleeding or discharge. Abnormal bleeding may take the form of postcoital spotting, intermenstrual bleeding, menorrhagia, or postmenopausal spotting. If bleeding has been chronic, a patient may complain of fatigue or other symptoms related to anemia. Serosanguineous or yellowish vaginal discharge, frequently associated with a foul odor, may accompany an advanced or necrotic carcinoma. Pelvic pain may result from locally advanced disease or tumor necrosis. Tumor extension to the pelvic side wall may cause sciatic pain or back pain associated with urinary tract obstruction and hydronephrosis. Metastatic tumor to the iliac and paraaortic lymph nodes can extend into the lumbosacral nerve roots and present as lumbosacral back pain. Urinary or rectal symptoms (e.g., hematuria, hematochezia, fistulae) can be associated with bladder or rectal invasion by advanced-stage cervical carcinoma.

Physical Findings

Invasive carcinoma of the cervix displays a wide range of gross appearances. Early lesions may be focally indurated or ulcerated, or present as a slightly elevated and granular area that bleeds readily on contact (Fig. 52.1). More advanced tumors have several types of gross appearance: exophytic, endophytic, or infiltrative. Exophytic tumors characteristically have a polypoid or papillary appearance and will often demonstrate contact bleeding. Endophytic tumors are usually ulcerated or nodular but may be clinically inapparent if located high within the endocervical canal. Such tumors frequently invade deep into the cervical stroma to produce an enlarged, hard, barrel-shaped cervix that may only be appreciated on rectovaginal pelvic examination. The infiltrative pattern of tumor growth may produce surrounding tissue necrosis and erosion of normal anatomic landmarks.

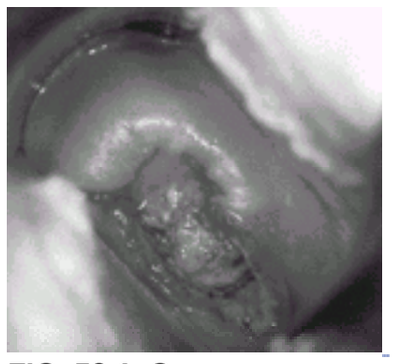

FIG. 52.1. Gross appearance of squamous cell carcinoma of the cervix. This is an ulcerative type of lesion.

Spread of Disease

Parametrial Extension Cervical cancer generally follows an orderly pattern of disease progression. Initially, tumor cells usually spread through parametrial lymphatic vessels, expanding and replacing parametrial lymph nodes (Fig. 52.2). These individual tumor masses enlarge and become confluent, eventually replacing the normal parametrial tissue. Less commonly, the central tumor mass reaches the pelvic sidewall by direct contiguous extension through the cardinal (Mackenrodt) ligament. Significant involvement of the medial portion of this ligament may result in ureteral obstruction and hydronephrosis.

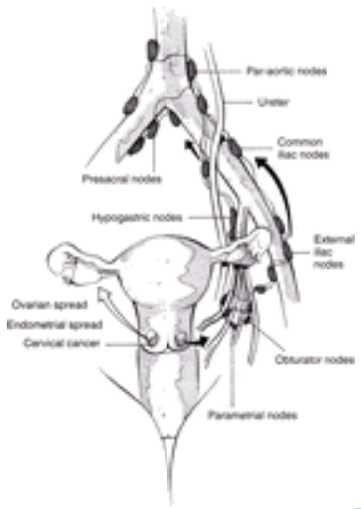

FIG. 52.2. Anatomic pathways of spread in invasive cervical carcinoma.

Lymph Node Involvement The pelvic lymph nodes will usually be the first site of embolic lymphatic spread of cervical cancer. The lymph node groups most commonly involved are the obturator, external iliac, and hypogastric (Fig. 52.2). The inferior gluteal and presacral lymph nodes are less frequently involved. Secondary nodal involvement (i.e., common iliac, paraaortic) rarely occurs in the absence of pelvic nodal disease. The percentage of involved lymph nodes increases directly with primary tumor volume. Rarely, retrograde lymphatic embolization may occur to the inguinal lymph nodes. Patients with locally advanced pelvic disease may have detectable metastatic spread to the scalene nodes. Consequently, careful clinical assessment of the groin and supraclavicular fossa areas should be included as part of the physical examination.
Vaginal Extension When the primary tumor has extended beyond the confines of the cervix, the upper vagina is frequently involved (50% of cases). Anterior extension through the vesicovaginal septum is most common, often obliterating the dissection plane between the bladder and underlying cervical tumor, making surgical therapy difficult or impossible. Posteriorly, a deep peritoneal cul-de-sac (pouch of Douglas) can represent an anatomic barrier to direct tumor spread from the cervix and vagina to the rectum.
Bladder and Rectal Involvement In the absence of lateral parametrial disease, anterior and posterior spread of cervical cancer to the bladder and rectum is uncommon. Approximately 20% of patients with tumor extending to the pelvic sidewall will have biopsy-proven bladder invasion.
Endometrial Involvement The endometrium is involved in 2% to 10% of cervical cancer cases treated with surgery, although the overall incidence (including nonsurgical cases) is unknown. Although endometrial extension does not alter a patient's stage of disease, it has been associated with decreased survival and a higher incidence of distant metastases.
Ovarian Metastasis Ovarian involvement with cervical cancer is rare but, when present, most likely occurs through the lymphatic connections between the uterus and adnexal structures. In patients undergoing surgical treatment for early-stage disease, ovarian metastasis is present in less than 1% of SCCs and slightly more than 1% of adenocarcinomas. The true incidence of ovarian involvement with advanced-stage tumors is unknown, as pathologic evaluation of the adnexae is not commonly performed in such cases.
Hematogenous Spread Hematogenous spread of cervical cancer is uncommon, particularly at the time of initial diagnosis. However, when blood-borne metastases do occur, the lung, liver, and bone are the sites most frequently involved. Metastasis to the bowel, adrenal gland, spleen, and brain are extremely rare.

DIAGNOSIS AND STAGING

Diagnosis and Evaluation of Disease Extent

Pathologic documentation of invasive disease should always be obtained prior to initiating therapy for cervical cancer. The International Federation of Gynecology and Obstetrics (FIGO) staging system used for the diagnosis and evaluation of cervical carcinoma is based on clinical evaluation (visual inspection, palpation, colposcopy, endocervical curettage, cervical biopsy, or conization), radiographic examination of the chest, kidneys, and skeleton, and ECC and biopsies. Cervical cancer is one of the few gynecologic malignancies (vaginal cancer being the other) that still uses a clinically based staging system by international convention, which facilitates comparison of results between institutions irrespective of the availability of diagnostic technological resources. Staging procedures allowed by FIGO convention are shown in Table 52.1. Lymphangiograms, arteriograms, computed tomographic (CT) scans, magnetic resonance imaging (MRI), and laparoscopy or laparotomy should not be used for clinical staging. However, information from such additional studies and procedures may be used to modify the treatment approach.

Physical examination	Examination under anesthesia recommended
Radiologic studies	Chest x-ray
	Intravenous pyelogram
	Barium enema
	Skeletal x-ray
Procedures	Colposcopy
	Cervical biopsy
	Conization
	Endocervical curettage
	Cystoscopy
	Proctoscopy
Optional studies*	Computed tomography
	Lymphangiography
	Ultrasonography
	Magnetic resonance imaging
	Radionucleotide scanning
	Laparoscopy/laparotomy

*Not allowed for staging purposes by the International Federation of Gynecology and Obstetrics (FIGO).

TABLE 52.1. *Staging procedures for cervical cancer*

In 1995, FIGO revised the clinical staging system of cervical carcinoma (Table 52.2). Stage I disease includes those neoplasms that are clinically confined to the cervix. In the current staging classification, stage IA tumors are those that are diagnosed by microscopic evaluation of a conization specimen (microinvasive carcinoma). Stage IA1 is defined as a tumor with stromal invasion no greater than 3 mm in depth beneath the basement membrane and no wider than 7 mm. This definition reflects data indicating that patients with less than 3 mm of invasion are at very low risk of metastatic disease and may be treated more conservatively. All grossly visible lesions should technically be classified as stage IB. The 1995 staging system divides stage IB lesions into stage IB1 (no greater than 4 cm in maximal diameter) and stage IB2 (greater than 4 cm in maximal diameter), reflecting the prognostic importance of tumor volume for macroscopic lesions limited to the cervix.

Stage	Clinical features
0	Carcinoma in situ, intraepithelial carcinoma
I	Carcinoma is strictly confined to the cervix
IA	Invasive cancer identified only microscopically. All gross lesions even with superficial invasion are stage IB cancers. Invasion is limited to measured stromal invasion ≤ 5 mm deep and <7 mm wide
IA1	Measured invasion of stroma ≤ 3-mm deep and <7-mm wide
IA2	measured invasion of stroma >3-mm deep but ≤ 5-mm deep and <7-mm wide
IB	Clinical lesions confined to the cervix or preclinical lesions greater than stage IA
IB1	Clinical lesions ≤ 4 cm in size
IB2	Clinical lesions >4 cm in size
II	Carcinoma extends beyond the cervix but has not extended to the pelvic wall. Carcinoma involves the vagina but not as far as the lower third.
IIA	No obvious parametrial involvement
IIB	Obvious parametrial involvement
III	Carcinoma has extended to the pelvic wall. On rectal examination, there is no cancer-free space between the tumor and the pelvic wall. The tumor involves the lower third of the vagina. All cases of hydronephrosis or nonfunctioning kidney are included, unless known to be due to another cause.
IIIA	No extension to the pelvic wall
IIIB	Extension to the pelvic wall, hydronephrosis, or nonfunctioning kidney
IV	Carcinoma has extended beyond the true pelvis or has clinically involved the mucosa of the bladder or rectum. Bullous edema does permit a case to be allocated to stage IV.
IVA	Spread of growth to adjacent organs
IVB	Spread to distant organs

FIGO, International Federation of Gynecology and Obstetrics.

TABLE 52.2. *FIGO staging of cervical carcinoma*

Determination of clinical stage depends on careful inspection and palpation of the cervix, vagina, and pelvis. Examination under anesthesia is recommended. It is important to palpate the entire vagina to determine whether disease is limited to the cervix (IB), extends to the upper two-thirds of the vagina (IIA), or also involves the

lower third of the vagina (IIIA) (Fig. 52.3). Tumor extension into the parametrial tissue (IIB) or to the pelvic sidewall (IIIB) is best appreciated on rectovaginal examination. It is impossible at clinical examination to decide whether a smooth and indurated parametrium is truly cancerous or only inflammatory, and the case should be considered stage III only if the parametrium is nodular on the pelvic wall or if the growth itself extends to the pelvic wall. Biopsy-proven invasion of bladder or rectal mucosa by cystoscopy or proctoscopy is required for a diagnosis of stage IVA disease. In the United States, the distribution of patients by clinical stage is stage I, 38%; stage II, 32%; stage III, 26%; and stage IV, 4%.

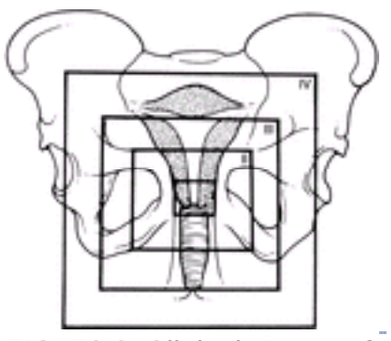

FIG. 52.3. Clinical stages of carcinoma of the cervix. In stage I, only the cervix is involved. In stage II, the parametrium or upper two-thirds of the vagina is involved. In stage III, the malignancy extends to the pelvic sidewall or involves the lower third of the vagina. Stage IV reflects involvement of the bladder or rectal mucosa (stage IVA) or distant metastasis (stage IVB).

When there is doubt concerning which stage a tumor should be assigned, the earlier stage is mandatory. Once a clinical stage has been determined and treatment initiated, subsequent findings on either extended clinical staging (CT, etc.) or surgical exploration should not alter the assigned stage. Assignment of a more advanced stage during treatment will result in an apparent but deceptive improvement in the results of treatment for earlier stage disease.

Surgical Staging

The current FIGO staging classification for cervical cancer is based on pretreatment clinical findings. Only the subclassification of stage I (IA1, IA2) requires pathologic assessment. Discrepancies between clinical staging and surgicopathologic findings range from 17.3% to 38.5% in patients with clinical stage I disease, to 42.9% to 89.5% in patients with stage III disease. This has led some authors to emphasize surgical staging of cervical carcinoma to identify occult tumor spread and determine the presence of extrapelvic disease so that adjunctive or extended-field radiation therapy may be offered. Transperitoneal surgical staging procedures (e.g. laparotomy), when followed by abdominopelvic irradiation, are associated with appreciable complications, particularly enteric morbidity. The extraperitoneal surgical approach can be performed through a paraumbilical or paramedian incision and allows accurate assessment of pelvic and paraaortic nodal status. Using this approach, an incision in the peritoneum is avoided and adhesion formation is minimized. It is associated with few complications and does not delay institution of radiation therapy. Laparoscopic surgical staging for cervical cancer has also been advocated; however, the safety and efficacy of this approach has yet to be determined.

PROGNOSTIC VARIABLES

Tumor Characteristics

Clinical stage of disease at the time of presentation is the most important determinant of subsequent survival, regardless of treatment modality. Five-year survival declines as FIGO stage at diagnosis increases: stage IA, 97%; stage IB, 70% to 85%; stage II, 60% to 70%; stage III, 30% to 45%; stage IV, 12% to 18%. Prognostic variables directly related to surgicopathologic tumor characteristics and their effect on survival were compiled by Kosary for the National Cancer Institutes Surveillance, Epidemiology, and End Results (SEER) program for the period of 1973 through 1987. This study included 17,119 cases of invasive cervical cancer and found that FIGO stage, tumor histology, histologic grade, and lymph node status are all independent prognostic variables relating to survival.

SCCs accounted for 74.9% of cases in the SEER database and can be categorized according to the degree of histologic tumor differentiation. Well-differentiated tumors account for about 5% of cervical SCCs and are composed of sheets and cords of cells with abundant acidophilic cytoplasm, clearly visible intercellular bridges, and often production of variable amounts of keratin. Moderately differentiated tumors are the most common variety, with 85% of SCCs falling in this category (Fig. 52.4). These tumors are characterized microscopically by masses and cords of spindle-shaped squamous cells with elongated nuclei and scant cytoplasm and more frequent mitoses. Poorly differentiated tumors have a rapid growth rate, with numerous mitoses and cells with closely crowded nuclei and scant cytoplasm. These tumors are difficult to recognize as having originated in squamous cells and constitute approximately 10% of cervical SCCs. The degree of histologic tumor differentiation does correlate with overall survival. In the SEER database, 5-year survival for patients with well-differentiated tumors was 74.5%; for those with moderately differentiated tumors it was 63.7%, and it fell to 51.4% for those patients with poorly differentiated carcinomas. Approximately 15% to 20% of cervical cancer cases are adenocarcinomas. After controlling for known prognostic variables, the SEER study found no difference in overall survival between patients with cervical SCC and adenocarcinoma. However, adenosquamous histology was associated with decreased survival. Survival is also orrelated with depth of tumor invasion into the cervical stroma and overall tumor volume.

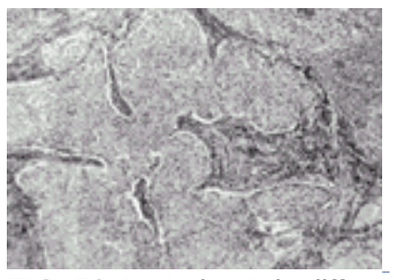

FIG. 52.4. Moderately differentiated squamous cell carcinoma of the cervix.

Among surgically treated patients, survival is directly related to the number and location of lymph node metastasis. The frequency of positive lymph nodes increases with the stage of disease (Table 52.3). For all stages of disease, when both pelvic and paraaortic lymph nodes are negative, the 5-year survival rate is 75.2%. Survival decreases to 45.6% with positive pelvic nodes, and the risk of recurrence is related to the number of nodes involved. The recurrence rate is 35% with one positive pelvic lymph node, 59% with two or three positive nodes, and 69% with metastases to more than three pelvic lymph nodes. When paraaortic nodes are involved, the 5-year survival rate ranges from 15% to 45%.

Stage	n	Positive pelvic nodes (%)	Positive paraaortic nodes(%)
IA1	179	0.5	0
IA2	178	6.2	<1
IB	1,926	15.9	2.2
IIA	110	24.5	11
IIB	324	31.4	19
III	125	44.8	30
IVA	23	55	40

TABLE 52.3. *Incidence of pelvic and paraaortic lymph node metastasis by FIGO stage of cervicalcarcinoma*

Host Factors

Whether or not patient age at diagnosis of cervical cancer is a significant and independent predictor of clinical outcome remains controversial. Some investigators have observed decreased survival in women younger than 35 to 40 years, who have a greater frequency of poorly differentiated tumors. Others have found no significant

difference in survival between younger and older patients.

Several hematologic parameters have been associated with cervical cancer survival outcome. The incidence of pretreatment anemia (hemoglobin of 12 g/dL or less) increases with advancing stage of disease, occurring in 25%, 33%, and 45% of patients with stages I, II, and III disease, respectively. Anemia is associated with a higher incidence of pelvic recurrences and decreased survival, primarily due to more frequent radiation therapy failures. Tumor hypoxia is the proposed mechanism of radio resistance in the presence of anemia. Another prognostic hematologic parameter is thrombocytosis (>400,000/mm ^{3}), which has been associated with decreased survival after controlling for cell type, stage, and age.

Coexistent medical conditions may also affect the success of treatment. Diabetes and hypertension are frequently associated with significant vascular disease and potentially contribute to both tumor hypoxia and decreased blood supply to normal pelvic tissues. Patients with these conditions are subject to a higher incidence of treatment complications and pelvic tumor recurrence, as well as decreased survival.

TREATMENT MODALITIES

Surgery and radiation therapy are the two primary therapeutic modalities most commonly used to treat invasive cervical carcinoma. In general, primary surgical management is limited to patients with stage I and IIA disease, while radiation therapy can be applied to patients with all stages of disease. For patients with early-stage disease, multiple factors should be considered in selecting the most appropriate treatment program. Age is not a contraindication to surgical management, provided the patient does not have significant medical comorbidity. Young patients desiring ovarian preservation and sexually active patients are preferentially managed surgically. Other reasons for the selection of radical surgery over radiation include concomitant inflammatory bowel disease, previous radiation for other disease, and the presence of a coexistent adnexal neoplasm.

Primary Surgery

Surgery provides the opportunity to perform a thorough pelvic and abdominal exploration, which can identify patients with a disparity between the clinical and surgicopathologic stages. Such patients can then be offered an individualized treatment plan based on their precise disease status. The primary surgical management of cervical cancer generally consists of hysterectomy. For patients with stage IA1 lesions who desire fertility preservation, cervical conization with clear surgical margins is acceptable treatment. The safety and efficacy of surgery to preserve fertility (e.g., radical trachelectomy) for patients with larger stage I lesions however has yet to be fully evaluated. There are five distinct variations or types of hysterectomy used in the treatment of cervical cancer.

Types of Hysterectomy

Type I A type I hysterectomy refers to the standard extrafascial total abdominal hysterectomy. This procedure ensures complete removal of the cervix with minimal disruption to surrounding structures and is appropriate treatment for stage IA1 disease.
Type II A type II hysterectomy is also referred to as a modified radical hysterectomy (Fig. 52.5, Fig. 52.6 and Fig. 52.7). This procedure involves dissection of the ureters from the parametrial and paracervical tissues down to the ureterovesical junction. This permits removal of all parametrial tissue medial to the ureters, as well as the medial half of the uterosacral ligament and proximal 1 to 2 cm of vagina. This operation is usually performed in conjunction with pelvic lymphadenectomy.

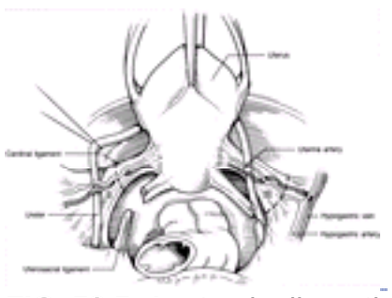

FIG. 52.5. Anatomic dissection of radical hysterectomy. The cardinal ligaments are transected (*dashed line*) at the level of the ureter (type II) or at the pelvic side wall (type III).

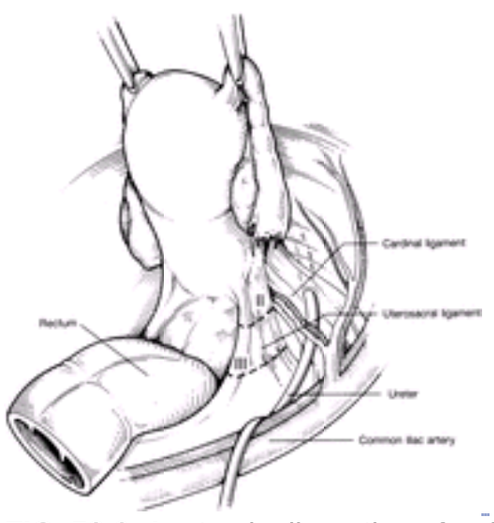

FIG. 52.6. Anatomic dissection of radical hysterectomy. The uterosacral ligaments are divided at the sacrum (type III) or midway between the sacrum and the uterus (type II).

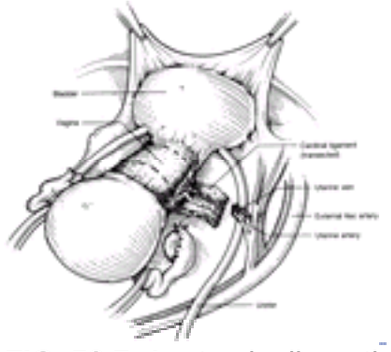

FIG. 52.7. Anatomic dissection of radical hysterectomy. In a type II radical hysterectomy, the upper 1 to 2 cm of vagina is excised. In type III radical hysterectomy, the proximal one-third to one-half of the vagina is removed.

Type III In a type III or radical abdominal hysterectomy, the ureters are completely dissected from within the paracervical tunnel, and the bladder and rectum are extensively mobilized (Fig. 52.5, Fig. 52.6 and Fig. 52.7). Establishing the paravesical and pararectal spaces facilitates removal of all the parametrial tissue out to the pelvic sidewall, complete resection of the uterosacral ligaments, and excision of the upper one-third to one-half of the vagina. Bilateral pelvic lymphadenectomy is performed with this procedure, removing all lymph-bearing tissue between the mid-common iliac vessels distally to the circumflex iliac vessels and from within the obturator fossa ventral to the obturator nerve.
Type IV/Type V A type IV or extended radical hysterectomy includes removal of the superior vesical artery, periureteral tissue, and up to three fourths of the vagina. In a type V or partial exenteration operation, the distal ureters and a portion of the bladder are resected. Type IV and type V procedures are rarely performed today because most patients with disease extensive enough to require these operations can be more adequately treated with primary radiation therapy.
Complications of Radical Abdominal Hysterectomy Modern surgical techniques and anesthesia have reduced the operative mortality associated with radical hysterectomy to 0.6%. Potentially fatal pulmonary embolism occurs in 1% to 2% of patients. Urinary and bowel fistula formation and incisional complications related to surgical treatment tend to occur early in the postoperative period and are usually amenable to surgical repair. Ureterovaginal and vesicovaginal fistulae occur in 2%

and 0.9% of patients, respectively. The most commonly observed complication after radical hysterectomy is urinary dysfunction resulting from partial denervation of the detrusor muscle during excision of the paracervical and paravaginal tissue. Radical hysterectomy results in vaginal shortening; however, with sexual activity gradual lengthening will occur. Pelvic lymphocyst formation occurs in 2% to 6.7% of patients following radical hysterectomy and pelvic lymphadenectomy. The incidence is somewhat lower when the retroperitoneal spaces are left open. Most lymphocysts are asymptomatic and do not require intervention; however, lymphocysts may occasionally produce pelvic pain, ureteral obstruction, or partial venous obstruction with thrombosis.

Primary Radiation Therapy

Radiation therapy can be used for all stages of disease and for most patients regardless of age, body habitus, or coexistent medical conditions. The recommended nomenclature for measurement of absorbed radiation dose is the gray (Gy); 1 Gy is equal to one joule (J) of energy absorbed per kilogram of substance. Radiation dose is also commonly expressed as centi-gray (cGy), with 100 cGy equal to 1Gy. By convention, the irradiation dose used in the treatment of cervical cancer is described relative to two anatomic landmarks within the pelvis. Point A is defined as a point 2 cm above the lateral vaginal fornix and 2 cm lateral to the uterine canal corresponding to the paracervical triangle. Point B reflects the dose delivered to the pelvic sidewall and is located 3 cm lateral to point A.

The technical treatment modalities used in modern radiation therapy for cervical cancer consist of a combination of external irradiation and local irradiation. External irradiation is delivered from a source remote from the body (e.g., linear accelerator, cobalt-60) and is used to treat the regional lymph nodes, decrease tumor volume, and reduce the anatomic distortion produced by larger tumor masses. External beam irradiation treatment for cervical cancer is usually delivered using a four-field technique (anterior, posterior, and lateral fields). The precise treatment volume is determined according to individual patient anatomy, but usually measures 15 cm × 15 cm to 18 cm × 18 cm. The pelvic radiation field extends 1 to 2 cm beyond the lateral borders of the bony pelvis and inferiorly beyond the border of the obturator foramen. The cephalad margin may be extended to 18 cm in length to treat the common iliac lymph nodes or even higher if paraaortic lymph node coverage is necessary. A typical external beam radiation treatment portal for cervical cancer is shown in Fig. 52.8.

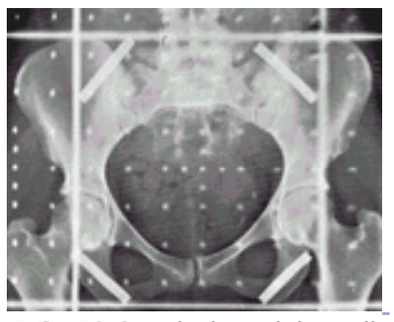

FIG. 52.8. Whole pelvis radiation treatment field for cervical cancer. In this case, the lower margin of the treatment field extends below the pubic symphysis to provide coverage of the proximal vagina. Lead tapes (white stripes) are used for excluding the corners of a square field, reducing the total irradiated volume by approximately 10%.

Brachytherapy, refers to a radiation source in direct proximity to the target tissue and may be delivered using a variety of intracavitary applicator devices, but the intrauterine tandem and vaginal colpostats are used most frequently for primary treatment (Fig. 52.9). Once adequate placement is assured, the device is after-loaded with radioactive isotope (e.g., radium-226, cesium-137, iridium-192). Alternatively, vaginal cylinders or interstitial needle implants may be used to deliver local radiation therapy, depending on patient anatomy and tumor distribution.

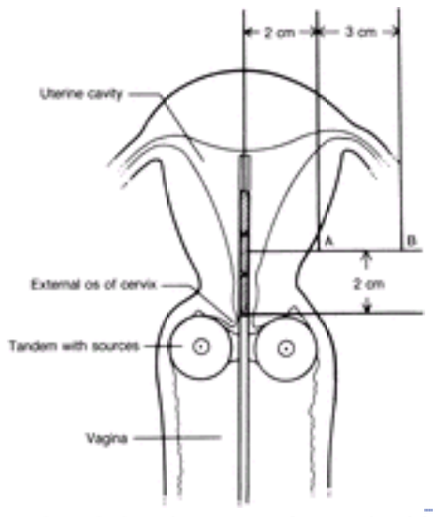

FIG. 52.9. Diagram of a typical intrauterine tandem and vaginal colpostat brachytherapy placement for cervical cancer showing the anatomic landmarks point A and point B.

The total dose delivered to point A is determined by the volume of disease to be treated and ranges from 6,500 to 7,000 cGy for small stage IB lesions to 8,500 to 9,000 cGy for bulky stage IIB and stage III lesions. For patients with documented paraaortic node metastasis, or those at high risk, 4,500 cGy of extended field irradiation is delivered to the paraaortic region. Cure rates with irradiation therapy are stage-dependent, with 5-year survival rates averaging 70% to 85% for stage I, 60% for stage II, 45% for stage III, and 18% to 20% for stage IV disease.

Concurrent Chemotherapy and Radiation Therapy In 1999, five multi-institutional, randomized controlled trials reported a survival advantage associated with the concurrent administration of chemotherapy and radiation therapy in the management of cervical cancer. Although these trials differed in their inclusion criteria, chemotherapy schedules, and prescribed radiation treatment, all demonstrated a similar improvement in progression-free survival (10%–27%) and overall survival (10%–17%). Many centers now administer concurrent treatment with chemotherapy and radiation therapy as standard practice for patients with locally advanced cervical cancer. Cisplatin (Platinol), 5-fluorouracil (Adrucil), and hydroxyurea (Hydrea) have been the chemotherapeutic agents most extensively studied as part of a combined modality treatment program. A commonly used contemporary regimen is cisplatin 40 mg per m^2 administered intravenously on a weekly basis during the radiation treatment interval.

Complications of Radiation Therapy Radiation therapy is associated with both acute and chronic complications. Perforation of the uterus may occur at the time of intracavitary insertion and, if unrecognized, may result in significant blood loss, radiation damage, and peritonitis. Appropriate management consists of removal of the implant and broad-spectrum antibiotic coverage if signs of infection are present. Vaginal fibrosis and stenosis is the most common chronic complication of radiation therapy for cervical cancer and is seen in up to 70% of cases. Ovarian function is lost in virtually all patients undergoing radiation therapy to the pelvis. Proctosigmoiditis occurs in up to 8% of patients undergoing radiation therapy for cervical cancer. Symptoms include abdominal pain, diarrhea, and nausea. An antispasmodic agent, a low-gluten and low-lactose diet, and steroid enemas may be useful; however, severe cases may require hyperalimentation and a diverting colostomy. Hemorrhagic cystitis is seen in approximately 3% of patients undergoing radiation therapy for cervical cancer. In contrast to surgical therapy, fistulous complications associated with radiation therapy tend to occur late and are more difficult to repair secondary to poorly vascularized tissues from radiation fibrosis and vasculitis. Rectovaginal and vesicovaginal fistulae each occur in approximately 1% of cervical cancer patients treated with irradiation. In such cases, biopsy specimens should be obtained from the edge of the fistula to rule out recurrent cancer. Diversion of the fecal (colostomy) or urinary (percutaneous nephrostomy) stream is usually required to allow adequate healing (3–6 months) prior to surgical repair. Two percent of patients experience small bowel obstruction as a consequence of radiation therapy; it is more common in those patients with vascular disease or a history of previous abdominal surgery. The most common site of small bowel obstruction is the terminal ileum, which is relatively fixed within the radiation field by the cecum. Complete small bowel obstruction or cases recalcitrant to conservative management require surgical intervention.

Chemotherapy

Chemotherapy as the sole mode of treating cervical cancer is indicated for patients with extrapelvic metastases (stage IVB) or those with recurrent disease who are not candidates for radiation therapy or exenterative surgery. Cisplatin has been the most extensively studied agent and has demonstrated the most consistent clinical

response rates. Complete clinical responses have been observed in 24% of patients, with an additional 16% demonstrating a partial response. Unfortunately, in most series, responses to cisplatin are short-lived (3–6 months). Other agents demonstrating at least partial activity against cervical cancer include carboplatin (Paraplatin), ifosfamide (Ifex), doxorubicin hydrochloride (Adriamycin), vinblastine sulfate (Velban), vincristine sulfate (Oncovin), 5-fluorouracil, methotrexate, and altretamine (Hexalen). There is little objective evidence to suggest that combination chemotherapy is superior to single-agent cisplatin treatment in improving the overall survival of patients with advanced or recurrent cervical cancer.

GENERAL MANAGEMENT BY STAGE

Stage IA1

The 5-year survival rate of these patients approaches 100% with primary surgical therapy. Extrafascial hysterectomy is adequate treatment for this group of patients. Conization may be used selectively if preservation of fertility is desired, provided the surgical margins are free of disease. In the absence of lymph–vascular invasion, the incidence of pelvic lymph node metastasis is 0.3%, and lymphadenectomy is not indicated. In the presence of lymph–vascular involvement, the risk of pelvic node metastasis increases to 2.6%. Pelvic lymphadenectomy and extrafascial hysterectomy should be performed in these cases. In patients who are medically inoperable, stage IA1 carcinoma can be effectively treated with intracavitary radiation.

Stage IA2

Microinvasive carcinoma with stromal invasion of 3.1 to 5.0 mm is associated with positive pelvic lymph nodes in 6.2% of patients. The preferred treatment for these lesions is modified radical (type II) hysterectomy with pelvic lymphadenectomy. Radiation therapy is equally effective from a survival standpoint but may carry a greater risk of post-treatment morbidity compared to modified radical hysterectomy.

Stages IB1, IB2, IIA

Both radical surgery and radiation therapy are equally effective in treating stages IB and IIA carcinoma of the cervix. Numerous uncontrolled studies support the merits of each modality, with no significant differences in pelvic tumor control or overall survival. Zander and colleagues reported on 1,092 patients with stages IB and II cervical cancer treated with radical (type III) hysterectomy and pelvic lymphadenectomy. Five-year survival rates were 84.5% for stage IB and 71.1% for stage II disease. Similar survival rates are obtained with primary radiation therapy. In one series, Perez and associates reported 5-year survival rates of 85% for 312 patients with stage IB disease and 70% for 98 patients with stage IIA disease treated with primary radiation therapy.

Treatment should be individualized for patients with bulky stage I (IB2) tumors. Tumor expansion of the upper endocervix and lower uterine segment can distort cervical anatomy and lead to suboptimal placement of intracavitary radiation sources. Consequently, the central failure rate has been reported as high as 17.5% in patients with cervical lesions greater than 6 cm treated with radiation alone. In such situations, a “completion” extrafascial hysterectomy is usually performed following radiation therapy. While many clinicians limit the use of radical hysterectomy to patients with small stage IB (<3–4 cm) or stage IIA lesions, there is evidence that acceptable survival rates can be obtained with primary surgical treatment in patients with bulky disease confined to the cervix. Five-year survival rates range from 73.6% to 82% after radical hysterectomy and pelvic lymphadenectomy for cervical lesions greater than 4 cm. Survival decreases to 66% at 5 years for lesions greater than 6 cm.

An alternative management plan for patients with bulky local disease is to administer chemotherapy in order to reduce the primary tumor volume prior to attempting radical hysterectomy. This approach has been termed *neoadjuvant chemotherapy.* Cisplatin, bleomycin sulfate (Blenoxane), and vinblastine has been the most extensively used drug combination. When chemotherapy is administered prior to surgery, complete clinical response rates range from 17% to 44%, with overall response rates of 80% to 90%. In addition to increasing surgical resectability, preoperative chemotherapy also decreases the number of positive pelvic lymph nodes and, in some studies, has seemingly improved 2- and 3-year survival rates.

Adjuvant Therapy Following Surgery Data are limited concerning the efficacy of postoperative pelvic irradiation in patients at high risk of recurrence after radical hysterectomy and pelvic lymphadenectomy. High-risk prognostic factors include positive pelvic lymph nodes, microscopic parametrial invasion, pelvic lymph node metastases, deep cervical invasion, and positive or close surgical margins. Sedlis and co-workers report results of a randomized, prospective trial of the Gynecologic Oncology Group comparing postoperative pelvic radiation therapy versus no further therapy for patients with high-risk stage IB cervical cancer following radical hysterectomy and pelvic lymphadenectomy. High- risk factors included large tumor diameter, deep stromal invasion, and the presence of tumor in capillary lymphatic spaces. For patients with these risk factors and negative pelvic lymph nodes, adjuvant pelvic radiation was associated with a statistically significant 47% reduction in the risk of disease recurrence. Survival analysis for this study however awaits additional data maturation.
Grossly Positive Lymph Nodes Encountered at Radical Hysterectomy The management of patients with grossly positive lymph nodes encountered at the time of radical hysterectomy has been controversial. Although there are no controlled studies, radiation therapy is commonly administered in such circumstances. In order to minimize postoperative radiation-related complications and preserve cervical anatomy for brachytherapy radiation placement, some clinicians advocate abandoning the surgical procedure once metastatic disease is confirmed by intraoperative histologic frozen section. Conversely, retrospective data suggest that postoperative irradiation after resection of all gross nodal disease and radical hysterectomy is associated with a lower rate of local recurrence and may provide a modest gain in survival, particularly for patients with three or more positive pelvic lymph nodes. Hacker and colleagues report their experience with patients undergoing complete resection of grossly positive lymph nodes in conjunction with radical hysterectomy and postoperative radiation therapy. The 5-year survival rates were 80% for patients with positive pelvic nodes and 48% for patients with positive paraaortic nodes; however, serious morbidity occurred in 18% of patients in this series. In addition, lower-extremity lymphedema has been reported in up to 23.4% of patients receiving combined modality therapy.

Stages IIB, III, IVA, and IVB

Radiation therapy is the treatment of choice for patients with stage IIB and more advanced disease. Radiation therapy for invasive cervical cancer is given as a combination of external and intracavitary treatments as described earlier. Long-term survival rates are approximately 60% for stage II, 45% for stage III, and 18% for stage IV disease. Patients with stage IVB disease are usually treated with chemotherapy alone or chemotherapy in combination with local irradiation for palliation of symptoms. These patients have a uniformly poor prognosis regardless of treatment modality.

Post-treatment Surveillance

Among patients with recurrent cervical cancer, recurrence is detected within 1 year in 50% of patients and within 2 years in more than 80%. Pelvic examination and lymph node evaluation, including supraclavicular nodes, should be performed every 3 months for 2 years and then every 6 months for an additional 3 years. As many as 70% of patients with recurrent cervical cancer in the pelvis will have abnormal cervical or vaginal cytology; therefore, appropriate cytologic smears should be obtained at the time of each routine examination. Any palpable pelvic mass should be evaluated by CT with fine-needle aspiration cytology if possible. A chest x-ray should be obtained annually to detect pulmonary metastases.

TREATMENT OF RECURRENT CERVICAL CANCER

General Considerations

Cervical cancer detected within the first 6 months after primary therapy is often termed *persistent* cancer, while that diagnosed later is referred to as *recurrent* disease. Appropriate treatment of recurrent cervical cancer is dictated by both the site of recurrence and the modality of primary therapy. In general, patients in whom locally recurrent disease develops following primary surgery should be considered for salvage radiation therapy. Conversely, surgical treatment should be considered for those patients with recurrent central disease who initially received irradiation. Distantly metastatic recurrent tumor is not amenable to either modality alone and is an indication for palliative chemotherapy and possibly radiation therapy for local control.

Surgical Treatment of Recurrent Cervical Cancer

Only patients with recurrent tumor confined to the central pelvis are candidates for surgical intervention. Total hysterectomy is inadequate treatment for centrally recurrent cervical cancer. Additionally, when radical hysterectomy is performed following maximum-dose radiation therapy, 20% to 50% of patients will experience ureteral strictures, urinary fistulae, or other serious complications. Therefore, pelvic exenteration is usually the procedure of choice for centrally recurrent cervical cancer.

Prior to exenterative surgery, a thorough investigation should be undertaken to rule out extrapelvic metastases. The clinical triad of unilateral leg edema, sciatic pain, and ureteral obstruction heralds tumor extension to the pelvic sidewall and is a contraindication to surgery. In most series, approximately 25% of patients with recurrent

cervical cancer are deemed satisfactory candidates for exenterative surgery.

Anterior exenteration is indicated for treatment of recurrent cervical cancer limited to the cervix, anterior vagina, or bladder. The procedure combines radical cystectomy with radical hysterectomy and vaginectomy. *Posterior exenteration* combines abdominal perineal resection of the rectum with radical hysterectomy and vaginectomy and is indicated for lesions confined to the posterior fornix and rectovaginal septum. *Total pelvic exenteration* is most often required for recurrent cervical cancer. The procedure involves the *en-bloc* excision of the bladder, uterus, rectum, and vagina (Fig. 52.10).

FIG. 52.10. Total pelvic exenteration performed for recurrent cervical cancer involves en-bloc resection of the bladder, vagina, uterus, and rectum. In this specimen, recurrent cervical cancer has replaced the cervix (uterine leiomyomata occupy the uterine fundus).

Using current surgical stapling devices, low-rectal reanastomosis can be performed in approximately 70% of cases. Reconstruction of the urinary system is accomplished using either an intestinal urinary conduit or one of the many techniques of continent urinary diversion (Miami pouch, Indiana pouch). A neovagina can be created by a variety of techniques using myocutaneous flaps (e.g., bulbocavernosus, gracilis, transverse rectus abdominus) or an omental flap with split-thickness skin graft. Modern surgical techniques and intensive care unit support have reduced the perioperative mortality to less than 7% in recent series. With proper patient selection and sound surgical judgment, 5-year survival rates after pelvic exenteration range from 45% to 61%.

GLANDULAR LESIONS OF THE CERVIX

Adenocarcinoma In Situ

Adenocarcinoma in situ (AIS) is characterized by replacement of the endocervical glandular cells by tall columnar cells with nuclear stratification, hyperchromatism, irregularity, and increased mitotic activity (Fig. 52.11). About 50% of women with AIS also have coexistent squamous cervical intraepithelial neoplasia (CIN). A diagnosis of AIS may be detected incidentally at the time of conization performed for CIN. Historically, a point of major concern regarding AIS is that these lesions were multifocal, so that conization margins were thought to be unreliable in predicting the presence of residual disease. In one study, Poyner and associates report on 28 patients with AIS in which 4 of 10 patients with negative conization margins had residual AIS in hysterectomy or repeat conization specimens. In contrast, studies using careful histologic sectioning indicate that cervical AIS lesions are usually located within the transformation zone and that true multifocality occurs in fewer than 15% of cases. A retrospective study from Shin and co-workers found only one case of residual or recurrent AIS among 98 patients undergoing conization with negative surgical margins and followed with conservative surveillance. As additional data accumulate, it appears that negative conization margins may be a more reliable indicator of disease clearance than previously thought. For young patients desiring to maintain reproductive capacity, AIS appears to be safely managed by cold knife conization and diligent surveillance. Clear surgical margins however are an absolute prerequisite to conservative management. For patients who have completed their childbearing, a simple hysterectomy should be performed because of the risk of recurrence, even in the presence of negative margins. Patients with unreliable follow-up and those with persistently positive conization margins should be offered simple hysterectomy as definitive therapy.

FIG. 52.11. Cervical adenocarcinoma in situ showing tall columnar cells with nuclear stratification, hyperchromatism, and irregularity.

Cervical Adenocarcinoma

Adenocarcinoma of the cervix accounts for approximately 10% to 15% of all invasive cervical neoplasms. As with SCC of the cervix, tumor size, depth of invasion, and histologic tumor grade have been identified as predictors of pelvic lymph node metastasis and overall survival. Although cervical adenocarcinoma has been reported to have a worse prognosis than similar stage SCC, this difference is due, at least in part, to the tendency of adenocarcinoma to grow endophytically and establish a large tumor volume prior to clinical detection. When cervical adenocarcinoma and SCC are comparatively matched by patient age, clinical stage, tumor volume, and treatment method, survival outcomes are not significantly different. In general, the same treatment algorithms can be applied to patients with adenocarcinoma of the cervix as to those with cervical SCC. Some authors have advocated performing a “completion” simple hysterectomy for patients with bulky, barrel-shaped adenocarcinomas of the cervix following primary radiation therapy. While this approach may decrease the risk of local recurrence, an associated survival benefit has yet to be conclusively demonstrated.

SMALL CELL CARCINOMA

Small cell carcinoma of the uterine cervix is similar to small cell “neuroendocrine” tumor of the lung and other anatomic locations. These tumors are clinically aggressive, demonstrating a marked propensity to metastasize to local and distant sites. At the time of presentation, disease is often widely disseminated, with bone, brain, and liver being the most common sites. Because of the high metastatic potential of small cell carcinoma, local therapy alone (surgery or radiation) rarely results in long-term survival. Multi-agent chemotherapy, in combination with external-beam and intracavitary radiation therapy, is a therapeutic approach currently under study. The two most commonly used chemotherapeutic regimens are vincristine, doxorubicin, and cyclophosphamide (VAC) and etoposide and platinum (i.e., cisplatin) (EP).

CARCINOMA OF THE CERVICAL STUMP

The natural history and patterns of spread of carcinoma of the cervical stump are similar to those of carcinoma of the intact uterus. The diagnostic evaluation, clinical staging, and principles of staging are also unchanged. In appropriate surgical candidates, early-stage disease can be treated with simple or radical trachelectomy with or without lymphadenectomy, depending on the volume of disease. Advanced-stage disease is treated with radiation therapy. However, the lack of a uterine cavity can make placement of intracavitary radiation sources difficult or impossible. In this case, vaginal colpostats alone or an interstitial needle implant technique can be used in combination with external-beam therapy.

INCIDENTAL CERVICAL CANCER FOUND AT SIMPLE HYSTERECTOMY

Invasive cervical cancer may be incidentally discovered in the surgical specimen after hysterectomy has been performed. For disease more advanced than stage IA1 (without lymph-vascular involvement), simple hysterectomy is inadequate treatment, as the parametria, vaginal cuff, and pelvic lymph nodes may harbor residual tumor. Additional treatment is dictated by the volume of disease and the status of the surgical margins of resection.

Radical surgery following simple hysterectomy for invasive cervical cancer generally includes radical parametrectomy, resection of the cardinal ligaments, excision of the vaginal stump, and pelvic lymphadenectomy. Although it may be technically difficult to perform an adequate radical resection, reoperation should be considered in selected clinical situations, particularly for young patients in whom ovarian preservation is desired. Use of postoperative adjuvant radiation therapy is dictated by surgical and pathologic findings.

Cervical carcinoma at the margins of resection after simple hysterectomy or the presence of gross residual tumor are both absolute indications for radiation therapy. Patients with such findings have a much less favorable prognosis than those without residual tumor and those with comparable disease who have been appropriately staged and treated with radiation alone. Radiation therapy is also well suited for older patients or those who are poor surgical candidates. Five-year survival is 95% to 100% for patients with microscopic disease, while 82% to 84% of those with macroscopic disease and negative surgical margins survive 5 years. If the surgical margins of resection are microscopically involved with carcinoma, 5-year survival ranges from 38% to 87%; survival drops to 20% to 47% for patients with gross residual tumor.

CERVICAL CANCER IN PREGNANCY

Cervical cancer is one of the most common malignancies in pregnancy, with an estimated incidence ranging from 1 in 1,200 to 1 in 2,200 pregnancies (1.6–10.6 cases per 10,000 pregnancies). Conversely, 1 of every 34 women diagnosed with cervical cancer is pregnant at the time of diagnosis. The most common complaint of pregnant patients with cervical cancer is abnormal bleeding. However, confusion between the symptoms of early cervical cancer and those of normal pregnancy frequently leads to a delay in diagnosis. Pathologic confirmation of the presence of invasive cervical cancer should be obtained by directed biopsy in the presence of a grossly visible lesion. Conization is only indicated for those patients with apparent microinvasive disease on directed biopsy or for patients with persistent cytologic evidence of invasive cancer in the absence of a colposcopically visible lesion. Diagnostic conization should only be considered when a diagnosis of invasive cancer will result in a modification of treatment recommendations, timing, or mode of delivery. From an obstetric standpoint, the optimal time to perform conization is between 14 and 20 weeks gestational age or after the time of fetal viability has been reached.

The same clinical staging system of cervical cancer is employed for both nonpregnant and pregnant patients alike (see Table 52.2). For pregnant patients with cervical cancer, the use of MRI may be an appropriate substitute for intravenous pyelogram (IVP) or CT if minimizing fetal exposure to ionizing radiation is desirable. Once the diagnosis of cervical cancer has been established, treatment recommendations are individualized and are dependent on the stage of disease, gestational age at the time of diagnosis, and the desires of the patient regarding continuation of the pregnancy. Patients with well-documented stage IA1 disease (conization with negative surgical margins) may be managed with vaginal delivery and reevaluation postpartum. If the patient has completed childbearing, a simple extrafascial hysterectomy would be appropriate, otherwise close clinical follow-up is required. For patients with stage IA2 disease, a modified radical cesarean hysterectomy with pelvic lymph node dissection is the preferred treatment. Patients with stage IB or IIA disease may be treated with surgery in the form of radical hysterectomy and pelvic lymph node dissection, either in conjunction with cesarean section or with the fetus in situ, depending on the gestational age. Radiation therapy is the treatment of choice for patients with stage IIB to IVA disease or those with stage IB and IIA disease who are not favorable candidates for radical hysterectomy. Radiation therapy may be initiated with the fetus in situ for nonviable pregnancies, with spontaneous abortion occurring 4 to 5 weeks after starting treatment. For more advanced gestations, classic cesarean delivery is performed initially, with radiation therapy commencing 2 to 3 weeks following delivery. The issue of delaying treatment in order to reach a gestational age consistent with fetal viability has been controversial. Although the data are limited and retrospective in nature, it appears that a treatment delay of 6 to 12 weeks is not detrimental for patients with localized (stage I) disease. Treatment delays are not recommended for patients with more advanced disease.

SUMMARY POINTS

- Regular cervical cytologic screening with the Pap smear is the single most effective means of reducing the incidence and mortality of invasive cervical cancer.
- By convention, cervical cancer is a clinically staged disease; however, ancillary tests and surgical staging may provide useful information and facilitate a treatment approach tailored to the true extent of disease.
- Surgery (radical hysterectomy with pelvic lymphadenectomy) and radiation therapy are associated with equivalent survival outcomes for patients with early-stage (I–IIA) cervical cancer.
- Patients with advanced-stage disease (IIB–IVA) should receive radiation therapy with curative intent, preferably in combination with concurrent chemotherapy.

Since the advent of widespread Papanicolaou (Pap) smear screening in the United States during the 1950s, the incidence of invasive cervical cancer and mortality from this disease has fallen approximately 70%. The Pap smear collects exfoliated cells from the surface of the cervix. Exfoliation occurs from normal, precancerous, and cancerous cervical epithelium. It is the detection of precancerous cells, which predate invasive disease by years, that leads to treatment of the cervical epithelium and prevention of invasive disease.

The management of the abnormal Pap test has undergone numerous updates, which are reflected in the consensus guidelines from the American Society of Colposcopy and Cervical Pathology (ASCCP). Full guideline disclosure can be reviewed at http://www.asccp.org/. These guidelines were the result of a widely inclusive consensus conference convened in 2001 and reflect the new terminology for Pap test classification, known as the Bethesda System, which also underwent consensus review in 2001. A full classification can be reviewed at http://bethesda2001.cancer.gov/.

Treatment should be based on a diagnosis that results from evaluation of the tissue's abnormal cervical cytology. Screening and subsequent treatment are aimed at the detection and elimination of preinvasive cervical disease, thus eliminating subsequent invasive disease. Management guidelines have been developed for preinvasive cervical disease.

EVOLUTION OF SCREENING CERVICAL CYTOLOGY AND THE BETHESDA SYSTEM

The evolution of the Pap smear is instructive in many aspects. First devised as a simple method to determine the reproductive cycle of laboratory animals by George Papanicolaou, it has evolved into a source of cellular material for sophisticated molecular and diagnostic techniques. Although apparently ever changing, the one consistent aspect of its past and future is the success Pap screening has had in the prevention of invasive cervical cancer.

Papanicolaou introduced collection of cervical cells from the posterior vaginal fornix as a method of finding early invasive cervical cancer. Ayers introduced direct sampling of the cervix with the spatula that still bears his name. Such direct sampling significantly increased the cellular yield.

The next major advance was the support that the beginnings of the American Cancer Society provided for increasing the visibility of the Pap smear. Such exposure led to increasing adoption of the technique, and this coincided with the realization that Pap smears could detect preinvasive disease, as well. Richart and colleagues identified the preinvasive component to squamous cell cancer of the cervix. This was achieved, in part, by use of the colposcope in defining the cervical transformation zone.

Terminology was developed for squamous preinvasive disease and reflected its origin in the cervical epithelium. The term *cervical intraepithelial neoplasia*, or *CIN*, was developed, and increasing involvement in the epithelial layer was reflected by CIN grades. CIN grade 1 (CIN 1) was used when fewer than one half of cells of the squamous cervical epithelium were abnormal. CIN 2 represented approximately two thirds involvement and CIN 3 a full-thickness epithelial abnormality. Until the early 1990s, some iteration of these categories was used to describe cervical cytology results. These terms still are used to describe the histology of squamous cervical lesions.

Technology also has led to changes in the way that we obtain cervical cytologic specimens. The first advance was the Ayers spatula, as noted above. Next, cotton swabs, often moistened with saline, were used to obtain cells directly from the cervical transformation zone. Although an improvement, a major advance in obtaining endocervical cells occurred when the endocervical brush was introduced in the 1980s. Although earlier thinking was that squamous metaplastic cells or endocervical cells were important in determining the adequacy of cervical screening, this concept has not been supported by the data. It has since become evident that a certain amount of squamous cellularity is more reflective of adequate sampling.

In the late 1980s, increased attention was paid to the potential false-negative result rate of the Pap smear, widely quoted to be as high as 50%. A false-negative Pap smear result does not reflect the current condition of the cervical epithelium and can arise from errors in screening, interpretation, or sampling. Several studies have shown that the inability of a Pap smear to render the true cervical diagnosis is more likely due to the smeared cellular sample not representing the state of the epithelium rather than the technical interpretation being misleading. Given these data, several efforts were made to reduce the false-negative rate and resulted in technology that allows for the cervical cellular sample to be rinsed into a preservative solution. Data have shown that up to 80% of the cells collected are thrown away after a conventional smear is made. Less than 10% are left on the collection device when the device is rinsed rather than smeared onto glass. From the concept of improving the cellular sample came the basis for liquid-based Pap tests, thus attempting to decrease the false-negative rate.

The Food and Drug Administration (FDA) has approved two liquid-based Pap tests. Both allow for the cellular material to be deposited in a liquid preservative that rinses the collection device and fixes the cells. The liquid-based Pap tests are the ThinPrep Pap Test (TPPT, Cytyc Corporation, Boxborough, MA, 1996 approval) and the AutoCyte PREP (TriPath Imaging, Burlington, NC, 1999 approval).

FDA labeling for the TPPT allows the makers of this system to claim that it is more sensitive than the conventional Pap smear for the detection of low-grade squamous intraepithelial lesion (LSIL) or greater disease. In 2001, they were allowed a claim that it was more sensitive for the detection of high-grade squamous intraepithelial lesion (HSIL) or greater disease. Further data had been required by the FDA to substantiate the LSIL or greater claim, and the data from a six-site clinical trial resulted in a greater than 53% increase in detection of HSIL or greater disease.

FDA labeling allows the makers of AutoCyte PREP to state that it is a replacement for the conventional Pap smear and leads to fewer unsatisfactory specimens. There is less published literature on this system than on the TPPT. Although there have been editorials indicating that the two systems are probably equivalent, the data sets as yet do not support equivalency, and there has been no head-to-head trial comparing the two systems.

Given the significant concern regarding the quality of Pap smears, the U.S. Government developed the Clinical Laboratories Improvement Amendment released in 1988. This guideline addressed the number of Pap smears that could be screened by cytotechnicians and the need for quality assurance review. Additionally, this amendment directed the National Institutes of Health to establish guidelines on Pap smear terminology in order for the cytology results to be more consistent. As a

result of this direction, the first Bethesda conference was held in 1990, leading to the development of the Bethesda System for Pap cytology reports.

The Bethesda System used the categories of:

1. No evidence of malignant cells
2. Atypical squamous cells of undetermined significance (ASCUS) for cells felt to represent some of the spectrum of changes found in precancerous cells but not diagnostic of such
3. LSIL for cells with findings consistent with either human papillomavirus (HPV) effects or consistent with CIN 1–type changes. The thinking was that there was little ability to discern cytologically koilocytic effect from CIN 1 changes.
4. HSIL for cells with findings consistent with CIN 2, 3, or carcinoma in situ. The ability to discern among these categories was limited, but these cytologic changes were distinct from CIN 1–HPV effect.

In 2001, the third Bethesda conference was held and resulted in some more subtle, yet very important, changes. At major issue was the category of ASCUS. This category is difficult to interpret clinically, and it was felt that more recent data regarding this category supported a change. The change was to remove from the ASCUS category those Pap tests that contained cells suspicious for HSIL but not diagnostic. Therefore, the category of atypical squamous cells suspicious for HSIL (ASC-H) was developed. Further, the remaining atypical Pap test results would be designated atypical squamous cells of undetermined significance (ASC-US).

The 2001 Bethesda System update did not alter the categories of LSIL and HSIL. It did designate a specific cytology category for adenocarcinoma in situ. In the glandular preinvasive categories, atypical glandular cells (AGC) also have an undetermined significance (AGC-US) and suggest neoplasia. Within the glandular neoplasia section, the cytopathologist is asked to designate further whether the cells are from the endocervix or endometrium, if possible.

Further, those in compliance with the 2001 Bethesda System will now report benign endometrial cells, when seen in the cytology specimen, for women age 40 and older. As a women nears and goes beyond the menopausal years, the presence of benign endometrial cells can be indicative of more significant endometrial cavity pathology, such as polyps, hyperplasia (both simple and atypical), and endometrial cancer.

Educational notes are recommended at the end of the Bethesda System report and now will reflect the recommendations of the ASCCP consensus conference guidelines. A further discussion of these consensus conference guidelines is presented later in this chapter.

Interestingly, the 2001 Bethesda conference also took into account data from the Atypical/Low-grade Triage Study (ALTS), which looked at the overall best way to find histologic high-grade precancer within the cytology categories of ASCUS and LSIL. The expectation of the 2001 Bethesda conference was to triage ASC-US cytology by testing for HPV high-risk (HR)-type DNA and sending to colposcopy those whose ASC-US Pap tests were positive. The full results and recommendation of the ALTS and the ASCCP consensus conference will be discussed later in this chapter.

EPIDEMIOLOGY AND MOLECULAR BIOLOGY OF HUMAN PAPILLOMAVIRUS INFECTION

Since the early 1990s, HPV has been accepted as a necessary but not sufficient cause in the development of invasive cervical cancer, both squamous cell cancer and adenocarcinoma. It is the natural history of an HPV infection that has given rise to the not-sufficient portion. Excellent data support the concept that the majority of HPV infections, particularly the initial exposure in a woman's teens and early 20s, regress spontaneously.

Although HPV-related diseases have been noted in the medical literature since the Roman-Hellenic era, it was not until researchers using electron microscopy identified mature viral particles in condylomata during the 1950s that a viral cause for these diseases was entertained strongly. The next breakthrough came with the isolation of HPV type 6 DNA from condylomata by zur Hausen and colleagues during the early 1980s. Since that time, more than 100 HPV types have been identified. A new type is designated when there are sufficient differences in the DNA sequences but still enough homology such that it is consistent with the overall family of papovaviruses.

Interestingly, HPV types have specific preferences for the type of epithelium that they infect. Our interest is in those HPV types that exclusively infect lower genital tract epithelium. These HPV types have been categorized further according to their ability to cause cervical neoplasia. Those HPV types that rarely, if ever, are found in preinvasive or invasive cervical cancer are put in the category of low-risk viruses. Conversely, those types found at least occasionally in high-grade cervical intraepithelial neoplasia or cancer are categorized as high-risk viruses (Table 53.1). The prototypes of HR HPV are HPV 16 and 18. Combined, these viral types are present in more than 90% of high-grade precancers and over 80% of invasive disease.

Low-risk HPV types	6, 11
High-risk HPV types	16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68

TABLE 53.1. *Human papillomavirus types*

The genetic areas of interest in HPV are the E6 and E7 (E, early) reading frames. The protein products of these areas bind tumor suppressor genes *p53* and *pRB*, respectively. Simply, these genetic regions can cause transformation but not immortalization in cell culture when derived from the HR HPV types. Low-risk types do not give rise to such changes. Disruption of these tumor suppressor genes causes a cascade of events including alteration of the cell cycle. The viral capsule is quite uniform within the types and is formed from the L1 and L2 (L, late) reading frames. These capsule proteins are utilized in prophylactic vaccine therapy, whereas various manipulations of either the protein or HPV DNA from E6 and E7 are used in therapeutic immunologic approaches. An in-depth discussion of these events can be found in reviews of HPV molecular biology.

Exposure to HPV appears to occur primarily by intimate sexual contact but does not require intercourse. Other avenues of exposure have been discussed but not verified, such as common pools, hot tubs, and bathrooms. How HPV infects the skin has not been proven definitively but most likely requires breaks in the epithelial surface. Once exposed, the recipient's options are to kill the virus or become infected. When infection occurs, replication of the viral particle requires mature squamous keratinocytes for capsule assembly. This is the underlying reason why HPV cannot yet be cultured successfully in routine microbiology laboratories as a method of HPV detection.

Prolonged HPV infection allows the virus to produce its proteins and, in the case of high-risk viral types, that means E6 and E7 proteins. It is this process that is tied intimately to the morphologic changes that we perceive as CIN and invasive disease. For low-risk types, expression of the viral proteins leads to a proliferative epithelial response and the formation of condylomata or, in some cases, low-grade CIN.

Epidemiologic case studies, often using HPV DNA detection techniques, indicate that widespread exposure of the female and male sexually active population has occurred, yet the majority of these HPV-related infections appear to regress spontaneously. Koutsky and colleagues followed young women manifesting evidence of their first exposure to HPV and found that all evidence of HPV appears to regress spontaneously within 9 to 18 months from first exposure. The reason for eradication of this viral infection is not known, but immune response to the infection is a leading theory.

Reasons for suspecting that an immune response to HPV infection is the source of regression of disease are well founded but have not yet been proven definitively. Those whose immune systems are compromised, such as organ transplant recipients and human immunodeficiency virus–infected individuals, have virtually no ability to clear their HPV infections, even with repetitive treatment. Even when patients who are seropositive for human immunodeficiency virus or who have acquired immunodeficiency syndrome are treated aggressively with antiretroviral therapy, their HPV infections remain.

Interestingly, young women first exposed to HPV will be most likely to manifest their infections by developing CIN 1, which is detected by Pap test and can be confirmed by biopsy. However, the HPV types involved in these lesions are predominately in the high-risk category. Although this finding has not led to a change in the definition of low-risk versus high-risk types, it indicates that clinically detectable cervical cytologic abnormalities most likely represent HR HPV no matter what the degree of morphologic abnormality.

More significant precancerous changes, such as CIN 2 or 3, tend to occur in the mid to late 30s and into the 40s. These morphologic changes are indicative of risk for progression to invasive disease and, again, are caused by HR HPV types. How these women, often in apparent monogamous relationships, became exposed to HPV remains an area of strong research. Some believe that this represents reexposure, while others feel that perhaps a form of viral latency is at play. Obviously, HPV does not exhibit the classic manifestations of a latent virus, and perhaps the best way to describe this situation is a lack of clinical symptoms of the HPV infection after

apparent spontaneous regression during the woman's 20s.

Underlying the information regarding HPV discussed to this point is that studies increasingly are showing that cytologically normal women who harbor HR HPV types in the cervix over a period of years are at increased risk for the development of high-grade preinvasive disease. Although not yet completely accepted clinically, certainly these women represent the at-risk pool among those who have had sequentially normal cytology findings on Pap testing. These data become increasingly significant as the woman's age advances to 30 years or older.

Many clinicians are not aware that women who practice a homosexual life style are also at risk for HPV exposure. They, like their heterosexual counterparts, require Pap test screening and develop evidence of HPV exposure with positive cervical cytology findings. An abnormal Pap test result in a homosexual women is no different in its etiology than in those with other sexual orientations.

HUMAN PAPILLOMAVIRUS TESTING METHODS

Because HPV cannot be cultured, its detection depends on the identification of its DNA. Since the advent of polymerase chain reaction (PCR) and similar DNA amplification methods, very minute amounts of viral DNA can be detected from infected cells. Generally, these methods require the extraction of the cell's DNA, and then the aggregate DNA is probed specifically for the presence of viral DNA. Using such techniques, although very sensitive, does not allow for identification of what cell in the sample carried the viral DNA. Therefore, contamination from sperm, white cells, or mucus of male origin may lead to false-positive HPV DNA test results. The most common methods for HPV DNA detection are PCR based and RNA-DNA hybrid detection, which is the method used in Hybrid Capture (HC; Digene, Gaithersburg, MD).

HC II is a relatively simple and inexpensive method of detecting and amplifying a specific DNA signal and is clinically relevant as the only FDA-approved test for HPV. Cells are disrupted with a base solution that liberates the aggregate sample's DNA. RNA probes specific for HPV types are then added to the solution and allowed to adhere to target DNA to form DNA-RNA hybrids. This sample is then exposed to antibodies to DNA-RNA hybrids. These antibodies are already adherent to the walls of a well and, thus, the DNA-RNA hybrids are fixed to the walls. Multiple antibodies that have alkaline phosphatase attached to them, thus amplifying the signal, then further detect these hybrids. The signal amplification can be up to 3,000-fold. A chemiluminescent dioxetane substrate is then added to the sample and it is cleaved by the alkaline phosphatase. The subsequent substrate produces a type of light that can be measured in a luminometer. Such light is reported as relative light units (RLUs). The RLU of an unknown is compared with that produced from a control sample containing 10 pg/mL of relevant HPV DNA. Final data is reported as a RLU-to-PC ratio, and a positive sample must have a value of 1.0 or greater.

The beauty of HC is that little additional equipment is necessary for the assay. Also, multiple HPV DNA probe types can be placed into the sample at one time, allowing for detection of multiple different HPV DNA sequences. The assay is separated into high-risk and low-risk groups. In the high-risk group, the assay contains RNA probes for types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68.

Problems noted in the literature with HC II surround its reproducibility and potential for cross-reactivity in the high-risk assay with low-risk types, which may be present in overwhelming amounts. Other issues surround whether or not the RLUs are directly proportional to the amount of HPV DNA present in the sample and, therefore, can be used as a method of viral load determination. No final consensus has been reached on that issue. Additionally, it is hard to discern from recent reports whether the relative changes noted in viral load are a byproduct of the size and grade of the cervical lesion or predictive of a larger lesion as Sun and others propose.

The general consensus is that HC II is as sensitive and specific as PCR-based HPV detection methods. PCR techniques have not yet been perfected that will multiplex for the presence of HPV DNA and discern high-risk HPV DNA from low-risk. However, in contrast to HC II, PCR does not appear to suffer from cross-contamination of its results from other HPVs that are not clinically relevant for that given patient or sample. Additionally, some researchers feel that sensitivity of PCR is slightly better than that of HC II and advocate that HPV-negative cytology be retested with PCR using the MY09-MY11 primers. Another potential advantage of PCR is the ability to determine specifically which HPV is present, whereas HC II will be able to determine only if the DNA lies within the high-grade or the low-grade category.

ASCUS/LSIL TRIAGE STUDY

Although only a small percentage, typically 10% to 14%, of ASCUS or of LSIL neoplasia actually represents a histologic high-grade lesion, such Pap test results are common enough to give rise to the majority, greater than 60%, of high-grade histology or CIN 2 or 3. Many clinicians would prefer not to perform colposcopy for the first ASCUS Pap test due to the frequency of this cytologic diagnosis.

More than 5% of all Pap tests per year in the United States reveal ASCUS. This would mean approximately 2 million colposcopies per year solely to evaluate ASCUS if all of these results were immediately triaged to colposcopy. LSIL represents approximately 2% of annual Pap test diagnoses. Given that the vast majority of histologic low-grade lesions or CIN 1 will regress spontaneously, one would prefer to follow patients with ASCUS/LSIL Pap test results, if possible.

The ALTS trial was developed to determine if CIN 3 lesions could be identified within these cytologic categories using either repetitive Pap tests, immediate colposcopy, or ancillary testing for the presence of HR HPV types. The colposcopy arm was considered the gold standard. Patients with a Pap test showing LSIL or ASCUS were randomized into either immediate colposcopy, interval Pap test follow-up, or HPV DNA testing using the HC II test to detect high-risk oncogenic viral types, with referral for colposcopy for positive test results. The main end point of the trial was a histologic diagnosis of CIN 3.

Approximately 640 patients were randomized into the LSIL arm when it was closed. Accrual was terminated due to the high percentage of patients found to have HR HPV by HC II results. Given that more than 80% of HC II results were HR positive, HPV DNA testing could not be utilized in this cytologically defined group for colposcopy triage.

In the ASCUS group, however, the results indicated that HC II HR-positive result was an effective parameter for triage for colposcopy and resulted in the greatest detection rate of CIN 3 from the three ASCUS study arms. HC II detection of HR types resulted in approximately 56% of this arm of the ASCUS study being referred for colposcopy. The repetitive Pap test arm reached equivalency over a year of follow-up when colposcopy was done for a repeat ASCUS result or greater. It is from this large pivotal trial and several smaller antecedent trials that the ASCCP based its recommendations for ASCUS and LSIL evaluation.

Since publication of the ALTS trial data, there has been some dissent regarding HPV testing of ASCUS Pap tests. Herbst and others have cited the difficulties in reproducing the ASCUS Pap test results as a potential pitfall of the trial results. Other obvious concerns for clinicians with the ASCUS triage to HPV testing are as follows: (a) discussing the HPV test results with patients and their families, (b) potential cross-over reactivity when high viral loads of low-risk HPV 6 and 11 are present, (c) potential increase in the ASCUS category because reflexive testing for this category will occur, (d) how to manage the ASCUS-positive, HC II HR-positive patient with a colposcopy that reveals no evidence of disease. The challenge will be to educate the consumer and medical personnel on how to handle these situations.

AMERICAN SOCIETY OF COLPOSCOPY AND CERVICAL PATHOLOGY CONSENSUS GUIDELINES FOR THE MANAGEMENT OF THE ABNORMAL PAP SMEAR

Following the 2001 Bethesda conference, the ASCCP held a consensus conference to discuss the changes in the Bethesda System and to utilize data from the ALTS and other clinical trial data to develop guidelines for the clinician in the management of abnormal Pap test results. These guidelines can be viewed in their entirety at http://www.asccp.org/.

For the Pap test that does not reveal any evidence of cytologic abnormalities, the ASCCP has indicated that routine screening should allow for physician-patient decision making. There was considerable discussion regarding how to determine if a woman is in a high-risk category and, therefore, should be screened more frequently compared with those women felt to be at low risk for the development of CIN. No true consensus was reached. The concept of HPV DNA testing for high-risk viral types by HC II in women with normal cytology as a means of determining risk was discussed, but it was felt that the data were insufficient to allow them to reach a conclusion.

In the category of ASCs, the ALTS data were utilized for ASC-US. Interestingly, little mention is made of ALTS use of the ASCUS category without further subcategories, and the ASCCP guidelines will use the 2001 Bethesda System category of ASC-US. Essentially, ASCCP guidelines indicate that the preferred method of evaluation of the ASC-US Pap test is two-fold. If it comes from a liquid-based sample, reflex testing for HR HPV DNA is done using HC II, and if it comes from a conventional Pap smear, secondary HPV testing is performed using a second co-collected sample. If no co-collection was performed, then for the ASC-US category, Pap smears are repeated at 6-month intervals and the patient is referred for colposcopy if results are repetitively ASC-US or greater. When HC II is done, those patients with ASC-US samples positive for HR HPV should have immediate colposcopy, whereas those negative for HR HPV can revert to yearly screening.

For those patients with ASC-US with HR HPV on HC II who do not have documented CIN at the time of colposcopy, repeat cytology testing at 6-month intervals is

recommended, with repeat colposcopy for any positive results. An alternative is to repeat the HPV DNA testing after 12 months and, if positive for high-risk types, repeat the colposcopy. Little is known as to the rates of CIN for the initial ASC-US and less for those who require follow-up of negative colposcopy findings. Postapproval studies will be extremely useful in guiding clinicians and patients.

Patients with ASC-H Pap test results should be referred for immediate colposcopy. Although there are no specific data for this category regarding the possibility of CIN 2 or 3 being found, it is inferred from previous reports that the possibility will be high enough to warrant colposcopic intervention. Postimplementation studies will be of interest. Additionally, the guidelines lead one to assume that HPV DNA testing would not be a useful triage tool for this category.

When negative colposcopy results are noted for ASC-H, the recommendation is to review the cytology and histology for correlation and confirmation. If again supportive of the respective diagnoses, then repeat cytology at 6-month intervals or retesting for HR HPV DNA after 12 months is acceptable, with repeat colposcopy for positive findings.

For LSIL, the ASCCP guidelines note that HPV DNA triage is not useful. This is based primarily on the ALTS data that revealed 83% of LSILs positive for HR types. Given these data, colposcopy is the preferred method of evaluation for LSIL. If colposcopically directed biopsies are consistent with CIN 1 or less, then continued screening with cervical cytology at 6-month intervals is acceptable. Another follow-up method postcolposcopy would be for patients with documented CIN 1 to undergo an HC II assay after 1 year and, if positive, move on to treatment. In any scenario, the guidelines recommend a follow-up period after histologically documented CIN 1 to allow for spontaneous regression. Those patients with cytologically demonstrated LSIL who have CIN 2 or 3 shown by biopsy should follow the guidelines for treatment.

The general guidelines for LSIL are for complete visualization of the transformation zone. When the colposcopy is unsatisfactory, an endocervical curettage is preferred, because it may reveal a diagnosis confirmed by this histology. If all histologic findings are negative, repeat cytologic studies at 6-month intervals or testing for HPV DNA after 1 year is appropriate.

When postmenopausal women have a Pap test consistent with LSIL, one should evaluate the Pap test for evidence of atrophy. If present, treatment with topical estrogen cream should be performed and the Pap test repeated after several weeks. Should the Pap test result then revert to normal, routine screening can be instituted. If still abnormal, colposcopy should be performed.

Pregnant women with LSIL should have colposcopy and biopsy performed when deemed appropriate by examination. Continual follow-up with either cytology or HPV DNA testing is warranted. Adolescents can be followed prospectively without colposcopy for the LSIL category. Either cytologic examination at 6-month intervals or follow-up HPV DNA testing after 1 year is acceptable.

There is no question that an HSIL detected with cytology most likely will reveal CIN 2 or 3 on colposcopically directed biopsies and, therefore, colposcopy is the preferred method. With HSIL cytology results, one would still recommend colposcopy, even if the HC II screen were negative for HR HPV DNA.

Pregnant women should receive colposcopy and directed biopsy of any identified lesion. Vascular changes are more marked during pregnancy, thus making simple interpretation of the lesion colposcopically without biopsy confirmation more difficult. Therefore, even though bleeding may occur, it is recommended that biopsy be performed to rule out invasive disease.

Many clinicians are concerned when HSIL cytology is followed by negative colposcopy and biopsy findings. The guidelines indicate that for a satisfactory colposcopy, follow-up at 4- to 6-month intervals is acceptable for up to 1 year. If cytology results are still positive without lesions noted at that time, then a loop electrical excisional procedure (LEEP) should be performed.

In glandular lesions, the ASCCP guidelines are explicit that the Pap test that shows AGC, whether further qualified or not, must be evaluated with colposcopy and endocervical sampling. For those Pap tests showing AGC that are further qualified as suggestive of neoplasia, a negative colposcopy with negative histologic assessment does not end the evaluation. In that setting, further tissue sampling is required, and the preferred method is by cold knife conization. The same intervention applies for repetitive Pap tests showing AGC that are not explained by colposcopic assessment.

When the glandular cytology is felt to be endometrial in origin, then endometrial sampling is indicated. Also, when the glandular cytology is not further qualified and the woman is perimenopausal or postmenopausal, again endometrial sampling is recommended.

The finding of benign endometrial cells on a Pap test in a woman over age 40 should trigger the consideration of endometrial sampling. A careful history of the woman's menstrual pattern or evidence of any recent changes should be sought in addition to questioning, when appropriate, about postmenopausal bleeding.

Cytologic findings consistent with squamous cell cancer always should trigger a further examination, either visual if the lesion is obvious or by colposcopy if not clinically apparent. There is no consensus as to how tissue sampling of possible occult squamous cell cancer should be performed, and many advocate a LEEP be done rather than cold knife conization.

For those whose cytology is consistent with adenocarcinoma in situ, colposcopy should be performed to identify any obvious areas of malignancy, but unless a diagnosis of adenocarcinoma in situ is found on biopsy, a diagnostic procedure is indicated, preferably a cold knife conization. Such a tissue excision should be evaluated for the presence of adenocarcinoma in situ and the possibility of early invasive adenocarcinoma.

TREATMENT

The criteria for treating preinvasive cervical disease depend on the histologic diagnosis, the location and size of the lesion, and the distance from the endocervical canal to the lesion. For CIN 2 or 3, treatment without delay is advised. In the case of CIN 1, persistence of the lesion for longer than 12 months is a reason for treatment. When the histology indicates a glandular lesion, cold knife conization (CKC) is indicated.

Treatment can be either ablative or excisional. Ablative techniques do not generate any further tissue specimens and include laser vaporization and cryosurgery. Such treatment requires a satisfactory colposcopic examination that identifies the entire transformation zone and the full extent of the lesion area. Excisional techniques will generate further tissue for histologic review and include conization by cold knife, LEEP, or laser excisional technique. Generally, when LEEP is used in the office, the same criteria used for ablation apply in order to minimize the potential for bleeding.

Mitchell and colleagues randomly compared cryosurgery, laser vaporization, and LEEP for patients with cervical squamous intraepithelial lesions. No essential difference was noted in success rates or complications among these techniques. As noted above, glandular lesions, either suspected by cytology or documented by histology, require surgical intervention. Because controversy still exists regarding the status of the type of conization for glandular disease, the ASCCP guidelines do recommend CKC for depth of excision and clarity of margins.

TECHNIQUES FOR TREATMENT OF SQUAMOUS INTRAEPITHELIAL LESIONS

Treatment techniques are listed in Table 53.2. It is important to remember that the final pathology after these excisional techniques occasionally will reveal apparently normal epithelium. The most likely reason for this is that the area of morphologic change was removed by a prior colposcopically directed biopsy.

Ablative
Cryosurgery
Laser vaporization
Excisional
Laser excisional conization
LEEP (loop electrical excisional procedure)
Cold knife (scalpel) conization
Hysterectomy

TABLE 53.2. *Techniques for treatment of squamous intraepithelial lesions*

Cryosurgery

The technique of cryosurgery initially was reported for treatment of CIN in the early 1970s. Using either carbon dioxide or nitrous oxide under pressure as the coolant, the cervical epithelium is frozen to a depth of 6 to 10 mm. The length of time for the freeze and the absolute temperature of the probe will determine the depth of penetration and subsequent tissue loss. Tissue is sloughed off slowly, over a period of 10 to 14 days, as a watery discharge. The most widely accepted technique for cryosurgery is to freeze the cervix for 3 minutes after formation of an ice ball on the cervix, followed by a 5-minute thaw and a repeated 3-minute freeze.

Although not as widely used as it was prior to LEEP, cryosurgery is less expensive and therapeutically will have results similar to LEEP when adequate caution is used with its application. In general, cryosurgical lesions need to be close to but not extend far into the cervical canal. They ideally need to be within a 2-cm radius from the canal, not occupy more than 50% of the cervical surface, and not involve the endocervical glands. Generally, cryosurgery is performed after childbearing has been completed.

Laser Vaporization

Initially discussed in the gynecology literature in the late 1970s, laser (light amplification by stimulated emission of radiation) became the mainstay of therapy throughout the 1980s and into the 1990s. Its use does require a learning curve, and the length of time for vaporization of cervical lesions should not exceed that taken by cryosurgery. Laser is light generated in the infrared spectrum by running electricity through a gas. For lower genital tract use, the gas used is carbon dioxide. The wavelength of such a laser is absorbed primarily by water. Thus, individual cells are heated instantaneously when the light contacts them, leading to their immediate vaporization by boiling the cellular water content. One can control the depth of laser penetration into the cervical epithelium quite closely by altering the spot size, the power, and the dwell time. Settings used lead to a lower power density that creates a larger area of vaporization and is achieved by a beam spot size of 2.0 to 2.5 mm. Generally, laser vaporization is done to a depth of 7 to 10 mm.

The procedure can be done safely in the office under local anesthesia, using nonsteroidal antiinflammatory drugs to reduce postprocedure discomfort. It is not uncommon to perform laser procedures in the operating room when the area to be treated is extensive.

Laser was widely replaced by LEEP. Tissue generation and ease of use have made LEEP attractive. However, treatment of extensive, preinvasive disease involving multiple lower genital tract structures, such as the cervix and vagina, often are performed in one sitting using laser.

Laser Excisional Conization

Rather than using laser for vaporization leading to ablation, one can use it to excise a conization specimen. The settings for the latter create a significantly greater power density, allowing the laser beam to act in an excisional rather than ablative manner. This is achieved by decreasing the spot size of the beam. Difficulty interpreting cone margins due to “char” artifact caused by laser excision and the ease of LEEP conization have reduced significantly the indications of laser conization.

Loop Electrical Excisional Procedure

LEEP, variably known as simply loop or LLETZ (large loop excision of the transformation zone), was made possible after modifications were developed in the wire loop and the electrosurgical current running through it. Now the current, a blend of coagulative and cutting electrosurgical currents, allows for excision with minimal bleeding and minimal coagulative artifact of the excisional margin.

Most practitioners who perform LEEP will do so in the office on patients with satisfactory colposcopy findings, with the extent of the lesion visible. Vasoconstrictive agents, such as epinephrine or pitressin, are combined with local anesthetics given in an intrastromal technique, circumferentially over the cervical face and avoiding the lesion area. Such treatment maximizes vasoconstriction and provides local anesthesia. Many practitioners will identify the transformation zone and lesion tissue by staining the cervix with modified Schiller iodine solution prior to excision. The procedure is best performed as a single pass encompassing the transformation zone and lesion. Coagulation of the surgical bed is then done with a roller ball cautery using a spark technique. Monsel solution commonly is placed in the surgical bed for hemostasis, thus avoiding sutures.

Cold Knife Cervical Conization

The role of CKC has become increasingly limited due to the widespread use of LEEP. Most clinicians feel that CKC should be performed when the margins of resection are important, because LEEP can leave a cautery effect difficult to interpret at the margin. The uses of CKC have been focused on evaluation of microscopic invasive disease, both squamous cell cancer and adenocarcinoma. Certainly there is support for CKC in adenocarcinoma in situ for evaluation of margins and depth of the conization sample. The incidence of adenocarcinoma in situ is increasing in women of childbearing age, and sparing of fertility is an important concern. Given this rise in incidence, much has been made regarding conservative management. Shin and others point out that deep conization of greater than 1½ to 2 cm with negative margins can assess the extent of adenocarcinoma in situ involvement and margin status. With negative margins, the patient can be highly reassured that no residual disease exists in the residual cervix.

CKC generally is performed under general anesthetic with the patient in the dorsal lithotomy position. The cervical transformation zone is identified by use of iodine solution, and the areas that are iodine negative are not part of the transformation zone.

Hysterectomy

Although not commonly used at this time, there still is a role for hysterectomy in the treatment of the abnormal Pap test. Such a need does arise in the scenario of repetitive high-grade CIN that recurs despite less invasive treatments. It is not uncommon in this situation to end up with cervical scarring that makes Pap test and colposcopy virtually impossible to perform. The patient, particularly postchildbearing, may opt for more definitive management with hysterectomy. However, she should be counseled that her abnormal cytology result rate posthysterectomy will not be zero. Preinvasive disease can occur in the upper vaginal vault at the hysterectomy cuff area.

Immunotherapy

Because HPV is necessary for the development of CIN and invasive cancer, one would assume that a prolonged infection is required for transformation. HPV-related cell surface proteins have been identified and certainly should induce an immune response. This immune response potentially could be supplemented by inducing a further immune response by the administration of similar HPV-related proteins. The concept is to enhance a T-lymphocyte response that will lead to eradication of the cervical lesion.

Several methodologies have been evaluated in phase 1 and 2 clinical trials looking to treat CIN 2 and 3 or invasive squamous cell carcinoma. The results have shown some responses but are not yet definitive.

Vaccines have been developed that employ the use of the HPV viral capsule. The capsule is produced by the L1 and L2 regions of the HPV genome and have very little variation from one type of HPV to another. Therefore, capsules generated in vivo from the proteins of these regions are being given as viruslike particles, or VLP, as vaccines against initial infection. The concept is to develop an antibody response to the VLP and thus create an antibody barrier to HPV infection transvaginally. It will be several more years before the preliminary clinical results are known, but initial antibody data from the cervix appear to support the induction of an immune response.

POSTTREATMENT SURVEILLANCE

Although the excisional and ablative methods are extremely effective for the treatment of CIN, there are instances of persistence and failure posttreatment. In general, these are found at the time of follow-up Pap testing. However, there is a growing interest in using HPV DNA after LEEP to predict which woman with positive margins after LEEP are at greatest risk of recurrence. At this point, there is no specific recommendation for HPV DNA testing post-LEEP, but it is certain to be evaluated further.

Most clinicians follow patients posttreatment with Pap tests every 6 months for a year and, if normal, yearly. Some have advocated the additional use of an endocervical curettage in the follow-up of women with glandular lesions, particularly adenocarcinoma in situ. If the Pap test result is abnormal, colposcopy should be performed to define the extent of disease and allow for directed biopsies.

SUMMARY POINTS

- The Pap test has a proven track record for success. Since its widespread inception in the 1950s, the incidence of invasive cervical cancer and related death has dropped significantly. Since then, the technique surrounding how cervical cytology is obtained and processed has changed, with increases in transformation zone sampling and decreases in apparent false-negative test result rates.
- In the 1960s, the categories of cervical intraepithelial neoplasia were used to describe preinvasive cervical cytology. CIN ranged from minor or grade 1 changes to the most severe cytologic atypia, designated CIN 3. In the 1990s, the Bethesda System created the categories of ASC-US, HSIL, AGC, and adenocarcinoma in situ to complement the invasive squamous cell cancer and adenocarcinoma categories.
- HPV is a necessary but not sufficient cause for the development of cervical precancerous and cancerous lesions. Testing for the presence of HPV DNA can improve the triage pattern of women whose Pap tests fall within the category of ASC-US. Data from the ALTS have shown that screening such Pap tests for the presence of HR HPV will better identify those women within the ASC-US cytology screening category who harbor high-grade CIN.
- Treatment advances stem from understanding that preinvasive and invasive cervical disease arises at the transformation zone. Treating this zone of change will completely eliminate preinvasive disease approximately 90% of the time or more. Therapies range from simple excisions of the abnormal cervical epithelium to laser or cryosurgical ablations, to surgical excisional biopsies of the cervix, to hysterectomy.

Endometrial Hyperplasia
Endometrial Carcinoma
Uterine Sarcomas

The uterus and endometrium are unique organs. Almost any type of tissue histology can and does arise from these pluripotent tissues. This chapter will present premalignant and malignant conditions of the uterus. This includes the premalignant condition endometrial hyperplasia, as well as the frankly malignant conditions of the uterus that comprise the following two broad categories: (a) epithelial cancer and (b) mesenchymal tumors. Both of these types of malignancies develop within the lining or the body of the uterus, and this chapter will describe the epidemiology, staging, and treatment of these cancers. The epithelial cancers are primarily comprised of endometrioid, clear cell, and papillary serous type tumors. The mesenchymal tumors are less common and are comprised of three broad categories, (a) mixed müllerian tumors, (b) stromal tumors, and (c) leiomyosarcomas.

ENDOMETRIAL HYPERPLASIA

Classification

Endometrial hyperplasia is an abnormal condition that usually represents an overgrowth of the endometrium. This terminology encompasses a wide variety of conditions. Some of these are clearly benign and some potentially malignant. Unfortunately, there have been so many different classifications over the years that there is significant confusion about the meaning of the term *endometrial hyperplasia.* For many years, it has been suggested that endometrial hyperplasia reflects the histologic representation of the continuum between normal proliferating endometrium and adenocarcinoma in situ. This theory was based on studies first reported by Gusberg and Kaplan in 1963. In that study, the authors reported that 20% of patients who had a hysterectomy were found to have a coexisting adenocarcinoma and that endometrial cancer developed in almost 12% of the remaining patients, with an average follow-up of 5.3 years. They concluded that the risk of cancer was significantly higher in women with endometrial hyperplasia than those without and that 10 years later the cumulative risk for cancer was approximately 30%.

During the ensuing years, several different classification schemes were developed, which resulted in increased confusion regarding both diagnostic criteria and prognosis of the various subtypes of hyperplasia. In the early 1990s the International Society of Gynecological Pathologists endorsed a classification that used both architectural features (the degree of glandular crowding and complexity) and cytologic features, especially cellular atypia. Simple hyperplasia is defined as abnormally thickened endometrium with histologic evidence of an increased ratio of glands to stroma; the glands are cystically dilated and somewhat irregular with some infolding and budding. Complex hyperplasia represents glandular crowding with even less intervening stroma, and the glands show significant infolding and budding (Fig. 54.1). Atypical hyperplasia refers to either simple or complex architectural patterns, in which the cells lining the glands show loss of polarity, nuclear enlargement with increased nucleus-to-cytoplasm ratio and prominent nucleoli, and irregularly condensed chromatin (Fig. 54.2). Cystic hyperplasia is a benign condition arising from inactive endometrium and is not premalignant.

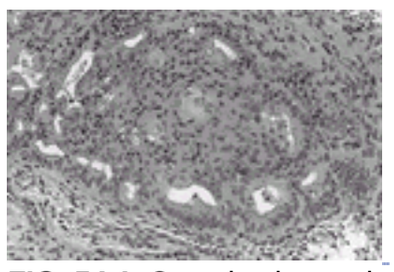

FIG. 54.1. Complex hyperplasia without atypia. Closely packed glands are connected by morular squamous metaplasia. No cytologic atypia is present.

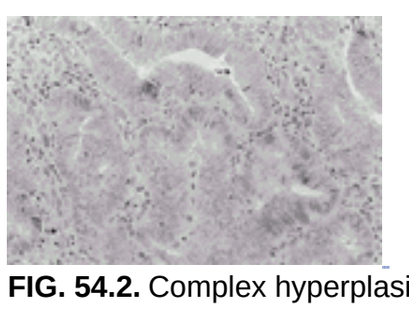

FIG. 54.2. Complex hyperplasia with atypia. Closely packed, irregular glands demonstrate cytologic atypia in the form of loss of polarity and rounding up of the nuclei

and nucleoli.

Since the study by Gusberg and Kaplan, additional studies have clarified some of the questions regarding this disorder. Using the new criteria, Kurman and colleagues reported that the risk of progression of endometrial hyperplasia to cancer varied according to the subtype. In this study of 170 patients, untreated endometrial hyperplasia regressed spontaneously in 74% and remained stable for more than 10 years in 18%. The risk of progression to cancer was 1% for patients with simple hyperplasia without atypia, 3% for those with complex hyperplasia without atypia, 8% for those with atypical simple hyperplasia, and 29% for patients with complex atypical adenomatous hyperplasia (Table 54.1).

TABLE 54.1. *Natural history of premalignant endometrial conditions*

Clinical Picture and Diagnosis

Endometrial hyperplasia usually becomes apparent with irregular vaginal bleeding. For this reason, this symptom should be evaluated with liberal use of the endometrial biopsy. Endometrial hyperplasia often is associated with a history of unopposed estrogen exposure, either exogenous or endogenous. In premenopausal women it is associated with obesity and anovulation. Therefore, women with known polycystic ovary syndrome or known anovulation are at increased risk for developing this disease, as are obese women. Any abnormal bleeding should be investigated in the postmenopausal woman, but features that would increase the suspicion of an abnormal endometrium are unopposed estrogen exposure from obesity or oral intake.

Cervical cytologic screening techniques are not a reliable means to diagnose endometrial abnormalities and should not be used to screen for endometrial abnormalities. Nonetheless the Pap smear can reveal endometrial abnormalities. Atypical glandular cells of undetermined significance (AGUS) should be evaluated aggressively, because the risk of having underlying endometrial pathology is high. Endometrial biopsy clearly should be included in the evaluation of this abnormal cytology. An endometrial biopsy is reported to be 97% as sensitive as a formal dilation and curettage (D&C). Therefore a D&C to evaluate these abnormalities is usually not necessary and should be used only when an endometrial biopsy cannot be performed, when persistent bleeding is unexplained by the biopsy, or when there is some uterine structural abnormality suspected, such as a polyp.

Management

Therapy for endometrial hyperplasia must be individualized and depends on histologic criteria, predisposing factors, patient age, and desire to maintain fertility. In addition to differences in overall prognosis, the various subtypes of endometrial hyperplasia also respond differently to progestin therapy. Ferenczy and Gelfand reported on the results of progestin therapy in 85 postmenopausal women with endometrial hyperplasia. Patients who had hyperplasia without atypia enjoyed complete reversal of the abnormality following treatment with medroxyprogesterone acetate, 10 to 20 mg daily. Patients with cellular atypia noted only a 50% response rate to the same treatment regimen. In patients with atypical hyperplasia, there was also an increased risk of recurrent hyperplasia or cancer after completion of the progestin therapy when compared with those who had hyperplasia without atypia (50% vs. 6%).

Premenopausal women can be treated with oral contraceptives for 3 months if they have no significant contraindications to their use. Most studies suggest that cancer will develop eventually in about 20% to 30% of patients with complex atypical adenomatous hyperplasia, but some have suggested a risk as high as 82% for those with untreated atypical hyperplasia. The risk of progression appears to be higher for postmenopausal than premenopausal women. The mean duration of progression from endometrial hyperplasia to carcinoma is about 10 years for lesions without atypia and 4 years for atypical lesions. In patients with atypical hyperplasia diagnosed by an endometrial biopsy specimen, a formal D&C should be considered to rule out a coexisting adenocarcinoma. It has been suggested that if gland epithelium is found within the stroma (i.e., stromal invasion) of the curettage specimen, even if the diagnosis is hyperplasia, there is a significant chance that the uterus still contains an endometrial cancer. If a diagnosis of carcinoma in situ is made by endometrial biopsy or D&C, in almost all circumstances a hysterectomy should be performed, because this is not a clearly reproducible diagnosis and actually may represent early invasive cancer or sampling error.

Progestational therapy is very effective in reversing endometrial hyperplasia without atypia. For these patients, either cyclic or continuous therapy is appropriate, using medroxyprogesterone acetate, 10 to 20 mg per day, or megestrol acetate (Megace), 20 to 40 mg per day, for either 14 days each month or daily. Therapy should be continued for 3 months, and then the endometrium should again be sampled to document response. The hyperplasia will revert to normal in 75% to 90% of patients treated with progestins. In patients who desire pregnancy, ovulation induction can be considered using either clomiphene or menotropins (Pergonal). If a patient does not desire pregnancy, oral contraceptive therapy should be considered. In those patients with persistent hyperplasia, definitive surgery should strongly be considered.

Patients with atypical hyperplasia often will opt for a hysterectomy and bilateral salpingo-oophorectomy when made aware of the risk of coexisting adenocarcinoma (approximately 20%) and the malignant potential of these lesions. A truly postmenopausal woman (last menses 2 or more years ago) should be encouraged strongly to undergo hysterectomy, with progestin therapy reserved for patients with severe medical problems that would make them very poor surgical candidates. If the decision is made to treat a patient medically, daily progestin therapy for 3 months is recommended, followed by repeat endometrial sampling. If hyperplasia persists in these patients, a D&C should be performed to rule out a coexisting malignancy, or a hysterectomy should be performed. At the time of hysterectomy, the uterus should be opened intraoperatively, with frozen section if indicated to document the presence and extent of any malignancy so that surgical staging can be performed at the same time, if appropriate.

An interesting, but still experimental, approach is insertion of an intrauterine contraceptive progesterone system (ICPS), which releases continuous therapeutic doses of progesterone or levonorgestrel. Until more experience is gained with the ICPS, it should not be employed outside a research setting. Two preliminary studies reported on the use of danazol (Danocrine) to treat women with adenomatous hyperplasia, and in both studies all women treated were noted to have reversal of the hyperplasia on repeat endometrial sampling. In all premenopausal women, menses resumed within 1 to 2 months following therapy. In the first study, atrophic changes were noted on repeat endometrial sampling even though the patients had normal serum estradiol levels, suggesting a direct effect on the endometrium.

A relatively recently described risk factor for endometrial hyperplasia and carcinoma is the use of tamoxifen citrate (Nolvadex) as an adjuvant treatment for breast cancer. Tamoxifen has been associated with a six-fold to seven-fold risk of developing endometrial cancer and an increased risk of endometrial hyperplasia, polyps, and growth of fibroids. The best method for monitoring women taking tamoxifen is unknown. Obviously, patients should have an annual pelvic examination and Pap smear. Endometrial sampling should be performed in all patients with abnormal uterine bleeding. Because tamoxifen acts as a weak estrogen, it is not unreasonable to consider annual endometrial biopsy or sonographic evaluation of endometrial stripe thickness. This recommendation, however, is not based on prospective studies but rather on an intuitive approach. According to current information, women taking tamoxifen have a greater than 84% chance of developing a thickened endometrium, making this technique relatively insensitive in evaluating the endometrium for pathology. Based on published studies, sonography is useful only for ruling out significant pathology if the endometrial stripe is less than 5 mm in thickness. Therefore, this may not be useful in screening women on tamoxifen.

In summary, the management of endometrial hyperplasia should be individualized, depending on the histologic findings and the patient's age health and reproductive desires. Treatment options include hormone therapy and surgery. Due to the increasing use of tamoxifen, gynecologists should expect to see more women using this medication and should be aware of the risk of both benign and malignant changes of the endometrium and be prepared to evaluate them for these abnormalities.

ENDOMETRIAL CARCINOMA

Incidence and Epidemiology

The American Cancer Society estimated that there were approximately 38,000 cases of epithelial endometrial carcinoma in the United States during 2001, accounting for about 7% of all malignancies in women. It ranks seventh in cause of death from cancer in women and accounts for about 6,000–6,500 deaths each year. At this time, endometrial cancer is the fourth most common cancer in women and is the most common gynecologic cancer. Occurring more frequently than endometrial cancer are lung, breast, and colon cancers. Endometrial cancer generally is thought to be a disease of postmenopausal women. However, one fourth of the cases may occur in women who are premenopausal and about 5% occur in women under the age of 40. Generally, the prognosis is good, with an overall survival rate for all cases of about 75%. Management for this disease has evolved over the past half-century. Preoperative radiation therapy followed by hysterectomy was the standard before the early 1980s, but now almost all patients are staged surgically, and postoperative management is tailored to the risk factors identified at the time of surgical staging. In 1988, this primary operative approach was formalized by FIGO (Federation of International Gynecology and Obstetrics) and now requires surgical staging to accurately assign stages and determine appropriate treatment and progress of this disease (Table 54.2).

TABLE 54.2. *FIGO staging for carcinoma of the corpus uteri*

According to data from the American Cancer Society, the number of deaths from endometrial cancer was about 4,000 in 1990. In 2000, the mortality from endometrial cancer increased to 6,500. The exact reason for this is increase is unclear. Many suggest that this increased incidence is caused by the increased use of estrogen replacement therapy. Several known pieces of information can be used to argue against this. First, death from estrogen-induced endometrial cancer is rare. These cancers usually are well differentiated and carry a low mortality rate. Also, the rate of endometrial cancer is increasing in countries such as Norway and Czechoslovakia, yet estrogens rarely are prescribed in these countries. The incidence of endometrial carcinoma has increased over the last 50 years, most likely because of the aging population, the increased frequency of certain predisposing conditions such as obesity, and improved methods of diagnosis.

Adenocarcinoma of the endometrium is mainly a malignancy of postmenopausal women and is increasingly virulent with advancing age. Peak age at diagnosis is between 50 and 65 years, and approximately 25% of all cases of endometrial carcinoma are diagnosed in premenopausal women and 5% in women younger than 40 years. Usually, but not always, these young women are either obese, chronically anovulatory, or both. Women with endometrial cancer diagnosed at an early age should be queried about family history. Endometrial cancer is the most commonly inherited gynecologic malignancy. It is the second most common cancer described in hereditary nonpolyposis colon cancer syndrome (HNPCC), also known as the Lynch syndrome.

Bohkman proposed that there may be two types of endometrial cancers, designated type I and type II. Type I endometrial cancer is estrogen dependent and is thought to progress typically from hyperplasia to frank cancer in a stepwise fashion. This type of malignancy typically occurs in younger, perimenopausal women with a history of exposure to unopposed estrogen. These tumors tend to arise in areas of hyperplasia, to be well differentiated, and to be associated with a more favorable prognosis. The latter type of cancer occurs in older women without estrogen stimulation of the endometrium, is not often associated with endometrial hyperplasia, and tends to be more commonly associated with poorly differentiated cancer or those of unusual histologic type. It generally carries a worse prognosis. Because cancer is a genetic disease and we now realize that it develops as the result of an accumulation of mutations in genes necessary for normal cellular function, the pathways necessary for the development of these two types of cancers may be different.

The main risk factor for endometrial adenocarcinoma is long-term unopposed estrogen exposure of either endogenous or exogenous origin. Obesity, nulliparity, and late menopause appear to be associated with high endogenous levels of unopposed estrogen. In obese women, there is an increased peripheral conversion of androstenedione to estrone by fat cells. Nulliparity seems to be associated with endometrial cancer, because ovarian dysfunction (chronic anovulatory cycles and polycystic ovaries) contributes to both the infertility and the unopposed estrogen levels. Estrogen-secreting tumors, such as granulosa cell tumors, are associated with endometrial cancer up to 25% of the time. Other risk factors include a history of pelvic irradiation, a history of breast or ovarian cancer, and use of tamoxifen (Table 54.3).

Obesity
Diabetes (not an independent risk factor)
Hypertension
Menopause after the age of 55
High socioeconomic status
Positive family history (60% by age 70 if HNPCC family)
Polycystic ovary syndrome
Unopposed estrogen exposure in postmenopause
Estrogen-secreting tumor
Urban residence
Pelvic irradiation
History of another adenocarcinoma
Tamoxifen use

HNPCC, hereditary nonpolyposis colorectal cancer.

TABLE 54.3. *Factors associated with an increased incidence of endometrial cancer*

Oral contraceptives appear to provide protection from endometrial cancer. At least eight population-based studies suggest that this is so. The use of oral contraceptives appears to decrease the risk of developing endometrial cancer in women 20 to 54 years of age by 50% over those women who never have used oral contraceptives. This protective effect appears to last for at least 10 years in women who used the pill for at least 1 year. Cigarette smoking also decreases the risk of endometrial cancer. There appears to be a dosage relationship to this benefit, such that the greater the number of cigarettes smoked the less the risk of developing cancer. In one study this decrease was quite profound, 30% when one pack was smoked and another 30% if more than one pack was smoked. Furthermore, the greatest risk reduction was in the heaviest women. This is not too surprising, because it is these women who are at the highest risk of developing endometrial cancer, so they might be expected to enjoy the greatest benefit from a factor which decreased their risk. This benefit of risk reduction is strongly outweighed by the increased risk of other health problems of smoking such as heart and lung disease and, therefore, appears to be small consolation.

The relationship between unopposed estrogen exposure and endometrial cancer is well described. Although the risk of endometrial cancer is increased in these women, their prognosis tends to be better. Women with unopposed estrogen use tend to have lower stage, lower grade lesions with better prognosis.

Race is another predictor of survival and type of endometrial cancer. White women have a higher incidence but also have a higher survival rate than black women. This originally was thought to be secondary to socioeconomic status, in that the diagnosis was made later because of less access to health care and, therefore, the cancer was of a higher stage. However, when these variables are controlled for, the survival appears to be less in black women than white. The exact reason for this is unclear. Black women have similar survival to white women when matched for poor prognostic factors. It appears that black women tend to have more poor prognostic variables. Many authors have evaluated this disparity and the etiology is not clear. With the advent of the human genome project, a better understanding of the genetic differences among cancers can be evaluated and understood. This may give us some insight into how they are expressed in different patient populations.

Breast cancer is the most common cancer diagnosed in women in the United States, thereby making tamoxifen a widely used drug in this country. It is estimated that about 80,000 women will start taking tamoxifen each year. Tamoxifen is a selective estrogen receptor modulator, and it has varying effects on estrogen-responsive tissue. The endometrium responds to tamoxifen stimulation much like it does to estrogen. Therefore, the effects of tamoxifen on the endometrium are like those of unopposed estrogen, so the risk of endometrial cancer in women on tamoxifen therapy is increased. In 1985, Killackey reported on three patients with breast cancer who were receiving tamoxifen and who developed endometrial cancer. This and many other reports suggest that there is a significant increase in the risk of developing endometrial cancer while on tamoxifen. The National Surgical Adjuvant Breast and Bowel Project (NSABP) is one of the best studies published on this subject. This study analyzed 2,843 patients with node-negative estrogen receptor–positive breast cancer who were randomized to placebo or 20 mg of tamoxifen a day. There was a significant increase in the risk of endometrial cancer in the tamoxifen arm such that the relative risk was almost 3 times that of the control arm. These data combined with others suggest that the increased risk of endometrial cancer in women taking tamoxifen is between 2 and 3 times that of the population not taking tamoxifen. Women who have breast cancer are also at increased risk to develop endometrial cancer. These studies often do not take this increased susceptibility into account and, therefore, may overstate the risk of endometrial cancer in women taking tamoxifen. The benefits of tamoxifen use for prevention of breast cancer recurrence, more than 120 per 1,000 women, far outweigh the risks of 6 endometrial cancers per 1,000 women.

Genetics

Cancer is the result of accumulation of mutations within the human genome. These mutations can be either acquired or inherited. As we come to understand more through the Human Genome Project and other research, we will come to understand even better the mechanism by which these cancers develop. It is, therefore, essential that clinicians be aware of the information provided by the human genome and use it to better help their patients

Endometrial cancer is the most commonly inherited gynecologic cancer. The clearest hereditary link to this disease is seen in HNPCC, also known as the Lynch syndrome after Henry Lynch, who first described this familial cancer syndrome. Clinical features of HNPCC were described first in the medical literature in 1913 by Aldred Warthin, who identified a clustering of predominantly stomach and endometrial cancers in the family of his seamstress. This inherited pattern of cancers gained little attention over the subsequent 50 years or more until characterized by Henry Lynch as the cancer family syndrome. Subsequently, the pattern of autosomal dominant risk of gastrointestinal cancers and gynecologic cancers became known as HNPCC, although some experts continue to use Lynch syndrome because they

think that it more accurately encompasses both the colorectal tumors and extracolonic cancers.

HNPCC is a clinically defined disease in which the primary genetic defect has been identified as mismatch repair genes. It is an autosomal dominant disease with a risk of penetrance of an inherited mutation of approximately 80%. That means that 80% of the patients who inherit one of these mutations will develop a cancer. During the 1990s, specific genes responsible for HNPCC were identified and are known as the mismatch repair genes, but the syndrome is based on family history. The criteria for defining this disease can be seen in Table 54.4 and Table 54.5. These criteria have evolved gradually from those factors focused on colorectal cancers to those that may encompass all cancers associated with the syndrome. Not all patients who fit the criteria of having clinical HNPCC have a mutation in these mismatch repair genes, indicating that we still have more to learn about the development of this disease. We believe that as many as 10% to 30% of cancers ultimately may be categorized as familial. Most of the inherited abnormalities in this group of patients are unknown. Only about 5% can be characterized as HNPCC or Lynch. Thus, the disease of interest, HNPCC, accounts for an important, but minor, percentage of all colorectal or endometrial cancers. We are just coming to understand that women with relatives with this disease can be at increased risk for other malignancies. This brings home the point that all women with cancers should have a detailed family history taken. This will assess their risk of developing cancers and determine any relative risk for their family members. For instance, the normal population has about a 2% chance of developing a colon cancer, versus 80% cumulative risk in a patient with clear HNPCC. When counseling patients, the cumulative risk of developing a cancer over the course of one's life is the most informative means of conveying this information. An example of cumulative risk assessment for various HNPCC cancers in a patient with HNPCC can be seen in Table 54.6.

I. Patient must meet ALL of the following:
1. Three or more relatives with a histologically verified colorectal cancer, one of whom is a first-degree relative of the other two (FAP should be excluded), AND
2. Colorectal cancer involving at least two generations, AND
3. One or more colorectal cancers diagnosed before the age of 50
II. Patient must meet ALL of the following:
1. Three or more relatives with a histologically verified HNPCC-associated cancer (colorectal cancer, cancer of the endometrium, small bowel, ureter, or kidney), one of whom is a first-degree relative of the other two, AND
2. Colorectal cancer involving at least two generations, AND
3. One or more colorectal cancer cases diagnosed before the age of 50

FAP, familial adenamatous polyposis; HNPCC, hereditary nonpolyposis colorectal cancer.

TABLE 54.4. *Amsterdam criteria*

Patient may meet ANY ONE of the following criteria:
1. Individual with cancer in families who meet the Amsterdam Criteria
2. Individual with two HNPCC-related cancers, including synchronous and metachronous colorectal cancers or associated extracolonic cancers: endometrial, ovarian, gastric, hepatobiliary, small bowel, or transitional cell carcinoma of the renal pelvis or ureter
3. Individual with colorectal cancer and a first-degree relative with colorectal cancer or HNPCC-related extracolonic cancer or a colorectal adenoma; one of the cancers diagnosed at an age younger than 45 years, and the adenoma diagnosed at age younger than 40 years
4. Individual with colorectal cancer or endometrial cancer diagnosed at age less than 45 years
5. Individual with right-sided colon cancer with an undifferentiated pattern (solid or cribriform) on histology, diagnosed at less than 45 years; solid or cribriform pattern defined as poorly differentiated or undifferentiated carcinoma composed of irregular, solid sheets of large eosinophilic cells and containing small glandlike spaces
6. Individual with signet-ring cell-type colorectal cancer diagnosed at age less than 45 years (signet-ring cell type defined as tumor composed of >50% signet-ring cells).
7. Individual with colorectal adenoma diagnosed at age <40 years.

HNPCC, hereditary nonpolyposis colorectal cancer.

TABLE 54.5. *Bethesda criteria*

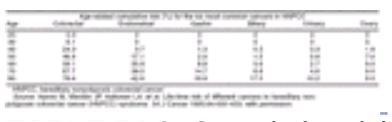

TABLE 54.6. *Cumulative risk*

Interestingly, the risk of a woman with HNPCC developing colorectal cancer may be less than that of a male with HNPCC (60% vs. 80%). Estrogen may play a protective role in this decreased risk. As stated previously, endometrial cancer is the second most common disease in women with HNPCC. An HNPCC mutation confers a significant cumulative risk of developing an endometrial cancer. In the normal population, a lifetime risk is about 1.5%, versus 60% if one has inherited a mismatch repair defect or has clinically defined HNPCC.

Genes responsible for the development of a cancer are oncogenes, which are dominantly expressed cellular control genes, and tumor suppressor genes, which are nondominant cellular control genes. A more recently described set of genes is called *mismatch repair genes.* These genes are responsible for ensuring fidelity in the DNA replicative process. The job of these genes is to search for and identify mismatches that occur during replication and to excise and repair the errors. In humans, they consist of the genes *MLH1, MSH2, MSH6, PMS1*, and *PMS2.* It is these genes that are responsible for the development of HNPCC cancers. When they are mutated and do not repair mismatches in the DNA, errors accumulate through normal division, and eventually an error occurs in a gene(s) responsible for control of cell growth. The importance of these mismatch repair genes is made clear when we see how highly conserved they are across species. The mismatch repair genes of *Escherichia coli* are not that different from the mismatch repair genes we find in humans. We now have the ability to test for mutations in these genes and are, therefore, able to assess the risk of an individual getting a cancer and passing on that risk to offspring. Any patient with endometrial cancer should have a thorough family history taken to detect the possibility of an inherited problem. If genetic testing is deemed appropriate, this may be offered to the patient and family. However, before genetic testing is recommended, the patient should undergo counseling by a trained genetic counselor.

In summary, HNPCC is a clinically defined disease described by the Amsterdam and Bethesda criteria. Over time, the focus on these syndromes has shifted to extracolonic cancers such as endometrial cancer. The Amsterdam Criteria II begin to take this into account, and the Bethesda criteria continued to expand on this concept. Importantly, as gynecologists we see a fair number of synchronous or metachronous ovarian and endometrial cancers. These often occur in younger women and should raise the suspicion of an HNPCC association. Any patient with cancer should have a detailed family history taken to assess her risk of developing another cancer and to help assess her family members' risk of developing a cancer. If appropriate, family members should be offered genetic counseling and possible testing for mutation in the mismatch repair system.

Diagnosis

There are no accepted routine screening methods for detecting endometrial cancer in asymptomatic women or in women at increased risk. Given the low incidence of endometrial cancer, this would be prohibitive from a cost standpoint. Furthermore, the complications of screening may be higher than the benefits. Clinical studies have evaluated routine endometrial biopsy, transvaginal ultrasonography, and Pap smears, but none of these techniques is sensitive or specific enough to be applied to the general population. Even though a routine Pap smear cannot be relied on as a screen for endometrial cancer, this malignancy should be suspected in any nonpregnant woman with atypical endometrial cells or in any postmenopausal woman with normal endometrial cells on a Pap smear. A Pap smear which reveals AGUS in a woman over the age of 35 should be evaluated by colposcopy, endocervical curettage, and endometrial biopsy to rule out endometrial cancer, in addition to a possible cervical lesion.

Abnormal uterine bleeding is the most common initial symptom of endometrial cancer. Any bleeding in a postmenopausal woman must be evaluated promptly, although overall only about 20% of these patients have a genital malignancy. The likelihood that postmenopausal bleeding is indicative of a uterine cancer clearly increases with increasing age. Perimenopausal women with abnormal bleeding must also undergo thorough investigation, with the most suspicious patterns being increased menstrual flow, a decreased menstrual interval, and intermenstrual bleeding. Whenever possible, the diagnostic procedure for evaluating the endometrium should be

an office endometrial biopsy which, under optimal conditions, approaches the accuracy of a formal D&C (greater than 90%). An endocervical curettage (ECC) usually should be performed in the evaluation of postmenopausal bleeding to rule out an endocervical carcinoma as the etiology. If the endometrial biopsy and ECC are satisfactory (with adequate tissue for a diagnosis) and demonstrate no significant abnormality, no further evaluation is necessary. If postmenopausal bleeding is persistent or recurrent or other high-risk factors exist, a fractional D&C should be considered. High-risk factors include atypical hyperplasia or endometrial polyps. Hysteroscopy should be considered if bleeding is recurrent or if either polyps or submucous fibroids are suspected. Many clinical studies now support the usefulness of transvaginal ultrasonography for evaluating the thickness of the endometrium in patients with postmenopausal bleeding. Various investigators have suggested that when the endometrial stripe is thinner than 5 mm, the cause of bleeding usually is related to atrophy, but there have been occasional reports of biopsy-proven malignancy even in patients with thin endometrial stripes. Additionally, almost all women on tamoxifen will have a thickened endometrium, making this test less useful in this patient population.

If endometrial adenocarcinoma is diagnosed, further evaluation of the patient is necessary prior to deciding on the therapeutic approach. A careful physical examination should be performed, with particular attention to supraclavicular and inguinal lymph nodes. A thorough evaluation of the abdomen should be performed, and a bimanual rectovaginal examination to evaluate the size and mobility of the uterus is important. The size and consistency of the cervix, the adnexal structures and parametrium, and the entire vagina, vulva, and rectum are important, and these structures should be evaluated for nodules, masses, induration, and plaquelike lesions that might signify metastatic disease. Any suspicious genital lesions should be sampled for biopsy, and the stool should be tested for occult blood. The histologic subtype and grade of tumor can be determined from the endometrial biopsy or D&C specimen, but it is important to remember that approximately one third of the time the final grade of tumor as determined on the hysterectomy specimen will differ from the original. Additionally, a chest radiograph and routine laboratory studies should be obtained. Based on other risk factors and symptoms, consideration should be given to performing a barium enema examination or a colonoscopy, and preoperative computed tomography or magnetic resonance imaging to evaluate the uterus for depth of invasion and to document occult metastatic disease. An additional test that successfully predicts either deep myometrial invasion or distant disease is the serum tumor marker CA-125. Several studies have documented that 53% to 87% of patients with clinical stage I disease who later were found to have had extrauterine disease at the time of surgery, had elevated CA-125, compared with only 2% to 12% of patients with surgically validated stage I disease. These studies may not be routinely necessary if the decision for full surgical staging can be made intraoperatively (i.e., if the necessary surgical expertise is available to perform pelvic and periaortic lymphadenectomy).

Because endometrial cancer is now staged surgically instead of using the old clinical schema, several practical considerations should be noted. In the past, preoperative irradiation was used in many patients, especially those with grade 2 or 3 lesions, positive ECC findings, or a large uterus. Depending on where the patient was treated, preoperative irradiation could consist of intracavitary radium or cesium for approximately 72 hours or external-beam irradiation of 4,000 to 4,500 cGy to the pelvis. Using these types of treatment plans, many patients received either unnecessary radiation or radiation that did not encompass all of their disease (e.g., paraaortic node metastasis). A second consideration is that all patients should at least be evaluated for full surgical staging, including selective pelvic and paraaortic node dissection. With the adoption of the new surgical staging scheme (see Table 54.2), most patients should undergo primary surgical therapy, including a hysterectomy, bilateral salpingo-oophorectomy, peritoneal cytologic analysis, and selective pelvic and paraaortic node dissection, as indicated. Because endometrial cancer can spread via both the lymphatics and the bloodstream, as well as transmurally or transtubally into the peritoneal cavity, a thorough exploration of the entire abdominal cavity is necessary to document any extrauterine metastasis. Only patients with technically inoperable tumors or medical conditions that make them poor operative candidates should be considered for primary radiation therapy. In these cases, patients should be staged using the older clinical staging schema.

Prognostic Factors

Several well-recognized factors can be used to predict the prognosis of a patient with adenocarcinoma of the endometrium. Preoperative evaluation, coupled with the findings at the time of surgical staging and final pathology, allows individualization of postoperative therapy. These factors are exceedingly important in selecting appropriate postoperative therapy for patients (Table 54.7).

Stage of disease
Histologic differentiation
Histologic type
Depth of myometrial invasion
Lymph node metastasis
Other extrauterine metastasis

TABLE 54.7. *Prognostic factors*

Staging

Until the late 1980s, endometrial cancer was clinically staged using clinical information obtained from examination of the patient and the fractional D&C (Table 54.8). This staging system, however, failed to recognize important prognostic factors, such as deep myometrial invasion and clinically occult extrauterine disease, and often underestimated the extent of disease. Because of these inadequacies, FIGO modified this staging schema in 1988 to reflect the information obtained from surgical exploration and pathologic evaluation of removed tissue. Endometrial cancer is now staged according to the FIGO staging system (see Table 54.2). The recommendation is for all medically operable patients with clinical stage I disease, regardless of tumor grade, to undergo an extrafascial total abdominal hysterectomy and bilateral salpingo-oophorectomy for both staging and therapeutic purposes. A radical hysterectomy may be appropriate in certain circumstances in which the disease is known to involve the cervix or parametrium. The abdominal wall incision should be adequate to perform both pelvic and periaortic lymph node sampling, if indicated by tumor grade and depth of invasion into the myometrium. Immediately after the peritoneal cavity is entered, fluid (either ascites or washing) is obtained for cytologic analysis.

Stage I	Disease confined to uterus
Stage II	Disease extends to cervix
Stage III	Disease extends to pelvis
Stage IV	Distant metastasis

TABLE 54.8. *Clinical staging*

Although the FIGO surgical staging schema has been in effect for more than 10 years, there is still considerable controversy as to which patients should undergo the pelvic and periaortic lymph node sampling as required by this schema. It is also unclear how to select these patients and which preoperative and intraoperative findings can be used to define the patient population most likely to benefit from this procedure. Many institutions send the uterus for frozen section analysis intraoperatively and use the pathologic determination of tumor grade and depth of invasion to determine the need for full surgical staging. Others use preoperative information obtained from the endometrial biopsy specimen and radiographic information, especially when patients need to be referred to another center for surgical staging. Because the error rate for poor prognostic features is high with intraoperative evaluation, more gynecologic oncologists are recommending that all patients undergo staging so that all necessary information is available for postoperative treatment planning.

In a large study by the Gynecologic Oncology Group (GOG) of 621 women with clinical stage I disease, 22% of patients were found to have disease outside the uterus. The sites of distant disease were evenly divided between periaortic and pelvic lymph nodes and positive peritoneal cytology. Adnexal involvement was less likely than nodal involvement or positive peritoneal cytologic findings. Equally important, an additional study documented that only 24% of patients with clinical stage II disease actually had pathologic confirmation of cervical involvement at the time of hysterectomy. On occasion, patients are found to have simultaneous endometrial and ovarian cancers, with a reported incidence rate of 1.4% to 3.8%. Although the difference between metastatic and synchronous primary tumors usually can be determined by routine pathologic examination, this determination occasionally cannot be made with any degree of certainty. The survival of patients with endometrial cancer by stage can be seen in Table 54.9.

Stage	5-Year survival
IA	91%
IB	88%
IC	81%
IIA	77%
IIB	67%
IIIA	69%
IIIB	41%
IIIC	32%
IVA	20%
IVB	5%

TABLE 54.9. *Survival by stage*

Tumor Grade

Grading provides a measure of tumor aggressiveness, and it is now an essential part of the FIGO staging for endometrial cancer. Tumor grade is one of the most important prognostic factors for predicting overall survival. Assignment of tumor grade is based on both architectural patterns, such as gland formation, and nuclear atypia and is affected significantly by interobserver reproducibility. It is also not unusual for the tumor grade from the endometrial biopsy to vary from the final tumor grade from the hysterectomy specimen. The higher the tumor grade, the more likely the patient will have deep myometrial invasion, as well as lymph node and other metastases. Grade is clearly an independent predictor of long-term survival, as well as a predictor of other poor prognostic features. Survival based on grade of the tumor alone can be seen in Table 54.10 and the relationship between grade and the depth of myometrial invasion can be seen in Table 54.11. Examples of the various degrees of differentiation can be seen in Fig. 54.3, Fig. 54.4 and Fig. 54.5).

Grade	Survival
1	96%
2	79%
3	70%

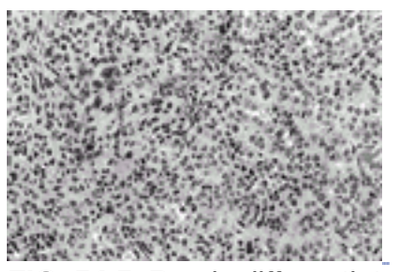

FIG. 54.5. Poorly differentiated adenocarcinoma. Predominantly solid carcinoma with very focal glandular differentiated

Depth of Myometrial Invasion

Depth of myometrial invasion is another important prognostic factor that directly correlates with the likelihood of extrauterine disease. In the new surgical staging criteria, maximum depth of myometrial invasion determines the subcategories within stage I disease. It is believed that increasing depth of invasion is associated with a higher likelihood of access to the lymphatic system, thereby increasing the incidence of both pelvic and periaortic lymph node metastasis. In a study by Boronow and others, only 1% of patients without myometrial invasion had pelvic lymph node involvement, compared with 25% having positive pelvic lymph nodes with outer-third involvement. Survival was also shown to be affected by depth of invasion, with an 80% to 90% 5-year survival with minimal invasion compared with 60% survival with deep invasion. For early-grade lesions, gross evaluation of depth of invasion is quite accurate at about 85% to 90%. As the cancer becomes less well differentiated, the gross evaluation is less accurate because the margins of the cancer are more infiltrative and less pushing. As the cancer becomes less well differentiated, there is a greater likelihood of deep myometrial invasion and an associated decrease in survival (see Table 54.11).

Lymph Node Metastasis

For patients with clinical stage I endometrial cancer, lymph node involvement is the most important independent prognostic factor, being associated with a six-fold increase in the risk of recurrent disease. In these patients, approximately 10% will have positive pelvic lymph nodes, and 6% will have positive periaortic lymph nodes, with periaortic node involvement being the most important predictor of survival. The incidence of lymph node involvement correlates with stage and grade of tumor, depth of myometrial involvement, and location of the cancer in the uterus (i.e., fundal versus lower uterine segment). In patients with clinical stage II disease, lymph node metastasis occurs in approximately 35%.

Adnexal and Intraperitoneal Involvement

Clinically occult adnexal metastasis occurs in approximately 10% of patients with clinical stage I disease, with most having other high-risk factors such as deep myometrial invasion or lymph node involvement. In patients with adnexal metastasis as their only high-risk factor, overall survival seems to be minimally affected. Other extrauterine intraperitoneal disease is associated with a significant decrease in survival.

Tumor Size

Schink and colleagues reported that the size of the endometrial tumor was of prognostic significance. They reviewed tumor size in 91 patients with disease apparently confined to the uterus and found that if the tumor was smaller than 2 cm, the chance of nodal metastasis was about 6%. However, if the tumor was larger than 2 cm, the chance of nodal metastasis was over 20%. In this study, tumor size was an independent prognostic variable.

Histologic Subtype

The histologic subtype of adenocarcinoma may have an independent impact on patient outcome. Approximately 80% of endometrial cancers are of endometrioid histology. These cancers can be of varying degrees of differentiation. There are thought to be of two subtypes as follows: (a) type 1 arises from endometrial hyperplasia, is estrogen dependent, and usually confers a better prognosis; (b) type 2 endometrial cancer tends to be more poorly differentiated, is not dependent on estrogen stimulation, and generally carries a worse prognosis. Squamous differentiation is seen in 15% to 25% of endometrioid tumors. The significance of squamous differentiation is unclear, and its impact has been debated for many years. In the past, the terms *adenoacanthoma* and *adenosquamous carcinoma* were used to identify adenocarcinomas with either benign or malignant squamous differentiation. More recently, Zaino and colleagues recommended that these terms be replaced with the more descriptive term *adenocarcinoma with squamous differentiation.* Although the squamous elements can have varying degrees of differentiation, they usually correlate with the glandular components. Furthermore, the differentiation of the glandular component appears to be the important prognostic feature.

Papillary serous and clear cell cancers of the endometrium are both quite rare (approximately 5% each) but have a significantly worse prognosis compared with that of endometrioid adenocarcinoma. Both of these histologic types are more common in older women, who tend to have distant disease, even when clinically it appears to be stage I (Fig. 54.6 and Fig. 54.7).

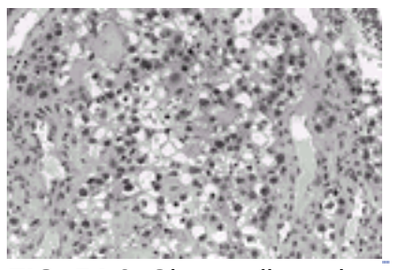

FIG. 54.6. Clear cell carcinoma. The tumor forms sheets of cells with cleared cytoplasm and pleomorphic nuclei.

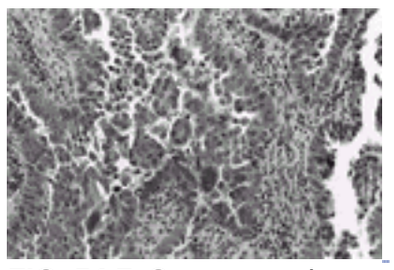

FIG. 54.7. Serous carcinoma. The tumor shows marked intraluminal complexity and high-grade nuclear atypia.

Age

Although it is recognized clearly that advancing patient age at diagnosis is associated with a poorer outcome, there is no agreement as to why this is true. In a study by Lurain and colleagues, increasing patient age was an independent prognostic factor associated with recurrent disease. No patient under age 50 years developed recurrent cancer, compared with 12% of women between 50 and 75 years and 33% of women older than 75 years. For every 1-year increase in age over 50 years, there was a 7% increase in the rate of recurrence. Younger patients tend to have early, well-differentiated lesions with no or minimal myometrial invasion. Younger patients also tend to be in better general health, thereby allowing more aggressive definitive surgery. It has been suggested that older women are more likely to ignore signs of vaginal bleeding, thereby delaying diagnosis until the stage is more advanced. Interestingly, however, the length of time between onset of bleeding and presentation to a clinician does not correlate with tumor stage, and patients with advanced stage disease have not necessarily delayed seeking medical care.

Peritoneal Cytology

The significance of malignant peritoneal cytologic findings obtained during surgical staging for endometrial cancer is controversial. In essentially all published studies, a positive peritoneal cytology result is associated with other high-risk features such as deep myometrial invasion, adnexal spread, positive lymph node metastasis, and cervical involvement. Several studies showed a two-fold to three-fold increase in the risk of recurrent disease in patients with positive peritoneal cytology, but often these patients have one or more other high-risk factors, and many times the recurrent disease is outside the peritoneal cavity. In patients found to have positive cytologic findings, it is unclear whether any currently available therapy would have any impact on eventual outcome.

Race

Even with correction for age and tumor stage, black women with endometrial cancer have a much poorer prognosis than white women. For all stages of endometrial cancer, white women have an 86% 5-year survival compared with a 55% 5-year survival for black women, and within each stage the relative survival is worse for blacks.

Other Factors

Many other factors have been shown to affect prognosis, including hormone receptor status of the tumor, DNA content or ploidy, proliferative index, and oncogene expression. Both estrogen receptor and progesterone receptor levels have been shown to be prognostic factors independent of tumor grade, with the progesterone receptor level being the more important for predicting overall survival. Progesterone receptor levels also can be used to predict which patients with advanced or recurrent disease are more likely to respond to hormone therapy.

Management

The primary management for endometrial cancer is surgery (Table 54.12), consisting of removal of the uterus, cervix, and adnexal structures. Surgical staging procedures, including careful exploration of the abdomen and pelvis and lymphadenectomy, often are done at the same time, as described above. As soon as the uterus has been removed, it should be sent to the pathology laboratory for frozen section to determine tumor grade and depth of invasion, as well as to obtain tissue for estrogen and progesterone receptor levels and other studies, as indicated. For patients in whom lymph node sampling is indicated (see Table 54.12), representative samples of lymph node–bearing tissue from the lower aorta and vena cava are removed. Pelvic lymph node sampling should remove nodes from common and external iliac and obturator regions. An omental biopsy may be performed and is indicated for patients with papillary serous and clear cell cancers. In patients who are very poor candidates for exploratory laparotomy (e.g., morbidly obese), vaginal hysterectomy or laparoscopically assisted vaginal hysterectomy should be considered. Every effort should be made to remove the adnexal structures; therefore, laparoscopically assisted vaginal hysterectomy may be preferable. If appropriate surgical expertise is available, the full surgical staging, including pelvic and periaortic lymphadenectomy, can be performed through the laparoscope. Until additional information is obtained, vaginal hysterectomy should be limited to very select patients who otherwise might be given radiation therapy only. In patients with clinically apparent cervical involvement, radical hysterectomy with bilateral salpingo-oophorectomy and lymph node dissection may be considered.

Risk group (incidence)	Positive pelvic nodes (%)	Surgery
Low risk (30%) Stage IA, IB Grade 1	3	TAH-BSO, peritoneal cytology
Moderate risk (50%) Stage IB Grade 2, 3	9	TAH-BSO, LND, peritoneal cytology
High risk (20%) Stage IC Grade 1, 2, 3	18	TAH-BSO, LND, peritoneal cytology

BSO, bilateral salpingo-oophorectomy; LND, lymph node dissection; TAH, total abdominal hysterectomy.

TABLE 54.12. *Surgical therapy of endometrial cancer*

Following surgery and review of the final pathology report, patients may be divided into risk groups based on the many prognostic factors discussed above. This classification can then be used to individualize the recommended postoperative therapy, if needed. Because formal surgical staging has been utilized widely for less than 10 years, most of the information on recommendations for postoperative radiation therapy are based on clinically staged patients. The risk of pelvic recurrence in patients with high-risk factors but negative surgical staging is largely unknown. The GOG study based on surgicopathologic correlation found that even when sampled lymph nodes were negative, patients with deep myometrial invasion and poorly differentiated cancers were still at a higher risk of recurrence. Even though the surgical staging procedures failed to document extrauterine pelvic disease, postoperative pelvic irradiation was associated with a decreased risk of local recurrence. It is not yet clear whether surgical staging can define a subgroup of stage I patients, other than the already identified low-risk patients, who can be treated without adjuvant radiation therapy.

Treatment for patients with stage II disease remains somewhat controversial. Most studies suggest that patients with cervical involvement are at a higher risk for vaginal vault recurrence, and often recommend adjuvant vaginal cuff irradiation. Whether or not those patients with otherwise negative surgical staging also need pelvic irradiation remains to be confirmed. With clinically apparent cervical involvement, treatment recommendations include either radical hysterectomy or preoperative irradiation followed by extrafascial hysterectomy.

Treatment for patients with documented extrauterine disease (stages III and IV) should be individualized to encompass the true extent of the disease. Therapeutic options include pelvic irradiation, extended-field irradiation to cover the periaortic lymph nodes, whole-abdomen irradiation, and systemic hormone therapy or chemotherapy. In most cases, management of distant metastasis with either high-dose progestins or chemotherapy is palliative only, with little expectation for long-term control of disease. The most widely used chemotherapy agents include doxorubicin hydrochloride (Adriamycin) and cisplatin (Platinol) or carboplatin (Paraplatin).

Progestins have been used for many years in the management of recurrent endometrial carcinoma, with approximately one third of patients having a favorable response. Patients with well-differentiated tumors have a higher response rate than those with moderately or poorly differentiated cancers. Although the role of estrogen and progesterone receptors in endometrial cancer therapy has not yet been accepted widely, it does appear that the responsiveness of recurrent tumor to progestin therapy is related to the content of both estrogen and progesterone receptors. If both receptors are present, the likelihood of a favorable response is good, regardless of tumor grade or other high-risk factors. If the concentration of receptors is low, it is unlikely that the recurrent tumor will respond to progestins, and other chemotherapy should be considered.

Endometrial cancer in approximately 10% to 15% of patients is inoperable, usually because of morbid obesity or severe intercurrent disease. In these patients, primary radiation therapy should be considered. In most cases, a combination of external beam and intracavitary irradiation should be used, and with definitive therapy approximately 85% to 90% of patients with early-stage disease will have control of uterine disease. The overall risk of recurrence in these patients with stage I disease correlates with tumor grade, with a 5-year survival of 94% for grade 1, 92% for grade 2, and 78% for grade 3 tumors.

Posttreatment Surveillance

Many studies have confirmed that after treatment of endometrial cancer, most recurrences will occur within 3 years. Approximately one half of these recurrences will be asymptomatic and, thus, the traditional recommendation has been to follow patients with physical examination and vaginal cytology every 3 to 4 months for the first 2 to 3 years, and then at 6-month intervals for at least 5 years. Serial serum CA-125 measurements also have been suggested for surveillance of patients who have been treated for endometrial cancer, although the level may be normal in patients with early recurrent disease. Because treated endometrial cancer will not recur in the great majority of patients, however, several studies have addressed the cost effectiveness of this traditional recommendation. In a study from the M.D. Anderson Cancer Center, 59% of patients with recurrence were asymptomatic, with over one half being picked up on physical examination, 26% by an elevated CA-125, and only 4% by vaginal cytologic examination. Because of these findings, these authors recommended that physical examination, serum CA-125 assay, and vaginal cytology be performed only every 6 to 12 months on asymptomatic patients. A Canadian study reported that only one recurrence was documented during more than 200 routine follow-up visits after treatment for endometrial cancer, using a schedule of examinations of every 3 months for the first year, every 4 months for the second year, and every 6 months thereafter. There was no difference in the salvage rates of recurrent disease picked up during routine surveillance compared with recurrent disease documented in symptomatic patients. In this study, no recurrence was picked up by vaginal cytology alone. In a third study from Duke University, an analysis of various follow-up techniques demonstrated that routine vaginal cytology and chest radiograph were not cost effective. The recommendation of these investigators is to follow patients every 6 months with examination alone, using additional testing to evaluate any symptoms.

Estrogen Replacement Therapy After Treatment

For many years, it has been thought that a history of endometrial cancer, even successfully treated, was an absolute contraindication to estrogen replacement therapy (ERT), because adenocarcinoma of the endometrium is considered an estrogen-dependent neoplasm. Because no scientific data support the contention that ERT is dangerous for patients who have had a hysterectomy for endometrial cancer and because the body of evidence is increasing in supporting the value of ERT in decreasing morbidity and mortality from heart disease, strokes, and osteoporosis, many physicians and patients are questioning the earlier proscription. During the last decade, there have been several small retrospective studies of patients given ERT following treatment for early-stage endometrial cancer (Table 54.13). In 1986, Creasman and coworkers reported on 221 patients with stage I endometrial cancer, of whom 47 (21%) were given postoperative estrogen replacement for a median of 26 months. Statistical analysis revealed no increased risk of recurrence or death between those who received ERT and those who did not when adjustments were made for tumor grade, myometrial invasion, nodal metastasis, peritoneal cytology, and age. In fact, the risk of recurrence was significantly higher in the untreated group (15% vs. 2%), as was the risk of dying of intercurrent disease. Similar study design and conclusions were reported 3 years later by Lee and others. In both of these studies, selection bias may have contributed to the results, but it does appear that a low-risk group of patients can be selected who can safely take estrogen replacement. Chapman and colleagues retrospectively reviewed information on 123 patients with stages I and II endometrial cancer, of whom 62 received ERT, and again documented no increase in recurrences or deaths from this malignancy. In a Committee Opinion in August 1993, the American College of Obstetricians and Gynecologists concluded that there are no definitive data to support specific recommendations regarding ERT for women previously treated for endometrial cancer. The opinion states that estrogens could be used for the same indications as for any other woman, except that the selection of appropriate candidates should be based on prognostic indicators and the risk that a patient is willing to assume. The gynecologic practice committee, due to the paucity of data, could not evaluate the need for progestational agents in addition to estrogens. A large GOG trial is underway to assess the risk of hormonal replacement in these patients.

TABLE 54.13. *Effect of estrogen replacement therapy on endometrial cancer recurrence*

UTERINE SARCOMAS

Sarcomas of the uterus carry a poor prognosis but, fortunately, they are rare and represent less than 5% of all uterine tumors. The incidence of these tumors is about 1.7 per 100,000 women per year in the United States. The classification of the various histologic types, in order of frequency, can be seen in Table 54.14. There is some retrospective evidence that sarcomas tend to arise more commonly in patients who have undergone pelvic irradiation in the past. A clear cause and effect relationship between irradiation and sarcomas has not been established, and new data have failed to corroborate the older literature.

Mixed homologous müllerian sarcoma (carcinosarcoma)
Mixed heterologous müllerian sarcomas
Leiomyosarcomas
Endometrial stromal sarcomas
Other sarcomas

TABLE 54.14. *Classification of uterine sarcomas by frequency*

These lesions arise primarily from two tissues: endometrial sarcomas arise from endometrial glands and stroma, and leiomyosarcomas from the myometrium itself. The malignant mixed müllerian tumors arise from the pluripotent endometrial stroma. Other sarcomas, such as angiosarcoma and fibrosarcoma, arise in supporting tissues. In general, uterine sarcomas are the most malignant type of uterine tumor and tend to differ significantly from endometrial adenocarcinomas with regard to patterns of spread and prognosis.

The relative incidence of the various subtypes of uterine sarcomas differs significantly in the literature, with mixed mesodermal sarcomas being the most common in recent studies. The staging criteria for uterine sarcomas are based on the FIGO classification for endometrial cancers (see Table 54.2).

Classification

Numerous classification schemes for uterine sarcomas have been proposed, depending on both cell type and site of origin. In 1959, Ober suggested a classification of the endometrial sarcomas. This does not include the pure sarcomas, which are self-explanatory. This classification and can be seen in Table 54.15. Generally, homologous tumors are comprised of tumors that should belong in the normal uterus, such as smooth muscle or endometrial stroma. Heterologous elements are those tissues that normally would not be found in the uterus, such as bone (osteosarcoma) or cartilage (chondrosarcoma). Most pathologists have adopted this classification, which has the advantage of being able to classify these malignancies for study, because most tumors fall into four major groups. Pure tumors are composed of only one cell type; whereas mixed tumors have more than one cell type. Homologous tumors contain tissue elements that are indigenous to the uterus, whereas heterologous tumors are defined as those that contain tissue elements foreign to the uterus (Table 54.15). Because the great majority of uterine sarcomas fall into one of four categories, the GOG has accepted a more simplified classification:

Homologous	Heterologous
Ober Classification	
Pure	
Stromal sarcoma (endolymphatic stromal myosis)	Rhabdomyosarcoma
Leiomyosarcoma	Chondrosarcoma
Angiosarcoma	Osteosarcoma
Fibrosarcoma	Liposarcoma
Mixed	
Carcinosarcoma	Mixed müllerian tumors (mixed mesodermal tumor)
Gynecologic Oncology Group Classification	
Leiomyosarcomas	
Endometrial stromal sarcomas	
Mixed homologous müllerian sarcomas (carcinosarcoma)	
Mixed heterologous müllerian sarcomas (mixed mesodermal sarcoma)	
Other uterine sarcomas	

TABLE 54.15. *Classifications of uterine sarcomas*

- Leiomyosarcoma
- Endometrial stromal sarcoma
- Mixed homologous müllerian sarcoma (carcinosarcoma)
- Mixed heterologous müllerian sarcoma (mixed mesodermal sarcoma)

Leiomyosarcoma

Leiomyosarcoma is a malignancy of smooth muscle. This sarcoma was thought to be the most common of the malignant mesenchymal tumors, a concept that is supported by literature before the 1970s. However, more recent data from the GOG and other sources suggest that leiomyosarcoma is the second most common sarcoma of the uterus and accounts for about 1 out of 7 of all uterine sarcomas, or about 16%. This information is detailed in GOG data published on 447 uterine sarcomas. This malignancy is found in younger women, with a median age at diagnosis between 43 and 53 years. Leiomyosarcoma is more common in black women and is associated with a poorer prognosis in these patients. The patterns of spread for leiomyosarcoma appears to be via both lymphatics and the vasculature, because distant metastases will develop in many patients even if lymph node biopsy results are negative at the time of surgery.

Although there is some disagreement about the exact histologic criteria required for a diagnosis of leiomyosarcoma, the most important factor appears to be the mitotic count of the tumor. Cellular myomas and bizarre leiomyomas may appear to be malignant, but if there are fewer than 5 mitoses per 10 high-power fields (HPF), the lesion is considered benign. Tumors with more than 10 mitoses per 10 HPF are malignant, and those with 5 to 10 mitoses per 10 HPF are thought to have an uncertain potential for malignancy. Many investigators agree that 5-year survival is related to the number of mitoses per 10 HPF, with a 95% to 98% survival with fewer than 5 mitoses per 10 HPF, approximately 40% survival with 5 to 10 mitoses per 10 HPF, and very poor survival (15%–20%) with more than 10 mitoses per 10 HPF. An example of a leiomyosarcoma can be seen in Figure 54.8. The etiology of leiomyosarcoma is unclear. As its name suggests, this tumor was thought to arise within benign leiomyoma. However, in most cases it appears to arise independently of these tumors. Hysterectomy was felt to be indicated for a rapidly enlarging uterus or rapidly growing fibroid tumors for fear that this represented degeneration of leiomyomas into a sarcoma. Investigators from University of Southern California addressed this question best. These authors retrospectively reviewed a large series of patients with “rapidly enlarging” leiomyomas and found the incidence of sarcoma to be very low. They recommended that surgery for a concern of leiomyosarcoma was not warranted for fibroid tumors that were enlarging rapidly, and reasons for surgery should focus on other issues such as symptoms of pressure, pain, or bleeding.

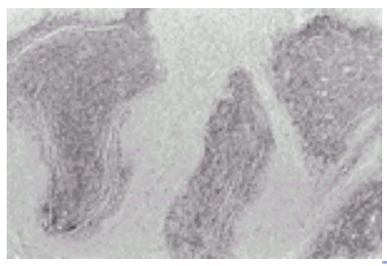

FIG. 54.8. Leiomyosarcoma. Interlacing fascicles of smooth muscle cells exhibit high-grade cytologic atypia and increased mitotic activity. Other areas of this tumor showed coagulative necrosis.

This sarcoma should be treated as any other uterine malignancy. This should include comprehensive staging with total abdominal hysterectomy, bilateral salpingo-oophorectomy, and pelvic and paraaortic lymph node dissection. The staging system for leiomyosarcomas is the same as for an endometrial cancer (see Table 54.2).

Endometrial Stromal Sarcomas

Endometrial stromal sarcomas are the least common of the three most common uterine sarcomas. The most-often-seen initial symptom of an endometrial stromal sarcoma is vaginal bleeding. These sarcomas are generally yellow in color, fleshy in texture, and often polypoid. At the time of diagnosis and treatment, usually by hysterectomy, 40% of patients have disease outside of the uterus. Endometrial stromal sarcomas are just as aggressive as the other uterine sarcomas and the prognosis is very similar.

Endometrial stromal tumors usually are divided into three groups: benign stromal nodules, endolymphatic stromal myosis and endometrial stromal sarcoma. Benign stromal nodules usually are well-circumscribed tumors with clearly defined pushing margins. These tumors may grow to many centimeters but are always benign. No cases of metastasis or recurrence have been reported. The second histologic type, endolymphatic stromal myosis, is an infiltrative tumor that generally has an indolent course. Another name for endolymphatic stromal myosis is low-grade stromal sarcoma. Gross inspection of the surgical specimen often reveals an infiltrative growth

pattern, and it can project from the cut surface in a worm-like manner that may also extend into blood vessels in the broad ligament. Microscopically, there are little cellular atypia and few, if any, mitoses. The clinical course is slowly progressive and management is usually by surgery alone. However, the tumor can recur many years after initial incidence. It is a hormonally responsive tumor and often grows in the presence of estrogen and can regress or stabilize when exposed to progestational agents. There are reports of low-grade endometrial stromal sarcomas being stabilized for many years with progestational therapy.

Endometrial stromal sarcoma, on the other hand, has a much more aggressive course, with frequent and widespread metastases and a very poor prognosis. As with leiomyosarcoma, the diagnosis of stromal sarcoma versus low-grade stromal sarcoma depends on the number of mitoses per 10 HPF, with 10 mitoses being the cutoff to categorize the tumor as an endometrial stromal sarcoma (Fig. 54.9). Despite this distinction, controversy still exists as to the prognostic significance of the number of mitoses seen. A study from the Mayo Clinic failed to identify this feature as an independent prognostic variable. As with most sarcomas, irradiation may control local disease but has little effect on overall survival. These tumors often exhibit high concentrations of both estrogen and progesterone receptors, and occasional responses have been seen when high-dose progesterone therapy is administered.

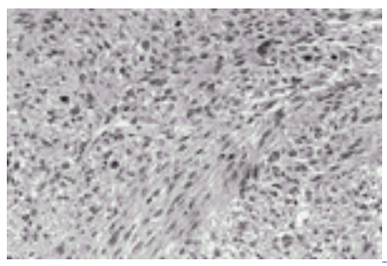

FIG. 54.9. Endometrial stromal sarcoma. Nests of bland endometrial stromal cells diffusely infiltrate the myometrium.

Mixed Müllerian Tumor

This malignancy is the most common uterine sarcoma, accounting for more than 50% of all cases in recent series. This malignancy is aggressive, and more than 60% of patients will have disease outside of the uterus at the time of diagnosis. It tends to metastasize early via lymphatic vessels, blood vessels, and local spread. It is more common in blacks than whites and is associated with prior pelvic irradiation in up to one third of patients. The main initial symptom is vaginal bleeding and, on examination, most patients are found to have an enlarged uterus, often with a polypoid mass protruding through the cervix. This tumor tends to be aggressive, with early metastasis to pelvic and periaortic lymph nodes and adjacent tissue. Hematogenous spread, especially to the liver and lungs, is common.

Histologically, it is composed of both sarcomatous and carcinomatous elements, with the sarcomatous element being divided into homologous types (tissue normally found in the uterus; Fig. 54.10) and heterologous types (tissue such as cartilage or bone not usually found in the uterus; Fig. 54.11). In some series, heterologous elements were associated with a worse prognosis. Rhabdomyosarcoma was the most common heterologous element in these cancers. In the most recent GOG series, the median progression-free interval of homologous tumors was 22.7 months, with a median progression-free interval of 62.6 months in the homologous tumors. Staging is very important in this tumor, because extrauterine disease correlates very strongly with survival. Almost no one with disease outside the uterus is cured of her disease. The single most important factor correlating with survival other than extrauterine disease is depth of myometrial invasion. Recurrences usually occur within the first 2 years and often are comprised of only the carcinomatous elements.

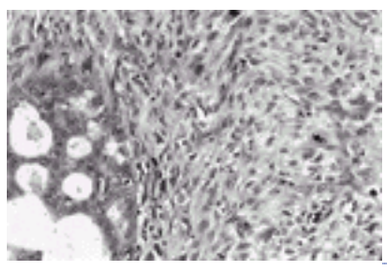

FIG. 54.10. Malignant mixed müllerian tumor, homologous type. Well differentiated.

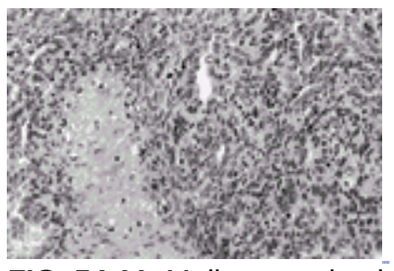

FIG. 54.11. Malignant mixed müllerian tumor, heterologous type.

Other Sarcomas

Pure heterologous uterine sarcomas are rare. Rhabdomyosarcoma is the most common and usually occurs in children. This used to be called *sarcoma botryoides* in children. Management of this rare group of tumors has changed over the last 50 years from primary surgery to chemotherapy. Müllerian adenosarcoma is a rare sarcoma originally described by Skully. This tumor usually causes vaginal bleeding and is of low malignant potential. Its course is indolent and prolonged, with an overall long-term survival rate of about 90%.

Treatment

Total abdominal hysterectomy with bilateral salpingo-oophorectomy is the treatment of choice for almost all uterine sarcomas. Because there is no formal staging system for sarcomas, most authorities feel that the endometrial staging system should be used. Local spread of a sarcoma can be treated with radiation therapy. This may not improve overall survival but will control local disease and diminish the likelihood of the morbidity of a pelvic recurrence. Unfortunately, there are no good prospective randomized trials evaluating the efficacy of postoperative radiation therapy on overall survival. The retrospective studies that do exist show only a benefit for local control. The largest study to address this issue by Salazar comprised more than 900 patients and failed to show a statistically significant survival benefit with postoperative radiation therapy, only a benefit of local control. One can argue that one must obtain control of microscopic local disease before one can cure the cancer. Typically 5,000 to 6,000 cGy is given with or without adjuvant brachytherapy. Investigators from the Mallinckrodt Institute of Radiology noted fewer pelvic recurrences when more than 5,000 cGy were used.

Some patients with leiomyosarcoma may experience an isolated pulmonary metastasis. These sometimes can be resected for cure. Significant 5-year survivals have been recorded in these rare situations. Recurrences of low-grade tumors should be considered for resection no matter where they are.

Recurrences also can be treated with chemotherapy. Many agents have shown activity (Table 54.16). Unfortunately, no therapy has shown a significant increase in overall survival.

Doxorubicin
Ifosfamide
Cisplatin
Etoposide
Mitoxantrone
Paclitaxel

TABLE 54.16. *Active agents in uterine sarcomas in order of response rate*

SUMMARY POINTS

- Uterine cancers comprise a wide variety of histologic types that carry a wide range of metastatic potential and survival.
- Endometrial hyperplasia is a premalignant precursor to endometrioid adenocarcinoma. Simple hyperplasia has a low propensity to progress to a cancer (less than 1%), whereas complex hyperplasia with atypia has a 30% chance of developing into a cancer.
- Endometrial cancer is the most common gynecologic cancer. Type I endometrial cancers are associated with relative estrogen excess. This can be endogenous, as in obese women who have significant conversion of steroids to estrone, or it can be exogenous, as in women who take unopposed estrogen replacement therapy.
- Type II endometrial cancers are not associated with estrogen and are comprised of more aggressive histologic types, such as poorly differentiated endometrioid, papillary serous, and clear cell cancers. These later types have a survival rate as poor as 60%, compared with a greater than 80% survival in the other histologic types.
- Management of endometrial cancers consists of comprehensive staging, including a total abdominal hysterectomy, bilateral salpingo-oophorectomy, pelvic washings, pelvic and paraaortic lymph node dissection, and careful abdominal exploration. Management may also include postoperative radiation therapy.
- Postoperative surveillance should include regular examination with Pap smear. The most common site of recurrence is at the vaginal cuff. Radiation treatment of an isolated cuff recurrence has a cure rate of 50% with external radiation therapy.
- Endometrial cancer is the most common inherited form of gynecologic cancer and is associated with HNPCC or Lynch II syndrome. It is important to take a careful family history to assess if the risk is high, and formal genetic counseling and genetic testing may be appropriate.
- Sarcomas are the most lethal of the uterine malignancies, with an overall survival of around 50%. There are several histologic types of sarcomas. The most common is the malignant mixed müllerian tumor, followed by the leiomyosarcoma, and finally by the endometrial stromal sarcomas. Therapy consists of exploratory laparotomy and staging procedure as outlined for endometrial cancers. Postoperative radiation therapy may be recommended, but this is associated only with decreased pelvic recurrence and not improved survival.

Hereditary Ovarian Cancer

Abnormalities of the ovary or fallopian tubes may result from physiologic changes, infectious processes, or benign or malignant neoplasms. Patients may exhibit a pelvic mass with or without other signs or symptoms. These disorders may occur at any age from childhood to senescence. Depending on patient age, the physiologic and pathologic manifestations and implications may differ. For example, teenage patients with a pelvic mass most likely will have a benign germ cell or epithelial ovarian tumor, whereas postmenopausal women have a significantly greater risk of epithelial ovarian carcinoma. The differential diagnosis and the radiologic and tumor marker workups will vary, depending on patient age and the initial complaints. The clinician must be vigilant and willing to evaluate the vague symptoms that are frequently the hallmark of many ovarian and tubal pathologies, especially in women over 40.

In recent years, we have gained an increased understanding of ovarian and fallopian tube tumor biology and molecular genetics, but these advances can be translated only slowly to the clinic. This chapter will outline ovarian and fallopian tube neoplasms, including the common epithelial histologies as well as the rarer germ cell and stromal tumors. Epidemiology and risk factors for these cancers, including inherited cancer susceptibility due to mutations in *BRCA1* and *BRCA2* genes will be discussed, as well as preventive and screening strategies.

GERM CELL TUMORS OF THE OVARY

Germ cell tumors occur most frequently in young women and girls and account for 90% of prepubertal ovarian tumors and 60% of ovarian tumors in women younger than 20 years. These tumors arise from the germ cells originating in the embryonic yolk sac. Patients usually complain of abdominal pain and have an associated pelvic or abdominal mass. Others might have acute abdominal pain as a result of ovarian rupture, hemorrhage, or torsion. A misdiagnosis of acute appendicitis has been made in these circumstances.

Mature Cystic Teratoma

Mature cystic teratomas, also known as dermoid cysts, are the most common benign ovarian neoplasm, with a peak incidence from ages 20 to 40 years. However, they also can be seen in infancy, as well as in menopausal woman. Mature cystic teratomas originate from primordial germ cells and are composed of well-differentiated derivatives of any combination of the three germ layers: ectoderm, mesoderm, endoderm. Ectodermal elements usually predominate. Although these mature tissues are benign in the vast majority of cases, on rare occasion they may undergo malignant transformation, with squamous cell carcinoma being the most frequent malignant histology.

Grossly, the tumors are round or oval with a smooth, glistening, gray-white surface. Most tumors measure 5 to 10 cm in diameter and are bilateral in 8% to 15% of cases. The tumors are usually unilocular but occasionally multilocular, and often are filled with hair and a fatty material similar to sebum (Fig. 55.1). A solid portion located at one pole of the cyst that often projects into the cavity is known as a *Rokitansky protuberance*, where all three germ cell layers are found. Tissues also can be found at the protuberance, including hair, teeth, bone, glia, neural tissue, cartilage, retina, smooth muscle, fibrous and fatty tissue, gastrointestinal and bronchial mucosa, and thyroid and salivary gland tissue. Microscopically, ovarian stroma is noted outside the cyst wall, with the cyst lined predominantly by squamous epithelium with underlying sebaceous and sweat glands (Fig. 55.2).

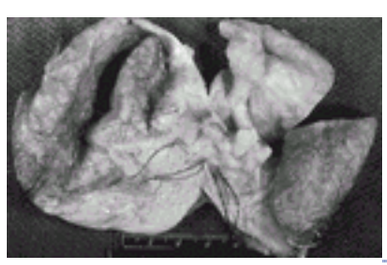

FIG. 55.1. Mature cystic teratoma. This mature cystic teratoma contains hair and teeth.

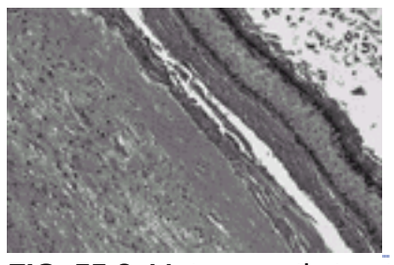

FIG. 55.2. Mature cystic teratoma. Microscopically, there is a keratinizing squamous epithelium on the right and mature glial tissue on the left.

In the past, benign cystic teratomas often were diagnosed on an abdominal radiograph in a young woman with acute abdominal pain, because osseous differentiation or teeth could be seen in the pelvis. Transvaginal sonography, however, has become the diagnostic tool of choice in most centers, although pelvic magnetic resonance imaging (MRI) can be helpful when the diagnosis is uncertain and may be especially useful when the mass is detected during pregnancy. Torsion is a frequent complication, because these are relatively buoyant and mobile tumors. Treatment usually involves ovarian cystectomy, with preservation of normal ovarian tissue and close inspection of the contralateral ovary. This often can be accomplished laparoscopically, when the dermoid cyst can be shelled out from the remaining normal ovary. Although concern for chemical peritonitis resulting from cyst rupture exists, with copious irrigation of the peritoneal cavity this complication can be avoided.

Struma Ovarii and Strumal Carcinoid

Rarely, ovarian teratomas will contain a single specialized tissue type. Struma ovarii is a subset of mature cystic teratomas in which the tumor is composed entirely or predominantly of thyroid tissue. Grossly, the cut surface shows gelatinous red to green-brown colloid, and microscopically mature thyroid tissue is seen (Fig. 55.3). Struma ovarii accounts for less than 3% of mature teratomas, with similar age distribution and similar clinical findings. However, thyroid gland enlargement is seen occasionally, and about 5% of patients with struma ovarii will experience signs and symptoms of thyrotoxicosis. Malignant changes in a struma ovarii are extremely rare, but can occur, and are most frequently of a follicular histology (unlike primary thyroid carcinomas). Approximately 30% of reported cases of malignant struma ovarii are associated with metastatic disease. Evaluation with iodine-131 scanning may be helpful, and treatment is often similar to that given for their thyroid carcinoma counterparts.

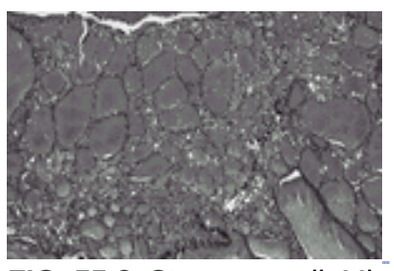

FIG. 55.3. Struma ovarii. Microscopically, the tumor is composed of normal thyroid tissue.

Strumal carcinoids are rare teratomas characterized by a mixture of thyroid and trabecular carcinoid tissues. Primary carcinoid tumors of the ovary account for less than 5% of ovarian teratomas and most likely arise from argentaffin cells found in the gastrointestinal or bronchial tissues that make up the teratoma. These tumors often are hormonally active due to the secretion of serotonin, bradykinin, and other peptide hormones that are secreted directly into the systemic circulation and are not inactivated by a “first pass” through the liver. Approximately 50% of ovarian carcinoids over 4 cm in diameter will be associated with the carcinoid syndrome, including episodic cutaneous flushing, diarrhea, and bronchospasm.

Malignant Germ Cell Tumors

Malignant ovarian germ cell tumors account for less than 5% of all ovarian cancers. Table 55.1 provides a listing of the World Health Organization classification of germ cell tumors of the ovary. Their male counterpart, testicular cancer, is approximately 10 times more common than ovarian germ cell tumors, and many of the chemotherapy regimens that are used for treating ovarian germ cell tumors have been adapted from clinical trials in patients with the corresponding type of testicular cancer. These interesting tumors tend to be diagnosed at an earlier stage than the common epithelial ovarian carcinomas, and they are very sensitive to chemotherapy and, in the case of dysgerminoma, to radiotherapy, as well. Germ cell tumors have distinct histopathologic characteristics and tumor markers that are useful in diagnosis and follow-up. Table 55.2 outlines the serum tumor markers typically associated with germ cell tumors.

TABLE 55.1. *World Health Organization classification of germ cell tumors*

TABLE 55.2. *Tumor markers associated with germ cell neoplasms: likelihood of elevation*

Dysgerminoma

Dysgerminoma is the most common malignant germ cell tumor of the ovary, accounting for 2% of all ovarian malignancies. Approximately 50% of the patients with this tumor are younger than 20 years, and 80% are younger than 30 years. Children with dysgerminoma may exhibit precocious puberty or primary amenorrhea. The serum lactate dehydrogenase level frequently is elevated and may serve as a tumor marker during treatment and follow-up.

Although dysgerminomas tend to be unilateral, approximately 10% to 15% of these tumors are bilateral. They are usually gray-white, smooth, and fleshy in appearance, and on cut surface they are usually solid. Hemorrhage and necrosis may be seen. Cystic areas suggest mixed germ cell elements that would require further careful sampling of the specimen. The microscopic appearance of an ovarian dysgerminoma is similar in histology to its male counterpart, testicular seminoma, with aggregates of tumor cells surrounded by connective tissue stroma containing many lymphocytes and foreign body giant cells (Fig. 55.4). The tumor cells are usually large, with clear or lightly granular cytoplasm containing abundant glycogen. Nuclei are vesicular and large, occupying one half of the cells and containing one or more nucleoli. Mitotic activity is almost always present. In less than 10% of patients, syncytiotrophoblastic giant cells may be detected, producing human choriogonadotropin (hCG) that may be demonstrated in tissue section by immunohistochemical techniques and in the serum by a modestly elevated hCG level. Syncytiotrophoblastic cells in a dysgerminoma do not have prognostic significance; however, serum ß-hCG levels can be used to monitor patients' responses to treatment and during follow-up.

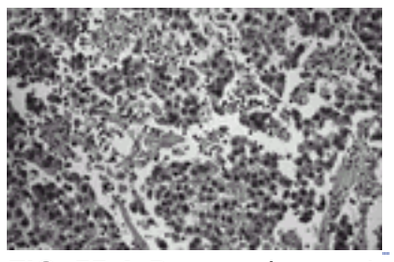

FIG. 55.4. Dysgerminoma. Loose aggregates of tumor cells are separated by connective tissue containing abundant lymphocytes.

Treatment is determined by patient age. Because most patients with dysgerminoma are of reproductive age, unilateral salpingo-oophorectomy and a full staging procedure with preservation of the contralateral ovary and the uterus are recommended, as long as there is no evidence of disease in the contralateral ovary. Table 55.3 is a listing of procedures required when a full staging procedure is performed. Table 55.4 illustrates the widely used International Federation of Gynecology and Obstetrics (FIGO) staging system for all ovarian cancers. Observational studies have revealed identical remission rates for conservative surgical treatment (e.g., unilateral salpingo-oophorectomy and staging) and complete extirpative surgery (e.g., bilateral salpingo-oophorectomy with or without a hysterectomy) in early-stage disease. Routine biopsy of the contralateral ovary is unnecessary if it is normal in appearance. If gross tumor is noted in both ovaries, a unilateral salpingo-oophorectomy of the larger ovary, a contralateral ovarian cystectomy, and a full staging procedure followed by chemotherapy may be appropriate in those patients who desire to retain fertility. Patients with advanced disease may require complete removal of the reproductive organs, which should be performed in consultation with a gynecologic oncologist.

Removal of ascites for cytologic evaluation. If there is no ascites, do peritoneal washing with 50–100 ml, of normal saline in the pelvis, the paracolic spaces, and infradiaphragmatic area.
Thorough examination of all peritoneal surfaces, intestine, and other viscera
BSO ± TAH or USO if tumor is limited to one ovary and future fertility desired
Cytoreductive surgery, reducing tumor size, including lymph nodes, to ≤1 cm residual size whenever possible
If tumor appears to be confined to the pelvis, the following procedures should be carried out:
Infracolic omentectomy
Biopsy of all suspicious areas or adhesions
Evaluation and sampling of paraaortic and pelvic lymph nodes
Routine biopsies from the cul-de-sac, right and left pelvic side walls, and the right and left paracolic spaces
Right diaphragmatic scraping or biopsy
Appendectomy, especially for mucinous tumors

BSO, bilateral salpingooophorectomy; TAH, total abdominal hysterectomy; USO, unilateral salpingooophorectomy.

TABLE 55.3. *Complete staging procedure for ovarian malignancy*

Stage I	Growth limited to the ovaries
Stage Ia	Growth limited to one ovary; no ascites; no tumor on the external surface; capsule intact
Stage Ib	Growth limited to both ovaries; no ascites; no tumor on the external surfaces; capsules intact
Stage Ic	Tumor either stage Ia or Ib but with tumor on the surface of one or both ovaries
Stage II	Growth involving one or both ovaries with pelvic extension
Stage IIa	Extension or metastasis to the uterus or tubes
Stage IIb	Extension to other pelvic tissues
Stage IIc	Tumor either stage IIa or IIb but with tumor on the surface of one or both ovaries; or with capsule(s) ruptured; or with ascites containing malignant cells; or with positive peritoneal washings
Stage III	Tumor involving one or both ovaries with peritoneal implants outside the pelvis or positive retroperitoneal or inguinal nodes Superficial liver metastasis equals stage III Tumor is limited to the true pelvis but with histologically verified malignant extension to small bowel or omentum
Stage IIIa	Tumor grossly limited to the true pelvis, with negative nodes but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces
Stage IIIb	Tumor of one or both ovaries with histologically confirmed implants of abdominal peritoneal surfaces ≤ 2 cm in diameter Nodes negative
Stage IIIc	Abdominal implants >2 cm in diameter or positive retroperitoneal or inguinal nodes
Stage IV	Growth involving one or both ovaries with distant metastases If pleural effusion is present, there must be positive cytologic test results to allot a case to stage IV Parenchymal liver metastasis equals stage IV

TABLE 55.4. *FIGO staging for ovarian cancer*

Dysgerminomas are very sensitive to both radiation and chemotherapy. Because they are found most frequently in young women, chemotherapy is the most appropriate postoperative treatment in these patients and should be offered to those with disease more advanced than stage Ia. Combination therapy with (a) vincristine sulfate (Oncovin), dactinomycin (Cosmegen), and cyclophosphamide (Cytoxan) (VAC) or (b) vinblastine sulfate (Velban), bleomycin sulfate (Blenoxane), and cisplatin (Platinol) (known as *VBP*) has been used with excellent results, especially in patients with stage I disease. The combination of bleomycin, etoposide, and cisplatin (BEP) has been even more effective in treating all stages of disease, with a sustained remission in essentially 100% of patients. The M.D. Anderson Cancer Center group and the Gynecologic Oncology Group (GOG) have used BEP in their treatment of dysgerminoma in all stages of disease and have reported a prolonged disease-free interval with three to six cycles of therapy, depending on disease status, residual disease, and tumor markers. In an effort to explore regimens with lower toxicity, the GOG reported a regimen of carboplatin and etoposide for completely staged and resected stage Ib to III dysgerminomas. Despite favorable results, BEP remains the recommended first line based on descriptive studies (type III evidence). In patients with pure dysgerminomas seemingly confined to the ovary (women who were staged inadequately), administration of three cycles of adjuvant BEP is recommended due to a recurrence rate of 20%. However, the scientific merit of this treatment plan requires further investigation. Another option is to offer a repeat surgery to fully stage the disease. There have been several reports of secondary neoplasm, especially hematologic malignancies, after the use of BEP and other etoposide-based regimens. Although these are rare occurrences, careful long-term follow-up and evaluation of risk–benefit ratio may be warranted to assess the efficacy of this regimen with and without etoposide.

Endodermal Sinus Tumor

Endodermal sinus tumor, or yolk sac tumor, is the second most common germ cell tumor, representing 1% of all ovarian malignancies. It may be pure or part of a malignant mixed germ cell tumor. The reported age distribution ranges from 16 months to 46 years, but most patients are younger than 30 years. The serum a-fetoprotein (AFP) level frequently is elevated in these patients (see Table 55.2), making it a useful diagnostic test in the initial workup, in the assessment of response to therapy, and in follow-up for recurrence. Symptoms are typical of those observed with other germ cell tumors. Several cases have occurred during pregnancy. No endocrine manifestations have been seen with the pure form of endodermal sinus tumor. More than 70% of patients with endodermal sinus tumors are diagnosed in stage I, although they are biologically virulent.

Grossly, tumors are usually gray-yellow, large, and solid, ranging from 3 to 30 cm in diameter. Bilateral involvement has been noted only in patients with metastatic spread to other organs. Foci of hemorrhage, necrosis, and gelatinous changes are present. Microscopically, endodermal sinus tumors display a wide range of histologic patterns. The microcystic pattern is characterized by a loose network of channels and spaces forming a honeycomb lined by flat pleomorphic mesothelial-like cells with large hyperchromatic or vesicular nuclei. Hyaline globules or droplets, which are positive with periodic acid–Schiff stain, are found commonly. The endodermal sinus pattern is characterized by perivascular formations called Schiller-Duval bodies (Fig. 55.5). Other patterns include the alveolar–glandular pattern, composed of alveolar, gland-like, or cystic spaces lined by flat or cuboidal epithelium; the polyvesicular vitelline pattern, in which numerous small vesicles are surrounded by connective tissue; and the solid pattern, consisting of aggregates of small pleomorphic undifferentiated cells. These histologic patterns do not have prognostic significance.

FIG. 55.5. Yolk sac tumor. A characteristic finding in the endodermal sinus pattern is the Schiller-Duval body.

In the past, patients with endodermal sinus tumors, even those with early-stage tumors, did poorly in spite of aggressive surgical and radiation treatments. With adjuvant chemotherapy after conservative pelvic surgery and staging laparotomy (see Table 55.3), there has been a marked improvement in the prognosis of patients with this malignancy. Adjuvant chemotherapeutic regimens for all nondysgerminomatous germ cell tumors (including endodermal sinus tumors, immature cystic teratoma, embryonal cell tumors, and others) are similar, because they are grouped together in treatment protocols in several major studies. The VAC regimen, first

introduced in the 1970s, resulted in a successful cure rate of more than 80% in patients with stage I disease but less than 50% in patients with more advanced stages, as reported by a GOG study and the M.D. Anderson group experience. The VBP regimen has shown superior results, compared with VAC, but toxicity is increased. However, no randomized clinical trials have been performed to compare the two regimens due to the rarity of these malignancies. More recently, the BEP regimen has shown an excellent response rate of over 95% in patients with local or advanced disease and has become the primary therapeutic regimen. Further studies, however, are needed to explore alternative regimens to reduce the rate of toxicity while maintaining the same efficacy. Second-look laparotomy should not be a part of posttherapy surveillance for this tumor or any other germ cell tumors. Salvage therapies, such as surgery followed by chemotherapy, in patients who have failed primary chemotherapy have shown some success; however, they are anecdotal at best due to the limited number of cases.

Immature Cystic Teratoma

Like mature cystic teratoma, immature cystic teratoma is composed of tissues derived from all three germinal layers, except that they also contain embryonic tissue. This group of tumors is the third most common malignant germ cell tumor, representing about 25% of all such tumors in patients younger than 20 years. Unlike mature cystic teratoma, which occurs in all ages but more frequently during the reproductive years, immature cystic teratoma essentially is found during the first two decades of life. It usually grows rapidly through its capsule, forming adhesions to the surrounding structures, and implants in the peritoneal cavity.

Tumors are usually smooth and unilateral, ranging from 9 to 28 cm. A mature cystic teratoma may be present in the other ovary. Tumors are predominantly solid, with some cystic areas filled with serous or mucinous fluid or fatty material (Fig. 55.6). The cut surface is soft and usually gray to pink to brown. Microscopically, the most common immature tissue present is neural, derived from the ectoderm (Fig. 55.7). A histologic grading system was, therefore, proposed based on the relative amount of mature and immature neuroepithelial tissues, mitotic activity, and degree of differentiation:

FIG. 55.6. Immature teratoma. This bulky neoplasm, removed from a 20-year-old woman, weighed 1,800 g. The neuroectodermal elements appeared opaque and friable *(arrow)*.

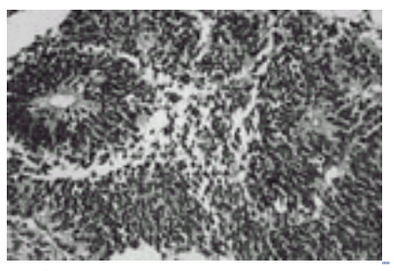

FIG. 55.7. Immature teratoma. These tumors are graded based on the presence and extent of neuroepithelial elements. Note the rosettes.

Grade 0-Mature tissue only
Grade 1-Limited immature neuroepithelial tissue and mitotic activity
Grade 2-Moderate amount of immature tissue and mitotic activity
Grade 3-Large quantities of immature tissue and mitotic activity

Prognosis correlates with histologic grade of tumors, because the presence of immature elements worsens the prognosis. In patients with stage Ia grade 1 disease, surgery alone, consisting of an exploratory laparotomy, unilateral salpingo-oophorectomy, and a complete staging procedure (see Table 55.3), is sufficient. For more advanced disease and high-grade tumors, postoperative adjuvant chemotherapy is necessary. Depending on disease extent, preservation of the contralateral ovary and the uterus is usually feasible. Serum AFP levels may be elevated (see Table 55.2). Chemotherapy is discussed in detail above.

Embryonal Carcinoma

Embryonal carcinoma is rare, accounting for less than 5% of all germ cell tumors. It usually occurs in children, with a median age of 15 years. Like its testicular counterpart, embryonal carcinoma is a highly malignant neoplasm. Because it often is seen as part of mixed germ cell tumors, serum AFP and hCG levels often are elevated. Clinically, it may be associated with precocious puberty, as well as abnormal vaginal bleeding in adults.

The gross pathologic picture is variable, but the tumor is usually large and soft, with a cut surface that is solid and gray-white with areas of hemorrhage and necrosis. Microscopically, embryonal carcinoma consists of primitive, undifferentiated sheets of variably sized epithelial cells (Fig. 55.8). Nuclei are vesicular, and mitoses are frequent. Syncytiotrophoblastic giant cells frequently are seen in the stroma or directly adjacent to clusters of embryonal carcinoma cells.

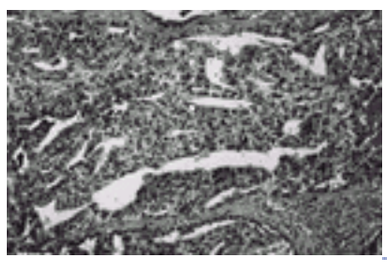

FIG. 55.8. Embryonal carcinoma. Tumor cells form syncytial aggregates that surround cleft-like spaces.

Polyembryoma

Polyembryoma is a rare germ cell tumor, characterized by numerous embryoid bodies that morphologically resemble normal presomite embryos. It is usually part of a mixed germ cell neoplasm and causes similar symptoms. The median age of patients with polyembryoma is 15 years. The tumor is usually unilateral, ranging from 10 cm to a mass that fills the entire abdominal cavity; cut section reveals mostly solid areas with hemorrhage and necrosis. Microscopically, embryonic bodies of varying degrees of differentiation are noted, including an embryonic disk, amniotic cavity, yolk sac, and extraembryonic mesenchyme (Fig. 55.9). Syncytiotrophoblastic cells have been detected, also. AFP, hCG, and sometimes human placental lactogen can be demonstrated in the serum and in cells by immunohistochemical staining.

FIG. 55.9. Polyembryoma. In less differentiated forms, embryoid bodies may have a bizarre appearance.

Choriocarcinoma

Choriocarcinoma is a rare germ cell tumor of either pure or mixed form. Pure choriocarcinoma usually is found in prepubertal children. Isosexual precocious puberty is a common clinical finding in premenarcheal patients. In postmenarcheal patients, the presence of other germ cell components is helpful in distinguishing ovarian germ cell tumors from a gestation choriocarcinoma. A diagnosis of ectopic pregnancy often is entertained in postmenarcheal patients due to the shared signs and symptoms. The gross appearance of choriocarcinoma depends on the composition of the germ cell elements. The tumor is usually arge, unilateral, and solid, with areas of necrosis and hemorrhage. Microscopically, both cytotrophoblasts and syncytiotrophoblasts are present (Fig. 55.10). Treatment is as described previously for the other germ cell tumors.

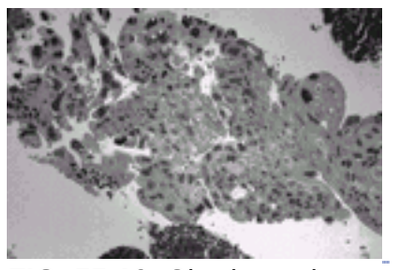

FIG. 55.10. Choriocarcinoma. There is a dimorphic population of malignant cytotrophoblasts and syncytiotrophoblasts. Associated hemorrhage is a common finding.

Gonadoblastoma

Gonadoblastoma almost always arises in a congenitally abnormal gonad, with associated sexual maldevelopment. Patients with gonadoblastoma most often have pure or mixed gonadal dysgenesis or are male pseudohermaphrodites. Predominantly, karyotypes 46,XY, 45,X/46,XY mosaicism and, rarely, 46,XX or 45,X have been associated with this tumor. Gonadoblastoma is much more common in phenotypic females than in phenotypic males, with a ratio of 4:1. It frequently is associated with dysgerminoma and occasionally with other germ cell neoplasms, including yolk sac tumor, embryonal carcinoma, and choriocarcinoma.

Patients with gonadoblastoma usually complain of primary amenorrhea, virilization, or developmental abnormalities of the genitalia. A karyotype should be included in the evaluation of the young women with a pelvic mass and any symptoms of abnormal sexual development. It is during the workup of these conditions that gonadoblastoma is usually diagnosed. It is detected most frequently during the second decade. Hot flushes and other menopausal symptoms have been noted after tumor excision, suggesting estrogen-secreting cells are in these tumors. However, the exact source of the androgen or estrogen production is unknown, because the steroid production was noted in the absence of Leydig or lutein cells.

Gonadoblastoma is more common in the right gonad than in the left and is bilateral in 38% of patients. The tumor can range from a microscopic lesion to a mass, measuring up to 8 cm in diameter, that is soft and fleshy to firm and hard, depending on the degree of calcification. When mixed with other malignant germ cell elements, it can grow even larger. Microscopically, gonadoblastoma is composed of cellular nests containing a mixture of germ cells and immature sex cord–stromal cells, such as Sertoli and granulosa cells (Fig. 55.11). Hyaline bodies and calcification are often present in the nests. In 50% of patients, a supervening dysgerminoma displaces most of the gonadoblastoma, pushing the cell nests to the periphery.

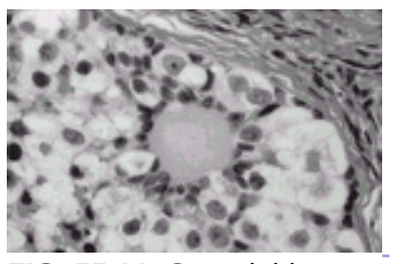

FIG. 55.11. Gonadoblastoma. Large germ cells are admixed with smaller sex cord derivatives that surround rounded hyaline material resembling a Call-Exner body.

Treatment for patients with gonadal dysgenesis is a bilateral gonadectomy, because they have an increased risk for a germ cell tumor, especially gonadoblastoma. If the gonads are not removed and tumors develop, the prognosis of patients with pure gonadoblastoma is excellent, as long as the tumor and the other ovary are both removed. The prognosis in patients with gonadoblastoma associated with dysgerminomatous elements remains very good, even with metastasis. If the gonadoblastoma is associated with other germ cell tumors, such as endodermal sinus tumor, embryonal carcinoma, or choriocarcinoma, the prognosis is poor if untreated. However, combination chemotherapy (BEP) results in significant improvement, as described previously.

SEX CORD–STROMAL TUMORS OF THE OVARY

Sex cord–stromal tumor accounts for approximately 8% of all ovarian tumors. The origin of tumor cells may be the coelomic and mesonephric epithelium or the mesenchymal stroma of the genital ridge. This category includes an array of tumors derived from the sex cords (granulosa and Sertoli cells) and from the gonadal stroma (theca and Leydig cells). The most common types of sex cord–stromal tumor are granulosa cell tumors and fibrothecomas, whose peak age of incidence is approximately 50 years. These tumors have the potential for steroid hormone secretion, with estrogen being the predominant hormone. They usually are not seen in women younger than 20 years, except for juvenile granulosa cell tumors. The classification of sex cord–stromal cell tumors is outlined in Table 55.5.

Granulosa stromal cell tumors
Granulosa cell
Thecoma-fibroma
Androblastoma: Sertoli-Leydig cell tumors
1. Well differentiated
Sertoli cell tumor
Sertoli-Leydig cell tumor
Leydig cell tumor
Hilus cell tumor
Steroid cell tumors
2. Intermediate differentiation
3. Poorly differentiated (sarcomatoid)

TABLE 55.5. *World Health Organization classification of sex cord–stromal tumors*

Thecoma

Thecoma is a benign tumor affecting all ages, with a predominance in the postmenopausal group; it is rare in patients younger than 35 years. It accounts for 2% of all ovarian tumors. Many women with a thecoma have abnormal or postmenopausal uterine bleeding; some have an endometrial adenocarcinoma as a result of unopposed estrogen produced by the tumor. Thecoma is composed of lipid-laden stromal cells resembling theca cells. Rather than arising as a de novo neoplasm, it may represent changes occurring in background cortical stromal hyperplasia.

Tumor size ranges from a nonpalpable incidental finding to a large solid mass with a diameter of 15 to 20 cm. It is usually unilateral and almost never malignant. Its outer surface is smooth, and its cut surface is typically solid, lobulated, and yellow. Cystic change may be seen. Microscopic evaluation reveals masses of oval or round cells with abundant, pale, lipid-containing cytoplasm. Hyaline plaques are noted often. A luteinized thecoma sometimes occurs, usually in younger women.

Treatment for thecoma is tailored to patient age and ranges from a total abdominal hysterectomy and bilateral salpingo-oophorectomy for menopausal or postmenopausal women to a salpingo-oophorectomy or ovarian cystectomy, if possible, in patients who desire to retain fertility.

Fibroma

Like thecoma, fibroma is a benign tumor affecting all ages, although most occur in women aged 40 to 60 years; less than 10% of patients are 30 years or younger. Fibroma is not associated with hormone production. In some cases, hydrothorax and ascites are found in association with a pelvic mass—a constellation of findings known as *Meigs syndrome.* In other cases, fibroma is seen in patients with a hereditary basal cell nevus syndrome, characterized by early-appearing basal cell carcinomas, keratocysts of the jaw, calcification of the dura, and mesenteric cysts.

Fibroma, like thecoma, ranges in size from a nonpalpable incidental finding to larger than 20 cm; it is usually unilateral but multinodular. Cut surface is firm and hard and has a whorled appearance. Microscopically, fibroma is composed of bundles of collagen-producing spindle cells arranged in a storiform pattern (Fig. 55.12). Hyalinization and intercellular edema are characteristic. The cytoplasm of tumor cells may contain small quantities of lipid, making distinction from thecoma difficult.

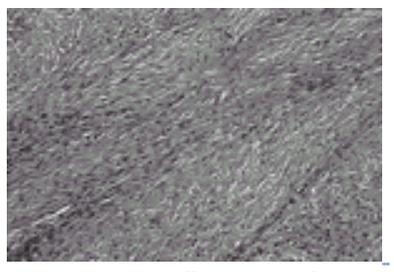

FIG. 55.12. Fibroma. The tumor is composed of intersecting bundles of spindled cells.

Treatment is similar to that for thecoma. In patients with Meigs syndrome, the hydrothorax and ascites usually resolve after resection of the pelvic tumor.

Juvenile Granulosa Cell Tumor

Approximately 44% of all juvenile granulosa cell tumors occur during the first decade of life and 97% during the first three decades. Isosexual pseudoprecocious puberty commonly is associated with this tumor, along with Ollier disease (enchondromatosis), Maffucci syndrome (enchondromatosis and hemangiomatosis), and abnormal karyotypes with ambiguous genitalia. Symptoms usually include abdominal pain, increasing abdominal girth, and hemoperitoneum due to rupture. Occasionally, it may be associated with pregnancy.

The gross appearance of juvenile granulosa cell tumor is commonly a large yellow-to-gray, solid and cystic mass, similar to the adult form. A mixture of granulosa and theca cells may be present. Microscopic features that distinguish juvenile granulosa cell tumor from the adult form are hyperchromatism of the tumor cells, which generally lack grooves, and the frequent luteinization of both the granulosa and theca cells (Fig. 55.13). The follicles are usually immature. Call-Exner bodies, which are pathognomonic of adult granulosa cell tumor, are rarely present in the juvenile form.

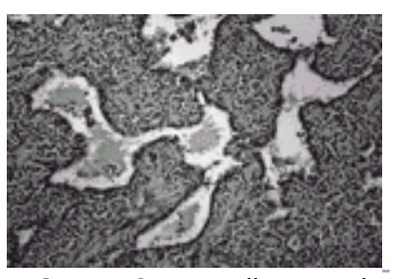

FIG. 55.13. Juvenile granulosa cell tumor. Tumor cells from follicles of varying sizes and shapes that contain weakly basophilic secretions.

Treatment in young women usually consists of a unilateral salpingo-oophorectomy with a complete staging (see Table 55.3), especially if preservation of reproductive function is desired and the tumor appears to be grossly confined to one ovary. Although the survival rate for patients with stage I disease is greater than 90%, juvenile granulosa cell tumor appears to behave more aggressively in advanced disease, with a survival rate of less than 50%. Isolated reports of successful treatment with various combination chemotherapies have been recorded. Due to the rarity of these tumors, a standard chemotherapeutic regimen has not emerged.

Adult Granulosa Cell Tumor

The adult form of granulosa cell tumor accounts for 1% to 2% of all ovarian tumors and 95% of all granulosa cell tumors. Although these tumors average 10 to 12 cm in diameter, a pelvic mass is not always detectable. Peak age of occurrence is 50 to 55 years, and most granulosa cell tumors produce estrogen, which in premenopausal women is manifested by menstrual irregularities such as menorrhagia, amenorrhea due to anovulation, or metrorrhagia. In postmenopausal women, vaginal bleeding results from endometrial stimulation. Endometrial hyperplasia or carcinoma is a relatively common occurrence, approximately twice that seen in premenopausal women. The best estimate for the frequency of associated endometrial carcinoma is 5%.

Grossly, the tumors are solid and gray-white or yellow, with cystic areas and hemorrhage. Microscopically, they are composed of granulosa cells and theca cells or fibroblasts, or both. Theca cells and fibroblasts are most likely a response of the ovarian stroma to granulosa cell proliferation, because only granulosa cells are found in metastatic sites. Granulosa cells may be round, polygonal, or spindle shaped, with scant cytoplasm and round or ovoid nuclei. Many different histologic patterns may be seen separately or together; these include the microfollicular pattern with its distinctive Call-Exner bodies (Fig. 55.14), macrofollicular, insular, trabecular, solid-tubular and, rarely, hollow-tubular patterns. Less differentiated forms include the watered silk or diffuse pattern. Rarely, a granulosa cell tumor undergoes sarcomatous transformation, producing the most aggressive form of the disease. Inhibin may be a useful immunohistochemical marker and serum inhibin levels can be used to monitor the clinical course.

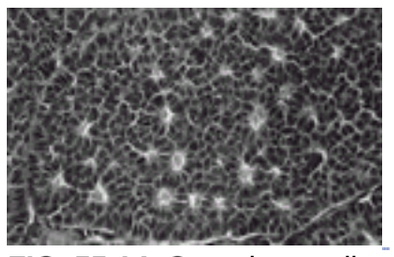

FIG. 55.14. Granulosa cell tumor. The microfollicular pattern is characterized by granulosa cells with angulated nuclei surrounding small cavities that simulate the Call-Exner bodies of the developing follicle.

Although most granulosa cell tumors have a very low potential for malignant behavior, with 90% of tumors being stage Ia, they do have a propensity for late recurrence up to 10 to 20 years or more after initial diagnosis. In addition to full surgical staging (see Table 55.3), surgery should include a total abdominal hysterectomy and bilateral salpingo-oophorectomy in postmenopausal patients. Conservative surgery is indicated in younger patients who wish to maintain fertility, if the tumor is confined to one ovary. Stage appears to be the most important prognostic factor. Although others include capsular rupture, tumor size, nuclear atypia, mitotic activity, and histologic pattern, studies of these factors have not been conclusive. It is difficult to evaluate the efficacy of chemotherapy in this group of tumors. Most retrospective series have been limited by their small sample size and short follow-up. Platinum-based therapy including the PAC, VBP, and BEP regimens have been the most successful, with a 5-year survival of 50%. Radiotherapy also has been used with varying success in studies limited by small numbers. In recurrent disease, surgery may offer the best mode of therapy. Chemotherapy and radiation therapy have been used.

Androblastoma and Sertoli-Leydig Cell Tumor

Hilus Cell Tumor Hilus cell tumor is a subtype of Leydig cell tumor, originating from the ovarian hilus. The other subtype, which is very rare, is a nonhilar-type Leydig cell tumor, derived from ovarian stromal cells and having similar clinical and pathologic features. The average age of patients with a hilus cell tumor is 58 years, and many show symptoms of abnormal menstruation, hirsutism, and virilization. Some may exhibit estrogenic manifestations. Hilus cell tumors are almost always benign. Grossly, this tumor is circumscribed, lobulated, solid, soft, and red to yellow. Tumor enlargement is usually minimal, and the tumor often is physically undetectable. Sometimes, it is discovered incidentally when the ovaries are sectioned for pathology examination for another purpose. Microscopic evaluation reveals circumscribed masses of steroid cells with abundant eosinophilic cytoplasm. Lipochrome pigment may be present, also. The diagnostic elongate eosinophilic crystalloids of Reinke must be found for the tumor to be definitively classified a Leydig cell neoplasm. Treatment of this benign tumor is unilateral salpingo-oophorectomy or ovarian cystectomy if preservation of fertility is desiredSK.

Sertoli-Leydig Cell Tumors

Sertoli-Leydig cell tumors are also termed Sertoli–stromal cell tumors and can be divided further into several subtypes (see Table 55.5). Stage and tumor differentiation seem to be important prognostic factors. Despite the name of these tumors, hormone production is not always associated with them. Tumors that produce hormones may result in masculine or feminine phenotypes, because few of the tumors actually produce estrogen or progesterone.

Sertoli Cell Tumor Sertoli cell tumors are very rare. Patients, ranging in age from 7 to 79 years (median, 33 years), usually exhibit a pelvic or abdominal mass. If the mass is functional, patients may experience some form of estrogenic effect, such as endometrial hyperplasia or isosexual precocious pseudopuberty. Androgenic and progestogenic effects may also occur. Most tumors are stage I unilateral masses that are well circumscribed, averaging about 9 cm in diameter. Cut surface reveals solid, yellow-to-brown, lobulated masses. Microscopic evaluation discloses closely packed hollow or solid tubules lined by Sertoli cells that can also contain abundant cytoplasmic lipid. An association between Sertoli cell tumors and Peutz-Jeghers syndrome has been reported in the literature. Most Sertoli cell tumors are benign or early-stage malignant neoplasms that are cured by surgery. Conservative surgery with a unilateral salpingo-oophorectomy is indicated in many of these patients who are young and desire preservation of ovarian function. Only rarely are these tumors poorly differentiated and aggressive. Experience with chemotherapy in these tumors is limited due to their rarity.

Sertoli-Leydig Cell Tumor Sertoli-Leydig cell tumor accounts for less than 0.5% of all ovarian tumors. It is seen most often in young women, with a mean age of occurrence of 25 years. Less than 10% of these tumors occur in women older than 50 years, and fewer than 5% occur in prepubertal girls. Sertoli-Leydig cell tumor often is associated with androgen production; however, virilization develops in only 50% of patients. This may be due to a lack of hormone production or insufficient androgen production. Typically, patients complain of oligomenorrhea followed by amenorrhea, breast atrophy, acne, hirsutism, temporal balding, deepening of the voice, and enlargement of the clitoris. The latter two symptoms may not resolve after tumor removal. Patients without endocrine manifestations may complain of abdominal swelling or pain. Occasionally, symptoms of estrogen production such as menorrhagia or menometrorrhagia may be seen. They are a result of the Sertoli cell component of the tumor or peripheral androgenic conversion. Sertoli-Leydig cell tumor must be distinguished from other virilizing tumors, such as adrenal tumors, which often are associated with an elevated urinary level of 17-ketosteroids; the urinary level of 17-ketosteroids in Sertoli-Leydig cell tumor is usually normal or only slightly elevated. Serum AFP level may be increased and may be useful as a tumor marker. The gross appearance of Sertoli-Leydig cell tumor is highly variable. Overall, it has an average diameter of 12 to 15 cm, and its cut surface is usually tan or yellow and may be cystic. Hemorrhage and necrosis frequently are seen in the poorly differentiated tumors. On microscopic examination, the tumor is composed of a mixture of Sertoli, Leydig, and undifferentiated gonadal stromal cells, with or without heterologous components, in varying proportions and degrees of differentiation. In well-differentiated lesions, Sertoli cells form tubules and Leydig cells are found in the intervening stroma (Fig. 55.15). Sertoli cells are cytologically bland, and mitotic figures are rare. Leydig cells may contain abundant lipochrome pigment or crystalloids of Reinke. Intermediate and poorly differentiated tumors are characterized by more immature components of the Sertoli and Leydig cells. Cartilage, mucinous epithelium, skeletal muscle, and other heterologous elements are found in 20% to 25% of these tumors, most of which are of intermediate differentiation. When heterologous elements have been found in poorly differentiated neoplasms, the tumors are clinically malignant. Sertoli-Leydig cell tumor with a retiform pattern may be seen with prominent hyalinized cores and papillae lined by stratified epithelial cells.

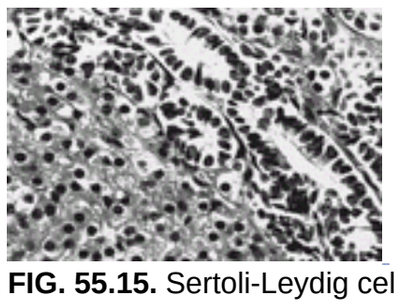

FIG. 55.15. Sertoli-Leydig cell tumor. This well-differentiated tumor is composed of hollow tubules lined by Sertoli cells and adjacent sheets of Leydig cells.

The treatment for Sertoli-Leydig cell tumor usually depends on patient age and tumor stage, degree of differentiation, and presence of heterologous elements in the tumor. The most important prognostic factor is stage. In young women with a stage Ia well-differentiated tumor and who desire future pregnancy, a unilateral salpingo-oophorectomy and a staging procedure are adequate treatment (see Table 55.3). However, more aggressive cytoreductive surgery, including a hysterectomy and bilateral salpingo-oophorectomy, tumor resection, and staging procedure may be indicated in postmenopausal patients or those with more advanced disease. Adjuvant therapy is recommended for patients who have stage Ia lesions with poorly differentiated elements or heterologous components or for those who have metastatic disease. However, due to the limited number of cases, no standard adjuvant therapy has been accepted for these patients. Most of the information available comes from small series and case reports. Treatment of advanced sex cord–stromal cell tumors, unlike that used for germ cell tumors, has not met with much success. Platinum-based therapies have yielded the best results, with an overall survival of approximately 50%. These include the PAC, VBP, and BEP regimens. As with chemotherapy, radiotherapy has been used successfully in a limited number of cases.

Steroid Cell Tumors Not Otherwise Specified Termed lipid cell or lipoid tumors in the past, these are tumors composed entirely of cells resembling typical steroid hormone–secreting cells (e.g., lutein cells, Leydig cells, and adrenal cortical cells), except that specific features such as location of origin in the hilus or crystalloids of Reinke are not identified. Steroid cell tumors not otherwise specified (NOS) account for approximately 0.1% of all ovarian tumors, with a mean age of occurrence of 43 to 60 years. Androgenic changes, occurring in 75% to 90% of patients, may be of many years' duration. Estrogenic and progestogenic changes are noted occasionally. Although the estrogenic manifestations may be a result of estrogen production by the tumors, the aromatization of androgen to estradiol in adipose tissue may be more plausible. Cushing syndrome may be found in some patients, accompanied by elevated serum cortisol levels. Diagnosis often depends on the clinical manifestation of virilization or the rare occasion of isosexual pseudoprecocity. Tumor removal results in rapid resolution of most of the hormonal effects, except for deepening of the voice and clitoromegaly. Grossly, steroid cell tumors NOS are solid, well circumscribed, and yellow to orange-tan, measuring 5 to 8 cm in diameter. Hemorrhage, necrosis, and cystic degeneration occasionally are observed. The cut surface of the tumor is soft and lobulated. Microscopically, tumor cells may resemble Leydig or hilar cells (Fig. 55.16). In other instances, cells have abundant pale cytoplasm, resembling adrenocortical cells. These cells are polygonal to round and larger than Leydig cells, with central nuclei and lipid-rich cytoplasm. The striking resemblance of many of these tumors to adrenocortical tumors has led some to speculate that they may arise from the adrenocortical nests. The association with manifestations of Cushing syndrome would seem to support this theory, and detailed examination has revealed the presence of these nests in the broad ligament and the ovarian hilus. Alternatively, given that steroid cell tumors NOS often are confined to the ovary may simply mean that adrenocortical hormones are being produced by cells of ovarian origin rather than by an ectopic adrenal tumor. Steroid cell tumors NOS are rarely malignant; approximately 10% to 15% of them recur or metastasize.

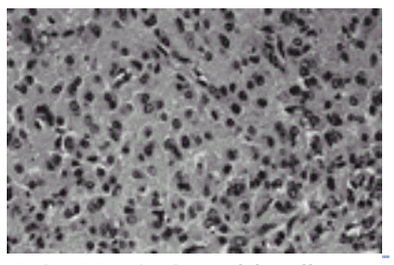

FIG. 55.16. Steroid cell tumor not otherwise specified. If crystalloids of Reinke were identified in these cells, the tumor would be classified a Leydig cell tumor or possibly a hilus cell tumor, depending on the its location. The granular appearance of the cytoplasm in these polygonal-to-rounded tumor cells suggests that they contain little lipid.

A unilateral salpingo-oophorectomy is adequate for stage Ia disease in young, reproductive age women. An abdominal hysterectomy and bilateral salpingo-oophorectomy with staging and resection of all extraovarian disease are indicated in women with advanced disease or in those beyond reproductive age.

EPITHELIAL OVARIAN TUMORS

Benign Neoplasms

Serous Cystadenoma Serous and mucinous cystadenomas are the most common benign epithelial ovarian neoplasms. Serous tumors account for approximately 25% of all benign ovarian neoplasms, with an age range of 20 to 50 years; they are bilateral in 12% to 20% of patients. Symptoms are variable. For many patients, the diagnosis is made during routine pelvic examination. Grossly, serous cystadenoma is a cystic, usually unilocular lesion, ranging from 5 to 15 cm in diameter. The inner lining of the cyst wall may be flat or partially covered by papillary projections. Microscopically, the epithelial lining can range from simple cuboidal cells, resembling the ovarian surface epithelium, to tall columnar cells, resembling the fallopian tube (Fig. 55.17). Ciliated and secretory cells may be present. Mitoses are rare, and nuclear atypia is absent. Psammoma bodies, which are concentric calcifications, are seen in 15% of tumors. Multiple, large, calcified deposits may be visible on radiologic examination of the abdomen. The stroma may vary from fibrous to cellular to hyalinized, with marked stromal edema. The papillary processes are fibrous and lined by a single layer of epithelial cells.

FIG. 55.17. Serous cystadenoma. The lining epithelium commonly appears tubal.

The preoperative workup depends on patient age and the degree of suspicion of malignancy. A unilateral salpingo-oophorectomy usually is performed in patients who have completed childbearing. In those desiring future reproduction, an ovarian cystectomy usually is performed. A bilateral salpingo-oophorectomy may be performed in selected individuals, particularly in those with bilateral tumors. In such cases, discussion of a hysterectomy is reasonable but not necessary.
Mucinous Cystadenoma Mucinous cystadenoma accounts for approximately 25% of all benign ovarian neoplasms, with an age range of 20 to 50; in 2% to 3% of patients it is bilateral. The tumor arises from the surface epithelium of the ovary, resembling müllerian-type epithelium of the endocervix, intestinal-type epithelium, or both these types. Because of the large size that this tumor frequently attains, patients usually have a palpable pelvic or abdominal mass and may have associated pain. Gross evaluation of a mucinous cystadenoma reveals that it is usually multilocular and larger than its serous counterpart, ranging up to 50 cm or more in diameter. The external surface is usually smooth, pinkish gray, and sometimes lobulated. Inside, locules tend to be small and contain thick, sticky, tenacious mucinous material (Fig. 55.18). Microscopically, the epithelium consists of a single layer of uniform tall columnar cells that resemble a picket fence in the endocervical type or may contain goblet, argentaffin, and Paneth cells in the gastrointestinal type (Fig. 55.19). Treatment is similar to that for serous cystadenoma. The appendix should be removed in any suspected ovarian mucinous tumor because of frequent synchronous appendiceal mucinous tumors (mucocele), even in a clinically normal-appearing appendix.

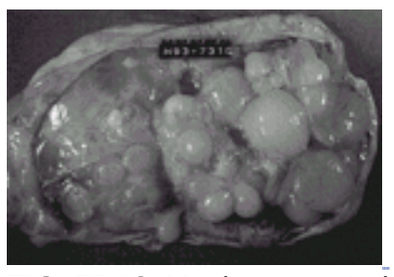

FIG. 55.18. Mucinous cystadenoma. The tumor is multilocular.

FIG. 55.19. Microscopic appearance of the lining of a mucinous cystadenoma. The “picket fence” epithelium is characteristic of this tumor.

Cystadenofibroma As the name suggests, cystadenofibroma is a variant of serous cystadenoma, containing both cystic and solid components. This benign tumor is usually unilateral and has a similar age distribution to that of serous cystadenoma. It is variably papillary to solid. Papillae are broad, firm, and nonfriable. Microscopically, solid areas are found to contain small cystic structures that are histologically identical to serous cysts. As with other benign epithelial ovarian tumors, treatment is individualized based on patient age and reproductive desire.
Brenner Tumor Also known as transitional cell tumor, Brenner tumor constitutes 2% of all primary ovarian tumors. Patients with this tumor range in age from 30 to 70 years, with a mean age of 50 years. Brenner tumor is thought to be derived from ovarian surface epithelium that undergoes a metaplastic transformation to cells resembling urothelium. It may occur synchronously with mucinous cystadenoma. Most transitional cell tumors are benign, but transformation to a malignant form has been observed. Clinical picture may be variable, because the patient may be asymptomatic or may have a palpable mass or pain. Occasionally, patients may experience vaginal bleeding, probably due to hormonal activity in the stroma. Grossly, the tumor is solid—less commonly cystic—and usually unilateral, although 6% to 7% of tumors are bilateral. Ranging in size from microscopic to as large as 30 cm in diameter, it is usually gray, white, or yellow, with a faintly lobulated cut surface. Microscopic review depicts a characteristic pattern of circumscribed epithelial nests of cells embedded in an abundant fibromatous stroma (Fig. 55.20). Epithelial cells may be round to polygonal, with eosinophilic or clear cytoplasm. When longitudinal grooves of the nuclei are present, the cells are described as having a “coffee bean” appearance. Often, these nests of epithelial cells undergo benign cystic changes lined by either transitional cells or mucinous cells. Treatment is usually resection of the tumor, and this may involve a cystectomy or salpingo-oophorectomy with or without a hysterectomy, depending on patient age and reproductive desires.

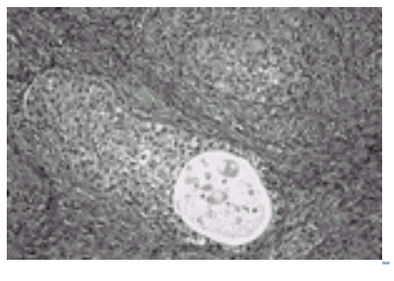

FIG. 55.20. Brenner tumor. Epithelial nests embedded in a fibromatous stroma may show cystic change. Longitudinal grooves in the cells can impart a “coffee bean” appearance.

Tumors of Low Malignant Potential

Epidemiology Ovarian tumors of low malignant potential (LMP), also known as atypical proliferating tumors, comprise a group of tumors showing greater epithelial proliferation than that seen in their benign counterparts although, by definition, they are still noninvasive. Recognized by FIGO in 1971, LMP ovarian tumors account for approximately 15% of all epithelial ovarian cancers; mean age of occurrence is 40 years. A meta-analysis performed by the Collaborative Ovarian Cancer Group found that, as with malignant epithelial ovarian cancer, parity, multiple births, history of breast-feeding, and oral contraceptive use are protective against LMP tumors. A history of infertility and use of fertility drugs may increase the risk of developing an LMP tumor, although these data are weak and controversial. Prospective trials are needed to resolve the controversy surrounding the use of fertility drugs and these tumors.
Clinical Features Patients are usually asymptomatic, but they may come to medical attention with a pelvic mass and complaints of abdominal or pelvic pain or both, increasing abdominal girth, or abnormal bleeding. Ultrasonography or a computed tomography (CT) scan may be helpful in making the diagnosis of an ovarian mass. Serum CA-125 levels are not always elevated. When they are, the tumor is usually of serous histology. LMP tumors usually have an indolent course. Many biomarkers, such as DNA ploidy, tumor markers, oncogenes, and tumor suppressor genes, have been studied in an attempt to define a high-risk group or predict tumor recurrence and thus indicate which patients might benefit from adjuvant treatment. To date, no such marker has been identified.
Pathologic Classification LMP ovarian tumors have been described for all epithelial subtypes; the most common types are serous and mucinous tumors. The absence of stromal invasion is an absolute criterion for making the diagnosis. Careful examination of the tissue blocks is necessary to minimize the potential for “sampling error” or omitting an area of invasive carcinoma in LMP tumors. Approximately 20% to 30% of ovarian tumors diagnosed as borderline by frozen section prove to be carcinomas with review of the permanent sections. The mean diameter of serous LMP tumors is 12 cm, and bilateral tumors are reported in 33% to 75% of patients. These tumors are usually cystic, with mural clusters of papillary projections (Fig. 55.21 and Fig. 55.22).

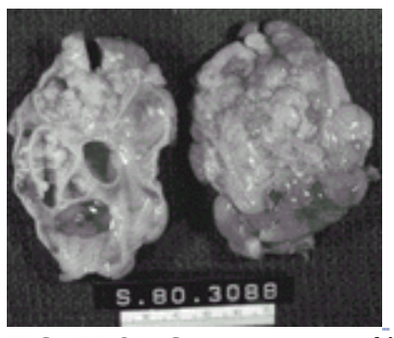

FIG. 55.21. Serous tumor of low malignant potential (atypical proliferating tumor). On the right is the external surface of the ovary; on the left the cut surface. The tumor is multicystic, and within some cysts are complex papillary projections.

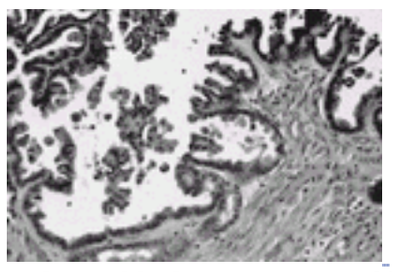

FIG. 55.22. Serous tumor of low malignant potential (atypical proliferating tumor). Ramifying papillae are lined by a relatively bland serous epithelium that forms tufts and seemingly free-floating clusters.

Mucinous LMP tumors are larger than their serous counterparts, with an average diameter of 17 to 20 cm; they are infrequently bilateral. They are characterized by multiloculated cystic masses, with smooth outer surfaces and areas of papillations and solid thickening on the inner surface. Microscopically, the epithelial lining of the cysts consists of tall, columnar, mucin-secreting cells, resembling the epithelium of the endocervix or intestine. Stratified epithelial cells may be atypical with hyperchromatic nuclei and mitotic figures, but without stromal invasion (Fig. 55.23).

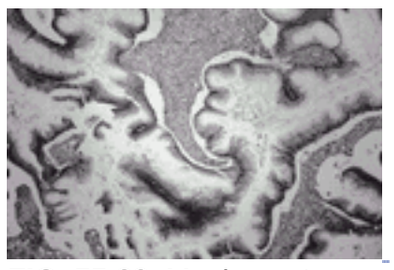

FIG. 55.23. Mucinous tumor of low malignant potential (atypical proliferating tumor). Epithelial proliferation results in pseudostratification and tufting. Mild cytologic atypia is present.

Stage for stage, the 5-year survival rate for patients with LMP epithelial ovarian tumors is far better than that for patients with malignant epithelial ovarian cancer. A review of the literature by several investigators revealed a survival rate of greater than 95% in patients with stage I LMP ovarian tumors. Furthermore, Kurman and Trimble found that a majority of patients with LMP tumors actually died with the disease, not from it, because invasive carcinoma developed in only 8 (0.8%) of 953 patients with a mean follow-up of 7 years. The other patients died from radiation- or chemotherapy-associated complications. Recognizing that a minority of LMP tumors behave aggressively like invasive ovarian carcinomas, Seidman and Kurman have challenged the current classification of LMP tumors in an attempt to develop a nomenclature that better reflects prognosis. These investigators believe that LMP tumors are actually a heterogeneous group of tumors, both histologically and clinically, that can be divided into malignant or benign phenotypes based upon certain features. For serous tumors, they propose that patient outcome depends upon the presence or absence of micropapillary features within the ovarian tumor and invasive versus noninvasive peritoneal implants. In a large meta-analysis of serous LMP tumors, they report that patients with micropapillary serous carcinoma have 5- and 10-year survival rates of 81% and 71%, respectively. Patients with a serous borderline tumor without invasive implants (atypical proliferative serous tumor) had 5- and 10-year survival rates of greater than 98%. However, in serous borderline tumor with invasive implants, survival rates drop to 60% to 70% after 5 and 10 years. The vast majority of patients with invasive implants, or with those which progressed to invasive carcinoma, were found to have micropapillary features within the primary ovarian tumor upon careful sectioning. Thus, atypical proliferative serous tumor and serous borderline tumor without invasive implants follow in a very benign clinical course, while micropapillary serous LMP tumors behave much like invasive ovarian carcinomas. Micropapillary serous carcinoma is characterized by thin, elongated micropapillae with minimal or no fibrovascular support arising directly from thick, more centrally located papillary structures (Fig. 55.24). Mitotic activity may be seen in some of the cases, ranging from one to three figures per 10 high-power fields. The distinction between invasive and noninvasive implants may be difficult. Noninvasive implants usually have a scant epithelial component surrounded by reactive spindle cells with imperceptibly meshed epithelial and stromal cells (Fig. 55.25). On the other hand, invasive implants usually have a more cellular epithelial component, with complex epithelial proliferation composed of multiple micropapillae and small round nests that display a destructive infiltrative growth (Fig. 55.26).

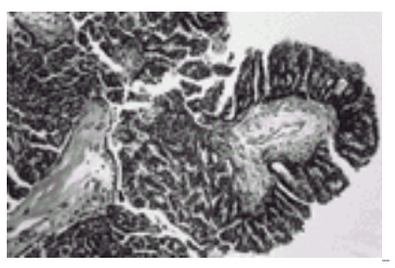

FIG. 55.24. Micropapillary serous carcinoma. In this fully malignant serous carcinoma, strands of neoplastic cells stream from thick, fibrous cores, stimulating a Medusa head.

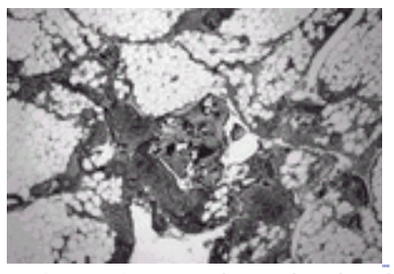

FIG. 55.25. Noninvasive implant in a serous borderline tumor. A circumscribed focus of tumor is surround by fibroadipose tissue that shows no stromal reaction. Cell nests are heavily calcified.

FIG. 55.26. Invasive implant in a serous borderline tumor. The tumor here is more cellular. The invasive implant extends below the peritoneal surface and is associated with reactive desmoplasia.

Mucinous LMP tumors tend to be confined to the ovary. Advanced stage tumors are typically associated with pseudomyxoma peritonei, and frequently represent metastatic disease from the gastrointestinal tract. In such cases, careful histopathological examination of the appendix is necessary to rule out an occult appendiceal primary. Primary mucinous carcinomas of the upper gastrointestinal tract and appendix can present with small primary lesions and large bilateral ovarian masses that stimulate primary ovarian carcinoma. Mucinous ovarian LMP confined to the ovary have an excellent prognosis, while the survival of patients with advanced stage disease is approxmiately 50%.

Pseudomyxoma Peritonei Pseudomyxoma peritonei may accompany mucinous neoplasms of the ovary and is characterized by extracellular gelatinous material in the pelvic and abdominal cavity. The primary site of origin of pseudomyxoma peritonei is debatable. Some series cite that the majority begin in the appendix, while others have described a synchronous origin in the ovary and appendix. Pseudomyxoma is associated most frequently with borderline or well-differentiated ovarian mucinous tumors in approximately 8% of cases and only rarely is seen in mucinous cystadenomas. The mainstay of treatment is cytoreductive surgery; multiple treatment modalities with systemic and intraperitoneal chemotherapies have not demonstrated survival benefit. Patients have a high recurrence rate, with variable times to recurrence. Most series agree that when patients have recurrent disease, repeat laparotomy is required to relieve symptoms. The overall 5-year survival rate is 50%, and most patients die from bowel obstruction.

Treatment The primary surgical treatment for patients with LMP tumors who have completed childbearing is identical to the recommendation for invasive ovarian disease, including a total abdominal hysterectomy, bilateral salpingo-oophorectomy, tumor debulking, and full staging (see Table 55.3). An appendectomy should be performed in patients with a mucinous LMP tumor because of the association with a synchronous primary appendiceal tumor. In younger patients with early-stage diagnosis and a desire for childbearing, conservative surgery with preservation of the uterus, the contralateral ovary, and in some cases the ipsilateral ovary (i.e., cystectomy) may be the appropriate treatment. Consultation with a gynecologic oncologist and pathologist can identify those patients who are candidates for conservative management. Several studies, both cohort and observational, have reported excellent outcome with conservative management of such patients. One of the largest studies reports a 12% recurrence rate for patients treated conservatively with either unilateral salpingo-oophorectomy (n = 110) or ovarian cystectomy (n = 74), versus 2.5% for patients treated with definitive hysterectomy and bilateral salpingo-oophorectomy. Recurrences or progression to carcinoma (1.5%) were more common among patients with invasive implants or advanced stage disease. The feasibility of doing a cystectomy for an LMP ovarian tumor and conserving the rest of the ovarian tissue in early-stage disease has been described but requires further study. LMP ovarian tumors have been diagnosed during pregnancy. Conservative surgery usually is performed, and pregnancy does not appear to be deleterious in regard to the prognosis for these patients. Most patients went on to deliver at full term without any complications.

Postoperative Therapy There is no evidence to suggest that adjuvant chemotherapy for patients with early-stage LMP tumors or with optimal cytoreduction of advanced LMP tumors improves survival. In fact, patients may be more likely to die from the side effects of adjuvant therapy than from the disease itself. Platinum-based therapy may be appropriate for a select group of patients with micropapillary serous tumors and invasive serous implants, based upon the high rates of recurrence in these patients. However, patients must be counseled that available literature does not demonstrate improved survival with chemotherapy. An ongoing prospective GOG trial will address these issues. Second-look laparotomy should not be a part of the standard therapy in treating these patients.

Malignant Neoplasms

Epidemiology Epithelial ovarian carcinomas account for 80% to 90% of all ovarian malignancies. Incidence rates in the United States are about 12 to 15 per 100,000 for white women, compared with about 8 to 10 per 100,000 for the U.S. residents of non-European heritage. The incidence rate continues to increase to about 40 cases per 100,000 women by age 50, and then continues to increase slowly to about 50 cases per 100,000 by age 65. Although the incidence rates in Asian nations are lower, studies have indicated increasing incidence rates in these countries. Other than race, risk factors for ovarian cancer identified by epidemiologic studies include age over 60 years, early menarche, late menopause, nulliparity, infertility, personal history of breast or colon cancer, and family history of ovarian, breast, or colon cancer. In some inherited cases, the increased risk of ovarian cancer may be more than 50%, depending on the type and number of family members affected and age of onset. Other factors that have been implicated but lack adequate epidemiologic evidence include high-fat diets, talcum powder, and infertility drugs. Use of an oral contraceptive, bilateral tubal ligation, and hysterectomy are protective. Epithelial tumors are derived from the ovarian surface epithelium, which is the site of ovulation. One hypothesis suggests that incessant ovulation contributes to ovarian carcinogenesis because of the repeated injury and repair of the ovarian epithelium secondary to monthly ovulation. Repair of the ovarian surface promotes proliferation-associated DNA damage. Data from the United States Collaborative Analysis support the suppression of ovarian activity as a means of preventing ovarian cancer. A study found that a high number of ovulatory cycles was associated with more genetic alterations in patients with ovarian cancer. Oral contraceptives appear to protect against ovarian cancer through suppression of ovulation and a direct antiproliferative effect of the progestins on ovarian epithelium.

Clinical Picture Many patients with epithelial ovarian cancer come to medical attention with advanced stage disease, with symptoms of abdominal fullness, pain, distension, early satiety, and weight loss. Other gastrointestinal symptoms include nausea, dyspepsia, constipation, or diarrhea. Abdominal distension can be due to ascites or a large abdominopelvic mass. Abnormal vaginal bleeding is seen in 30% of the cases. The most common physical signs are ascites, manifested by a fluid wave and the absence of shifting dullness, and a pelvic mass. The mass is frequently firm, hard, and fixed, with multiple nodularities. Small tumors may not be palpated easily in the presence of ascites. Possible sites of spread within the abdomen are multiple (Fig. 55.27).

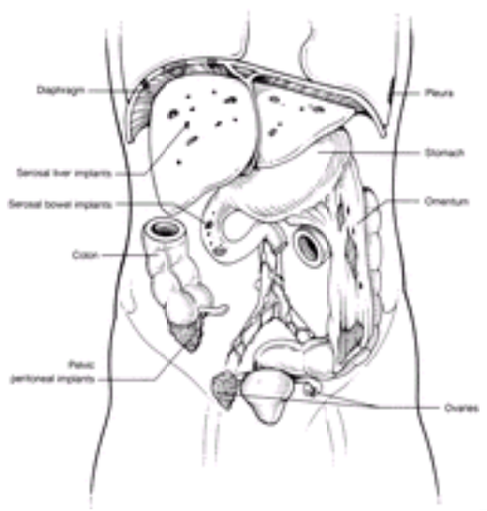

FIG. 55.27. Possible sites of spread of epithelial ovarian cancer.

Preoperative Evaluation All patients should have a complete blood cell count and serum chemistry analysis, including liver function tests, performed. These tests, although routinely done preoperatively, will select patients who may be at higher anesthetic risk. For example, any liver or kidney dysfunction may require further

investigation, or anemia may justify a workup and transfusion prior to surgery. Serum tumor markers should be assayed. Although CA-125 is the best tumor marker for women with epithelial ovarian carcinoma, it can be elevated in a variety of benign gynecologic conditions and other nongynecologic malignancies. CA-125 will be elevated in more than 80% of patients with serous epithelial ovarian cancer. Although it is not useful for screening, CA-125 has higher sensitivity and specificity for detecting ovarian cancer in the postmenopausal patient. Preoperatively, CA-125 may be useful in helping to predict the potential for malignancy and, if elevated, it can be used to follow response to therapy and detect an early recurrence. Chest radiographs are performed routinely to look for malignant pleural effusions, which occur in 10% of patients, and metastatic pulmonary disease, which is very rare. Barium enema examination is not performed routinely but may be helpful in patients with a left lower quadrant mass, blood in the stool, obstipation, or anemia, or in patients with carcinomatosis in whom a primary gastrointestinal tract malignancy must be ruled out. Barium enema examination is not very useful in predicting the need for colon resection. Mammography may be performed to rule out a possible metastatic or synchronous breast carcinoma. Sonography is the most useful diagnostic examination in the evaluation of a pelvic mass. It is an easily accessible and inexpensive imaging modality that provides an accurate description of ovarian morphology. Some characteristics associated with ovarian cancer include irregular ovarian cyst borders, solid elements, papillary projections, bilateral ovarian pathology, and ascites. Color Doppler imaging evaluates blood flow to an ovarian mass and can suggest a malignant process based upon abnormal neovascularization. Several studies suggest that color Doppler imaging improves detection of ovarian cancers, although it lacks the ability to definitively identify malignancy. Three-dimensional ultrasonography has the potential benefit of enhanced imaging of the ovarian architecture and measuring the ovarian cyst volume; however, its application in evaluation of an adnexal mass has not been fully studied. CT scan may be helpful in characterizing the liver, lymphatic spread, the omentum, and the mesentery. CT scan may be helpful in distinguishing a gynecologic malignancy from a metastatic pancreatic neoplasm for which surgery may not be warranted. MRI in patients with an ovarian mass has not been shown to have any clear advantage over CT scanning, except for the evaluation of pregnant patients whose ultrasonographic examination was inconclusive and CT scan would result in undesirable ionizing irradiation. Other studies such as bone and liver scintigraphy do not add any useful information. Intravenous pyelograms or renal scans may be helpful in patients with abnormal renal function or abnormal findings on ultrasonography, but they rarely are used. Immunoscintigraphy using CYT-103 or OC-125 that detects occult extraabdominal or miliary metastasis is experimental but may be helpful in patients prior to second-look laparotomy or in those with recurrent disease. Positron emission tomography (PET) is a form of computer-assisted imaging that uses radionuclide-labeled analogues of glucose labeled with positron-emitting isotopes. Cancer cells are detected by their increased glucose metabolism compared with noncancerous cells. PET has been examined in several preliminary studies involving the preoperative evaluation for suspected recurrent or metastatic ovarian tumors. Although the results are promising, PET's role in the preoperative evaluation of such patients awaits further study.

Staging Staging is a critical step in the treatment of ovarian cancer. It is done at the time of surgical exploration in accordance with the FIGO system revised in 1987 (see Table 55.4). Proper staging is absolutely necessary, because it impacts both prognosis and subsequent treatment method (see Table 55.3). Observational studies have shown that 30% of patients who were thought to have stage I or stage II disease found during initial surgery had more advanced disease with more comprehensive restaging laparotomy. A midline vertical incision is recommended, and it should be extended to above the umbilicus, if necessary, to allow proper exposure of the upper abdominal cavity for tumor debulking. If an ovarian malignancy is discovered unexpectedly through a low transverse incision, the rectus muscle can be either severed or detached from the pubic symphysis to enhance surgical exposure.

Pathology

Serous Carcinoma Serous tumor is the most common epithelial ovarian carcinoma, accounting for 40% to 50% of all such tumors. In most patients, serous tumors are bilateral and are disseminated at the time of diagnosis. They are soft, friable, mostly cystic, containing turbid or bloody fluid and having extensive papillary projections. Papillary excrescences also may be seen on the external surface or attached to adjacent structures (Fig. 55.28).

FIG. 55.28. Serous carcinoma. The tumor forms large, bilateral, solid, and cystic masses that have grown through the capsule. Tumor also involves the uterine serosa.

Microscopic evaluation in well-differentiated serous carcinoma reveals well-formed papillary structures that grow into cystic spaces or on the peritoneal surface of the tumor. Psammoma bodies are present in most cases (Fig. 55.29). With less differentiated tumors, the papillary pattern becomes less visible, the mitotic activity more brisk, and tumors become solid sheets of uniform, dark cells that are often slightly spindled and have a high nucleus-to-cytoplasm ratio.

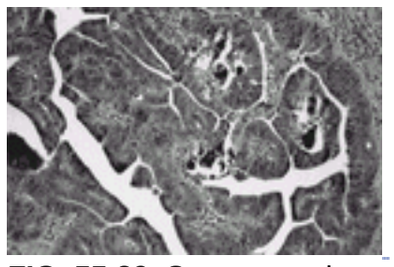

FIG. 55.29. Serous carcinoma. In this tumor, papillae are lined by high-grade tumor cells with prominent nucleoli. Psammoma bodies are present.

Mucinous Carcinoma Mucinous carcinoma represents 5% to 10% of all epithelial ovarian malignancies. Bilaterality is less common, present in less than 15% of cases. Disseminated spread is seen much less frequently than in patients with serous carcinoma. Mucinous carcinoma is usually larger than its serous counterpart, measuring approximately 15 to 30 cm in diameter. The tumor is multiloculated, solid and cystic, and filled with thick, viscous mucin. Microscopically, invasive, well-differentiated mucinous carcinoma typically is composed of more than three layers of epithelium, with prominent mucin production (Fig. 55.30). It may show only subtle irregularities in gland contour and irregular budding, with no other stromal signs of invasion. In moderately differentiated carcinoma, the glands are more back-to-back, with obvious stromal invasion, cellular stratification, and nuclear atypia. In poorly differentiated mucinous carcinoma, cells are disorganized, embedded in a dense reactive ovarian stroma. Signet-ring cells may be present, as in a Krukenberg tumor. Mucinous tumor often contains a wide range of histologic differentiation; therefore, extensive sampling must be performed to obtain the correct diagnosis.

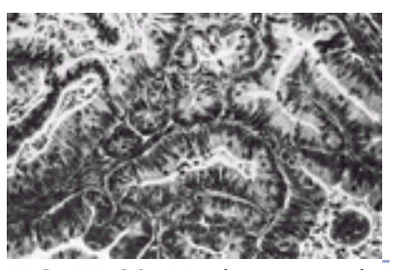

FIG. 55.30. Mucinous carcinoma. Infiltrating, crowded glands are lined by tall columnar cells with pale cytoplasm. Note the atypical, stratified nuclei (original magnification × 160).

Endometrioid Tumor Endometrioid carcinoma accounts for 20% of all epithelial ovarian malignancies. It is the second most common type of epithelial ovarian carcinoma and is bilateral in 30% of cases. In up to one third of patients, endometriosis has been noted in the same ovary or elsewhere in the pelvis. In addition, a synchronous endometrial adenocarcinoma has been seen in 20% of patients; these tumors are superficial and are associated with endometrial hyperplasia. Well-differentiated ovarian endometrioid adenocarcinoma is characterized by well-developed glands lined by tall, columnar, pseudostratified or multilayered epithelium like its uterine counterpart (Fig. 55.31). Squamous differentiation may be seen in about 30% of tumors and is usually benign. As tumors become less differentiated, the glandular pattern becomes less organized, and a solid growth pattern becomes predominant. Mitoses are more frequent, and nuclei are more high grade.

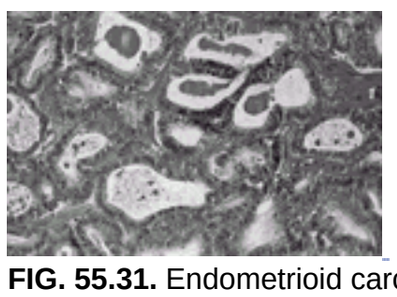

FIG. 55.31. Endometrioid carcinoma. In a well-differentiated endometrioid carcinoma, the glands are smoothly rounded, closely packed, and lined by an endometrioid type of columnar epithelium.

Clear Cell Tumor Clear cell carcinoma constitutes 5% to 10% of malignant epithelial ovarian tumors. It is bilateral in 15% to 20% of patients and confined to the ovary in 60%. Despite the limited spread of disease at the time of diagnosis, clear cell carcinoma is a notoriously virulent tumor. It frequently is associated with endometriosis,

with 25% of tumors arising from the lining of the endometriotic cysts. A mixed form of epithelial ovarian carcinoma with clear cell tumor and endometrioid or serous carcinoma can occur, suggesting a similar histogenesis. Microscopically, clear cell tumor may be characterized by sheets of polyhedral clear cells divided by fine connective tissue septa. Cells usually have abundant glycogen in the cytoplasm that is responsible for the clear appearance of the cells. The other characteristic feature is the tubulopapillary pattern formed by the columnar secretory cells with nuclei that bulge into the lumina of the glands, giving a hobnail appearance (Fig. 55.32). Eosinophilic cells instead of secretory columnar cells may surround tubules or papillae, or a mixture of these cells may be present.

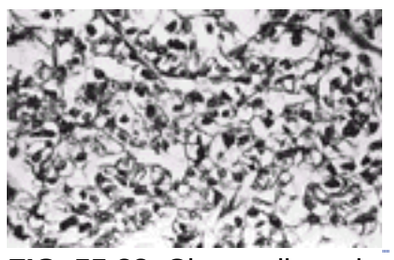

FIG. 55.32. Clear cell carcinoma. In clear cell carcinoma, tumor cells are polygonal, with central nuclei and abundant clear cytoplasm (original magnification × 250).

Undifferentiated Tumor Accounting for 5% to 10% of all ovarian malignancies, undifferentiated tumor exhibits such poor differentiation that it cannot be classified into any of the categories previously described. There is a variable histologic pattern, ranging from sheets of large anaplastic cells, to undifferentiated small cells, to large pleomorphic giant cells with eosinophilic cytoplasm. The prognosis is usually very poor because patients often seek treatment in advanced stages with large tumor burdens.

Brenner Tumor Malignant Brenner tumor is very rare. It ranges from 10 to 30 cm in diameter and is usually unilateral. Microscopically, malignant Brenner tumor exhibits solid sheets of heterogeneous epithelial cells with minimal stroma. Nuclear grade and mitotic activity are high. Histologically, these cells resemble transitional cells, like those in the urologic tract. Differentiation from a carcinoma of urinary origin is based on clinical picture and surgical findings. Origin in the ovary is supported by finding a transition from a benign or proliferating Brenner tumor.

Müllerian Mesenchymal and Mixed Tumors These rare ovarian tumors are divided into subtypes, including adenosarcoma and malignant mixed mesodermal tumor; they are associated with a poor prognosis. Histologically, they resemble their uterine counterparts. Adenosarcoma contains a benign epithelial component and a sarcomatous mesenchymal component. Malignant mixed mesodermal tumor has both malignant epithelial and malignant mesenchymal components (i.e., carcinosarcoma). Similar to epithelial ovarian tumors, these tumors usually are surgically staged. However, optimal cytoreduction and adjuvant chemotherapy regimens for these patients may not be as effective as they are for patients with the other types of epithelial tumors. The chemotherapeutic regimens are also different, but studies are limited by the rarity of these tumors. Agents that have been tried include doxorubicin (Adriamycin), cisplatin, and ifosfamide (IFEX), and paclitaxel (Taxol).

Treatment

Surgery Surgery is the most important aspect in the initial care of patients with epithelial ovarian cancer. Surgery alone is curative for many patients with early-stage ovarian carcinoma. For more advanced disease, surgery establishes the diagnosis and allows appropriate staging and cytoreduction, optimally to less than 1 cm of residual disease. Conservative surgical management of young women who desire to preserve fertility with a unilateral salpingo-oophorectomy with a full staging procedure may be appropriate for stage Ia disease. The contralateral ovary should be evaluated carefully, because there is a 5% chance of occult metastasis or a separate primary carcinoma. Biopsy of the contralateral ovary is no longer recommended unless there are grossly apparent abnormalities. Such patients also must have strict follow-up. Although a hysterectomy and removal of remaining adnexae is recommended for women who have completed childbearing, this recommendation is not based on randomized clinical trials. Primary cytoreduction of ovarian carcinoma has been recommended for almost 30 years. The theory is that removal of large tumor nodules allows better penetration of chemotherapeutic agents and removes potential foci of chemoresistance. Optimal cytoreduction is defined as residual disease smaller than 1 cm. Several reports over the last 25 years have shown that the diameter of the largest residual disease correlates with response rate, progression-free interval, and overall survival. The GOG evaluated survival by maximal diameter of residual disease (data from protocols 52 and 97) and found that the survival rate for patients with residual disease of 2 cm or greater is about 20% after 4 years, compared with a 60% survival rate after 4 years in those with only microscopic residual disease. For patients with residual disease less than 2 cm, the survival rate was 40% after 4 years (Fig. 55.33). Median survival of patients who have received optimal cytoreduction was approximately twice that of patients with suboptimal cytoreduction.

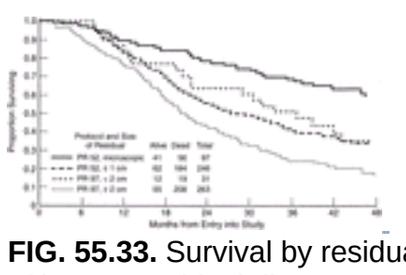

FIG. 55.33. Survival by residual disease: Gynecologic Oncology Group, protocols 52 and 97. (From Hoskins WJ, McGuire WP, Brady MF, et al. The effect of diameter of largest residual disease on survival after primary cytoreductive surgery in patients with suboptimal residual epithelial ovarian carcinoma. *Am J Obstet Gynecol* 1994;170:974–980, with permission.)

There has been great debate in the literature regarding the relative importance of surgical cytoreduction as compared with the inherent tumor biology of the cancer as determinants of patient survival. Patient age, the number and size of tumor nodules at time of diagnosis, and tumor grade have been cited as significant predictors of outcome. Other series have found that optimal surgical cytoreduction did not equate the survival benefit experienced by patients who initially had small-volume disease. Some investigators have suggested that platinum-based therapy has had a larger impact on survival than surgical debulking. Data, including a large meta-analysis, have demonstrated that maximal initial surgical cytoreduction was the most powerful predictor of patient survival. Patients with ovarian cancer are more likely to have optimal cytoreduction under the care of a gynecologic oncologist than with general surgeons or general gynecologists. Despite the benefit of improved survival, most patients with ovarian cancer in the United States never see a gynecologic oncologist. Ongoing efforts to educate physicians and patients regarding appropriate referral to specialized centers are needed. At the end of chemotherapy, patients who are clinically in complete remission may be offered second-look evaluation to determine the success of therapy, as measured by the presence of any residual tumor cells. The reasons for second-look evaluation are as follows: (a) to determine disease presence, thus allowing continued therapy in an attempt to improve survival, (b) to debulk any residual carcinoma, and (c) a prognostic tool for patient survival. Most second-look evaluations can be completed successfully via the laparoscope among surgeons with adequate expertise, and second-look laparoscopy has equivalent rates of detection of residual disease when compared with laparotomy. A laparoscopic approach reduces the length of hospital stay (frequently done as outpatient surgery) and patient recovery time. Older studies have shown that survival rates for those who underwent second-look surgery, as compared with those who did not, were essentially the same, suggesting no benefit for the procedure. However, these studies have not evaluated the effect of newer chemotherapy and more effective salvage therapies. Although second-look surgery should not be considered standard of care, it should be performed in patients enrolled in clinical trials to evaluate the efficacy of newer first-line therapies and the efficacy of better salvage therapies in improving survival. Secondary cytoreduction at the time of second-look laparotomy also has been examined in several studies that revealed a benefit in a select group of patients with gross disease that is reduced successfully to microscopic disease. However, only a minority of patients will have gross residual disease after clinical response to platinum-based chemotherapy. More recent data suggest that the presence or absence of residual disease at second-look surgery is one of the most significant prognostic factors for patient survival. Therefore, until more accurate diagnostic tests can be identified to determine residual disease after standard treatment, second-look surgery may be offered to patients with advanced stage disease in clinical remission to help determine prognosis, with the caveat that the procedure has prognostic value but no impact on survival. Interval debulking surgery is performed after neoadjuvant chemotherapy in patients with advanced ovarian cancer. Although it remains a controversial subject, the Gynecological Cancer Cooperative Group of the European Organization for Research and Treatment of Cancer conducted a large randomized study documenting the benefit of interval debulking surgery. All patients received three cycles of cyclophosphamide and cisplatin followed by randomization to debulking versus no debulking surgery, and all patients then received three more cycles of chemotherapy. The study revealed that interval debulking surgery resulted in significantly better progression-free and overall survival (Fig. 55.34). Although the 6-month improvement in median overall survival is relatively small, interval debulking surgery may be considered in patients in whom cytoreduction was not optimal during initial surgery, yet who have responded to neoadjuvant chemotherapy.

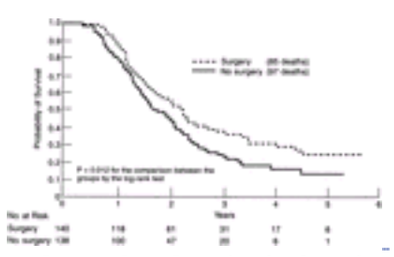

FIG. 55.34. Survival of patients with advanced epithelial ovarian cancer according to whether or not they underwent debulking surgery. (From van der Burg MEL, van Lent M, Buyse M, et al. The effect of debulking surgery after induction chemotherapy on the prognosis in advanced epithelial ovarian cancer. N Engl J Med 1995;332:629–634, with permission.)

Secondary cytoreductive surgery in patients with recurrent epithelial ovarian carcinoma has also been evaluated in several studies. Most of these reports show a statistically significant survival benefit for patients whose cytoreduction was optimal during secondary surgery. The likelihood of successful secondary cytoreduction and improved patient survival increases for patients with a longer disease-free interval (>12 months), unifocal disease, and initial optimal cytoreduction.

Chemotherapy Following surgery, most patients will require chemotherapy. However, for patients with completely staged Ia or Ib grade 1 or 2 ovarian cancers, no survival benefit has been demonstrated with adjuvant chemotherapy. The studies have shown clear benefit to adjuvant chemotherapy in select patients with stage Ia or Ib grade 3 and stage Ic disease compared with observation. The GOG and the Gruppo Italiano Collaborativo in Oncologia Ginecologica studies found that patients with stage Ia or Ib grade 1 or 2 disease had comparable survival with observation and melphalan. In contrast, high-risk patients with stages Ia, Ib, Ic and II disease had improved disease-free intervals with cisplatin-containing regimens compared with observation, intraperitoneal phosphorus-32, or melphalan (Alkeran). The optimal number of cycles of chemotherapy for early-stage disease remains unclear, and it is the objective of a current prospective trial to compare the efficacy of three versus six cycles of paclitaxel and cisplatin in patients with early-stage ovarian cancer. Various chemotherapeutic agents are active against ovarian cancer. Platinum-based therapy has been the mainstay of treatment for ovarian cancer for over 25 years. Combination platinum-based regimens have demonstrated superior response rates to those obtained with single-agent platinum, although there is insufficient evidence to suggest longer overall survival in these patients. The lack of survival benefit in some trials may relate to the high crossover treatment of patients who failed on one treatment arm and received other study treatments, as well as the varied length of patient follow-up in these studies. Paclitaxel, a microtubule stabilizer, was found to have significant activity in many cancers, including epithelial ovarian carcinoma. In 1996, the GOG published a study comparing the efficacy of paclitaxel and cisplatin with cyclophosphamide and cisplatin as first-line adjuvant therapy in patients with suboptimally debulked epithelial ovarian carcinoma (stages III or IV). Disease-free survival and overall survival for the paclitaxel-cisplatin group was statistically longer than for the cyclophosphamide-cisplatin group (median survival 38 to 24 months). Paclitaxel-cisplatin was also more effective in patients with advanced stage ovarian cancer after optimal cytoreduction. Substitution of carboplatin for cisplatin and decreased paclitaxel infusion times have reduced cost and patient side effects compared with the paclitaxel-cisplatin regimen. A subsequent prospective randomized trial replaced paclitaxel with docetaxel (Taxotere), another microtubule stabilizing agent, and found comparable response rates with less peripheral neuropathy. During the last 5 years, many new drugs have been found to be active second-line agents for epithelial ovarian cancer including topotecan, etoposide, altretamine (Hexalen), docetaxel (Taxotere), gemcitabine hydrochloride (Gemzar), vinorelbine tartrate (Navelbine), and doxorubicin hydrochloride liposomal injection (Doxil). Both topotecan, a topoisomerase inhibitor, and doxorubicin have shown promising activity in patients with recurrent, platinum-resistant disease with response rates of 20% to 30%. A large, prospective trial is randomizing patients to one of several combination multiagent chemotherapy regimens using gemcitabine, doxorubicin, or topotecan with paclitaxel-carboplatin as the control arm, to better define the best first-line regimen for patients with advanced stage ovarian cancer. Neoadjuvant chemotherapy to reduce the tumor load before performing a laparotomy is being investigated. Based on available noninvasive testing, it is difficult to predict accurately which patients will not be candidates for a successful cytoreduction. Furthermore, neoadjuvant therapy has been employed only in small retrospective observational series. Although neoadjuvant chemotherapy has resulted in less morbidity from subsequent cytoreductive surgery, this approach has not translated into higher survival rates in the limited number of patients studied. Intraperitoneal therapy allows direct exposure of a tumor to a drug concentration that may be 10-fold to 1,000-fold higher than that achieved with systemic therapy. In theory, this approach may have value for epithelial ovarian cancer, but its superiority has not yet been demonstrated despite extensive study. The clinical situations in which intraperitoneal therapy may be considered include salvage therapy for patients with disease of 5 mm or less, consolidation therapy for patients with surgically documented complete chemotherapeutic response, initial therapy for patients with high-grade early-stage tumors, or combination intraperitoneal therapy with systemic infusion. A randomized trial of intraperitoneal cisplatin and intravenous cyclophosphamide chemotherapy as first-line therapy showed promising survival rates with much less toxicity than older standard intravenous cisplatin-cyclophosphamide regimens. This study suggests that combination intraperitoneal cisplatin with an intravenous agent as primary therapy may be advantageous. However, optimal intraperitoneal regimens remain to be defined and will require randomized trials comparing intraperitoneal infusion with other approaches.

Radiation Therapy Abdominopelvic radiation therapy has been used postoperatively in selected patients who have microscopic or small-volume residual disease; however, with more effective chemotherapy, radiation therapy is an infrequently used adjuvant therapy for ovarian cancer. One of the largest series, compiled by investigators in Toronto, treated patients with stage II and III disease with abdominopelvic radiation and showed a 10-year disease-free survival of 38% (n = 91) for patients with residual smaller than 2 cm and 6% (n = 91) for patients with residual larger than 2 cm. Further studies on the usefulness of radiation therapy for ovarian cancer are warranted.

Prognosis With the addition of improved chemotherapeutic regimens and aggressive surgical cytoreduction, survival has improved in patients with advanced stage ovarian cancer. The overall 5-year survival is approximately 50%. Further strides in the management of ovarian cancer will require more knowledge of the molecular alterations that cause it. Advances in molecular biology indicate that ovarian tumorigenesis results from an accumulation of sequential genetic mutations. With a better understanding of the neoplastic transformation of ovarian epithelium, targeted therapies may be directed against the specific genetic aberrations in an individual cancer to improve patient outcome. Several innovative trials have combined gene therapy or immunotherapy and standard chemotherapy with promising early results. Ongoing efforts in both basic and clinical research are critical for the development of prevention strategies, screening for early detection, and better therapies.

FALLOPIAN TUBE CARCINOMA

Primary Fallopian Tube Epithelial Carcinoma

Fallopian tube carcinoma accounts for approximately 0.1% to 0.5% of all gynecologic malignancies. Peak incidence occurs at ages 60 to 64 years. Epidemiologic data suggest that age and nulliparity are associated with fallopian tube carcinoma, similar to endometrial and ovarian carcinomas. The constellation of symptoms including pelvic pain, a pelvic mass, and serosanguinous vaginal discharge (Latzko's triad) occur in the minority of cases. The most common symptom is vaginal staining or bleeding. Hydrops tubae profluens is characterized by colicky lower abdominal pain relieved by a profuse, serous, watery, yellow, intermittent vaginal discharge. The most common physical sign is a pelvic or abdominal mass. This mass often is thought to be an ovarian mass, with the correct diagnosis made only during surgery. Occasionally, a Pap smear revealing abnormal glandular cells with negative cervical or endometrial findings may lead the clinician to the diagnosis of fallopian tube cancer. Serum CA-125 levels often are elevated in advanced disease, as is noted in patients with ovarian carcinoma. Fallopian tube carcinoma is staged according to the FIGO. In contrast to ovarian cancer, most patients are diagnosed with early-stage disease: stage I, 37%; stage II, 21%; stage III, 31%; stage IV, 10%. (Table 55.6).

TABLE 55.6. *FIGO staging for fallopian tube cancer*

Fallopian tube carcinoma usually is characterized by swollen tubes secondary to intraluminal growth. Most fallopian tube adenocarcinomas are serous and histologically identical to ovarian serous carcinoma (Fig. 55.35). Other types of epithelial fallopian tube carcinoma have been reported but are very rare. Several diagnostic criteria have been established to differentiate fallopian tube malignancy from ovarian and other primary tumors. Microscopically, the tumor must arise from the endosalpinx, with a histologic pattern consistent with tubal mucosal epithelium. The transition from benign to malignant epithelium is helpful for diagnosis. The ovaries and endometrium are either normal or have tumor smaller than that in the tube. As in epithelial ovarian carcinoma, fallopian tube epithelial tumors commonly spread by exfoliation and implantation throughout the peritoneal cavity. The extensive lymphatic channels within the fallopian tube facilitate lymphatic dissemination of tumor, and paraaortic lymph node metastases are common.

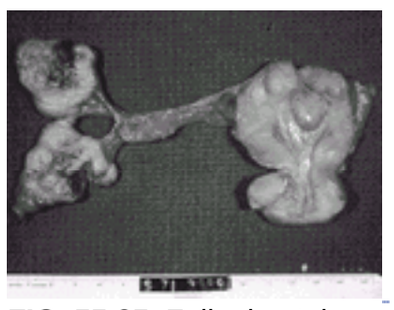

FIG. 55.35. Fallopian tube carcinoma. The fallopian tube lumen and its wall have been replaced by tumor.

Surgery remains the principal treatment, including a total abdominal hysterectomy, bilateral salpingo-oophorectomy, tumor debulking, and a full staging, as with ovarian cancer (see Table 55.3). Treatment of primary fallopian tube epithelial tumors is based on the standard management for ovarian carcinoma, due to the lack of large-scale studies for this rare tumor. Platinum-based therapies are recommended following cytoreductive surgery, based on several series showing superior

response rates and survival compared with those obtained with other agents.

Due to the rarity of fallopian tube cancer, paclitaxel has not yet been widely studied in this disease. However, based on data from ovarian cancer, platinum-taxane chemotherapy is used for patients with fallopian tube cancer. As in ovarian carcinoma, the prognosis is dependent upon the extent of disease and the amount of residual tumor at the end of surgery. Second-look surgery may be helpful in determining treatment efficacy and persistent disease but, as in ovarian carcinoma, it is not considered standard therapy.

Fallopian Tube Sarcoma

Sarcomas of the fallopian tubes may be classified as pure or mixed. They are exceedingly rare—fewer than 50 cases have been reported—and usually are found in postmenopausal women. Abdominal pain and watery or bloody vaginal discharge with signs of peritoneal spread are common findings. An ovarian origin must be ruled out by clearly identifying residual normal ovarian structure. The life expectancy of patients with these sarcomas usually is measured in months. As described in case reports, radiation and chemotherapy have not been effective.

Metastatic Disease

Metastatic fallopian tube disease is more common than primary tumors of the fallopian tubes. It often originates from a primary tumor of the ovary or endometrium and rarely from a primary cancer of the breast, gastrointestinal tract, or uterine cervix. Lymphatic involvement and an intact tubal epithelium distinguish a metastatic tumor from a primary fallopian tube tumor. The diagnostic criteria outlined above assist in differentiating between primary and metastatic fallopian tube tumors.

PRIMARY PERITONEAL CARCINOMA

Carcinoma may arise from the nonovarian epithelium of the peritoneal cavity and can involve diffusely all peritoneal surfaces, with minimal or absent involvement of the ovaries. These tumors share many of the clinical and histologic features of ovarian carcinoma. Most of these tumors are of serous histology. Clinical criteria have been established to distinguish peritoneal serous papillary carcinoma (PSPC) from its ovarian papillary serous counterpart, and molecular analyses of PSPC confirm that it is a distinct entity from ovarian carcinoma. Based upon these criteria, an estimated 7% to 15% of all cases of papillary serous ovarian cancer could be reclassified as PSPC.

The etiology of PSPC remains unknown. Considering the common embryologic origin of ovarian and peritoneal epithelium, a “field effect” of malignant epithelial transformation could involve multiple sites in the müllerian tract. Cases of PSPC have been described following prophylactic oophorectomy in patients with strong family histories of ovarian cancer or with documented *BRCA* mutations. PSPC appears to be another phenotypic variant of the *BRCA*-associated cancer syndromes. PSPC is staged and treated like ovarian carcinoma, with comparable response rates and survival.

HEREDITARY OVARIAN CANCER

Hereditary Forms of Ovarian Cancer

Approximately 5% to 10% of patients with ovarian cancer are thought to have an inherited genetic predisposition. Although this represents a small percentage of patients with ovarian cancer, great emphasis has been placed on these genetic mutations, given their clinical, social, and ethical implications.

Hereditary ovarian cancer syndromes are linked to dominantly inherited genetic mutations. A detailed family history from both maternal and paternal sides of the family must be obtained to determine the genetic susceptibility for the women at risk. Average age at diagnosis for this group of patients is often younger than for the general population, and most tumors are of serous histology.

The breast-ovarian cancer syndrome accounts for up to 85% of all hereditary ovarian cancer cases and is associated most frequently with mutations in the *BRCA1* or *BRCA2* genes. The *BRCA1* and *BRCA2* genes were identified and linked to hereditary breast and ovarian cancer in the 1990s. *BRCA1* is located on chromosome 17q12-21, and *BRCA2* is located on chromosome 13q12-13. Although the precise function of the *BRCA* genes is unknown, they appear to be involved in the recognition and repair of DNA damage. A sample pedigree of a breast-ovarian cancer syndrome family is illustrated in Fig. 55.36. The presence of a *BRCA*-associated syndrome is suspected whenever a pedigree reveals three or more affected relatives in two generations, bilateral or premenopausal breast cancers, a relative with breast and ovarian cancer, or a male with breast cancer in the pedigree (Table 55.7).

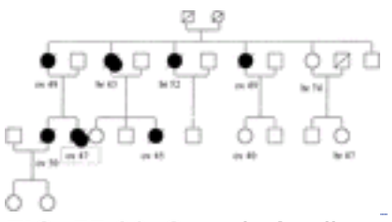

FIG. 55.36. Sample family pedigree.

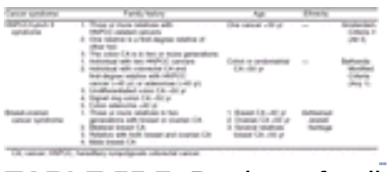

TABLE 55.7. *Pertinent family history—risk factors for genetic mutations*

Many mutations have been described, located throughout the *BRCA1* and *BRCA2* genes, with nonsense mutations or frameshift mutations being predominant. Nonsense mutation occurs when a single nucleotide substitution results in a stop codon, and frameshift mutation occurs when one or more nucleotides are deleted to produce a downstream stop codon. Certain ethnic groups have higher carrier frequencies of founder *BRCA* mutations. Three specific founder mutations, 185delAG and 5382insC on *BRCA1* and 6174delT on *BRCA2*, have been seen in approximately 2% to 2.4% of the Ashkenazi Jewish population. Studies have found that 40% to 60% of Jewish patients with ovarian cancer have a mutation in *BRCA1* or *BRCA2*, in contrast to 5% of non-Jewish women with ovarian cancer.

The lifetime risk of ovarian cancer for patients with *BRCA1* mutations is 20% to 60%, and the risk for a *BRCA2* mutation carrier is 10% to 35%. Patients with *BRCA1*-associated ovarian cancer appear to be diagnosed at a younger age than patients with sporadic ovarian cancer or *BRCA2*-associated ovarian cancer. Studies show that *BRCA2* mutations also are associated with other malignancies, including cancer of the pancreas, biliary tract, and prostate and melanoma (Table 55.8).

Cancer site	Gene mutations	Cancer risk with mutation (by age 70)	Population cancer risk
Breast	*BRCA1*	87%	11%
	BRCA2	87%	
Ovary	*BRCA1*	20%–60%	1.0%–1.5%
	BRCA2	10%–35%	
	MMR	9%–12%	
Fallopian tube	*BRCA1*	Increased	3.6/1,000,000
	BRCA2	Increased	
Endometrium	*MMR*	42%–60%	1.5%
Colon	*MMR*	54%–82%	2%

MMR, mismatch repair.

TABLE 55.8. *Cancer risks by site for gene mutation carriers*

Data have also demonstrated that fallopian tube carcinoma can occur in patients with an inherited genetic predisposition to ovarian cancer by virtue of germline mutations in the *BRCA* genes. A large population-based series of patients with fallopian tube cancer found that 16% of patients had inherited mutations in *BRCA1* or *BRCA2.* Based upon these data, fallopian tube carcinoma should be considered a clinical component of the *BRCA*-associated breast-ovary cancer syndrome. Patients with germline *BRCA* mutations who elect to have prophylactic surgery should have both ovaries and fallopian tubes removed, with careful histologic evaluation to eliminate occult fallopian tube carcinoma. It is unknown whether hysterectomy is necessary, in addition to salpingo-oophorectomy, in order to remove the cornual portion of the fallopian tube as surgical prophylaxis for these patients.

Hereditary nonpolyposis colorectal cancer (HNPCC) syndrome accounts for approximately 10% of all hereditary ovarian cancer cases. It is an autosomal dominant genetic syndrome characterized by three or more first-degree relatives with colon cancer (over 70% in the proximal colon) or endometrial cancer, where one is a first-degree relative of the other two, and two of them must be diagnosed with cancer before age 50 years. Four genes that are part of the DNA mismatch repair (MMR) pathway have been identified as being responsible for the HNPCC phenotype: *hMSH2* (chromosome 2p), *hMLH1* (chromosome 3p), *hPMS1* (chromosome 2q), and *hPMS2* (chromosome 7p). Most affected patients are found to have defects in either *hMSH2* or *hMLH1.* An inherited defect in any one of these genes increases an individual's risk of developing cancer because of an impaired ability to repair somatic genetic mutations. Family members with HNPCC syndrome are at risk for cancer at other gastrointestinal sites, the urologic tract, and the ovary. The risk of endometrial cancer among women in the HNPCC syndrome is estimated to be 40% to 60% by the age of 70 compared with 1.5% in the general population. Limited studies have reported a 3.5-fold increase in the risk of ovarian cancer in members of these families (see Table 55.8).

Clinical Implications

Genetic Testing Although hereditary cancers account for only 10% of ovarian malignancies, individual risk assessment and appropriate genetic testing can identify those individuals with significant lifetime risk. The first concern in genetic testing is the scientific and technical utility of the tests: the reliability of tests, their predictive value, their interpretation, and ultimately their ability to prevent cancer in patients who have positive test results. The second major concern relates to the ethical, legal, and social implications of gene testing. The proper selection of patients for testing is very important. Genetic counseling is imperative. As testing for these genes becomes more available to the public in both commercial and academic settings, clinicians and patients must work together to ensure that the results are used in a fashion that will consider carefully the ethical, legal, and psychosocial issues that may arise from genetic testing. Multidisciplinary services that include pretest and posttest counseling, screening, treatment, and psychosocial sessions have been established in the major referral centers. Patients must be counseled regarding the potential advantages and disadvantages of genetic testing, as well as the utility of screening and prophylactic measures that are available. American Society of Clinical Oncology guidelines recommend offering testing to anyone with a greater than 10% risk of carrying a mutation based on pedigree analysis, and only if the test result will influence medical management. First- and second-degree relatives of an affected individual from a family with breast-ovarian cancer syndrome should be offered genetic testing if they carry a mutation of the *BRCA1* or *BRCA2* gene. Certain ethnic groups, such as Ashkenazi Jews, are at increased risk for carrying a *BRCA* mutation, and a lower threshold for genetic testing may be appropriate in these individuals. Genetic testing for the MMR genes should be considered when there is a first-degree relative with a known mutation and when the patient meets the Amsterdam or the Bethesda Criteria for HNPCC syndrome (see Table 55.7). A comprehensive family history can provide an estimate of an individual's risk of carrying a genetic mutation; however, genetic testing provides more accurate information regarding the chance that an individual patient will develop cancer. The best way to determine if a cancer-associated mutation is present in a family is to test an affected family member, who is usually the most likely proband to carry a deleterious mutation. The first family member often will need comprehensive gene sequencing, and subsequent individuals can then be tested for the identified mutation, which may be unique to the particular family. In the Ashkenazi Jewish population, genetic testing for the three founder mutations is required because of the high carrier frequency in this population and occasional reports of individuals carrying both *BRCA1* and *BRCA2* mutations. Test results may come back positive or negative for an identifiable mutation or may report a mutation of indeterminate clinical significance. When a test result returns negative, interpretation will depend on the patient's family history. If an affected family member has tested positive for a mutation, then the patient has likely not inherited the deleterious mutation, and her cancer risk approximates that of the general population. If there is no documented positive mutation in the family, it is still possible that the patient has a cancer-associated mutation that is not detectable with testing. Approximately 12% of testing results are genetic variants or polymorphisms, reported as indeterminate clinical significance. Further study of these genetic variants and associated cancer risks in large populations will help reduce the number of indeterminate reports.

Follow-up and Management

Screening Follow-up and treatment of patients with an inherited genetic predisposition to ovarian cancer is complex due to the variable penetrance of genetic alterations and the lack of effective early detection methods. Serum CA-125 levels and transvaginal ultrasonography with color Doppler flow are the two modalities that have shown potential usefulness in surveying these patients. CA-125 levels may be elevated in other benign diseases and may not be elevated in early stage I ovarian cancer; thus, it lacks sufficient sensitivity. Transvaginal ultrasonography is very sensitive in detecting adnexal masses; however, it cannot differentiate between malignant and benign masses, resulting in a high false-positive result rate and unnecessary surgery, especially in premenopausal women. Consequently, screening of the general population is not warranted with the currently available technology. There is no conclusive evidence to support screening patients with higher risk of ovarian cancer. Ovarian surveillance modalities have not improved significantly the detection of early-stage invasive epithelial ovarian cancers, with minimal impact on the survival among the screened patients. One prospective study of high-risk women demonstrated enhanced survival among the screened population versus historic controls; however, conclusions are limited by small patient numbers. Despite the available data, the National Institute of Health *Consensus Statement on Ovarian Cancer* and the Cancer Genetic Studies Consortium recommend screening starting at ages 25 to 35 years as part of the annual or semiannual routine examination for women with germline *BRCA1* or *BRCA2* mutations. The benefit, however, is not proven, because the evidence is based on expert opinion only. Table 55.9 lists the provisional recommendations for cancer surveillance for the carriers of *BRCA1* and *BRCA2* mutations. Screening and prophylactic surgery for patients with HNPCC-associated mutations is also based on expert opinion, although colonoscopy and stool occult blood testing have been shown in randomized clinical trials to reduce the incidence of and mortality from colon cancer (see Table 55.9).

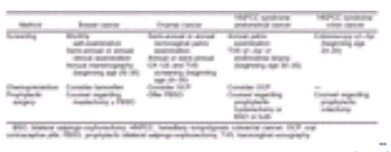

TABLE 55.9. *Recommendations for treatment of women at high genetic risk for gynecologic malignancies*

Prevention Chemoprophylaxis with oral contraceptive pills (OCP) for 5 years decreases ovarian cancer risk by 50% in the both general population and in high-risk women. A case-controlled study of 207 known *BRCA* mutation carriers and their sister controls found a 60% reduction of ovarian cancer risk with OCP use. Other risk-reducing strategies such as tubal ligation and hysterectomy have also demonstrated reduced incidence of ovarian cancer among many high-risk women.
Prophylactic Salpingo-oophorectomy Prophylactic bilateral salpingo-oophorectomy (PBSO) is another preventive strategy for patients with *BRCA* mutations to reduce cancer risk. Given that most hereditary ovarian cancer occurs after the age of 35 to 40, prophylactic oophorectomy is an option in carefully selected patients at unequivocally high risk for ovarian cancer who have completed their childbearing. This procedure can be performed laparoscopically, and the decision for concomitant hysterectomy is individualized. The surgical pathologist must be alerted to perform a careful examination of the high-risk patient's ovaries and fallopian tubes given the reports of occult ovarian and tubal carcinoma in these specimens ranging in frequency from 2% to 15%. The efficacy of PBSO in hereditary breast-ovarian cancer syndrome has been evaluated in several studies. Prospective studies have documented a significant reduction in both ovarian, peritoneal, and breast carcinoma among *BRCA* mutation carriers following PBSO, one study of 248 patients found a 98% decrease of ovarian and primary peritoneal cancers, and a 50% reduction in subsequent breast cancer compared with age-matched controls. This supports the findings of another prospective study that documented a 50% reduction of breast cancer with PBSO among premenopausal and postmenopausal *BRCA* mutation carriers that persisted irrespective of the use of hormone replacement therapy. Despite oophorectomies, primary peritoneal cancer has been reported in 0.4% to 10.7% of high-risk patients, and patients must be counseled regarding this disease. It is believed that that all coelomic epithelium, including the peritoneal covering of the entire abdominal pelvic cavity, is prone to malignant transformation in *BRCA* mutation carriers. Several other significant issues remain unresolved regarding the physiologic adjustments to premature surgical menopause and the safety of hormone replacement therapy in this group, especially in those at high risk for breast cancer. Recommendations from other agencies or groups are as follows:

- American College of Obstetricians and Gynecologists (1992). Women with familial ovarian or hereditary breast-ovarian cancer syndromes who do not wish to maintain their reproductive capacity may be offered PBSO. Such women should have a documented familial syndrome, preferably established via a full pedigree analysis by a geneticist. These women should be informed that removal of the tubes and ovaries does not provide 100% protection; primary peritoneal carcinoma has been reported after bilateral salpingo-oophorectomy in some cases.
- National Institutes of Health *Consensus Statement on Ovarian Cancer* (1994). The probability of a hereditary ovarian cancer syndrome in a family pedigree increases with the number of affected relatives, with the number of affected generations, and with young age of onset of disease. Therefore, prophylactic oophorectomy should be considered in these patients after careful weighing of the risks and potential benefits. The risk of ovarian cancer in women from families with hereditary ovarian cancer syndrome is sufficiently high to recommend prophylactic oophorectomy at age 35 years or after completion of childbearing.

SUMMARY POINTS

- Germ cell tumors are the most common gynecologic malignancy in young women. The cure rate is 90% due to the significant advancement of chemotherapeutic regimens. The most commonly used regimen is BEP. The risk of secondary malignancy, especially hematologic, with the use of etoposide must always be considered when this regimen is administered.
- Sex cord–stromal tumors, such as granulosa cell and Sertoli-Leydig cell tumors, have the potential for steroid hormone secretion, with estrogen being the most frequently produced hormone. Aside from juvenile granulosa cell tumors, sex cord–stromal tumors rarely occur in women under 20 years. Primary treatment usually entails primary tumor resection and staging. When the pathology is malignant, the need for chemotherapy must be individualized, because no standard treatment regimen has been established.
- Tumors of LMP account for approximately 15% of epithelial ovarian cancers and have an earlier age of onset, around 40 years. All epithelial histologic subtypes of LMP tumors exist, with serous being the most common. Pseudomyxoma peritonei, characterized by extracellular gelatinous material in the peritoneal cavity, may accompany mucinous LMP tumors. Therapy for LMP tumors is surgical excision and appropriate tumor staging and, when necessary, debulking.
- Although significant strides have been made in the treatment of epithelial ovarian cancer, the 5-year survival rate remains approximately 50%. Continued efforts are needed to understand the etiology of these tumors, which ultimately will result in the development of prevention strategies, early detection, and improved therapies. Optimal cytoreductive surgery followed by platinum-taxane combination chemotherapy is the current standard treatment for advanced stage disease.
- Identification of the genes that are responsible for several familial ovarian cancer syndromes, especially *BRCA1* and *BRCA2*, has opened up new areas of investigation and provided valuable information for understanding the development of both hereditary and sporadic ovarian carcinomas. Although there is no level I evidence to support the use of screening and prophylactic surgery in patients who are at high risk for ovarian cancer, these modalities may be considered to reduce the chance of disease development. Oral contraceptive pill use may also decrease ovarian cancer incidence in these high-risk women.

Laparoscopic Approach to the Adnexal Mass

The optimal management of the adnexal mass has perplexed clinicians for many years. As long as women have been offered medical care, the adnexal mass has presented a diagnostic as well as therapeutic problem. During the 21 st century, we have made many inroads into understanding the development, complications of, and malignant potential of the adnexal mass. Additionally, we have made some advancements in its management: operative laparoscopy has been developed carefully and is approaching appreciable levels of sophistication such that recovery from surgical intervention is at a minimum.

Some considerations of management of the adnexal mass include the following: What is the mass? Should it be followed? How should it be followed? Should a woman have surgery for this? What route of surgery should be undertaken? Should an oncologist assist in the surgical management in the event that the mass is malignant? All of the above questions are timely and ideally should have precise answers such that we may offer optimal care for women. However, many of these issues still are being explored. With the advent of genetic discovery and technical advancement, we hope we will be able to better understand the etiology of the adnexal mass as well as offer management with minimal morbidity.

In this chapter, general background information, modes of diagnosis, ancillary studies, and surgical management of the adnexal mass will be discussed. Our hope is that with the tools available, a rational approach toward the adnexal mass will be presented such that the right choice will be offered for each patient with a minimum of concern for the physician and patient. Efficient diagnostic evaluations should be performed, with the goal of offering the appropriate patient a surgical procedure and expectantly following patients for whom one might predict the mass would resolve, thereby sparing a trip to the operating room. Management of the adnexal mass should be made with confidence and a clear schema and treatment plan. Taken altogether, management of the adnexal mass should be well understood by everyone in clinical gynecologic practice. A triage scheme should be available and understood such that for every patient and every kind of mass a treatment plan is readily available, one that will minimize the chance of malignancy and minimize morbidity should the patient need surgical management.

GENERAL OVERVIEW

In the grand scheme of things ovarian cancer is considered rare; however, it is often fatal. In light of this, management of the adnexal mass is a serious endeavor. Five to ten percent of all women in the United States will undergo surgical evaluation for an adnexal mass and, of these, up to one fifth will have ovarian cancer. Up to 300,000 women are hospitalized each year for evaluation of an adnexal mass and the majority of these patients undergo surgery. The skill then lies in determining which masses will be malignant such that the appropriate surgical preparations will have been undertaken; additionally, masses that may not need exploration then can be followed. Thus, the appropriate evaluation is important and includes a complete history, physical examination, and radiologic studies, as well as serum markers.

Adnexal mass refers not only to ovarian abnormalities but to masses originating in the fallopian tube, ovary, broad ligament, bowel, as well as uterine masses that lateralize (Table 56.1). Taking a pertinent history is, therefore, important. In addition to ascertaining the quality, severity, and duration of abdominal symptoms, review of menstrual cycle characteristics in premenopausal women, history of pelvic infectious disease, and any gastrointestinal syndromes may guide the diagnosis to one area or another.

TABLE 56.1. *Masses occurring in the adnexal region*

Review of the family history, in particular for the occurrence of ovarian cancers, is extremely important. Scientific discoveries within the last decade have determined that specific gene mutations may increase the risk of ovarian cancer in certain subsets of the female population. In the general population, the lifetime risk of ovarian cancer is in 1 in 70 women, approximately 1.7%; however, even without the a specific gene mutation, having one family member with ovarian cancer increases a patient's risk to 5%, and with two relatives with ovarian cancer the risk increases to 7%. Regardless of how alarming it is to identify a family member with the disease, however, less than 10% of ovarian cancer patients will have this significant family history. The most common syndrome associated with familial transmission of ovarian cancer is hereditary breast-ovarian cancer. Of all hereditary cases, this syndrome accounts for the majority of familial ovarian cancers. Many of these cases are associated with germ-line mutations in *BRCA1* and *BRCA2* genes. *BRCA1* is a tumor suppressor gene that, in a “normal” format, controls and regulates abnormal cell growth. In a patient affected by a mutation, this gene does not function to regulate cellular growth and, thus, malignancy evolves. Although advances in science have enabled us to identify many of these mutations, there are other abnormalities in this gene may contribute to not only ovarian cancer but breast cancer. Further investigations are underway to identify these additional gene mutations. *BRCA2* is another well-known gene associated with breast-ovarian cancer. In particular, an abnormality in this gene has been found in 1% of the Ashkenazi Jewish population and, presumably, ovarian cancer in this population has been associated with germ-line mutations in *BRCA2.* If a mutation is found in *BRCA1*, a lifetime risk of ovarian cancer is estimated between 28% and 44%, and up to 27% in patients with a *BRCA2* abnormality. Ovarian cancer also can be part of a constellation of cancers which include colorectal cancer, stomach cancer, endometrial cancer, and ovarian cancer. This is referred to as *hereditary nonpolyposis colorectal syndrome.* The risk of ovarian cancer is increased to up to 10% of patients who have this syndrome. In the face of germ-line mutations in these genes, ovarian cancer develops at an earlier age, often premenopausally, than in the majority of ovarian cancer cases, which tend to develop postmenopausally. Given the identification of familial risk, registries have been developed to investigate further the association of ovarian cancer in patients and their relatives. For patients with *BRCA* mutations, increased surveillance is recommended. Monthly breast examinations are encouraged beginning at an early age; some recommend beginning between ages 18 and 21. Additional examinations by a physician are recommended twice a year beginning in the mid-20s. Yearly mammograms are recommended also, beginning at this time. There is some interest in chemoprevention, such as tamoxifen to reduce the risk of breast cancer,

and bilateral prophylactic mastectomy is being explored to reduce the risk of incurring breast cancer. Additionally, if a *BRCA* mutation is present, surveillance for ovarian cancer is recommended. This includes transvaginal ultrasonography and measurement of serum CA-125 beginning in the mid-20s. Bilateral prophylactic oophorectomy may be recommended after a woman has completed her family. Chemotherapeutic prevention of ovarian cancer may be instituted in the form of oral contraceptives. It is well accepted that oral contraceptives reduce the risk of ovarian cancer for women in the general population and may also decrease the risk in women carrying a *BRCA* mutation.

During the physical examination, a full female-oriented examination should be performed including a node survey and breast, abdominal, and pelvic examination. In cases of advanced cancer, nodular masses often are found in the abdomen and pelvis. However, for the most part, this would be quite clear when a patient with ovarian cancer arrives. Thus, in regard to determining whether an adnexal mass is malignant in the early stages, the physical examination may not be helpful. Lastly, the radiologic study and evaluation of a patient with, perhaps, mild symptoms would be of utmost importance.

DISTRIBUTION OF ADNEXAL MASSES BASED ON AGE

One way to approach the adnexal mass is to think of it in regard to the patient's age. The majority of ovarian cancers occur postmenopausally. For the young woman in her late teens and up to mid-20s, the majority of ovarian cysts are, of course, benign. Hemorrhagic corpora lutea and follicular cysts are common. In this age range, however, tubal abnormalities should be strongly considered. They include ectopic pregnancies and sequelae from tubal infections. Of concern in this age group, however, is the solid mass. The germ cell tumors, which for the most part are solid and unilateral, occur rarely but only in this age group. In these cases, preoperative consultation with a gynecologic oncologist may be in order.

In the older yet still reproductive age group, benign masses still prevail. Again, hemorrhagic corpora lutea and follicular cysts are common, as are dermoid cysts. Ultrasonographic characteristics of the ovarian mass in these cases will be helpful. Again, ovarian cancer in this age group is not common. Lastly, the age group for which there is most concern is the postmenopausal group. Albeit infrequent, ovarian cancers predominate, although the majority of masses in the this group are benign.

COMMON EPITHELIAL MASSES

The majority of ovarian masses are benign and, of these, the most common histologic type is epithelial, whether benign or malignant. The epithelial tumors are, for the most part, of the following types: serous, mucinous, endometrioid, clear cell, and transitional cell.

Serous Tumors, Benign and Malignant

Serous tumors are the most common histologic type and account for approximately 50% of all ovarian cancers. The benign counterpart accounts for 50% to 70% of all benign ovarian neoplasms. Although a patient of any age can manifest a benign serous tumor, the average age is 40 years. These tumors appear to be simple on ultrasonographic evaluation in that for the most part, although there may be some small internal echoes, these are purely cystic in appearance. They can be large and are mostly fluid filled. Benign serous tumors are bilateral in 20% of cases.

In contrast, invasive serous ovarian carcinomas account for 50% of all ovarian epithelial cancers. They are often bilateral and occur menopausally. The serous tumor is the prototype for invasive ovarian cancer, the “garden variety” histologic type. As with most ovarian cancers, the tumors are widely disseminated at the time of diagnosis.

Mucinous Tumors, Benign and Malignant

Benign mucinous tumors, mucinous cystadenomas, account for 25% of all benign ovarian neoplasms. They occur at a slightly younger age than serous benign tumors and can occur in young women, as well. They are less often bilateral, with both ovaries involved in only 3% of cases. They tend to be large and can be multiloculated. These are the tumors that have been reported to weigh up to 100 kg. Histologically, the cells are mucin filled and show endocervical or intestinal differentiation. These are the second most common type of ovarian neoplasm. Their invasive counterpart, the mucinous cystadenocarcinoma, represents 15% of invasive ovarian epithelial cancers.

Endometrioid Tumors, Benign and Malignant

The third epithelial type is the endometrioid neoplasm. These neoplasms recapitulate the endometrium and, thus, the epithelial component resembles the endometrial glandular cell. Benign tumors of this histologic type are less common and are associated histologically with changes of adenofibroma or cystadenofibroma. The endometrioid malignant ovarian neoplasm represents up to 25% of ovarian epithelial cancers and is usually moderate in size, ranging up to 20 centimeters. Most ovarian endometrioid neoplasms are malignant. The malignant form tends to be bilateral in 30% of cases. When an endometrioid ovarian invasive cancer is found, up to 25% of patients will have concomitant uterine endometrial cancer or endometrial hyperplasia. Pelvic endometriosis may be found also, and one hypothesis is that these lesions arise from preexisting endometriosis. When an endometrioid invasive cancer is found in the ovary it is the duty of the pathologist to clarify whether this is a metastasis from a primary uterine cancer.

Clear Cell Tumors

The fourth general category of epithelial ovarian neoplasms is the clear cell tumor. Benign clear cell tumors rarely are diagnosed. However, the invasive form of this, the clear cell carcinoma, represents 10% of all ovarian cancers. The clear cell component usually coexists with another epithelial type. The clear cell histology also is associated with endogenous endometriosis in the pelvis in up to 25% of cases.

Transitional Cell Tumors

Lastly, transitional cell tumors, which mimic the epithelium found in the bladder, are rare. The Brenner tumor is a well-known transitional cell tumor and accounts for 2% of all ovarian epithelial tumors. Brenner tumors are considered benign, although a malignant variant has been identified.

Other Common Benign Tumors

The dermoid cyst is a common benign tumor found in all ages. This tumor is comprised of three germ cell layers, which explains the term teratoma. The three germ layers include the ectoderm, mesoderm, and endoderm. It is the most common type of ovarian germ cell neoplasm and occurs frequently. This teratoma accounts for 25% of all ovarian neoplasms and is most commonly found in the reproductive age group; however, it can be found in younger women and in postmenopausal women. The mature teratoma can grow to quite a large size before a patient has pain or notices abdominal swelling. Up to 15% of cases are bilateral and these tumors can grow to a large size, weighing several kilograms (Fig. 56.1). These tumors are well known for their smooth, glistening, pearly white surface. Either cystectomy or adnexectomy can be performed to treat these neoplasms effectively. These tumors are interesting because of a radiologic finding of teeth or bone or cartilage on plain film. Additionally, they have a characteristic finding on ultrasonography and computed tomography (CT) scan. Within the cyst wall is a protuberance called *Rokitansky protuberance.* These neoplasms are well known for the greasy sebaceous material associated with hair, bone, or teeth found within the cyst. Thyroid tissue, salivary gland tissue, and gastrointestinal and bronchial epithelium can be found, associated with bone, cartilage, and smooth muscle. Other ectodermal tissues, including brain, neural, retina, and choroid plexus, are also found. Clinical complications associated with the presence of these neoplasms include torsion rupture and infection. More uncommonly, hemolytic anemia and malignant transformation may also occur.

FIG. 56.1. Removal of a large dermoid cyst.

Endometriomas of the ovary involve bilateral ovaries in up to 50% of cases. These cysts often are associated with dense adhesions to the broad ligament or cul-de-sac and are difficult to excise. The contents are usually chocolate colored and thickened. Cystectomy can be performed successfully in many cases. The presence of endometriomas indicates advanced endometriosis, and usually other pelvic sites are involved, such as the cul-de-sac or other peritoneal structures. Bilateral salpingo-oophorectomy is curative, if clinically appropriate, in that estrogen drives the growth of these cysts. Ovarian endometrioid carcinoma can be associated with these benign neoplasms.

Physiologic cysts can appear as adnexal masses. These include follicular cysts and corpus luteal cysts, which are most common in the reproductive age group and range from small to moderate in size. Follicular cysts are unilocular, and the ultrasonographic image should be that of a simple cyst; however, if there is a region of clotted blood this area will appear as cystic or solid. The interpretation of this is dependent upon the ultrasonographer. However, given that these benign physiologic cysts prevail in the reproductive age group, a laparoscopic approach could be offered should surgical evaluation be necessary.

RADIOLOGIC EVALUATION OF THE ADNEXAL MASS

Whether suspicion of an adnexal mass arises as a result of a patient's symptoms or suspicious findings during a pelvic examination, radiologic imaging is usually the next step in the diagnostic evaluation. For gynecologic problems, fortunately, transvaginal ultrasonography gives the best visualization of the adnexal region. Previously, transabdominal ultrasonography was used routinely to visualize the adnexa. However, the transvaginal approach, by virtue of the proximity of the probe to the adnexa, gives startlingly clear characterization of the adnexal region.

Description of an adnexal mass should include qualitative modifiers. If the mass is cystic, comments such as whether the cyst is simple (indicating that there are no internal echoes or populations of suspicion) or complex should be made. The size and whether there has been interval growth should be noted.

Additionally, solid components are important, because malignant masses often will have solid sections. Several studies have indicated that the incidence of malignancy increases when masses are multiloculated and contain solid areas. Other reports indicate that the most suggestive finding of malignancy is inner wall abnormalities, such papillations, or a solid area. Other important features found on ultrasonography actually can be reassuring, such as calcium found next to fat as noted in dermoid tumors. Thus, adnexal masses that have solid components, inner wall papillations, or nodularity should not be observed further and surgical evaluation would be in order (Fig. 56.2).

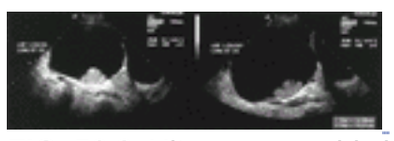

FIG. 56.2. Ultrasonographic image of an ovary with internal wall papillations. The final pathology of this ovarian cyst was clear cell adenocarcinoma.

An ultrasonographic evaluation can clarify the etiology of the mass. Although not definitive, suggestions that the masses may arise from the tube, such as the form of hydrosalpinges or tuboovarian abscesses, can be helpful. This is operator dependent and, as such, obtaining an ultrasonographic examination from a quality center would be of utmost importance in managing patients with adnexal masses (Fig. 56.3 and Fig. 56.4).

FIG. 56.3. Ultrasonographic image of a tuboovarian abscess.

FIG. 56.4. Ultrasonographic image of a cystadenofibroma.

Most ovarian malignancies occur in the postmenopausal group. In addition to the abnormal findings noted above for which surgery is recommended, growth of a mass in any age group is most likely an indication for surgical evaluation. It has been suggested, however, that in the postmenopausal population, a cystic mass that is simply cystic, that is has no nodularity, papillations, nor solid areas, may be managed conservatively. In a study of over 7,000 postmenopausal women, unilocular ovarian cysts measuring less than 10 centimeters in diameter in asymptomatic women were infrequently malignant. The patients in whom unilocular cysts were detected were observed, and 50% of the masses resolved within 60 days. Of the residual patients, all the masses were found to be benign when evaluated during surgery. Thus, these findings should be reassuring for the postmenopausal patient with unilocular cysts, in particular if the cysts are stable over several ultrasonographic examinations.

In addition to ultrasonographic findings, Doppler sonography may add some information. Doppler ultrasonography allows an evaluation of ovarian blood flow. With emission of a sound wave from a stationary source, reflection of the sound wave from a moving target is relative to its velocity. The strategy of using Doppler ultrasonography in ovarian masses would be to detect abnormal blood flow associated with neoangiogenesis often associated with ovarian malignancy. Thus, several indices have been developed for standardization of the study of ovarian blood flow. These include systolic-to-diastolic ratio, resistance index, and pulsatility index. Doppler analysis of flow is performed at multiple points, then color coded according to the direction of blood flow and superimposed on the anatomic location. A Doppler study can be performed quickly and is felt to add to the sonographic diagnosis. In a normal ovary, pulsatility and resistance indices are low. These indices also show changes relative to phases of the menstrual cycle. In contrast, in ovarian tumors, are associated with development of new blood vessels required to support growth of the aberrant tissue, the newly formed vessels have no smooth muscle vasculature, and thus the Doppler signalling is abnormal.

In the event that ultrasonographic findings are uncertain or more information is needed before surgical evaluation is undertaken, CT can be helpful. The conventional CT scan obtains images one slice at a time. Slice thickness is usually 8 to 10 millimeters, and patient immobilization is critical for obtaining clear views. Each slice is then reconstructed by the computer to result in a full image of the pelvis. Usually radiopaque oral agents are used to opacify the gastrointestinal tract. Intravenous contrast can be administered to visualize vascular and genitourinary structures. Ovarian nodularity, septations, and fat can be characterized well by CT scan. Additionally, if there is a concern that ultrasonographic findings may be reflecting a loop of bowel, CT can clarify this by using contrast. CT scans are fairly accurate for diagnosing a dermoid cyst given the combination of fat and calcification in these neoplasms (Fig. 56.5). If there is some concern that an adnexal mass may be uterine, such as in the case of myomas, CT can clarify this. Lastly, if an abdominal and pelvic CT scan is ordered, information regarding the rest of the lower abdomen and upper abdomen can be obtained.

FIG. 56.5. Computed tomography image of dermoid cysts. **A:** Internal calcification.

Magnetic resonance imaging (MRI) uses magnetic fields and radio waves. As compared with CT scan, which uses x-ray attenuation, multiple tissue characteristics are analyzed by MRI. One of the advantages is that no ionizing radiation is used for MRI. Patients with electrical pumps or implants such as pacemakers cannot undergo MRI evaluation. Gadolinium is used as intravenous contrast to better visualize organs and abnormalities. Compared with MRI, the CT scan is less expensive and usually more readily available. When evaluating disease, MRI may provide additional information but, for the most part, similar information is gained from either modality when evaluating the adnexal mass.

A new modality, positron emission tomography (PET), is undergoing investigation for clinical use in the evaluation of gynecologic malignancies. This radiologic test is based on the uptake of 18F-fluoro-2-dioxyglucose. This scan differs greatly from previous scans, which measure the differences between normal tissue and cancerous tissue; it is hypothesized that cancer tissues process this glucose analog differentially such that when a PET scan is performed, the emission of images is different in abnormal tissues. Theoretically, then, this technique is potentially more sensitive than classic imagining methods for detecting metastatic disease. The glucose analog is given intravenously, then the scan is performed and images are displayed for interpretation. This study usually is performed in the nuclear medicine department. Some investigators have suggested that the PET scan is more sensitive than CT or MRI for detecting the recurrence of ovarian cancer. Other investigators differ and note that the false-negative and false-positive result rates are quite high. The PET scan is an experimental modality; its use may increase with more experience. We have yet to understand fully its use in the evaluation of gynecologic malignancies, and insurance reimbursement issues still exist.

TUMOR MARKERS

The purpose for using tumor markers is two-fold as follows: (a) to measure these preoperatively to try to predict the malignant nature of the mass in question so that surgical preparations may be undertaken and (b) to follow disease once established. Traditionally, the most important tumor marker for epithelial ovarian cancers is CA-125. This antigen is expressed epithelially when a CA-125 level is ordered, and the amount of expression is measured by antibody assay using OC-125. CA-125 is relevant in particular to epithelial ovarian cancers, for which a cutoff of 35 U/mL has been determined to divide normal from abnormal levels. This has been accepted as the standard for clinical practice in the United States. Numerous studies have shown CA-125, drawn preoperatively, to be unreliable as a predictor of the malignant nature of a mass. During early stages of cancer, such as stage I disease, only 50% of patients will have elevated levels. Additionally, many other adnexal masses and disease processes may express elevated levels of CA-125 (Table 56.2 and Table 56.3). For screening purposes, many investigators have moved on to a combination of CA-125 with other tumor markers or with ultrasonographic findings. To date, there have been no successful screening protocols using serum and ultrasonographic preoperative data to accurately predict adnexal malignancy. Lastly, in the event of an ovarian epithelial neoplasm, preoperative CA-125 levels have been found to be controversial in regard to final outcome.

Gynecologic
Endometriosis
Leiomyomata
Adenomyosis
Pelvic inflammatory disease
Luteal phase menstruation
Ovarian hyperstimulation
Pregnancy (normal or ectopic)
Ovarian cystadenoma
Nongynecologic
Congestive heart failure
Chronic renal failure
Chronic liver disease
Colitis
Pneumonia
Systemic lupus erythematosus
Peritonitis of any etiology
Poorly controlled diabetes
Pancreatitis

Lung cancer
Breast cancer
Pancreatic cancer
Vaginal cancer
Endometrial cancer
Fallopian tube cancer

TABLE 56.3. *Other malignancies associated with elevated CA-125*

For following disease progression and regression, however, CA-125 levels have been invaluable. For monitoring responses to treatment, elevated levels accurately reflect progression or regression of disease in over 90% of patients. Thus, CA-125 is useful preoperatively as a baseline for ovarian cancer and is one of the main methods of following disease progression, in combination with radiologic imaging and clinical examination.

CA-125 levels can be elevated postoperatively because of surgical manipulations of the abdominal organs. If a preoperative CA-125 level was not drawn and a diagnosis of cancer is made intraoperatively, a postoperative CA-125 level should be measured, taking into consideration that elevated levels may be seen due to surgery. The elevation may not be so important, because it will be the rate of decline and actual resolution of elevated levels that would be most indicative of disease prognosis. Of note, the half-life of CA-125 is 20 days.

Numerous other markers have been studied to attempt to predict ovarian malignancy preoperatively and to follow cancer should it be diagnosed. Other tumor antigens include CA-15-3, CA-72-4 (TAG-72), CA-130, and CA-19-9. However, only CA-125 is in common use, and our clinical protocols include this antigen for following disease. The other tumor markers have not been as successful, in that their accuracy is less than that of CA-125 and many assays may not be readily available. A new tumor marker, lysophosphatidic acid (LPA), has been studied and may be promising in ovarian cancer. This lipid mediator can be assayed in serum and has been found to be elevated in patients with cancer.

SURGICAL EVALUATION

Once it has been decided that a mass requires surgical evaluation, the patient is scheduled for surgery and the surgeon must decide which approach to attempt. Gynecologists have been trained to make essentially two kinds of incisions when using an open approach. The most common transverse incision is the Pfannenstiel incision, also known as the *bikini incision.* Usually performed at the superior aspect of the pubic hair region for cosmetic reasons, its exposure is limited. When space is not a consideration for node dissection or removal of a large mass, the Pfannenstiel is useful in that it heals well, is reportedly less painful, and is associated with a lower incidence of wound dehiscence as compared to vertical incisions. Other transverse approaches include the Cherney and Maylard incisions. To perform a Cherney incision, a transverse skin incision is made, and the rectus muscles are identified at the insertion into the pubic synthesis and divided, commonly using electrocautery. With the rectus muscle out of the way, pelvic exposure is greatly enhanced and, thus, this incision is very useful when additional pelvic exposure is needed, yet the cosmetic aspects of a transverse incision are preserved. Closure of this incision is straightforward. The rectus tendons should be reapproximated to the inferior tendon of the rectus sheath using permanent sutures. Thus, in this incision, the rectus muscles are preserved. Alternatively, another space-endowing incision is the Maylard. Again using the transverse skin incision, once the rectus muscles are identified, the inferior epigastric vessels which reside in the lateral aspect of the rectus muscles are identified and ligated. The rectus muscles are divided using electrocautery. If approached cautiously and slowly, division of the rectus muscles is not complicated by bleeding. As with the Cherney incision, the Maylard incision affords greater exposure to the pelvic region than does a Pfannenstiel.

Alternatively, when a malignancy is suspected and surgical staging may be required, a vertical incision is used because of accessibility to the upper abdomen should this be needed; clearly, transverse skin incisions are limiting for exploration and management of disease found in the upper abdomen. There are two major vertical incisions, the paramedian incision and midline vertical incision. In performing a paramedian incision, the skin incision is just lateral to midline. Some consider these incisions stronger because of the displacement of the skin defect over the rectus muscle defect. The incidence of incisional hernia formation is decreased. However, the midline incision is used most commonly. With the need for upper abdominal exposure, the midline incision is ideal because of the ability to extend the incision superiorly.

Exposure is usually ideal with the midline incision, although in many cases the Cherney and Maylard incisions offer better exposure of the pelvis. Because the midline facial area is less vascular, the entry in the midline can be performed quickly, with minimal damage to rectus muscles and nerves. Also, blood loss is decreased with a midline incision. However, this is considered one of the weaker incisions and hernias, dehiscence, and eviscerations occur more readily with this incision than with others.

In summary, several incisions are available to gynecologists. Choice of incision is critical to successful evaluation of the gynecologic problem at hand. If malignancy is suspected, then the midline incision is recommended. However, suspicion of malignancy is based on a thorough knowledge of the risks, taking into consideration the radiologic characteristics of the mass and the patient's age. Thus, by a “best guess” scenario of the malignant potential of the adnexal mass being evaluated, the incision should be chosen.

Once the abdomen is open, it is recommended that washings be obtained before manipulation of the pelvic organs, so that a true assessment of cytologic spread can be undertaken. This can be performed in many ways. Simply, a large syringe can be used to inject the pelvis with fluid, and then the fluid is withdrawn using the empty syringe. Alternatively, various suction devices are available for use in the operating room to efficiently remove pelvic washings. The solution recommended for pelvic washings is isotonic so that lysis of cells does not occur. Plasmalyte warmed to body temperature is recommended. When obtaining washings, it is helpful to cup one's hand in the abdomen and aspirate the collective washings from this so as to not to aspirate epiploica. A small amount of heparin is added to the collection, which is then transported to the cytology department for evaluation.

After washings are obtained, a thorough exploration of the upper and lower abdomen is in order. In the upper abdomen, the diaphragm and omentum should be palpated for possible metastatic sites. Also, by reaching under the omentum for the root of the mesentery, the periaortic region should be palpated for adenopathy. Because the intent is to pack away bowel so that pelvic visualization is optimized, lysis of adhesions may be necessary to release small bowel loops that may be adherent in the pelvis. After doing so, using laparotomy sponges to collect the bowel, a retractor can be placed. Care should be taken in thin patients not to compress the psoas muscle and cause femoral nerve damage. Then the adnexal mass of interest is examined. If the pelvic mass is an ovarian cyst, either a cystectomy or an oophorectomy can be performed, depending upon the preoperative discussion with the patient and the index of suspicion for malignancy. For most postmenopausal women, an oophorectomy is planned. If there is any question as to whether the mass is truly malignant and the patient desires preservation of her ovaries, a cystectomy can be performed; if malignancy is suggested by frozen section, completion of the oophorectomy can be performed later during the surgery. In a quality hospital, frozen section analysis should have high correlation, upwards of 90%, with the final pathology findings.

Classically, when a malignancy is found in a postmenopausal woman, complete surgical staging, including total hysterectomy and bilateral salpingo-oophorectomy, is performed. Washings from the pelvis, both gutters, and diaphragm should be obtained. Bilateral pelvic sidewall, paracolic gutter, cul-de-sac, and anterior vesical biopsy samples should be obtained. These can be obtained by lifting a small portion of peritoneum and excising sharply. If there is bleeding at the biopsy site, the area can be cauterized for hemostasis. In lieu of obtaining a diaphragm biopsy, which can be performed using a cervical biopsy forceps, a scraping of this area can be performed. The right side of the diaphragm is scraped with a Pap smear spatula. The dominant hand is extended into the right upper quadrant and the diaphragm scraped. Cells are smeared from the spatula onto a slide and fixed with traditional preservative or submerged in liquid cytology media. When only an ovary(ies) is(are) affected without evidence of extraovarian spread, pelvic lymph node and periaortic node sampling should be performed, as well as omental biopsy. Lymph node dissection is not commonly performed by the general gynecologist so will not be described here; however, several excellent references describe the technique. Possible resources for the gynecologist who does not often perform lymph node dissection ideally include consultation with a gynecologic oncologist. However, if one is not available, a surgical oncologist or a urologic oncologist may be of assistance.

After ascertaining that all sites are hemostatic and sponge and instrument counts are correct, the abdomen is closed. For vertical incisions, two running sutures meeting in the midline should be sufficient for a fascial closure. If there is any concern that this closure would not be durable, as in patients who are malnourished or are on steroids or other immunosuppressive agents, interrupted closure with a permanent suture may be undertaken. Successful closure of the abdomen often is taken for granted but is a very important part of any surgical procedure. Wound infection and skin separations are unpleasant for the patient; however, serious complications such as fascial dehiscence can result. Although the Smead-Jones closure traditionally has been felt to be the most secure, it is very time consuming and may not afford any extra advantage for the patient when compared with mass abdominal wall closure. When using the Smead-Jones closure, monofilament permanent suture often is used. Alternatively, single interrupted sutures encompassing the entire abdominal wall can be used. However, using two sutures and running the fascia from the opposite poles to the midline is equally effective. This, of course, shortens operating room time and the amount of time the patient is under anesthesia.

There are many compelling reasons to stage an ovarian cancer. First of all, the extent of tumor is clearly described within our staging system, thus making communication among physicians and the clinical implications quite clear. Given a certain stage of disease, a patient may obtain appropriate therapeutic or adjuvant chemotherapy or radiation therapy. Staging in ovarian cancer is particularly important, because microscopic metastases are serious implications for postoperative treatment. In a classic study, up to 30% of patients thought to have stage I ovarian cancer based on incomplete surgical staging were upgraded to a more advanced stage when microscopic metastases were discovered during a later surgery. Therefore, if full staging, which includes pelvic and periaortic lymph node dissection, had not been included, these patients would have been treated incorrectly. Unfortunately, despite the availability of gynecologic oncologists in this country, full staging still is not offered to all patients. Not only are node dissections omitted, full palpation of the upper abdomen and omental biopsies are omitted. Although the missing staging procedures sometimes can be attributed to a skill issue such as lymph node dissection, failure to evaluate the diaphragm or perform straightforward peritoneal biopsies usually reflects the surgeon's lack of understanding of the necessity of full staging for ovarian malignancies. Complete staging is described in Table 56.4.

Total hysterectomy
Bilateral salpingo-oophorectomy
Omentiectomy
Pelvic node excision
Paraaortic node excision
Peritoneal biopsies (cul-de-sac, vesical peritoneum, right and left paracolic gutters, and pelvic sidewalls)
Peritoneal washings from pelvis, paracolic gutters, and infradiaphragmatic areas
Biopsy or scraping of right side of diaphragm

TABLE 56.4. *Complete staging for ovarian cancer*

SPECIAL CLINICAL SITUATIONS

Ovarian cancer is usually a disease of postmenopausal women. Thus, when faced with surgical evaluation of an adnexal mass, should a total hysterectomy and bilateral removal of adnexa be required, the implications are not as striking. However, in the case of a young woman with an incidental malignancy found during surgery, there is the added dilemma of how to address the unaffected organs after removal of the adnexa. For the young woman in whom a malignancy is suspected, conservative treatment is recommended (Table 56.5). Conservative surgery may be considered in women who are nulliparous with only suspected stage I disease (cancer confined to an ovary). After conservative surgery, should more advanced disease be diagnosed after pathologic evaluation of resected specimens, additional surgery may be undertaken as needed after consultation with an oncologist.

Unilateral salpingo-oophorectomy (includes removal of the ovary at the infundibulopelvic ligament)
Pelvic lymph node sampling
Periaortic lymph node sampling
Omentiectomy
Peritoneal biopsies from cul-de-sac, vesical peritoneum, right and left pelvic sidewalls, and paracolic gutters
Biopsy or scraping of right side of the diaphragm
Peritoneal washings from pelvis, paracolic gutters, and infradiaphragmatic areas
Biopsy of the contralateral ovary if it appears suspicious

TABLE 56.5. *Surgical staging for ovarian cancer in young women*

For young patients who wish for preservation of fertility options, all efforts should be made to perform a cystectomy. Samples can be sent for frozen section to determine if the ovarian mass is benign or malignant. If there is a question of malignancy, staging should be performed. Care should be taken to understand the patient's wishes for reproduction before performing surgical staging. In these cases it is clearly best to discuss all possible options preoperatively with the patient; in general, masses in premenopausal women are benign. However, in the event that a malignancy is found, if the contralateral ovary appears to be normal the uterus and ovary can be preserved, and the rest of the staging is as for the postmenopausal woman. That is, pelvic and periaortic node dissection, peritoneal and omental biopsies, and washings should be obtained. In the young patient, if there are bilateral masses and it is suspected that both ovaries are involved, thought should be given to preserving the uterus, given the advances made in assisted reproductive technology. Egg donation and other services may be available for this patient should

removal of both ovaries be indicated.

Another special scenario is management of the mass with borderline histology, also known as tumors of low malignant potential. Ovarian low malignant tumors have been described for all of corresponding invasive epithelial ovarian neoplasms. Serous and mucinous histologies make up the largest proportion of these tumors. Histologically, low malignant tumors differ from truly invasive lesions in that invasion into ovarian stroma is not detected; the epithelial lining is multilayered, and only mild nuclear atypia is present. These tumors account for up to 16% of ovarian malignancies. As compared with truly invasive ovarian cancers, the majority of tumors of low malignant potential are early stage and confined to one ovary. Once resected, regardless of stage, the role of adjuvant or therapeutic chemotherapy is unclear (unlike that for invasive epithelial ovarian cancers); this disease is felt to not benefit from adjuvant chemotherapy and remains a surgically treated disease. CA-125 levels are elevated in some patients with tumors of low malignant potential. In these cases, monitoring this marker for the recurrence of disease may be useful.

In the postmenopausal population, management is straightforward. At the minimum, unilateral salpingo-oophorectomy is performed and, more frequently, a bilateral salpingo-oophorectomy and often hysterectomy are performed. Again, the majority of tumors of low malignant potential are of early stage and prognosis is good. In the young population, a cystectomy is a possibility. Although recurrence rates may be higher after cystectomy, mortality rates from recurrent disease appears to be unchanged. When cystectomies are performed in these cases, women desiring children may be able to gain a few years and complete a family before undergoing or requiring more definitive surgery.

Adnexal masses in the young women may also be of germ cell origin. This is a special clinical scenario in that these neoplasms occur exclusively in young women. The main complaints include abdominal pain, with a pelvic mass found during examination. Some patients have acute abdominal pain resulting from torsion or rupture and hemorrhage of these masses. When evaluating a patient whose condition is not acute, the radiologic image usually reflects a solid mass with some cystic changes. The most common germ cell ovarian tumor is a dysgerminoma (Fig. 56.6). This is also the most common ovarian malignancy for young and pregnant women. This germ cell tumor is unusual in that it has a high incidence of bilaterality. Should a solid tumor be found and a germ cell tumor suspected, a-fetoprotein, human chorionic gonadotropin, and LBH levels may be drawn preoperatively, although none of these is necessarily predictive of finding a germ cell tumor. During surgery, given that most of these patients have not completed childbearing and that germ cells tumors most often are confined to the ovary, a conservative approach such as unilateral adnexectomy can be performed. Routine biopsy of the contralateral ovary in the case of a dysgerminoma is not recommended, even though the bilaterality rate is higher than with other germ cell tumors.

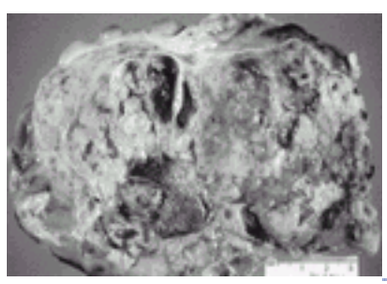

FIG. 56.6. Dysgerminoma in a 17-year-old girl.

Another germ cell neoplasm that occurs in young women is the endodermal sinus tumor. This tumor is classically associated with elevated a-fetoprotein and may be found in conjunction with a dysgerminoma. These tumors confer a worse prognosis. The malignant counterpart of the dermoid cyst, a malignant teratoma, may also be found in this population. These tumors are uncommon. In summary, if a germ cell tumor is diagnosed in a young person, a unilateral procedure may be performed if there is no suspicion of metastatic disease to the contralateral ovary or pelvis. If in doubt, a conservative approach would be best, with preservation of other reproductive organs and the possibility of returning for another laparotomy should this be indicated.

LAPAROSCOPIC APPROACH TO THE ADNEXAL MASSES

The role of laparoscopy in the management of the adnexal mass has advanced tremendously over the last decade. Laparoscopic technique has been developed and equipment is available such that laparoscopic surgery has never been easier. The advantages of a laparoscopic approach to management of the mass include shorter hospital stay, less pain, shorter recovery time, less expensive process by virtue of fewer days of hospitalization, and the potential to minimize the development of adhesions. Alternatively, the risks and complications of a laparoscopic approach differ from those associated with laparotomy. Although striking when reported and laparoscopic complications such as puncture of a vessel can be severe, altogether they are uncommon. Minimal requirements for a laparoscopic approach to the adnexal mass include adequate surgical skill to perform competently either a cystectomy or adnexectomy, accurate and prompt frozen section services, and the availability of staging in a timely fashion should rupture or advanced disease be diagnosed (Table 56.6). With the laparoscopic approach, once the mass is removed frozen section is completed as usual. Should the mass be malignant, staging should be undertaken as usual, either laparoscopically if the surgeon is skilled or by proceeding to laparotomy. If rupture of the mass occurs and the frozen section confirms malignancy, in general it is recommended that staging be performed promptly. However, should there be spill of ovarian contents inadvertently or in the process of performing a cystectomy, although the stage is upgraded to stage Ic ovarian cancer, it is unclear that the prognosis is much worse; however, in many cases the patient would be committed to adjuvant chemotherapy.

Surgical skills appropriate for performing cystectomy or adnexectomy

Personnel and facilities for timely surgical staging available

TABLE 56.6. *Criteria for laparoscopic removal of adnexal mass*

A unique complication associated with the laparoscopic approach to the mass with malignant potential is the occurrence of port-site implants. Studies have reported port-site dissemination and metastasis in 20% to 50% of patients. The mechanism for metastasis to these sites is direct tracking of tumor cells through port sites. Suggestions for decreasing the risk of port site metastasis in the event ovarian cancer is found at laparoscopy include resection of the port site or copious irrigation at the time of removal of instruments through the port site.

The key to successful laparoscopic management of an adnexal mass then returns to the main issue, selection of the appropriate patient given a best guess scenario of whether a mass is benign or malignant. A postmenopausal woman with a complex mass has a higher chance of malignancy and, therefore, the surgeon planning a laparoscopic approach should absolutely have a contingency plan should malignancy be discovered. Alternatively, because the chance of malignancy is less frequent in the premenopausal group, laparoscopic approach usually is appropriate in this age group. Until we can predict absolutely which masses are malignant, a combination of age and radiologic appearance, in particular ultrasonographic findings, should be integrated to determine the best approach for each patient.

SUMMARY POINTS

- Inroads have been made into the management of the adnexal mass. These include conservative management of the simple cyst in the postmenopausal woman and offering a laparoscopic approach to adnexal masses.
- An ideal method for determining preoperatively whether a mass is benign or malignant has not been discovered. Should we be able to predict this, plans and preparations could be made accordingly.
- All surgeons managing the adnexal mass should know the appropriate cancer staging procedures for the postmenopausal woman and the young woman desiring preservation of fertility. Even if the surgeon is not technically equipped to perform the actual node dissection, assistance frequently can be arranged. In the event a malignancy is diagnosed, appropriate staging is imperative to save the patient another surgical procedure and to determine the extent of the disease so that adjuvant therapy can be prescribed.
- New tumor markers and radiologic approaches are being pursued fervently such that soon we may be able to more accurately distinguish malignant from benign adnexal masses. In the meanwhile, appropriate medical and surgical management of the adnexal mass is the responsibility of all gynecologic surgeons.

Gestational trophoblastic neoplasia (GTN) encompasses a broad spectrum of benign and malignant tumors derived from the trophoblast of the human placenta. Although they are rare in incidence, they have the potential to become rapidly fatal diseases that afflict young women in their peak reproductive years.

Traditionally, GTN is divided into three histologic categories: hydatidiform mole, invasive mole (chorioadenoma destruens), and choriocarcinoma. Partial hydatidiform moles and placental site trophoblastic tumors (PSTT) are further recognized as histologically and clinically separate entities under the broad classification of GTN.

Despite the apparent diversity of GTN, these diseases are all derived from the human placental trophoblast and the paternal genome, with only occasional maternal genetic contribution. Human chorionic gonadotropin (hCG) is secreted by these neoplasms and serves as a sensitive tumor marker that correlates well with the clinical course for all GTNs except PSTT.

In 1956, metastatic gestational choriocarcinoma, the most malignant form of these diseases, was shown to be curable with chemotherapy. Many studies have now demonstrated the curability for most of these women, although individualization of therapy remains fundamentally important.

Patients may be treated for *malignant* GTN on the basis of clinical, radiographic, and serologic (hCG level) determinations without a definitive histologic diagnosis. For this reason, the generic term of *GTN* is useful, especially when treating patients with metastatic disease that is not readily accessible for pathologic evaluation. Except for PSTT, the initial histologic features of any lesion identified as GTN are less important than the clinical data and hCG level.

This chapter will review the wide spectrum of these human neoplasms and discuss important concepts regarding diagnosis, management, and surveillance for women with GTN.

HYDATIDIFORM MOLE

Two distinct types of molar gestations are recognized: partial and complete hydatidiform moles, both of which have distinct cytogenetic origins, pathologic features, and clinical behavior. Although it is not as clear whether partial hydatidiform mole represents a form of GTN or an extreme form of hydropic degeneration of the placenta in a chromosomally abnormal pregnancy, partial moles should be considered a variant of complete hydatidiform moles with risk of malignant sequelae. Most patients with primary molar gestations do not require adjuvant chemotherapy and may be monitored after therapeutic evacuation with serial hCG level determinations until either spontaneous regression occurs or the patient develops criteria for malignant disease.

Complete Hydatidiform Mole

Complete hydatidiform mole is identified macroscopically by edema and swelling of virtually all chorionic villi, without identifiable fetal parts or amniotic membranes. Hydropic villi are usually 1 to 3 centimeters in diameter, giving the gross appearance of grapelike vesicles. Microscopically, the chorionic villi are hydropic with marked interstitial edema. Fetal vessels are absent in the stroma of the villi. Proliferation of cytotrophoblast and syncytiotrophoblast is observed. Regardless of the degree of trophoblastic proliferation, all patients should be followed in similar fashion. All hydatidiform moles secrete hCG, and this marker is used to monitor tumor regression after evacuation.

Complete moles are almost uniformly diploid with completely paternal chromosomal composition. Most are 46,XX, although a minority will demonstrate a 46,XY karyotype. The most common origin of complete hydatidiform mole is fertilization of an empty egg by a haploid sperm followed by reduplication, although some may result from dispermic fertilization of an empty egg.

Unlike women with partial hydatidiform moles, approximately one third to one half of these patients have uterine enlargement greater than expected for gestational dates. Fetal heart tones are absent. Patients often have vaginal bleeding and spontaneous abortion of the atypical hydropic vesicles. Theca lutein cysts are detected clinically in approximately 20% of patients with complete moles. Pulmonary decompensation, pregnancy-induced hypertension, and hyperthyroidism are observed occasionally. The clinical diagnosis of molar gestation is supported by a characteristic mixed echogenic “snowstorm” image filling the uterus on an ultrasonographic scan.

Partial Hydatidiform Mole

Approximately 1% of pregnancies have a triploid karyotype and resolve following spontaneous abortion; partial hydatidiform moles represent a subset of these pregnancies, with placental histologic features that share features with complete hydatidiform moles. A comparison of karyotypic, pathologic, and clinical features of partial and complete hydatidiform moles is shown in Table 57.1. Partial moles often are associated with identifiable fetal parts or amniotic membranes. Grossly, the placenta demonstrates a mixture of normal and hydropic villi. Microscopic features include normal and hydropic chorionic villi with focal mild hyperplasia of trophoblastic elements. Scalloping of the hydropic villi is common, with trophoblastic inclusions in the stroma. Fetal vessels frequently are observed, with nucleated fetal erythrocytes within the vessels. Normal amniotic membranes are identified often, even if a fetus is not found.

TABLE 57.1. *Features of complete and partial hydatidiform moles*

Partial moles almost always are associated with one haploid maternal and two haploid paternal sets of chromosomes. Presumably, this results from dispermic fertilization of a haploid ovum or fertilization of a haploid ovum with a diploid sperm.

Women with partial hydatidiform mole usually have a clinical diagnosis of spontaneous abortion or missed abortion. Often, hydropic villi are not identified on ultrasonography, and the diagnosis is not suspected until after evacuation of the pregnancy. Initial hCG levels are lower than those seen in patients with complete hydatidiform mole, and prompt postevacuation regression of hCG levels occurs in most cases. Unlike patients with complete moles, who have a 10% to 30% incidence of malignant sequelae, fewer than 5% of the patients with partial moles develop criteria requiring chemotherapy. Regardless of this low risk of malignant sequelae, all women with partial hydatidiform moles should undergo hCG surveillance after evacuation, similar to that recommended for patients with complete hydatidiform mole. If there is any doubt that the products of a conception are molar, postevacuation hCG monitoring should be done.

Invasive Mole

Invasive moles (chorioadenoma destruens) are histologically identical to complete moles, but with invasion into the myometrium without intervening endometrial stroma. Invasive moles usually are diagnosed within 6 months of molar evacuation. Untreated invasive moles tend to invade the uterine wall locally, which can result in uterine perforation and hemorrhage. Direct vascular invasion and metastasis may occur rarely. In these cases, biopsies of distant metastases reveal hydropic villi consistent with invasive mole instead of solid sheets of anaplastic cells consistent with choriocarcinoma.

The identification of an invasive mole from uterine curetting may be difficult unless there is sufficient myometrium to document direct myometrial invasion. Most frequently this is a clinical diagnosis made when persistent, nonmetastatic GTN is diagnosed.

Choriocarcinoma

Choriocarcinoma is a highly anaplastic malignancy derived from trophoblastic elements. No chorionic villi are identified. Grossly, the tumor has a red, granular appearance on cut section with focal, often extensive, central necrosis and hemorrhage. Histologically, the lesion consists of mixed syncytiotrophoblastic and cytotrophoblastic elements with numerous abnormal mitoses, multinucleated giant cells, and extensive areas of necrosis and hemorrhage. Choriocarcinoma rapidly invades the myometrium and uterine vessels, and systemic metastasis results from hematogenous embolization. The lung and vagina are the most common sites of metastasis, with secondary dissemination to the central nervous system (CNS), kidney, liver, and gastrointestinal tract.

Choriocarcinomas may develop after any type of pregnancy. Approximately 50% of cases are preceded by hydatidiform mole, and the remaining are distributed equally between a normal antecedent term gestation and abortion or ectopic pregnancy. Gestational choriocarcinoma has been observed several years after the last known pregnancy. Spontaneous regression of the primary uterine site has been well documented from autopsy series of patients before the development of effective chemotherapy.

Placental Site Trophoblastic Tumor

PSTTs are locally invasive neoplasms derived from intermediate cells of the placenta. These rare neoplasms are composed of a monomorphic population of intermediate cytotrophoblast cells that secrete human placental lactogen (hPL) and relatively small amounts of hCG. Typically, there is local myometrial invasion with rare systemic metastasis. PSTTs are significantly more resistant to standard chemotherapy than other forms of GTN, and hysterectomy is the initial therapy of choice.

INCIDENCE AND EPIDEMIOLOGY

Approximately 3,000 cases of hydatidiform mole and 500 to 750 cases of malignant GTN are diagnosed in the United States each year. Hydatidiform mole is identified in approximately 1 in 1,500 to 2,000 pregnancies in the United States. There is a marked geographic variation in the incidence of this disease, with rates 5- to 15-fold higher in the Far East and Southeast Asia than in the Western industrialized nations. Some of this variation may be accounted for by the methodology of studies reporting the incidence of molar gestation, because many data were reported from the experience at referral centers and may overestimate the true incidence of molar pregnancies in the general population. Racial differences also may account for some of the geographic variations; Japanese immigrants to Hawaii have an incidence of molar gestation intermediate between that of native Hawaiians and native Japanese. Nutritional factors may also be important in the development of hydatidiform mole, including deficiencies of protein or animal fat and fat-soluble carotene.

Known risk factors for hydatidiform mole include previous molar pregnancies and maternal age. Women with a history of hydatidiform mole have a 4 to 5 times higher risk for development of a subsequent molar gestation. Women at the extremes of reproductive age are also at increased risk of developing a hydatidiform mole. Several studies have confirmed that risk increases with advanced maternal age, and others have suggested an increased risk for younger women or adolescents. The impact of paternal age on the incidence of hydatidiform mole is difficult to separate from the effect of maternal age.

The incidence of partial hydatidiform mole is unknown. Presumably, many are undiagnosed due to insufficient histologic analysis of tissue from spontaneous and induced abortions. Some pathologists may not be familiar with the diagnosis of partial hydatidiform mole, and karyotyping seldom is performed on material obtained from spontaneous abortions. One report reclassified approximately 10% of all moles in their studies as partial hydatidiform moles on the basis of histologic analysis.

Invasive mole follows approximately 15% to 20% of complete hydatidiform moles. In the United States, choriocarcinoma will follow in approximately 1 in 40 moles, 1 in 5,000 ectopic pregnancies, 1 in 15,000 abortions, and 1 in 150,000 normal pregnancies.

MANAGEMENT

The basic principles of management of the patient with hydatidiform mole include establishment of the diagnosis, evacuation of the molar gestation, and close surveillance of hCG levels after evacuation. Patients with complete hydatidiform moles frequently have spontaneous abortion of hydropic villi, which are pathognomonic for molar pregnancy. Absent fetal heart tones, uterine enlargement different from that expected for the gestational age, hyperemesis, preeclampsia, and a markedly elevated hCG level are clinical indications that may suggest a hydatidiform mole. Ultrasonography is now the diagnostic method of choice for evaluating patients with suspected hydatidiform mole. Ultrasonography demonstrates a characteristic image of multiple echogenic regions within the uterus corresponding to hydropic villi, focal intrauterine hemorrhage, and absence of fetal parts (Fig. 57.1).

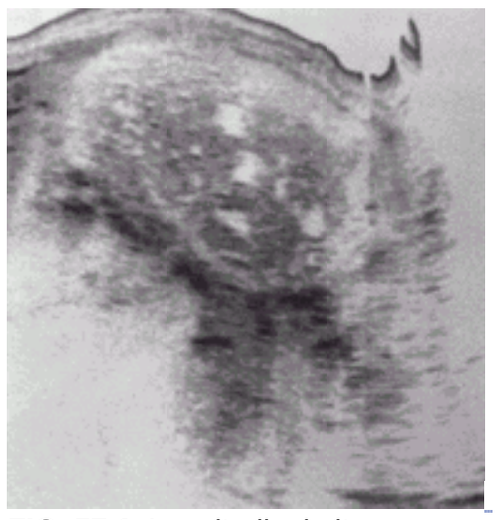

FIG. 57.1. Longitudinal ultrasonography reveals a hydatidiform mole. The mixed echoic pattern is caused by hydropic villi and focal intrauterine hemorrhage.

Evaluation of the patient before evacuation of the hydatidiform mole is directed toward preparing the patient for evacuation, obtaining baseline hCG level information, screening for occult metastatic disease, and screening for associated hyperthyroidism. The following studies are recommended:

- Complete physical and pelvic examinations
- Complete blood count determination
- Blood chemistry levels, including renal, hepatic, and thyroid function tests
- Baseline serum hCG level
- Chest radiograph
- Pelvic ultrasonography

Suction dilation and curettage (D&C) offers a safe, rapid, and effective method of evacuation of hydatidiform mole in most patients. Some patients who do not desire preservation of reproductive function may benefit from primary hysterectomy for evacuation of hydatidiform mole and concurrent sterilization. However, these patients must be followed closely after hysterectomy, because malignant sequelae may still develop. Hysterotomy or induction of labor for molar evacuation is not recommended.

Suction D&C for evacuation of hydatidiform mole has a low complication rate in patients with uterine sizes corresponding to less than 16 weeks of gestation. Oxytocic agents are administered immediately after cervical dilation to aid in postoperative hemostasis. Patients with excessive uterine enlargement have a higher risk of pulmonary complications associated with D&C, which may be related to trophoblastic deportation, preeclampsia, fluid overload, anemia, and hyperthyroidism. In patients with hydatidiform mole complicated by uterine enlargement greater than that of 16 weeks of gestation, baseline arterial blood gas analysis should be obtained preoperatively, with consideration of invasive hemodynamic monitoring (Swan-Ganz catheterization) during the procedure. Evacuation should be performed only after a euvolemic status has been established and blood products readily available for possible transfusion.

Primary hysterectomy is a reasonable alternative for termination of molar gestation in patients with hydatidiform mole who have completed childbearing and desire sterilization. Hysterectomy reduces the incidence of malignant sequelae after evacuation of hydatidiform mole from approximately 20% after suction D&C to less than 5% after hysterectomy. However, this does not eliminate the need for careful follow-up or complete hCG surveillance after termination of hydatidiform mole, because malignant GTN may develop even after hysterectomy. Concurrent surgical extirpation of the adnexae should be considered, as with hysterectomy for benign indications.

Theca lutein cysts are detected clinically in approximately 20% of patients with molar gestations. These cysts are thin walled and highly vascular, and develop as a response to ovarian hyperstimulation from the high hCG levels produced by hydatidiform moles. They typically regress spontaneously over several weeks following molar evacuation. It is preferable to avoid surgery or ovarian manipulation in patients with uncomplicated theca lutein cysts. Rarely, because of abdominal distension and respiratory compromise, they may require aspiration with ultrasonic guidance. Enlarged cysts may undergo torsion, infarction, or rupture, and oophorectomy should be considered in these circumstances.

Some centers prescribe prophylactic short courses of methotrexate or dactinomycin chemotherapy at the time of molar evacuation to decrease the incidence of malignant sequelae in patients with high-risk features. However, prophylactic chemotherapy does not eliminate the chance of subsequent malignancy nor the need for hCG surveillance. Routine prophylactic chemotherapy at the time of molar evacuation for patients with uncomplicated hydatidiform mole is not recommended if reliable hCG surveillance is available.

Surveillance Following Molar Evacuation

The wide availability of sensitive hCG assays provides a backbone for postmolar evacuation triage and therapy. Several sensitive hCG assays are available, measuring the ß-subunit of hCG by radioimmunoassay or by radioimmunometric assay. These assays can detect hCG levels elevated above the baseline variations of pituitary gonadotropins. These sensitive hCG assays should be used to monitor patients with GTN after evacuation of hydatidiform mole and during therapy of patients with malignant GTN. Urinary or serum pregnancy screening tests should not be used to follow patients with GTN, because the assays do not have sufficient sensitivity to permit detection of minimal elevations of hCG levels.

The recommendations for postmolar follow-up include determination of serum ß-hCG levels every 1 to 2 weeks after evacuation until hCG level is undetectable. Subsequently, hCG levels should be determined for 2 to 4 weeks after the first normal level to confirm spontaneous hCG regression, followed by hCG surveillance every 1 to 2 months for 6 months after the first normal hCG level. In addition, hCG levels should be checked 6 weeks after all subsequent pregnancies due to the patients' elevated risk of subsequent GTN.

Most women with molar pregnancies undergo hCG level regression after evacuation to normal limits and require no further therapy. Strict contraception is recommended during hCG surveillance to avoid an intercurrent pregnancy that would interfere with monitoring. The hCG elevation of an early normal pregnancy may mask the hCG rise associated with postmolar malignant GTN.

Although an early report implicated oral contraceptives as a risk factor for postmolar malignant GTN, subsequent investigators found no significant increase in the risk of malignant GTN associated with the use of oral contraceptives after molar evacuation. After completion of 6 months of hCG level surveillance with normal results, patients may attempt pregnancy if desired. Because the risk of recurrent molar pregnancy is about 1%, they should undergo early screening of all pregnancies with ultrasonography to exclude recurrent molar gestations. Figure 57.2 illustrates an algorithm for diagnosis and follow-up of patients with hydatidiform mole.

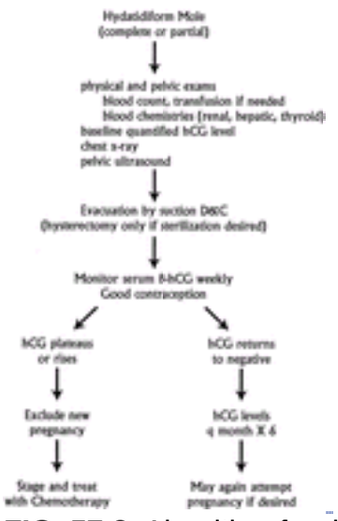

FIG. 57.2. Algorithm for diagnosis and treatment of a patient with hydatidiform mole.

False-positive hCG Test Results

The sensitivity and specificity of serum ß-hCG levels makes it an ideal tumor marker in both diagnosis and surveillance of GTN. However, hCG, a glycoprotein comprised of both a- and ß-subunits, linked by eight oligosaccharides, has significant heterogeneity in its structure and antigenicity. Free subunits, degraded molecules, molecules with irregular side chains, and fragments of hCG are present in sera of women in pregnancy, with trophoblastic disease, and with nontrophoblastic neoplasms. Furthermore, hCG variants that include hyperglycosylated hCG, nicked hCG, hCG missing the ß-subunit C-terminal peptide, free ß-subunit, and nicked free ß-subunit may also be present. Although all professional laboratory hCG assays use antibodies to different sites on the ß-subunit, variations in antibody use may lead to measurements of different hCG-related molecules.

The heterogeneity of hCG and the variability between different hCG assays may result in false-positive test results. The phenomena of “phantom hCG” and “phantom choriocarcinoma” have resulted in erroneous diagnoses of invasive GTN and choriocarcinoma, with unnecessary subsequent chemotherapy and hysterectomy. The U.S.A. hCG Reference Service recommends that when false-positive hCG results are suspected, urine hCG testing for detection of the ß-core fragment, the terminal

degradation product of hCG and its variants, should be performed. Evaluation also should include serum testing by a laboratory using a different ß-hCG assay. In cases with absence of urine hCG and failure to detect serum ß-hCG by an alternative laboratory, the initial elevated level likely represents a false-positive test result.

False-positive results also may be due to the presence of heterophilic antibodies. These antibodies are able to complete with hCG in antibody binding used in commercial hCG assays, and may result in persistent positive results. Treatment with a heterophilic antibody blocking reagent has been shown to reduce the incidence of false-positive results, and these reagents have been added to the protocol used by the U.S.A. hCG Reference Service.

MALIGNANT GESTATIONAL TROPHOBLASTIC NEOPLASMS

Malignant Sequelae Following Molar Evacuation

The spectrum of malignant sequelae after evacuation of hydatidiform mole includes intrauterine molar proliferation without invasion (i.e., retained mole), invasive mole, choriocarcinoma, and the clinical identification of metastatic GTN without a histologic diagnosis. The purpose of hCG level surveillance is early detection of trophoblastic neoplasia before the development of complications related to local proliferation, uterine invasion, or distant metastasis.

Before the development of effective chemotherapy for GTN, approximately 9% of women required hysterectomy for malignant sequelae after evacuation of hydatidiform mole. Many series of patients have been reported since the development of chemotherapy, with a wide range in the rate (9% to 36%) of patients requiring therapy after evacuation of hydatidiform mole. These observed differences in the frequency of malignant GTN may reflect inclusion of partial moles in some studies, a different incidence of metastatic disease in patient populations, or different hCG level regression criteria used to define malignant GTN and assign therapy in the various studies.

Histologic and clinical features can be used to define high- and low-risk groups of patients after molar evacuation but are of little value in determining the need for therapy in individual patients. Trophoblastic proliferation, uterine enlargement, theca lutein cysts, respiratory distress syndrome after molar evacuation, and postevacuation uterine hemorrhage all are associated with a higher frequency of postmolar malignant GTN. Prompt uterine involution and regression of theca lutein cysts are favorable prognostic signs. However, the definitive method for predicting development of postmolar malignant GTN is observation of the pattern of hCG regression.

Serial hCG levels are obtained at 1-week intervals with chest radiographs every 2 to 4 weeks as long as the hCG levels are elevated. Patients are treated with chemotherapy according to several criteria as follows: hCG level rise, hCG level plateau for 3 or more consecutive weekly levels, appearance of metastasis, or histologic evidence of invasive mole or choriocarcinoma.

Diagnosis

Malignant GTN is diagnosed in women with rising or paltering hCG levels or identification of metastasis after evacuation of a hydatidiform mole. Histologic diagnosis of invasive mole or choriocarcinoma is a criterion for malignant GTN. Patients who developed malignant GTN after nonmolar gestations often sought treatment for atypical symptoms attributable to distant metastases. Gastrointestinal or urologic hemorrhage, hemoptysis, or neurologic symptoms due to cerebral hemorrhage may be the clinical features. Irregular uterine bleeding or amenorrhea may be observed. Rarely, patients have clinical hyperthyroidism. Under these circumstances, the diagnosis of malignant GTN is facilitated with serum hCG testing and the exclusion of normal pregnancy. The possibility of metastatic GTN should be considered in any woman of the reproductive age group who has metastatic disease involving the lungs or distant sites from an unknown primary site of malignancy.

After the diagnosis has been made, the following clinical, laboratory, and radiographic evaluations are recommended for a patient with malignant GTN:

- Physical and pelvic examinations
- Baseline hCG level
- Complete blood count and baseline chemistry determinations
- Chest radiograph
- Pelvic ultrasonography
- Computed tomography (CT) of brain, chest, and abdomen–pelvis

Before a woman is treated for malignant GTN with chemotherapy, it is essential to exclude an intrauterine pregnancy with a pelvic ultrasonographic scan. Approximately 50% of patients with malignant GTN have pulmonary metastasis detected by routine chest radiographs. The clinical significance of small pulmonary metastases detected only by whole-lung CT scans is unknown. Because CNS and hepatic metastases may develop without clinical or radiographic evidence of pulmonary or vaginal metastases, the remainder of the radiologic studies are recommended strongly, regardless of whether abnormalities are detected by physical examination or chest radiograph. The role of magnetic resonance imaging studies or positron emission tomography in the evaluation of women with GTN is not yet defined.

Occult CNS metastases may be detected using lumbar puncture with simultaneous serum and cerebrospinal fluid (CSF) hCG determinations. The plasma-to-CSF hCG ratio is normally greater than 60:1 in the absence of CNS metastasis and is usually less than 60:1 in patients with CNS metastasis. Some investigators have reported falsely lowered plasma-to-CSF hCG ratios for patients without GTN undergoing first-trimester abortions and for patients with nonmetastatic GTN. CSF hCG determinations are most frequently utilized in evaluation of patients who have developed resistance to chemotherapy, with residual disease documented by elevated serum hCG levels, when the site of disease is obscure. Routine CSF hCG determination, however, is not part of initial GTN staging.

Surgery may be useful for patients with malignant GTN, but it rarely is indicated for staging or diagnosis alone. Histologic evaluation of tissue obtained by D&C may confirm the diagnosis and may be useful in the patient experiencing vaginal bleeding, but the procedure carries the risk of uterine perforation and hemorrhage. Laparoscopy, craniotomy, and thoracotomy rarely are justified to establish the primary diagnosis of malignant GTN, because this diagnosis can be made on the basis of elevated hCG levels with radiographic evidence of metastasis after excluding pregnancy.

All patients with malignant GTN must be thoroughly evaluated for metastatic disease. Selection of the initial therapy and subsequent survival largely depend on identification of poor prognostic factors in patients with metastatic disease. Figure 57.3 demonstrates an algorithm of management of malignant GTN.

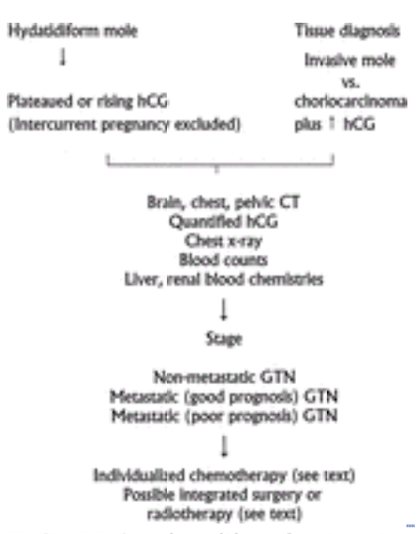

FIG. 57.3. Algorithm for treatment of a patient with malignant gestational trophoblastic disease.

Staging and Classification

Due to considerable overlap in the clinical course of the histologic entities that constitute malignant GTN, and because a complete histologic evaluation of an individual patient with GTN is rarely possible, a variety of classification and staging systems have been used to assess risk and assign initial therapy and prognosis for these

patients. Several clinical findings are important in categorizing patients for treatment, and any classification system must take these factors into consideration to be clinically useful.

A simple clinical classification system based on risk factors for malignant sequelae may be used to assign initial therapy for patients with malignant GTN. This system takes into account factors that predict failure of initial single-agent chemotherapy to effect cure and allows identification of patients who would benefit from initial aggressive multidrug chemotherapy (Table 57.2). After radiographic studies have been completed, the patient is considered to have nonmetastatic GTN if there is no evidence of extrauterine spread of disease. This category is not subdivided into good-prognosis and poor-prognosis categories because these patients can achieve approximately 100% remission rates using current chemotherapeutic regimens. The histologic diagnosis of choriocarcinoma mandates treatment but does not change the initial choice of therapy. If there is any clinical or radiographic evidence of extrauterine metastasis, the patient is classified as having metastatic GTN. These patients are divided further into good-prognosis and poor-prognosis categories on the basis of factors that predict the failure of primary single-agent chemotherapy with methotrexate or dactinomycin.

I. Nonmetastatic GTN
A. Not defined in terms of good versus poor prognosis
II. Metastatic GTN
A. Good prognosis (i.e., absence of high-risk factors)
1. Pretreatment serum β-hCG level <40,000 mIU/mL
2. Less than 4-month duration of symptoms attributable to disease
3. No evidence of brain or liver metastasis
4. No significant prior chemotherapy
5. No antecedent term pregnancy
B. Poor prognosis (i.e., any single high-risk factor)
1. Pretreatment serum β-hCG level >40,000 IU/mL
2. More than 4-month duration of symptoms attributable to disease
3. Brain or liver metastasis or both
4. Failed prior chemotherapy
5. Antecedent term pregnancy

GTN, gestational trophoblastic neoplasms; hCG, human chorionic gonadotropin.

TABLE 57.2. *Clinical classification of malignant gestational trophoblastic neoplasia*

The International Federation of Gynecologists and Obstetricians (FIGO) developed a staging system for GTN that is based on the anatomic site of disease, conforming to the FIGO staging systems for other gynecologic malignancies:

Stage I: Disease confined to the uterine corpus
Stage II: Metastasis to the vagina or pelvis
Stage III: Metastasis to the lung
Stage IV: Other extrapelvic metastasis

Although essentially all patients with stage IV disease are at high risk, this system does not recognize the prognostic importance of other factors, such as the initial hCG level, other direct and indirect measurements of tumor burden, or duration of disease.

The World Health Organization (WHO) devised a prognostic index scoring system (Table 57.3) based on Bagshawe's analysis of the prognostic factors of his patient population. In addition to using a weighted scale for risk factors analyzed by the clinical classification, such as hCG level and duration of disease, the system identifies a graded range of additional risk factors. Ectopic pregnancies and abortions have an intermediate risk between molar and term pregnancies. Blood types and age contribute to the score. The size of the largest tumor, the number of metastatic sites, and site of metastasis are considered indirect approximations of tumor burden. After computation of each risk factor, the patient is considered to be at low risk if the score is 4 or less, at intermediate risk with a score of 5 to 7, and at high risk with a score of 8 or more. The WHO prognostic index scoring system has been found to correlate well with survival after conventional combination chemotherapy protocols. Not all of the WHO factors, however, have been evaluated critically to determine whether the graded scoring system is valid. Figure 57.3 illustrates a plan of evaluation and therapy for patients with malignant GTN.

TABLE 57.3. *World Health Organization prognostic scoring system for gestational trophoblastic neoplasia*

Therapy

Before the development of effective chemotherapy against malignant GTN, surgical therapy was not successful in curing most patients, even women with nonmetastatic disease confined to the uterus. Since the introduction of methotrexate in the 1950s, malignant GTN has become the most curable of human solid tumors. Therapy should be conducted by physicians who have considerable experience in the management of these diseases, and a reliable hCG assay should be available so that therapeutic changes can be instituted quickly when necessary. Although chemotherapy has largely supplanted surgery and radiation therapy as the first-line management of malignant GTN, these modalities continue to play an important role in the management of patients with malignant GTN.

Chemotherapy The initial chemotherapy should be selected on the basis of one of the systems of classification of malignant GTN (Table 57.4). Patients with nonmetastatic and good-prognosis GTN are treated initially with single-agent chemotherapy regimens using methotrexate or dactinomycin. Patients with poor-prognosis metastatic GTN require initial chemotherapy using combinations of active agents. Currently, the most frequently used combination is the EMA-CO regimen (etoposide, methotrexate with folic acid rescue, dactinomycin alternating with cyclophosphamide, and vincristine [Oncovin]).

TABLE 57.4. *Chemotherapy for malignant gestational trophoblastic neoplasms*

Chemotherapy for Nonmetastatic Disease The most widely used initial chemotherapy regimen for patients with nonmetastatic GTN includes courses of alternating doses of methotrexate (1 mg/kg [maximum 50 mg] on days 1, 3, 5, and 7) and folinic acid rescue (0.1 mg/kg on days 2, 4, 6, and 8), both administered intramuscularly. A variety of other agents and schedules, including daily and “pulsed” dactinomycin, also have been used to treat nonmetastatic GTN, with essentially equivalent remission rates. Reports indicate that weekly courses of methotrexate administered intravenously as a single dose of 30 mg/m ^{2} have an advantage over other schedules of methotrexate in reducing cost and toxicity and are equally effective. Close hematologic and renal and liver chemistry monitoring must be done during therapy. Multiple studies show remission rates in this stage of disease to approach 100% when patients are treated appropriately. Although methotrexate and dactinomycin continue to be the mainstays of treatment for low-risk disease, there is no consensus on a single superior regimen. The Gynecologic Oncology Group, a multicenter collaborative clinical trials association, is accruing patients into a randomized, phase III trial of weekly intravenous methotrexate versus pulsed dactinomycin as primary management for low-risk GTN. The major goals of therapy for patients with nonmetastatic GTN include administration of active, relatively nontoxic regimens of chemotherapy with close hCG level monitoring. For most of these patients, chemotherapy alone is adequate treatment, and surgery is unnecessary. However, primary hysterectomy may be used for patients who desire sterilization, because this may reduce the number of cycles of chemotherapy necessary to achieve remission and cure.

Chemotherapy for Good-prognosis Metastatic Disease Initial therapy with repetitive cycles of 5-day courses of single-agent methotrexate or dactinomycin is preferred for patients with good-prognosis metastatic GTN. For these patients without high-risk factors, the ultimate sustained remission rate also approaches 100%. Patients are treated initially with repetitive 5-day cycles of methotrexate administered intravenously at a dose of 0.4 mg/kg per day or dactinomycin administered intravenously daily at a dose of 500 μg. Chemotherapy is repeated every 14 days. Again, hematologic and renal and liver chemistry monitoring must be done, and colony-stimulating factors may be required to keep the treatment on schedule. Remission rates with either agent are approximately 60%, and most patients with drug-resistant disease are salvaged with the alternative single agent. Occasionally, patients may require hysterectomy or other surgical procedures to extirpate loci of persistent disease or else require a change in therapy to a multidrug chemotherapy regimen.

Chemotherapy for Poor-prognosis Disease Multidrug chemotherapy is used as the initial therapy for patients with poor-prognosis metastatic GTN. Survival is poor for this group if the initial therapy is with only a single agent, and it is important to diagnose poor-prognosis, high-risk features in these patients so that appropriate initial therapy may be instituted in a timely fashion. The most successful and least toxic multiagent regimen is EMA-CO. Other salvage regimens include MAC (methotrexate,

actinomycin D, and cyclophosphamide [Cytoxan]), and the modified Bagshawe regimen of hydroxyurea, methotrexate, vincristine, cyclophosphamide, dactinomycin, and doxorubicin (Adriamycin). Because VP-16, cisplatin, 5-fluorouracil, vinca alkaloids, and bleomycin all demonstrate activity against GTN, other salvage regimens are based on combinations employing some of these agents. Regardless of regimen, another cycle of chemotherapy is administered as soon as toxicity from the previous cycle has cleared. Use of stem cell factor support should be used when needed to keep the treatment on schedule. Although toxicity may be marked with these combinations, aggressive initial multiagent chemotherapy usually is necessary to ensure optimal survival for patients in this category. Patients with poor-prognosis metastatic GTN should be treated at centers that specialize in the therapy of patients with GTN. Physician experience with GTN and these aggressive multimodality therapies appears to improve the outcome for these patients. Patients with poor-prognosis metastatic GTN who have failed standard chemotherapy regimens are extremely challenging when designing appropriate coordination of chemotherapy and other therapeutic modalities to achieve salvage. Frequently, patients must be treated without regard for toxicity and must be supported through episodes of profound bone marrow suppression, sepsis, and nutritional deprivation to have a chance at salvage.

Surgical and Radiation Therapy

Hysterectomy Due to improvements in chemotherapy, hysterectomy rarely is indicated as the initial therapy for women with malignant GTN. However, for patients with nonmetastatic or good-prognosis metastatic GTN with uterine disease, hysterectomy appears to decrease the duration of hospital stay and number of courses of chemotherapy required to achieve remission. Delayed or secondary hysterectomy is required as salvage therapy for approximately 10% of patients in these categories, but chemotherapy alone is successful in curing approximately 85% of patients with nonmetastatic and good-prognosis metastatic GTN. Among women with poor-prognosis metastatic GTN, preservation of childbearing capacity must be of secondary importance, but primary or delayed hysterectomy does not appear to offer as many benefits as in the therapy of patients with low-risk disease. Surgical procedures for the purpose of removing sites of GTN are performed during a cycle of chemotherapy. Theoretically, this prevents dissemination of disease caused by embolization of GTN during the surgical manipulation of tissues. The complications of surgery and wound healing do not appear to be increased using this approach.

Thoracotomy Thoracotomy with pulmonary segmental resection has been the most frequently performed procedure other than hysterectomy to remove drug-resistant disease. The radiographic regression of pulmonary nodules may lag far behind the response measured by hCG levels, and the persistence of a lung nodule after hCG normalization should not necessarily be interpreted as indicating persistent disease. There have been reports of success with resection of solitary pulmonary nodules in carefully selected women with drug-resistant disease. Before considering pulmonary resection, it is important to exclude the possibility of disease elsewhere. If the patient has not had a hysterectomy, occult pelvic GTN should be evaluated with arteriography or other imaging techniques, such as magnetic resonance imaging. Prompt hCG remission after pulmonary resection predicts a favorable outcome.

Brain and Liver Metastasis Whole-brain and whole-liver irradiation are used often as adjuncts to chemotherapy in the treatment of patients with metastasis to these sites. Whole-brain irradiation of 3,000 cGy over 10 days should be instituted immediately in conjunction with chemotherapy after brain metastasis is diagnosed. The rationale for this treatment is to prevent hemorrhage from these highly vascular metastases. With this approach, survival rates of approximately 85% are achieved for patients receiving primary therapy for brain metastasis; survival rates of approximately 50% are achieved for all patients with brain metastasis, including those developing metastasis during chemotherapy or at the time of recurrence. An alternate approach includes the combined use of high-dose systemic methotrexate with intermittent intrathecal methotrexate. Craniotomy is not often required for the primary therapy or diagnosis of brain metastasis from GTN and usually is not successful when used alone. However, neurosurgical consultation should be obtained early in the course of therapy in the event that hemorrhage into brain lesions occurs and craniotomy is required for stabilization of the patient. Whole-liver irradiation of approximately 2,000 cGy delivered over 10 days may be used to treat liver metastasis and prevent hepatic hemorrhage. Some investigators have not used hepatic irradiation to avoid exacerbation of the toxic hepatic effects of chemotherapy. Others have advocated selective occlusion of the hepatic artery by means of ligation or embolization when bleeding has occurred. Patients with hepatic metastasis have a poor prognosis and require aggressive chemotherapy, with careful monitoring during therapy to maximize the chances for survival. Whole-organ irradiation does not appear to compromise tolerance of aggressive chemotherapy.

Placental Site Trophoblastic Tumors PSTT is a rare placental neoplasm that is histologically and clinically distinct from other forms of GTN. PSTTs lack significant volume of syncytiotrophoblast elements and do not secrete high levels of hCG. As such, serum hCG levels are not a reliable tumor marker for PSTT as they are in other forms of GTN. PSTT usually is locally aggressive, with invasion into the myometrium. It typically is resistant to traditional chemotherapeutic agents. Most women with PSTT require hysterectomy, although anecdotal reports suggest a minority may be cured by D&C alone. Rarely, PSTT may pursue a more aggressive course, characterized by distant metastasis and rapidly progressive disease.

Monitoring Therapy

Laboratory Evaluations During chemotherapy, hematologic, renal, and hepatic indices should be monitored carefully. Toxicity from methotrexate-based and dactinomycin-based chemotherapy is relatively predictable. Unless a patient is receiving salvage chemotherapy for drug-resistant or recurrent GTN, new cycles of therapy should be withheld unless the total leukocyte count is greater than 3,000 cells/mm ^{3}, the platelet count is greater than 100,000 cells/mm ^{3}, and the renal and hepatic indices are normal. Radiographic studies of metastatic lesions and pelvic examination should be repeated frequently to monitor response to therapy. More important than radiographic surveillance is closely following the hCG level response during therapy. Sensitive assays of the hCG levels should be performed at 1-week intervals during therapy. Chemotherapy should be changed if the hCG titer has not dropped at least 25% after a treatment cycle or if toxicity does not permit adequate dosage or frequency of administration.

Human Chorionic Gonadotropin Level Remission and Surveillance Complete remission is defined as three consecutive weekly hCG levels in the normal, undetectable range. After remission has been achieved, hCG levels should be followed every 1 to 2 weeks for the first 3 months after completion of therapy, every 2 to 4 weeks for the subsequent 3 months, and every 1 to 2 months for the completion of the first year of surveillance. Recurrent episodes of GTN usually develop within a few months after completion of therapy, but late recurrences develop in a few cases. The assay of hCG levels should be repeated indefinitely at 6-month intervals. Patients are counseled to avoid pregnancy through the first year of hCG surveillance; most are treated with oral contraceptives for efficiency and to avoid low-level interference with the hCG assays caused by luteinizing hormone.

Prevention of Recurrent Disease

Despite the accuracy of hCG assays, a tumor burden of 10 ^{4} cells may exist despite normal serum hCG levels. Recurrence rates after therapy for GTN have been 3% to 26%, depending on the patient population being studied. Patients with poor-prognosis metastatic GTN usually have a much higher recurrence rate than patients with low-risk disease. Most investigators agree that consolidation chemotherapy should be administered beyond the first normal hCG level. Typically, patients undergo one additional cycle of chemotherapy beyond the first normal hCG level for nonmetastatic disease, two cycles of consolidation chemotherapy for good-prognosis metastatic GTN, and three to four cycles of maintenance chemotherapy for poor-prognosis metastatic GTN. Toxicity must be considered in continuing therapy for these patients.

Reproduction After Therapy

Most women treated for GTN are cured by chemotherapy without resorting to hysterectomy. Several reports have documented that there is little or no increased risk of congenital malformation of infants during subsequent pregnancies. There may be a slight increase in the incidence of spontaneous abortions in this population, but this increase may be an artifact of increased hCG surveillance and identification of preclinical pregnancies in women who have previously received treatment for GTN. There is also an increased incidence of repeat molar gestation in patients who have had a hydatidiform mole (approximately 1%). Patients who have received intensive therapy for poor-prognosis metastatic GTN often undergo hysterectomy during therapy or may develop ovarian failure as a result of prolonged multidrug chemotherapy. Only a few patients in this category with uterine conservation are able to conceive or desire to attempt pregnancy after therapy.

Although the risk of congenital anomalies is not increased significantly after chemotherapy for malignant GTN, obstetric complication rates may be. Major obstetric complications can be observed in as many as 9% of these pregnancies. The incidence of placenta accreta, in particular, appears to be increased.

Women who have been treated successfully for GTN should be advised that pregnancy should be deferred for at least 1 year after therapy to allow for hCG level surveillance. They should be reassured about the low incidence of congenital malformations and recurrent GTN in subsequent pregnancies. An ultrasonographic scan should be performed early in pregnancy to exclude the possibility of recurrent molar gestation. A chest radiograph and serum hCG level should be obtained 6 to 8 weeks after delivery to screen for the rare case of recurrent choriocarcinoma developing after a subsequent normal pregnancy.

SUMMARY POINTS

- Gestational trophoblastic neoplasia represents a spectrum of human tumors, ranging from benign with potential malignant sequelae to highly malignant.
- Primary hydatidiform mole (complete) usually becomes apparent as a pregnancy with threatened first-trimester vaginal bleeding. Other frequent findings include discordant uterine size, ovarian cystic enlargement, and hyperemesis, but may include hyperthyroidism and preeclampsia.
- Evacuation of hydatidiform mole is best done by suction D&C, with caution used regarding trophoblastic deportation and pulmonary embolization.
- Individualization of therapy is critical for successful treatment of patients with GTN. Although chemotherapy is the primary modality for therapy, surgery and radiotherapy may also have a role.
- The hCG level is a sensitive and reliable marker for GTN and can be used effectively to aid in diagnosis, monitor therapy, and maintain follow-up evaluation.

MEDICAL ETHICS

Physicians in obstetric and gynecologic practice confront ethical concerns and issues that arise when the physician's judgment about what is in the patient's interest differs from the patient's judgment about what is in her or her fetus's interest. One way to manage such differences is to assert the primacy of the physician's judgment. This strategy has been discredited in medical ethics, because it leads to paternalism in the care of patients. Paternalism can occur when medical judgments fail to take account of the patient's values and beliefs regarding her own health and medical care. To avoid paternalism, one might opt for the alternative of the primacy of the patient's judgment. The problem with this approach is that it reduces the physician to the status of a mere technician and may require the physician to act in ways that contradict reasonable medical judgment.

In this chapter we apply the methods of ethics to the problem of differences between the obstetrician-gynecologist and the patient about what is in the patient's interest in a way that avoids these two extremes. We develop a framework for clinical judgment and decision making about the ethical dimensions of the obstetrician-gynecologist–patient relationship. To achieve this goal, we first define ethics, medical ethics, and the fundamental ethical principles of medical ethics, beneficence, and respect for autonomy. Second, we show how these two principles should interact in gynecologic clinical judgment and practice. Third, we show how these two principles should interact in obstetric judgment and practice, emphasizing the example of cesarean delivery. Fourth, we examine ethical issues in managed care, emphasizing the virtues of the physician as a professional. We emphasize a preventive ethics approach that appreciates the potential for ethical conflict and adopts ethically justified strategies to prevent those conflicts from occurring. Preventive ethics helps to build and sustain a strong physician–patient relationship.

ETHICS, MEDICAL ETHICS, AND ETHICAL PRINCIPLES

Ethics is the disciplined study of morality and draws on the disciplines of the humanities, especially philosophy. Medical ethics is the disciplined study of morality in medicine and concerns the obligations of physicians and health care organizations to patients, as well as the obligations of patients. It is important not to confuse ethics with the many sources of morality in a pluralistic society. These include, but are not limited to, law, our political heritage as a free people, the world's religions (most of which now exist in our country), ethnic and cultural traditions, families, the traditions and practices of medicine (including medical education and training), and personal experience. These sources of morality are useful reference points for ethical inquiry.

The traditions and practices of medicine, including education and training, constitute an obvious source of morality for physicians. They provide an important reference point for ethics in medicine, because they are based on the obligation to protect and promote the interests of the patient. This obligation tells physicians what morality in medicine ought to be, but in very general, abstract terms. Providing a more concrete, clinically applicable account of that obligation is the central task of medical ethics.

To make concrete the general obligation of protecting and promoting the interests of the patient, medical ethics focuses on the question of “How *ought* the physician conduct himself or herself with patients?” Among relevant tools of ethics for answering this question are ethical principles, because they help the physician to interpret and implement his or her general moral obligation to protect and promote the interests of the patient, which has been the traditional moral foundation of the physician–patient relationship.

Principle of Beneficence

The principle of beneficence requires one to act in a way that is expected reliably to produce the greater balance of goods over harms in the lives of others. To put this principle into clinical practice requires a reliable account of the goods and harms relevant to the care of the patient and of how those goods and harms should be reasonably balanced against each other when not all of them can be achieved in a particular clinical situation, such as a request for an elective cesarean delivery. In medicine, the principle of beneficence requires the physician to act in a way that is expected to produce reliably the greater balance of clinical goods over harms for the patient.

Beneficence-based clinical judgment has an ancient pedigree, with its first expression found in the Hippocratic Oath and accompanying texts. It makes an important claim: to interpret reliably the interests of the patient from medicine's perspective. This perspective is provided by accumulated scientific research, clinical experience, and reasoned responses to uncertainty. It is thus not the function of the individual clinical perspective of a particular physician and therefore should not be based merely on the clinical impression or intuition of an individual physician.

On the basis of this rigorous clinical perspective, which should be evidence based as often as possible, beneficence-based clinical judgment identifies the goods that can be achieved for the patient in clinical practice based on the competencies of medicine. The goods that medicine is competent to seek for patients are the prevention and management of disease, injury, handicap, and unnecessary pain and suffering and the prevention of premature or unnecessary death. Pain and suffering become unnecessary when they do not result in achieving the other goods of medical care, for example, allowing a woman to labor without effective analgesia.

There is an inherent risk of paternalism in beneficence-based clinical judgment. By this we mean that beneficence-based clinical judgment, if it is *mistakenly* considered to be the sole source of moral responsibility and, therefore, moral authority in medical care, invites the unwary physician to conclude that beneficence-based judgments can be imposed on the patient in violation of her autonomy. Paternalism is a dehumanizing response to the patient and, therefore, should be avoided in the practice of obstetrics and gynecology.

The preventive ethics response to this inherent paternalism is for the physician to explain the diagnostic, therapeutic, and prognostic reasoning that leads to the clinical judgment about what is in the interest of the patient so that the patient can assess that judgment for herself. This general rule can be put into clinical practice in the following way. The physician should disclose and explain to the patient the major factors of this reasoning process, including matters of uncertainty. (Note that this does not require that the patient be provided with a complete medical education.) The physician should then explain how and why other clinicians might reasonably differ from this clinical judgment. The physician should then present a well-reasoned response to this critique. The outcome of this process is that beneficence-based clinical judgments take on a rigor that they sometimes lack, and the process of their formulation includes explaining them to the patient. It should be apparent that beneficence-based clinical judgment frequently will result in the identification of a continuum of clinical strategies that protect and promote the patient's interests, such as the choice of a particular method of contraception. Awareness of this feature of beneficence-based clinical judgment provides an important preventive ethics antidote to paternalism by increasing the likelihood that one or more of these medically reasonable, evidence-based alternatives will be acceptable to the patient. This feature of beneficence-based clinical judgment also provides a preventive ethics antidote to “gag” rules that restrict physician's communications with the managed care patient. All beneficence-based alternatives must be identified and explained to all patients, regardless of how the physician is paid, especially those that are well

established in evidence-based obstetrics and gynecology.

The process of explaining beneficence-based clinical judgment enhances the patient's ability to understand and deal effectively with the technical aspects of medical care, an important consideration in obstetric-gynecologic practice (e.g., prophylactic oophorectomy at the time of hysterectomy or the nature and limits of obstetric ultrasonography). Data suggest the need for such enhancement. The Louis Harris survey prepared for the President's Commission on Ethics in Medicine presents an important finding: “The vast majority of physicians report that they address most aspects of the condition and treatment with their patients as a matter of course. This is substantiated by the large majority of the public, who report that their physicians usually discuss these matters with them.” This survey also reports a “large and reliable difference of approximately 15 to 25 percentage points” between the proportion of physicians who report themselves as discussing some aspects of medical care and the proportion of the public who report that their physicians discuss such matters as diagnosis and prognosis, nature and purpose of treatment, pros and cons of the treatment, and side effects. The process of disclosure described above, if adopted as a standard of care, could well close these significant gaps in the care of female and pregnant patients, especially in the managed care setting.

One advantage for the physician in carrying out this approach to communicating with the patient would be, we believe, to increase the likelihood of compliance. This is an especially pertinent consideration in gynecologic practice, in which the patient often must monitor herself for clinical changes (e.g., a woman at risk for ectopic pregnancy) and take an active role in preventive medicine (e.g., breast self-examination) as well as in obstetric practice (e.g., self-observation for unusual weight gain or bleeding). Another advantage would be to provide the patient with a better-informed opportunity to make a decision about whether to seek a second opinion. The approach outlined above should make such a decision less threatening to her physician, who already has shared with the patient the limitations on clinical judgment. A final advantage may be a reduction in the percentage (20%) of physicians who reportedly dismiss patients who disagree with them and in the high percentage (36%) of patients who report that they have stopped using physicians who disagree with them, as reported in the same Louis Harris survey.

Principle of Respect for Autonomy

In contrast to the principle of beneficence, there has been increasing emphasis in the literature of ethics in medicine on the principle of respect for autonomy. This principle requires one always to acknowledge and carry out the value-based preferences of others, unless there is compelling ethical justification for not doing so, (e.g., prescribing antibiotics for viral respiratory infections). The female or pregnant patient increasingly brings to her medical care her own perspective on what is in her interest. The principle of respect for autonomy translates this into autonomy-based clinical judgment. Because each patient's perspective on her interests is a function of her values and beliefs, it is impossible to specify the goods and harms of autonomy-based clinical judgment in advance. Indeed, it would be inappropriate for the physician to do so, because the definition of her goods and harms and their balancing are the prerogative of the patient. Not surprisingly, autonomy-based clinical judgment is strongly antipaternalistic in nature.

To understand the moral demands of this principle, we need an operationalized concept of autonomy to make it relevant to clinical practice. To do this, we identify the following three sequential autonomy-based behaviors on the part of the patient: (a) absorbing and retaining information about her condition and alternative diagnostic and therapeutic responses to it, (b) understanding that information (i.e., evaluating and rank ordering those responses and appreciating that she could experience the risks of treatment), and (c) expressing a value-based preference. The physician has a role to play in each of these. They are, respectively, (a) to recognize the capacity of each patient to deal with medical information (and not to underestimate that capacity), provide information (i.e., disclose and explain all medically reasonable alternatives, supported in beneficence-based clinical judgment), and recognize the validity of the values and beliefs of the patient, (b) not to interfere with but, when necessary, to assist the patient in her evaluation and ranking of diagnostic and therapeutic alternatives for managing her condition, and (c) to elicit and implement the patient's value-based preference.

The legal obligations of the physician regarding informed consent were established in a series of cases during the 20th century. In 1914, *Schloendorff v. The Society of The New York Hospital* established the concept of simple consent, that is whether the patient says “yes” or “no” to medical intervention. To this day in the medical and bioethics literature, this decision is quoted: “Every human being of adult years and sound mind has the right to determine what shall be done with his body, and a surgeon who performs an operation without his patient's consent commits an assault for which he is liable in damages.” The legal requirement of consent further evolved to include disclosure of information sufficient to enable patients to make informed decisions about whether to say “yes” or “no” to medical intervention. There are two legal standards for such disclosure. The professional community standard defines adequate disclosure in the context of what the relevantly trained and experienced physician tells patients. The reasonable person standard, which has been adopted by most states, goes further and requires the physician to disclose “material” information, what the lay person of average sophistication should not be expected to know. This second standard has emerged as the ethical standard, and we therefore urge obstetrician-gynecologists to adopt it. On this standard the physician should disclose to the patient her or the fetus's diagnosis (including a differential diagnosis when that is all that is known), the medically reasonable alternatives to diagnose and manage the patient's condition, and the short-term and long-term benefits and risks of each alternative.

A particularly important dimension of informed consent in practice involves what have come to be known as “advance directives.” Spurred by the famous case of Karen Quinlan in New Jersey in 1976, all states have enacted advance directive legislation.

The basic idea of an advance directive is that a patient, when autonomous, can make decisions regarding her medical management in advance of a time during which she becomes incapable of making health care decisions. The ethical dimensions of autonomy that are relevant here are the following:

1. A patient may exercise her autonomy now in the form of a request for or refusal of life-prolonging interventions.
2. Autonomy-based request or refusal, expressed in the past and left unchanged, remains in effect for any future time during which the patient loses autonomy.
3. That past autonomy-based request or refusal should, therefore, translate into physician obligations at the time the patient becomes unable to participate in the informed consent process.
4. In particular, refusal of life-prolonging medical intervention should translate into the withholding or withdrawal of such interventions, including artificial nutrition and hydration.

The living will is an instrument that permits the patient to make a direct decision, usually to refuse life-prolonging medical intervention in the future. The living will becomes effective when the patient is a “qualified patient,” usually terminally or irreversibly ill, and is not able to participate in the informed consent process as judged by her physician. Court review is not required. Obviously, terminally or irreversibly ill patients who are able to participate in the informed consent process retain their autonomy to make their own decisions. Some states prescribe the wording of the living will and others do not. The physician should become familiar with the legal requirements in his or her own jurisdiction. A living will, to be useful and effective, should be as explicit as possible. The legal basis for the living will is the legal right of self-determination, the right of any competent adult to determine what shall be done to her body. A number of state courts have made it clear that this right extends to the refusal of both hydration and nutrition. The reader should become familiar with hospital policies on advance directives, which should reflect applicable law.

The concept of a durable power of attorney is that any autonomous adult, in the event that that person later becomes unable to participate in the informed consent process, can assign decision-making authority to another person. The advantage of the durable power of attorney for health care is that it applies only when the patient has lost decision-making capacity, as judged by her physician. Court review is not required. It does *not*, as does the living will, require that the patient be terminally or irreversibly ill. However, unlike the living will, the durable power of attorney does not necessarily provide explicit direction, only the explicit assignment of decision-making authority to an identified individual or “agent.” Obviously, any patient who assigns durable power of attorney for health care to someone else has an interest in communicating her values, beliefs, and preferences to that person. The physician can play a facilitating role in this process. Indeed, in order to protect the patient's autonomy, the physician should play an active role in encouraging this communication process so that there will be minimal doubt about whether the person holding durable power of attorney is faithfully representing the wishes of the patient.

The main clinical advantages of these two forms of advance directives are that they encourage patients to think carefully in advance about their request for or refusal of medical intervention and that these directives, therefore, help to prevent ethical conflicts and crises in the management, especially of terminally or irreversibly ill, patients who have decision-making capacity. Unfortunately, the use of advance directives is not as widespread as it should be. The reader is encouraged to think of advance directives as powerful, practical strategies for preventive ethics for end-of-life care and to encourage patients to consider them carefully, especially patients with gynecologic disease—particularly gynecologic cancers—that could become or are life threatening.

INTERACTION OF BENEFICENCE AND RESPECT FOR AUTONOMY IN GYNECOLOGIC JUDGMENT AND PRACTICE

Beneficence-based and autonomy-based clinical judgments in gynecologic practice are usually in harmony (Fig. 58.1). A woman may have an adnexal mass of 10 cm. The gynecologist would explain this diagnostic finding and the potential for malignancy and torsion of the mass, as well as the unlikelihood of spontaneous resolution. In beneficence-based clinical judgment, surgical management provides a clear-cut greater balance of medical goods over harms for the patient, whereas nonsurgical management provides a clear-cut greater balance of medical harms over goods for the patient. Beneficence-based clinical judgment requires a careful explanation of these matters to the patient, with no restriction from managed care gag rules, and supports a definitive recommendation for surgical management. Respect for the patient's autonomy also requires explanation of these matters, but it goes further and obligates the physician to elicit the patient's value-based priorities for the management of the newly diagnosed condition, which almost always coincides with beneficence-based clinical judgment.

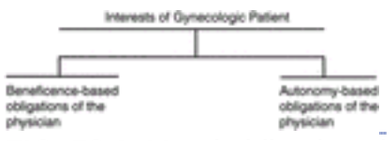

FIG. 58.1. Moral obligations in gynecologic care.

Synergy between beneficence and respect for autonomy occurs when the physician's management plan is carried out in conjunction with the patient's informed consent.

Sometimes, beneficence-based and autonomy-based clinical judgments are in conflict. In situations of conflict, neither beneficence nor respect for autonomy in and of itself should be viewed as a “trump,” to borrow a term from the game of bridge. That is, beneficence does not always override respect for autonomy, nor vice versa. Instead, both principles should be understood as theoretically equally weighted. Thus, their differences must be negotiated in clinical judgment and practice. The competing demands of both principles must be balanced and negotiated in the specific clinical case to determine which management strategies protect and promote the patient's interests. In the technical language of ethics, we are treating these principles as *prima facie* or potentially overridable in nature.

The process of negotiating conflict between the two principles is a function of the following several factors involved in gynecologic clinical judgment: Subject matter, probability of net medical benefit, availability of reasonable alternatives, and the ability of the patient to participate in the informed consent process (Fig. 58.2).

FIG. 58.2. Factors that influence the relative weight of beneficence-based and autonomy-based obligations to the gynecologic patient.

When the subject matter is primarily technical in nature, such as the selection of an effective antibiotic regimen or intraoperative surgical technique, clinical judgment is justifiably beneficence based. This is because technical matters largely concern the evidence-based determination of medical goods and harms for aggregates of patients with a particular diagnosis and treatment plan. Such decisions are justifiably within the gynecologist's purview. The individual values and beliefs of a particular patient cannot readily be taken into account in this process. In contrast, when the patient's basic values and beliefs are at stake, such as the workup or treatment of infertility or elective abortion, clinical judgment is justifiably autonomy based. This is because particular diagnostic or treatment interventions can directly and adversely affect the basic values and beliefs of a particular patient, a matter that only an individual patient can decide. Such decisions are justifiably within the patient's purview.

When the probability of net medical benefit for the patient of diagnostic or therapeutic medical intervention is high, such as chemotherapy for some forms of gestational trophoblastic disease or surgical correction of a prolapsed uterus, beneficence-based clinical judgment is dominant. This is because, in such circumstances, the net benefit is clear-cut. The gynecologist is, therefore, justified in recommending interventions that have a high probability of net medical benefit. By contrast, when that probability is low, such as with experimental therapy for advanced ovarian malignancy or prophylactic oophorectomy at age 40 to 45 years, clinical judgment is justifiably autonomy based. This is because, when there is no clear-cut benefit and significant risks of intervention exist, the patient is in the best position to determine which trade-off makes the most sense. The gynecologist is, therefore, justified in offering these alternatives but not in recommending one as indisputably the best.

When there is no reasonable alternative to manage the patient's condition (e.g., removal of a ruptured ectopic pregnancy or screening for cervical cancer by Pap smears), clinical judgment is appropriately beneficence based, because there is no other alternative that to any degree protects and promotes the interests of the patient. The gynecologist is, therefore, justified in strongly recommending the intervention in question. By contrast, when there are reasonable alternatives, such as surgery versus radiotherapy for stage Ia cervical cancer or a method of contraception versus tubal ligation, clinical judgment is appropriately autonomy based. This is because reasonable alternatives all promote the patient's interests to a significant degree, and no one alternative can exclude any other as unreasonable. The gynecologist is justified in presenting or offering the reasonable alternatives.

When the ability to implement the informed consent process is low, as for a patient with severe or profound mental retardation or in a life-threatening emergency without time for consent, clinical judgment is justifiably beneficence based. This is because it is impossible to determine the patient's relevant values and beliefs because of either significant irreversible cognitive impairment or urgent lack of time. The gynecologist is, therefore, justified in basing clinical decision making primarily on beneficence. By contrast, when the ability of the patient to participate in the informed consent process is not low, as in a speaker of a foreign language or the existence of a legally valid advance directive, then clinical judgment is justifiably autonomy based. This is because the ability of the patient to participate in the informed consent process is presumed in the absence of compelling reasons to the contrary.

As a rule, the result of the informed consent process should be implemented. When the patient refuses to accept any of the alternatives supported in beneficence-based clinical judgment, the physician is ethically and legally obligated to engage in what is known as “informed refusal.” This legal and ethical obligation arises from the 1980 case of *Truman v. Thomas* from California. Dr. Thomas had delivered several of Mrs. Truman's babies and, during the delivery of her last child, recommended that she have a Pap smear. She refused to have this test until she could pay for it and did not accept Dr. Thomas's offer to perform it without charge. Mrs. Truman next visited Dr. Thomas with advanced cervical cancer, from which she died. During the malpractice action brought by her survivors, Dr. Thomas stated that, although they were of clinical concern to him in the management of Mrs. Truman, he did not tell Mrs. Truman of the risks of having detectable presymptomatic changes in her cervix indicative of cervical cancer or that he was concerned that she could die from such disease. The California Supreme Court ruled that, because risks were of clinical salience to Dr. Thomas—they were the motivation for his offering the Pap smear—he should have informed Mrs. Thomas about these risks so that her refusal would be informed. This case changed practice and introduced the concept of informed refusal into medical law and ethics.

The ethical and legal obligation of the physician in the matter of informed refusal is very clear and not difficult to fulfill. The patient should be informed in straightforward, but not harsh or hostile, terms the medical risks that she is taking in her refusal of a diagnostic or therapeutic intervention supported in beneficence-based clinical judgment. The risks to be disclosed are those that are salient in clinical judgment. If they are important to the physician, that is, motivating the offer or recommendation of the diagnostic test or therapy, they are salient and should be disclosed. This discussion should be documented thoroughly in the patient's chart. This is all that the law requires. Good ethical practice suggests strongly that this disclosure should be followed by a recommendation that the patient reconsider her refusal. As a matter of good ethical practice, the physician should respond, in the end, to adamant refusal by offering a trial of respect for the patient's refusal, asking her to return for an office visit, and to reconsider her refusal once she has had some experience with it. This preventive ethics approach avoids the need to abandon the patient, keeps lines of communication open, and sends a powerful ignal of concern by the physician to the patient about the medical folly of her refusal.

Patients' demands for inappropriate management are the reverse side of this coin. We suggest the following preventive ethics strategy in response:

1. Is the intervention reliably expected to have its intended, usual anatomic or physiologic effect? If in reliable, especially evidence-based, beneficence-based clinical judgment it is not expected to do so, then the physician should not offer it. There is no obligation to offer or to perform medical interventions that are futile in this strict sense, such as providing a feeding tube for a patient with cachexia caused by cancer.
2. Is the intervention reliably expected to have some minimal clinical benefit, defined as maintaining some minimal level of ability to interact with the environment and thus grow and develop as a human being? Is the patient in a persistent or permanent vegetative state? If, in reliable beneficence-based clinical judgment, the intervention is not expected to have benefit, then the physician should offer it and then recommend against it. We suggest this approach to respect patients or surrogate decision makers who are vitalists, those who value the preservation of life at any cost. The physician should explain that this is *not* a value in medical ethics and never has been. Moreover, the intervention in question, whether it is initiated or continued, will just sustain a false hope of recovery.
3. If the patient or the patient's surrogate persists in the demand, then the physician should consult with colleagues and then the ethics committee, which should have a clear policy on response to demands by patients or their surrogates for futile intervention.

INTERACTION OF BENEFICENCE AND RESPECT FOR AUTONOMY IN OBSTETRIC CLINICAL JUDGMENT AND PRACTICE

The ethical principles of beneficence and respect for autonomy play a more complex role in obstetric clinical judgment and practice (Fig. 58.3). There are obviously beneficence-based and autonomy-based obligations to the pregnant patient. The physician's perspective on the pregnant woman's interests provides the basis for the physician's beneficence-based obligations to her, whereas her own perspective on those interests provides the basis for the physician's autonomy-based obligations to her. Because of an insufficiently developed central nervous system, the fetus cannot meaningfully be said to possess values and beliefs. Thus, there is no basis for saying that a fetus has a perspective on its interests. There can, therefore, be no autonomy-based obligations to any fetus. Hence, the language of fetal rights has no meaning and therefore no application to the fetus in obstetric clinical judgment and practice, despite its popularity in public and political discourse in the United States and other countries. Obviously, the physician has a perspective on the fetus's health-related interests, and the physician can have beneficence-based obligations to the fetus, *but only when the fetus is a patient.* Because of its importance for obstetric clinical judgment and practice, the topic of the fetus as a patient requires detailed consideration.

FIG. 58.3. Moral obligations in obstetric care.

Two Senses of the Concept of the Fetus as a Patient

The concept of the fetus as a patient is essential to obstetric clinical judgment and practice. Developments in fetal diagnosis and management strategies to optimize fetal outcome have become widely accepted, encouraging the development of this concept. This concept has considerable clinical significance because, when the fetus is a patient, directive counseling (i.e., recommending a form of management) for fetal benefit is appropriate, and when the fetus is not a patient, nondirective counseling (i.e., offering but not recommending a form of management for fetal benefit) is appropriate. However, these apparently straightforward roles for directive and nondirective counseling are often difficult to apply in actual perinatal practice because of uncertainty about when the fetus is a patient. One approach to resolving this uncertainty would be to argue that the fetus is or is not a patient in virtue of personhood, or some other form of independent moral status. We now show that this approach fails to resolve the uncertainty and we, therefore, defend an alternative approach that does resolve the uncertainty.

Independent Moral Status of the Fetus

One prominent approach for establishing whether or not the fetus is a patient has involved attempts to show whether or not the fetus has independent moral status. This is the first sense of the concept of the fetus as a patient. Independent moral status for the fetus means that one or more characteristics that the fetus possesses in and of itself and, therefore, independently of the pregnant woman or any other factor, generate and therefore ground obligations to the fetus on the part of the pregnant woman and her physician.

A striking variety of characteristics have been nominated for this role, such as moment of conception, implantation, central nervous system development, quickening, and the moment of birth. It should come as no surprise that, given the variability of proposed characteristics, there is considerable variation among ethical arguments about when the fetus acquires independent moral status. Some take the view that the fetus has independent moral status from the moment of conception or implantation. Others believe that independent moral status is acquired in degrees, thus resulting in “graded” moral status. Still others hold, at least by implication, that the fetus never has independent moral status so long as it is in utero.

Despite ever-expanding theologic and philosophic literature on this subject, there has been no closure on a single authoritative account of the independent moral status of the fetus. This is an unsurprising outcome because, given the absence of a single method that would be authoritative for all of the markedly diverse theologic and philosophic schools of thought involved in this endless debate, closure is impossible. For closure ever to be possible, debates about such a final authority within and between theologic and philosophic traditions would have to be resolved in a way satisfactory to all, an inconceivable intellectual and cultural event.

We propose to abandon these futile attempts to understand the fetus as a patient in terms of independent moral status of the fetus and turn to an alternative approach that makes it possible to identify ethically distinct senses of the fetus as a patient and their clinical implications for directive and nondirective counseling. In its first sense, that of the independent moral status of the fetus, the fetus as a patient has no stable or clinically applicable meaning. We, therefore, consider a second sense of the concept of the fetus as a patient.

Dependent Moral Status of the Fetus

Our analysis of this second sense of the concept of the fetus as a patient begins with the recognition that being a patient does not require that one possess independent moral status. Rather, being a patient means that one can benefit from the applications of the clinical skills of the physician. Put more precisely, a human being without independent moral status is properly regarded as a patient when the following two conditions are met: that a human being (a) is presented to the physician, and (b) there exist clinical interventions that are reliably expected to be efficacious, in that they are reliably expected to result in a greater balance of clinical goods over harms for the human being in question. This is the second sense of the concept of the fetus as a patient, what we call the dependent moral status of the fetus.

The authors have argued elsewhere that beneficence-based obligations to the fetus exist when the fetus is reliably expected *later* to achieve independent moral status as a child and person. That is, the fetus is a patient when the fetus is presented for medical interventions, whether diagnostic or therapeutic, that reasonably can be expected to result in a greater balance of goods over harms for the child and person the fetus can *later* become during early childhood. The ethical significance of the concept of the fetus as a patient, therefore, depends on links that can be established between the fetus and its later achieving independent moral status.

Viable Fetal Patient

One such link is viability. Viability is not, however, an intrinsic property of the fetus because viability must be understood in terms of both biologic and technologic factors. It is only by virtue of both factors that a viable fetus can exist ex utero and thus achieve independent moral status. Moreover, these two factors do not exist as a function of the autonomy of the pregnant woman. When a fetus is viable, that is, when it is of sufficient maturity that it can survive into the neonatal period and achieve independent moral status given the availability of the requisite technologic support, and when it is presented to the physician, the fetus is a patient.

Viability exists as a function of biomedical and technologic capacities, which are different in different parts of the world. As a consequence, there is no worldwide, uniform gestational age to define viability. In the United States, we believe that viability occurs at approximately 24 weeks of gestational age.

When the fetus is a patient, directive counseling for fetal benefit is ethically justified. In clinical practice, directive counseling for fetal benefit involves one or more of the following: recommending against termination of pregnancy, recommending against nonaggressive management, or recommending aggressive management. Aggressive obstetric management includes interventions such as fetal surveillance, tocolysis, cesarean delivery, and delivery in a tertiary care center when indicated. Nonaggressive obstetric management excludes such interventions. Directive counseling for fetal benefit, however, must take account of the presence and severity of fetal anomalies, extreme prematurity, and obligations to the pregnant woman.

It is very important to appreciate in obstetric clinical judgment and practice that the strength of directive counseling for fetal benefit varies according to the presence and severity of anomalies. As a rule, the more severe the fetal anomaly, the less directive counseling should be for fetal benefit. In particular, when lethal anomalies such as anencephaly can be diagnosed with certainty, there are no beneficence-based obligations to provide aggressive management. Such fetuses are dying patients, and the counseling, therefore, should be nondirective in recommending between nonaggressive management and termination of pregnancy, but directive in recommending against aggressive management for the sake of maternal benefit. By contrast, third-trimester abortion for Down syndrome or achondroplasia is not ethically justifiable, because the future child has a high probability of growing and developing as a human being.

The strength of directive counseling for fetal benefit in cases of extreme prematurity of viable fetuses does not vary. In particular, this is the case for what we term just-viable fetuses, those with a gestational age of 24 to 26 weeks, for which there are significant rates of survival but high rates of mortality and morbidity. These rates of morbidity and mortality can be increased by nonaggressive obstetric management, whereas aggressive obstetric management may influence outcome favorably. Thus, it appears that there are substantial beneficence-based obligations to just-viable fetuses to provide aggressive obstetric management. This even more the case in pregnancies beyond 26 weeks of gestational age. Therefore, directive counseling for fetal benefit is justified in all cases of extreme prematurity of viable fetuses, considered by itself. Of course, such directive counseling is appropriate only when it is based on documented efficacy of aggressive obstetric management for each

fetal indication. For example, such efficacy has not been demonstrated for routine cesarean delivery to manage extreme prematurity.

Any directive counseling for fetal benefit must occur in the context of balancing beneficence-based obligations to the fetus against beneficence-based and autonomy-based obligations to the pregnant woman (see Fig. 58.3). Any such balancing must take into account that a pregnant woman is obligated only to take reasonable risks of medical interventions that are reliably expected to benefit the viable fetus or child later. A unique feature of obstetric ethics is that the pregnant woman's autonomy influences whether, in a particular case, the viable fetus ought to be regarded as having been presented to the physician.

Obviously, any strategy for directive counseling for fetal benefit that takes account of obligations to the pregnant woman must be open to the possibility of conflict between the physician's recommendation and a pregnant woman's autonomous decision to the contrary. Such conflict is best managed preventively through the informed consent process as an ongoing dialogue throughout a woman's pregnancy, augmented as necessary by negotiation and respectful persuasion.

Previable Fetal Patient

The only possible link between the previable fetus and the child it can become is the pregnant woman's autonomy. This is because technologic factors cannot result in the previable fetus becoming a child. The link, therefore, between a fetus and the child it can become when the fetus is previable can be established only by the pregnant woman's decision to confer the status of patient on her previable fetus. The previable fetus, therefore, has no claim to the status of patient independently of the pregnant woman's autonomy. The pregnant woman is free to withhold, confer upon or, having once conferred, withdraw the status of patient from her previable fetus according to her own values and beliefs. The previable fetus is presented to the physician solely as a function of the pregnant woman's autonomy.

Counseling the pregnant woman regarding the management of her pregnancy when the fetus is previable should be nondirective in terms of continuing the pregnancy or having an abortion if she refuses to confer the status of patient on her fetus. If she does confer such status in a settled way, at that point beneficence-based obligations to her fetus come into existence, and directive counseling for fetal benefit becomes appropriate. Just as for viable fetuses, such counseling must take account of the presence and severity of fetal anomalies, extreme prematurity, and obligations owed to the pregnant woman.

For pregnancies in which the woman is uncertain about whether to confer such status, the authors propose that the fetus be *provisionally* regarded as a patient. This justifies directive counseling against behavior that can harm a fetus in significant and irreversible ways, such as substance abuse, especially alcohol, until the woman settles on whether to confer the status of patient on the fetus.

In particular, nondirective counseling is appropriate in cases of what we term *near-viable fetuses*, those that are 22 to 23 weeks of gestational age, for which there are anecdotal reports of survival. In our view, aggressive obstetric and neonatal management should be regarded as clinical investigation (i.e., a form of medical experimentation), not a standard of care. There is no obligation on the part of a pregnant woman to confer the status of patient on a near-viable fetus, because the efficacy of aggressive obstetric and neonatal management has yet to be proven.

In Vitro Embryo Patient

A subset of previable fetuses as patients concerns the in vitro embryo. It might seem that the in vitro embryo is a patient because such an embryo is presented to the physician. However, for beneficence-based obligations to a human being to exist, medical interventions must be reliably expected to be efficacious.

Recall that, in terms of beneficence, whether the fetus is a patient depends on links that can be established between the fetus and its eventual independent moral status. Therefore, the reasonableness of medical interventions on the in vitro embryo depends on whether that embryo later becomes viable. Otherwise, no benefit of such intervention can meaningfully be said to result. An in vitro embryo, therefore, becomes viable only when it survives in vitro cell division, transfer, implantation, and subsequent gestation to such time that it becomes viable. The process of achieving viability occurs only in vivo and is, therefore, entirely dependent on the woman's decision regarding the status of the fetus as a patient, should assisted conception successfully result in the gestation of the previable fetus. Whether an in vitro embryo will become a viable fetus, and whether medical intervention on such an embryo will benefit the fetus, are both functions of the pregnant woman's autonomous decision to withhold, confer upon or, having once conferred, withdraw the moral status of patient from the previable fetus that might result from assisted conception.

It, therefore, is appropriate to regard the in vitro embryo as a previable fetus rather than as a viable fetus. As a consequence, any in vitro embryo should be regarded as a patient only when the woman into whose reproductive tract the embryo will be transferred confers that status. Thus, counseling about preimplantation diagnosis should be nondirective. Preimplantation diagnostic counseling should be nondirective because the woman may elect not to implant abnormal embryos. These embryos are not patients, so there is no basis for directive counseling. Information should be presented about prognosis for a successful pregnancy and the possibility of confronting a decision about selective reduction, depending on the number of embryos transferred. Counseling about how many in vitro embryos should be transferred should be rigorously evidence based.

When to Offer, Recommend, and Perform Cesarean Section

When to offer, recommend, and perform cesarean delivery is a common clinical ethical challenge in day-to-day obstetric practice, a challenge that will only increase with the growing influence of managed care and widespread quality assurance in hospitals. In this section we provide an ethically justified and clinically comprehensive algorithm for offering, recommending, and performing cesarean delivery, with particular reference to managed care, based on the ethical principles of beneficence and respect for autonomy and the concept of a fiduciary (Fig. 58.4 and Fig. 58.5).

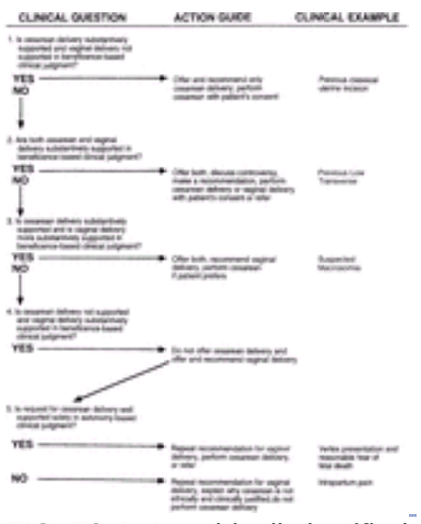

FIG. 58.4. An ethically justified, clinically comprehensive algorithm for offering, recommending, and performing cesarean delivery. (From Chervenak FA, McCullough LB. Identification and management of ethical conflict in the patient–gynecologist relationship. J Reprod Med 1993;38:553–557, with permission.)

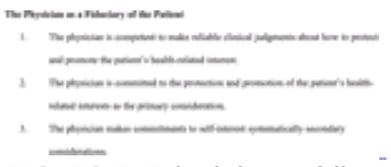

FIG. 58.5. Principles guiding the physician acting as patient fiduciary.

Our algorithm has five questions that define five clinical categories and begins by asking, “Is cesarean delivery substantively supported and vaginal delivery not supported in beneficence-based clinical judgment?” For example, when there is a previous classic incision in the uterus, cesarean is clearly preferable to vaginal delivery because cesarean prevents the fetal and maternal risk of a ruptured classic incision in up to 12% of cases. Vaginal delivery in these circumstances would result in a substantial increase in maternal and fetal morbidity and mortality. Because vaginal delivery involves unnecessary and preventable harms that are both quantitatively and qualitatively important, and cesarean prevents these harms, no well-founded beneficence-based clinical judgment could support offering vaginal

delivery to a woman with a previous classic uterine incision. Only cesarean delivery should be offered and recommended to such patients. With the patient's consent, it should then be performed.

The second question concerns those clinical circumstances, such as previous low transverse uterine incisions, in which there is scientific controversy as to whether elective cesarean delivery is the better alternative. There are competing well-founded beneficence-based clinical judgments regarding how to balance the fetal benefit of preventing harm against the maternal risks associated with cesarean delivery. Whenever multiple management strategies are supported substantively in beneficence-based clinical judgment, all should be offered to the pregnant woman so that she can exercise her autonomy meaningfully. Such disclosure empowers the woman to emphasize her own perspective in balancing maternal and fetal risks. Not offering all management options substantively supported in beneficence-based clinical judgment is an unjustified form of paternalism. It is ethically appropriate to offer and perform either cesarean or a trial of vaginal delivery. A physician is justified in making a recommendation based on his or her evaluation of the controversy.

The third question concerns clinical circumstances when cesarean delivery is substantively supported in beneficence-based clinical judgment, but attempted vaginal delivery is supported more substantively. Attempted vaginal delivery is the better alternative but not the only one, as in the case of suspected macrosomia in the absence of certain factors such as diabetes. Clinical and sonographic prediction of macrosomia is not precise. Although cesarean is supported substantively in beneficence-based clinical judgment, trial of labor is supported more substantively. To avoid unjustified paternalism, both cesarean and a trial of vaginal delivery should be offered. Because a trial of vaginal delivery is the better option, it should be recommended. In addition, a cesarean is also supported substantively in beneficence-based clinical judgment, so it is justified to perform a cesarean if that is the patient's preference.

In the authors' view, in most remaining cases the woman should not routinely be offered cesarean delivery, because beneficence-based clinical judgment supports that vaginal delivery is appropriate and cesarean delivery is not appropriate (the fourth question). Cesarean delivery involves a quantitative increase of risks of unnecessary and preventable maternal morbidity and mortality, risks that are decreased by vaginal delivery. The qualitative nature of the unnecessary and preventable risks of cesarean delivery looms large in this beneficence-based calculus. As a consequence, it is not ethically justified to offer cesarean delivery, and only vaginal delivery should be offered and recommended routinely. If evidence accumulates that vaginal delivery poses a long-term risk to some women's health, such as damage to the pelvic floor, then it would be justified to offer and discuss cesarean delivery as a reasonable alternative. That is, this patient population should be managed under question three, even question two, depending on the strength of the evidence.

In rare cases (question five), patients request cesarean delivery not indicated on beneficence-based grounds, raising the challenging concept that autonomy-based indications in limited and rare circumstances can be well supported. For example, one of us (FAC) approved a cesarean delivery for a patient who expressed a legitimate fear of spontaneous fetal death and for whom there were no maternal contraindications to cesarean. She understood and accepted the maternal morbidity and mortality associated with cesarean delivery. An effort was made to dissuade the patient, but she considered and rejected it. A patient's preference that is based on deeply held values that are reaffirmed after a serious attempt to change her decision meets the test for being well supported in autonomy-based clinical judgment.

We can now answer a question that Feldman and Freiman asked more than 10 years ago: “If an informed patient opts for prophylactic cesarean section at term, can it be denied?” If such a request is well supported in autonomy-based clinical judgment, which will be rare, it should be carried out by the physician, or an appropriate referral should be made. Feldman and Freiman also suggested that patients should be informed of the “very real risks associated with the passive anticipation of vaginal delivery after fetal maturity has been reached.” However, we conclude that this obligation does not exist, because an affirmative answer makes the incorrect assumption that cesarean delivery is supported in beneficence-based clinical judgment.

Well-supported requests for cesarean delivery contrast with those that are not well supported in autonomy-based clinical judgment (i.e., when the goals expressed in the patient's preference for cesarean can be achieved without delivering by cesarean). For example, a woman who is in pain during labor may request cesarean delivery for relief of the pain. However, this goal can be achieved by administration of analgesia, whereas cesarean delivery for pain relief will result in more pain and unnecessary risk of morbidity and mortality. The preference is internally inconsistent and, therefore, not well supported in autonomy-based clinical judgment.

On the basis of our algorithm, there are four ethical indications for cesarean delivery as follows: (a) when it is the only reasonable alternative in beneficence-based clinical judgment, (b) when it is the more substantively supported in beneficence-based clinical judgment, (c) when it is substantively supported in beneficence-based clinical judgment and the patient prefers it, and (d) when it is well supported in autonomy-based clinical judgment, a purely autonomy-based but rare indication.

This algorithm underscores the importance of the professional integrity of the physician's role in the informed consent process. In some clinical situations, such as a previous low transverse uterine incision, there are advantages of elective repeat cesarean delivery for the physician, including time saved, convenience, and possibly increased remuneration. It is a clear and unacceptable violation of the professional integrity of the physician's role in the informed consent process for the physician to distort this process in pursuit of such personal, not professional, advantages.

One business strategy of managed care models is to impose shared economic risk on the physician and sometimes on the patient, with a view toward influencing both to use resources with economic efficiency. Strategies such as capitation for covered lives will put the economic interests of obstetricians and other physicians at risk every time they use a costly surgical intervention such as cesarean delivery. On the basis of our algorithm, the response of the physician always should be to offer a cesarean delivery when it is substantively supported in beneficence-based clinical judgment (i.e., when question one, two, or three in our algorithm of Figure 58.4 is answered in the affirmative). Gag rules, in contrast, are inconsistent with good ethical practice.

We believe the doctor and the patient should be insulated from shared economic risk when the first clinical question is answered in the affirmative because vaginal delivery would fall below standard of care, and managed care providers, like physicians, are fiduciaries of patients. As such, physicians are obligated ethically not to practice below standard of care, which is established by beneficence-based clinical judgment. Physicians who recommend cesarean delivery in response to clinical question two should negotiate payment plans that insulate them from risk when no one else is available to deliver breech-presenting infants vaginally. This is because economic attempts to resolve genuine clinical controversies in any specialty are scientifically arbitrary and, therefore, inconsistent with the integrity of medicine as a profession.

Payment for cesarean delivery in response to question three is ethically complex. Managed care organizations (MCOs) want the lowest possible rate of cesareans, yet an ethically more important consideration is that physicians have fiduciary obligations to be advocates for their patients. For example, some women are justifiably averse to a trial of vaginal delivery after low transverse cesarean delivery and cannot be persuaded to change their decision. Such factors justifiably influence the definition of the lowest acceptable rate of cesarean delivery. The imposition of shared economic risk is an ethically acceptable strategy only when physicians take the leading role in defining an acceptable cesarean delivery rate for this clinical circumstance. To do otherwise violates the integrity of medicine as a profession.

For cesarean delivery and other procedures that are performed in the clinical circumstances of question five (see Fig. 58.4), physicians should negotiate payment arrangements that require the patient to bear all the economic risk, because the indication for the procedure is solely autonomy based. Managed care plans and other payers have an ethical obligation as fiduciaries to provide care that is consistent with well-formed beneficence-based clinical judgment. Claims on resources that are based solely on autonomy and not on beneficence are, in principle, limited. It follows that patients have, at best, disputable claims on such resources when the indication for their use is purely autonomy based. In general, when the only justification for a procedure or other use of resources is autonomy based, physicians are justified in negotiating payment arrangements that shift some, or even all, economic risk to the patient.

Shared economic risk should have no effect on offering and recommending procedures that are substantively supported in beneficence-based clinical judgment. This aspect of the informed consent process should be kept immune from shared economic risk by managed care companies. The physician's role as the fiduciary of the patient in advocating ethically defensible degrees of shared economic risk cannot be overemphasized. In our view, the degree of shared economic risk should be nonexistent for clinical questions one through four and imposed entirely on patients who want cesarean delivery for question five (see Fig. 58.4).

MANAGED CARE AND THE VIRTUES OF THE OBSTETRICIAN-GYNECOLOGIST

In the previous sections we have made reference to managed care. In this section we provide a more detailed analysis of the ethics of managed care, with particular reference to the virtues of the obstetrician-gynecologist. The practice of obstetrics and gynecology is coming under managed care, which involves a set of strategies used by both private and public payers to control the cost of medical care. Two main business tools are used to achieve this goal, creating (a) conflicts of interest in how physicians are paid, diplomatically called *sharing economic risk*, and (b) increasingly strict control of clinical judgment and practice through such means as practice guidelines, critical pathways, physician report cards, and retrospective chart review. These business tools generate ethical challenges to obstetrician-gynecologists that seriously threaten the virtues that define the fiduciary character of medicine as a profession.

The physician-fiduciary, as a primary consideration, is expected as a matter of routine and habit to fulfill obligations to protect and promote patients' interests rather than pursue one's own interests. Virtues are those traits and habits of character that routinely focus the concern and behavior of an individual on the interests of others and thereby habitually blunt the motivation to act on self-interest as the physician's primary consideration. We believe that four virtues constitute the physician–patient relationship based on the physician as fiduciary.

The first virtue is *self-effacement.* This requires the physician not to act on the basis of potential differences between the patient and the physician such as race, religion, national origin, education, gender, manners, socioeconomic status, hygiene, or proficiency in speaking English. Self-effacement prevents biases and prejudices arising from these differences that could adversely impact on the plan of care for the patient.

The second virtue is *self-sacrifice.* This requires physicians to accept reasonable risks to themselves. As one example, physicians manifest this virtue in their willingness to care for patients with infectious diseases such as tuberculosis, hepatitis, and human immunodeficiency virus infection, all of which are a potential threat to the physician's health. In both fee-for-service and managed care, this virtue of self-sacrifice obligates the physician to turn away from economic self-interest and focus on the patient's need for relief when the two are in conflict.

The third virtue, *compassion*, motivates the physician to recognize and seek to alleviate the stress, discomfort, pain, and suffering associated with the patient's disease and illness. Self-effacement, self-sacrifice, and compassion provide the basis for a powerful ethical response to the business tool of conflicts of interest by the physician.

This response is strengthened by the fourth virtue, *integrity.* This virtue imposes an intellectual discipline on the physician's clinical judgments about the patient's problems and how to address them. Integrity prescribes rigor in the formation of clinical judgment. Clinical judgment is rigorous when it is based on the best available scientific information or, when such information is lacking, consensus clinical judgment and on careful thought processes of an individual physician that can withstand peer review. In settings that lack such quality control mechanisms, physicians confront a powerful incentive to make the pursuit of remuneration via fee-for-service the primary consideration. Integrity is thus an antidote to the pitfalls of bias, subjective clinical impressions, and unexamined clinical common sense that can undermine evidence-based practice. Integrity provides the basis for the physician's ethical response to the business tool of control of clinical judgment and practice.

None of these four virtues is absolute in its ethical demands. The task of medical ethics is to identify both the application and the limits of these four virtues. The concept of legitimate self-interest provides the basis for these limits. Legitimate self-interest includes protecting the conditions for practicing medicine well, fulfilling obligations to persons in the physician's life other than the patient, and protecting activities outside the practice of medicine that the physician finds deeply fulfilling.

Managed Care and the Physician as Fiduciary

Fee-for-service unconstrained by fiduciary obligations could and did lead to harm to patients from nonindicated over-utilization of resources. It is a violation of the standard of care to subject patients to unnecessary active intervention in order to achieve personal economic gain.

Managed care unconstrained by fiduciary obligations puts patients at risk of harm by denying access to the standard of care. This will occur if patients are subjected to unnecessary risk from withholding appropriate care and intervention in order to achieve economic efficiency. A primary goal of managed care is to achieve this economic efficiency through price competitiveness in order to retain and grow market share.

Financial incentives to the physician and supervision of clinician decision making with strict controls of utilization of services are the business tools managed care uses. Forms of payment by managed care plans, such as capitation and withhold, deliberately impose an economic conflict of interest on the physician. Every time the physician uses a resource, such as consultation, diagnostic testing, or surgical procedures, the physician pays an economic penalty. The ethical challenge occurs when the patient's interests are subordinated to the pursuit of financial rewards and thereby harmed by this under-utilization. This conflict of interest becomes actual when a physician signs such a payment contract.

The physician's decision in signing contracts is subject to considerations of legitimate self-interest. For example, failure to sign a contract with a plan that has captured 20% of one's patients will result in a significant loss of income that the physician may not be able to replace through other contracts. Because there is usually an excess of physician supply in large markets, physicians as suppliers who fail to sign contracts in a buyer's market do so at their economic peril. Therefore, rational calculation of one's legitimate concern to protect income from significant reduction may strongly incline a physician to sign virtually every contract presented as a matter of prudent protection of legitimate self-interest.

However, the virtue of self-sacrifice prohibits the physician from making the avoidance of such financial risk the *primary* consideration. Avoiding financial risk as one's *primary* consideration involves an ethically pathologic process that leads naturally and quickly to the abandonment of self-effacement (economically driven managed care for some patients but not for others), compassion (patients' health-related concerns do not matter but are only a means to maximize revenues), and integrity (the standard of care is sacrificed to maximize revenues). Importantly, physicians are not sanctioned by society to engage in the destruction of medicine as a fiduciary profession.

Adhering to the demands of the virtues provides the antidote to this unacceptable sequence of ethical failure. Physicians should negotiate changes in payment contracts to make economic conflicts of interest as manageable as possible. It is not realistic to call for elimination of conflict of interest, as some have done. It is important to recall that fee-for-service involves conflicts of interest that also cannot be eliminated.

Physicians should not assume that MCOs are unwilling to negotiate contracts to reduce the severity of economic conflicts of interest. Physicians should, therefore, make a good faith effort to negotiate these matters. If the MCO refuses to negotiate and the economic risk of not signing the contract is significant, then the physician should voluntarily accept the ethical responsibility to be alert to and manage these conflicts of interest well. First, integrity requires that the physician avoid the self-deception of underestimating any potential influence on clinical judgment and practice by the conflict of interest. Second, once these contracts are signed, the virtues add an important dimension to total quality management: diligent monitoring of conflicts of interest to prevent them from resulting in substandard care should be among the physician's “accountabilities.” Third, the realities of managed care mean that, for the near term at least, increasing financial sacrifice may be required to protect the integrity of medicine as a fiduciary profession. Fourth, in group practice, there should be a fair sharing of economic self-sacrifice. In particular, individual efforts to tune the system to one's economic advantage in a group, for example, avoiding the care of high-risk pregnancies, and to the disadvantage of colleagues should be avoided.

The second business tool of managed care, increasingly strict control of clinical judgment and practice, is a heterogeneous phenomenon. Some managed care plans are poorly capitalized and poorly managed. They compete by price, with little or no attention given to the quality of their services. A “bottom line” mentality dominates, with economic savings and net revenue maximization the overriding values. These poorly managed companies have little or no understanding of or interest in the fiduciary nature of medicine, so their controls of clinical judgment and practice are driven almost entirely by economic considerations.

Physicians subject to management controls by such companies face the very difficult challenge of trying to get such companies to constrain their economic interests by their fiduciary obligations, a daunting task but not, we believe, an impossible task. The concerns of ethics, especially to protect the integrity of the fiduciary enterprise, may be swept aside frequently when they are not ignored altogether. Nonetheless, physicians in such MCOs are the ultimate bulwark on which patients and society must be able to rely to protect patients from management's unbridled pursuit of economic self-interest. Physicians, therefore, should strenuously resist and seek to change management controls driven solely by economic considerations. Evidence-based medicine is a powerful tool for achieving this goal. If physicians refused to cooperate with such poorly managed companies, systematic dissociation would result in a loss of market share or, more optimistically, better management.

Antitrust legislation needs to be changed to permit group responses to this kind of MCO. We realize that this may not be a politically realistic proposal. Antitrust legislation may legally prevent physicians from banding together to deal with this problem. Thus, regulatory relief through state and federal governments becomes an ethically justified strategy to stop the abuse of these plans.

There is a contrast that provides a cause for optimism. Well-managed and well-capitalized plans can be as much concerned with quality as with economic efficiency. The trend of some large Fortune 500 employers to require National Committee on Quality Assurance certification will reinforce the importance of quality. The virtues, as we have shown above, have an important role to play in the definition of quality. The concept of quality should be expanded beyond the usual measures of morbidity, mortality, and customer satisfaction to include monitoring for and managing threats to the fiduciary character of medicine.

One approach to doing so concerns the development and use of practice guidelines, an important form of evidence-based medicine. It appears that well-managed plans will rely increasingly on this as their primary business tool rather than the strategy of creating conflicts of interest with its disruptive and demoralizing effects. Nonetheless, practice guidelines pose a number of ethical concerns.

First, guidelines have the potential to impede economic efficiency, an important value of all MCOs. Economically inefficient plans are threatened with significant loss of market share or even extinction through local market competition by MCOs competing solely by price.

Second, every step of a guideline absorbs monetary resources that would otherwise be available for, among other purposes, physician remuneration, or return to investors in the case of for-profit plans. An interest in job security and maximizing income could, therefore, subtly enter into physicians' judgments about the value of

deleting, adding, or altering diagnostic and therapeutic steps to a guideline. As a consequence, uncertainty about whether a particular step of a guideline adds clinical value may lead to the elimination of that step if doing so increases economic efficiency. This subtle form of conflict of interest should be monitored closely so that the virtues of integrity and self-sacrifice are not unduly threatened.

Third, curtailment of steps in a guideline also might result in physicians concentrating only on the clinical care for which they have direct and immediate answers. The failure to pursue unanswered questions may result in less complete care and failure to develop new clinical competencies, a long-term negative effect on the standard of care.

The integrity of medicine as a fiduciary enterprise justifies, indeed requires, practice guidelines that acknowledge the heterogeneity of patients' conditions and the natural history of diseases and their management, to avoid inadvertent and preventable harm to patients' interests. In defense of such guidelines, which must be as scientifically rigorous as possible—integrity requires this, too—physicians will be obligated by the virtue of integrity to take the unpopular and, at times, antibusiness position of defending economic inefficiency as the necessary price of protecting medicine as a fiduciary profession. Failure to do so amounts to willful failure of the physician's fiduciary responsibilities.

Being a physician-controlled MCO provides no immunity against the ethical challenges of the business tools of managed care. These new physician-owned provider entities will not provide a solution in and of themselves to the ethical threats of conflict of interest and control of clinical judgment and practice. The virtue-based arguments we made will apply to these new entities, without exception.

There is no conclusive evidence that preserving medicine as a fiduciary profession is impossible, even given the enormous economic power of MCOs. Ethics teaches us that business and economic power are not absolute and should always be called to account for their consequences. Society has not given MCOs the moral authority or permission to destroy the fiduciary character of medicine as a consequence of the pursuit of economic interest and power. Nor has society given physicians moral authority or permission to cooperate willfully with this destruction. Quite the opposite, society counts on physicians, because ultimately society can count on no one else to preserve and advocate for the fiduciary character of the medical profession.

CONCLUSION

In this chapter we have provided a general ethical framework for both gynecologic and obstetric clinical judgment and practice. Implementing this framework on a daily basis is essential to creating and sustaining the physician–patient relationship in obstetrics and gynecology. This framework emphasizes preventive ethics, an appreciation that the potential for ethical conflict is built into clinical practice and the use of such clinical tools as informed consent and negotiation to prevent such conflict from occurring. We have provided guidelines for preventing conflict about futile management in gynecologic practice and about cesarean delivery in obstetric practice. We have also shown how the virtues provide a basis for a powerful and effective preventive ethics response to the business tools of managed practice.

SUMMARY POINTS

- In clinical decision making, the obstetrician-gynecologist should take account of both beneficence-based and autonomy-based obligations to the patient.
- The obstetrician-gynecologist should discuss the need for advance directives (living will and durable power of attorney) with patients with gynecologic diseases that could become or are life-threatening.
- The viable fetus is a patient, while the previable fetus is a patient as a function of the pregnant woman's decision to confer this status.
- Offering, recommending, and performing cesarean delivery should be based on the obstetrician-gynecologist's beneficence-based and autonomy-based obligations to the pregnant woman and fetal patient.
- The professional virtues of self-effacement, self-sacrifice, compassion, and integrity are essential for the obstetrician-gynecologist to fulfill fiduciary obligations to patients.
- Obstetrician-gynecologists should resist managed care that is driven solely by economic considerations and cooperate with managed care that is based on evidence-based processes and outcomes.

THE RATIONALE FOR EVIDENCE-BASED MEDICINE

Silverman has chronicled a tragic but instructive story of how the goal of medicine to provide health can be thwarted despite the best of intentions. From 1942 to 1954, more than 10,000 children worldwide were blinded because of a relatively minor change in health care practice. In an effort to improve the survival of premature infants, clinicians exposed newborns to high concentrations of oxygen with the unintended but disastrous consequence of retrolental fibroplasia.

The practice of administering high concentrations of oxygen in the first few days of life was initiated largely on the basis of theoretical considerations and was promulgated in pediatric teaching and research centers. As stated by Silverman, “the retrolental fibroplasia catastrophe would not have been extensive if pediatric leaders had insisted that scientific rules of evidence must be satisfied before any new technique in management of premature infants was used in teaching centers” ([1]).

Silverman also cites Eugene Braunwald, who has likened the dissemination of medical techniques before proper evaluation “to a genie who has escaped from a bottle—it is virtually impossible to undo the confusion resulting from such unrestrained therapeutic exuberance” ([1]). Once the use of high-concentration oxygen therapy for premature infants was established, stopping the practice took more than a decade of effort.

The example cited has parallels throughout the history of medicine. The practice of medicine into the 16th century was based largely on the teachings of the Greek physician Galen (A.D. 138–201) whose pronouncements were embraced without apparent question for centuries. The 17th century saw some questioning of the authority on which medical practice was based. A glimpse of the state of medicine at that time illustrates why such questioning was needed. As King Charles II of England lay dying in 1685, he was cared for by a dozen or more physicians who administered “an enema containing antimony, sacred bitters, rock salt, mallow leaves, violets, beetroot, chamomile, fennel seed, linseed, cinnamon, cardamom seed, saffron, cochineal and aloes.” When these measures did not succeed, the king's physicians forced “a mixture of Raleigh's antidote, pearl julep, and ammonia” down his throat ([2]).

Not until the 19th and 20th centuries, however, did the questioning of traditional medical authorities lead to major advances. A great leap forward occurred in 1865, when Claude Bernard, a French physiologist, described experimental reasoning in his text *An Introduction to the Study of Experimental Medicine.* This was followed in 1937 with a classic text by A. Bradford Hill describing the use of statistical methods for clinical research.

Randomized controlled trials conducted in the early to mid-20th century clearly indicated the value of basing medical practice on observation and experiment. Perhaps the most dramatic example of randomized controlled trials in that period was the United Kingdom's Medical Research Council's trial of using streptomycin to treat tuberculosis. Streptomycin became available in 1946, but it was in short supply. The Medical Research Council used a portion of existing supplies to test the drug's effectiveness in treating tuberculosis; those patients receiving streptomycin had a clear survival advantage compared to those treated with bed rest.

Once the value of scientific inquiry as the basis for clinical practice had been established, Cochrane argued for an ongoing assessment of the effectiveness of available treatments and services, in part as a matter of social justice. He was concerned that the limited resources for health care in the United Kingdom's National Health Service be efficiently used for effective treatments, thereby enhancing the likelihood that effective treatments would be more widely available. In his classic text, *Effectiveness and Efficiency: Random Reflections on Health Services*, published in 1971 (Cambridge University Press), Cochrane outlined criteria for the evaluation of effectiveness and efficiency in clinical practice. His efforts, along with those of his colleagues at the U.K. Medical Research Council who had conducted early randomized controlled trials, contributed heavily to what is today termed “evidenced-based medicine.”

The need for evidence-based medicine is as apparent in obstetrics and gynecology as it is in other disciplines. Our history includes bloodletting as standard treatment for eclampsia into the 20th century and the persistence of the practice of routine episiotomy to the present despite the lack of evidence supporting the practice. The rapid incorporation of unproven technologies into widespread use has had a major effect on the practice of obstetrics and gynecology. Conversely, some therapies, such as corticosteroid therapy for women at risk of giving birth prematurely, have been underused despite compelling evidence of their effectiveness.

THE PRACTICE OF EVIDENCE-BASED MEDICINE

Clinical epidemiologists at McMaster University participating in the Evidence-based Medicine Working Group have defined evidence-based medicine as “the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients” ([3]). The terms “conscientious” and “judicious” emphasize the need for individualized care. “Conscientious use” requires that evidence be applied consistently when individual circumstances warrant, and “judicious use” requires integration of clinical expertise and evidence to balance risks and benefits of tests and treatments for the individual—based on the individual's circumstance and preferences. By this definition, evidence-based medicine is practiced when clinical expertise is integrated with the best available evidence from a systematic search of the relevant literature. The Working Group further explained that evidence-based medicine “de-emphasizes intuition, unsystematic clinical experience, and pathophysiologic rationale as sufficient grounds for clinical decision-making and stresses the examination of evidence from clinical research” ([4]).

Many clinicians took offense from this latter assertion, claiming that evidence-based medicine advocates not only downplay clinical expertise and pathophysiology, but are promoting cookbook medicine, in which all that is required for optimal clinical decisions is a knowledge of the medical literature. Evidence-based medicine advocates deny that they ever intended this and went on to explain: “Good doctors use both individual clinical expertise and the best available external evidence, and neither alone is enough. Without clinical expertise, practice risks becoming tyrannized by evidence, for even excellent external evidence may be inapplicable to or inappropriate for an individual patient. Without current best evidence, practice risks becoming rapidly out of date to the detriment of patients” ([3]).

As also noted by Sackett and colleagues, evidence-based medicine is not “cookbook” medicine, “cost-cutting” medicine, or restricted to evaluation of randomized trials and meta-analyses ([3]). Evidence-based medicine cannot be “cookbook” because it integrates clinical expertise, patient choice, and external evidence. Successful

integration requires the individualization of therapy; the obstetrician-gynecologist must decide whether information obtained from relevant literature pertains to the individual patient, and the obstetrician-gynecologist and patient must determine which evidence-based therapeutic options are preferable.

Evidence-based medicine is not “cost-cutting” medicine because its focus is not on costs, but on effectiveness and efficiency. The most effective therapy for an individual may also be the most expensive therapy; thus, the practice of evidence-based medicine could lead to increased, not decreased costs. Finally, evidence-based medicine uses proper randomized controlled trials and well-conducted meta-analyses when available. However, the best available evidence in medicine, including obstetrics and gynecology, often comes from observational studies.

Grimes has identified five barriers to technology assessment that apply to evidence-based medicine in general:

1. the unchallenged acceptance of authority
2. the acceptance of new technology without critical appraisal
3. the tendency to let existing dogma prevail
4. pedantry in medical education
5. the practice of medicine by uncontrolled clinical impressions or “the last disaster we encountered or hear about” ([5]).

Haynes and Haines went on to identify some additional barriers as well as possible solutions, shown in Table 59.1.

TABLE 59.1. *Barriers and solutions to the practice of evidence-based medicine*

We will focus on the use of information and abstraction services in this chapter, as these provide valuable, practical resources for practitioners attempting to discern the current best evidence for clinical care decisions.

Debate continues about the extent to which new technologies or treatments should be assessed before being incorporated into practice and where the burden of proof for effectiveness should lie. Should promising new interventions be assumed to be effective until there is evidence they are not, or should they be assumed to be ineffective until there is evidence they are effective? Philosophically, the practitioner of evidence-based medicine will, in most cases, lean toward the latter approach.

A MODEL FOR THE PRACTICE OF EVIDENCE-BASED MEDICINE

The concepts of evidence-based decision making have continued to evolve. Haynes and colleagues proposed the model in Figure 59.1.

FIG. 59.1. An updated model for evidence-based clinical decisions. (From Haynes RB, Devereaux PJ, Guyatt GH. Clinical expertise in the era of evidence-based medicine and patient choice. *ACP Journal Club* 2002;Mar-Apr [*in press*]).

Depending on the circumstances, one component may play a greater role than others in decision making, but ideally, all components are brought into play. The clinical expertise component ensures that the best available evidence is applied to the individual clinical circumstances and in concert with the wishes and likely actions of the patient. This model obviously precludes “the mindless application of rules and guidelines” ([6]).

The discussion of evidence-based medicine is incomplete without recognizing the existence of substantial “gray zones” in clinical practice. As with other medical disciplines, the practice of obstetrics and gynecology includes some clinical questions that can be informed by compelling evidence and many others for which adequate evidence is lacking. As noted by Naylor, “Evidence-based medicine offers little help in the many gray zones of practice where the evidence about risk–benefit ratios of competing clinical options is incomplete or contradictory.” Alternatively, “[w]hat is black and white in the abstract may rapidly become gray in practice, as clinicians seek to meet their individual patients' needs.” ([7]). The latter circumstance is a gray zone potentially embraced by the model of evidence-based medicine presented here. Clinical expertise is required to ensure that evidence is applied in the best interest of individuals—even though it means practicing in a “gray zone.” The former circumstance is clearly a constraint on the practice of evidence-based medicine.

Clinicians frequently and readily make decisions in the absence of compelling evidence. McDonald has argued that such decisions are made by principles, axioms, and ad hoc rules or “heuristics” that should be explicit. Formal characterization of the rules of medical decision making in the absence of evidence or in the presence of inconsistent evidence would provide both clinicians and their patients a better understanding of how medical uncertainty is dealt with.

PUTTING EVIDENCE-BASED MEDICINE INTO PRACTICE

Information to guide medical decision making is proliferating, whereas discretionary time for most clinicians is shrinking. The practice of evidence-based medicine initially required the obstetrician-gynecologist to understand and apply principles of clinical epidemiology, to efficiently search the literature, and to critically appraise the literature in solving clinical problems and making the best possible medical decisions. In recent years, the burden of searching and appraisal has been substantially reduced, for common clinical topics, at least, by the evolution of increasingly robust, evidence-based resources, in which evidence on a given problem is searched for exhaustively, assessed rigorously, and updated frequently. These are especially strong in the area of therapeutic interventions, for example, the Cochrane Library, available on CD and the Internet (http://www.update-software.com/cochrane). The busy obstetrician-gynecologist has three choices in evaluating available evidence and incorporating that evidence into practice:

1. practicing evidence-based medicine independently
2. using evidence-based medical summaries developed by others
3. using evidence-based practice protocols developed by others.

Depending on the topic, time, and evidence-based resources available, the consummate evidence-based practitioner should be able to pursue whichever route seems most likely to be satisfactory to deal with the problem at hand. The latter two approaches are addressed briefly here. The first approach is discussed in detail, as it includes the basic skills needed when no credible evidence-based resource is readily available.

USING EVIDENCE-BASED MEDICAL SUMMARIES

Evidence-based medical summaries go beyond traditional review articles, which have been shown to have little scientific merit. Several levels of summaries now exist, with increasing levels of integration around specific clinical topics. At the top level are resources such as *Clinical Evidence* from the British Medical Journal Publishing Group (http://www.evidence.org/), in which systematic reviews and best available individual studies are summarized for specific clinical topics, including pregnancy and

childbirth and women's health. Below this level, several sources of summaries of studies and systematic reviews exist. For example, there are a number of journals of secondary publication of structured abstracts and clinical commentaries that have been selected based on explicit criteria intended to select valid and clinically important articles. Such criteria eliminate 98% of the clinical literature. Examples of these journals are *ACP Journal Club, Evidence-Based Medicine, Evidence-Based Obstetrics and Gynecology, Evidence-Based Nursing*, and *Evidence-Based Mental Health. Evidence-Based Obstetrics and Gynecology* is published quarterly (http://www.harcourt-international.com/journals/ebog), and covers reproductive endocrinology, infertility, maternal–fetal medicine (including general obstetrics), gynecologic oncology, urogynecology, and general gynecology. *ACP Journal Club, Evidence-Based Medicine*, and *Evidence-Based Nursing* also include broad coverage of women's health issues, but at a less specialized level, and can be accessed electronically (as http://www.acpjc.org/, http://ebm.bmjjournals.com/; http://ebn.bmjjournals.com/, respectively). *ACP Journal Club, Clinical Evidence*, the Cochrane Library, and the Database of Abstracts of Reviews of Evidence, along with MEDLINE and other bibliographic databases, can all be searched individually or simultaneously through Ovid's Evidence-Based Medicine Reviews service, available at most medical and many major hospital libraries, and often available by remote Internet access (e.g., from home and clinic), according to library policy. Of these, the most helpful source of reviews of evidence concerning interventions currently available is the Cochrane Library. This library is described further under “Task 2: Search the Evidence” later in the chapter. A limited number of reviews on topics including diagnostic tests, prognosis, and etiology are available from the other sources listed previously.

Systematic reviews, in contrast to narrative reviews, are intended to answer specific clinical questions in depth. Systematic reviews use explicit methods to assemble relevant studies, critically appraise those studies, and synthesize the studies to address a clinical question. Methods for systematic reviews have been developed to limit systematic error (bias) and random error (chance); the value of a systematic review depends largely on how faithfully these methods have been followed.

When the quantitative results of individual studies in a systematic review are combined using statistical methods, the review is called a meta-analysis. Meta-analysis is increasingly used to summarize the obstetric and gynecologic literature. A properly done meta-analysis can provide a wealth of information for clinical decision making; a poorly conducted meta-analysis can be misleading. Criteria for evaluating the quality of a meta-analysis have been described (Table 59.2).

1. Is the purpose of the study (i.e., the hypothesis) clearly identified and is it an overview of a randomized trial of the treatment you are interested in?
2. Does it include a methods section that describes an active, comprehensive effort to include all relevant studies in the analysis?
3. Were explicit inclusion and exclusion criteria used to specify studies eligible for the meta-analysis?
4. Was there an assessment of publication bias (i.e., bias resulting from reporting only those results that are statistically significant, which tends to overestimate the effect under study)?
5. Was a blinded assessment of individual study quality conducted appropriately and systematically?
6. Were the pooled data appropriate for testing the hypothesis?
7. Were multiple raters used to assess coding? If so, were they blinded and were measures of interrater reliability provided?
8. Were the selection and coding of data based on sound clinical principles or convenience?
9. Was documentation provided that explained how the data were coded and analyzed?
10. Was the comparability of cases and controls assessed?
11. Was heterogeneity testing conducted to assess consistency of results from study to study and reported appropriately?
12. Were results reported in sufficient detail to enable replication of results by the reviewer?
13. Were alternative explanations for observed results considered in the discussion?
14. Were the conclusions generalized appropriately and did they stay within the domain of the literature review?
15. Were guidelines provided for future research?

TABLE 59.2. *Questions to ask in evaluating a published meta-analysis*

Obstetricians-gynecologists using meta-analyses for decision making should be fully aware that the value of the meta-analysis is constrained by the value of the individual studies being synthesized. The use of meta-analysis may inappropriately confer a cloak of respectability around a collection of poor quality studies. A collection of studies of poor quality is nothing more than that. A properly executed and reported review, however, should make the limitations of the studies it summarizes apparent to the careful reader, and provide an accurate assessment of the state of knowledge, even if the knowledge is not as advanced as the user might prefer.

Whether meta-analysis should be restricted to randomized controlled trials has been debated. Proper randomized trials provide better evidence about health care interventions than observational studies. A major purpose of meta-analysis is to increase statistical power. Pooling of data from randomized controlled trials is likely to provide a more precise estimate of a treatment effect than individual trials alone. Pooling observational studies to increase statistical power may introduce bias that is difficult to interpret. Most authorities believe that observational studies should be synthesized separately from randomized controlled trials, if they are synthesized at all.

USING EVIDENCE-BASED PRACTICE PROTOCOLS

Evidence-based practice protocols have been developed to guide clinical decision making. The stages of development of practice protocols are similar to that described for the clinician practicing evidence-based medicine independently. They are:

- defining the problem
- identifying and critically appraising available evidence
- translating the evidence into clinical policy ([8]).

Rules for developing clinical guidelines have been developed by the Institute of Medicine. The Canadian Task Force on Periodic Health Examination established a process to rate the quality of evidence for guideline development that has been adopted by others, including the U.S. Preventive Services Task Force and the American College of Obstetricians and Gynecologists (ACOG).

The general intent of practice guidelines is to “inform medical decisions and to decrease variations in care by systematically influencing clinical decisions” ([9]). However, guidelines may be influenced by the author's intent—whether it is improving quality of care, saving costs, or reducing liability. Regardless of perspective, the common denominator should be policies firmly based on evidence where evidence is available. Whether or not clear evidence is available, the basis on which policy decisions were made should be explicit.

In 1995, ACOG established an evidence-based guidelines process. Guidelines initially called *Practice Patterns* and now called *Practice Bulletins* are based on evidence that is evaluated and graded. Considerations regarding costs are also addressed.

Evidence suggests that, in general, practice guidelines have the potential to improve patient care. Weingarten has argued for careful testing of practice guidelines to determine which improve patient care ([9]). Even good guidelines will become obsolete if not kept up to date, so date of preparation is important to consider.

PRACTICING EVIDENCE-BASED MEDICINE INDEPENDENTLY

The obstetrician-gynecologist who practices evidence-based medicine independently needs to be able to accomplish four basic tasks ([10]):

1. frame the clinical problem into a researchable question
2. design and conduct a thorough search of the literature relevant to the question
3. evaluate the quality of evidence obtained from the literature search and summarize the best available evidence to address the clinical question
4. apply the best available evidence to the care of the individual patient, taking into account each patient's circumstances, values, and preferences.

Education in evidence-based medicine works best if clinical questions arise from current dilemmas in patient care. This technique keeps the level of interest high, the applicability pertinent, and the effort current. Convenient access to a computer for on-line searching is preferable and increasingly powerful, but some searching for some topics may need to take place among journals and textbooks. In this section, we follow one scenario through all four tasks of practicing evidence-based medicine.

Task 1. Ask an Answerable Question

Framing the clinical question is the first and one of the most important steps in practicing evidence-based medicine. The question should be focused and answerable. Sackett and colleagues have suggested that a well-built, answerable question has four parts: a description of the patient or problem, a statement of the intervention

being considered, a statement of the alternative to the intervention, and a description of the desired outcome ([10]). Many times the question will be obvious, such as the starting dose of a new medication, and the resource will be handy, such as a formulary book. Other times, the question will not be clear or there may be several kinds of questions that would apply to a single patient problem. To illustrate how to ask an answerable question, we will present a clinical scenario and follow it through the evidence-based medicine process. The example we have chosen is a question about treatment. Other possible topics for questions include diagnostic tests, prognosis, harm, and the evaluation of guidelines.

Example A 36-year old, gravida 2, para 1 presents to labor and delivery at 31 weeks gestation. She reports leaking fluid for approximately 4 hours. The current pregnancy has been otherwise uncomplicated. Physical examination reveals no signs of infection and confirms membrane rupture. The patient is having a few small, irregular contractions that she cannot feel; fetal heart tones are 120 beats per minute with good variability; her cervix is 2 to 3 cm dilated. For this example, we have constructed the following question, “In patients who have preterm premature rupture of the membranes, would steroid therapy to reduce the complications of prematurity, when compared with observation alone, lead to lower mortality or morbidity from premature delivery?” In our example, the description of the patient is addressed (“in patients who have preterm, premature rupture of membranes”), the intervention being considered is stated (“would steroid therapy to reduce the complications of prematurity”) as is the alternative (“when compared with observation alone”). The question concludes with a description of the desired outcome (“lead to lower mortality or morbidity from premature delivery”). Several different questions can be framed from this clinical scenario. The first question we framed was designed to select a therapy. A question about determining etiology (e.g., “In patients with a pregnancy resulting in preterm premature rupture of the membranes, is a culture for group B *Streptococcus* more likely to be positive compared to patients with rupture of the membranes at term?”) Similarly we could have asked about prevention, such as, “In patients with a history of preterm premature rupture of the membranes, does first trimester screening and treatment for bacterial vaginosis reduce the likelihood of recurrence with subsequent pregnancies relative to no screening and treatment?” Sometimes it may be difficult to identify an answerable question. In other cases there may be more questions than time to answer them. Prioritization would ensure that the most important issue for the patient or the question most likely to be encountered again in clinical practice will be answered.

Task 2. Search for Evidence

Once the question has been framed, the pertinent evidence must be searched. The first step in this task is determining the resource most likely to be helpful in the search. The best resource may differ depending on the question posed. For treatment effectiveness or safety, the most useful and scientifically sound sources will be randomized controlled trials and systematic reviews. If one expects that a sufficient number of randomized trials have been conducted to warrant a useful systematic review, a good initial step to assess questions about treatment would be to search Ovid's Evidence-Based Medicine Reviews and search the Cochrane Library, Clinical Evidence, ACP Journal Club, and MEDLINE simultaneously.

Example The use of steroids for reducing neonatal morbidity has been a recognized therapy since the 1970s and enough clinical trials have been reported that systematic reviews have been published. Thus, we chose to search the Cochrane Library, a database with systematic reviews. After locating the Cochrane Library on the Internet or loading the program from purchased disks, we identify the Cochrane Library introductory page. After clicking on the search icon, we enter the word “steroid” as a key word and the search is initiated by clicking on the search button. At the top of the page, the index lists the types of information available for our search. Under the heading, “systematic reviews,” is a subheading, “complete reviews.” By scrolling down the list under this subheading, we quickly (in less than 1 minute) identify a recent (January 1996) critical review “Corticosteroids prior to preterm delivery.” The Cochrane Library is one of the specialized databases developed by a group of individuals committed to preparing, maintaining, and disseminating systematic reviews of the effects of health care. These systematic reviews use explicitly defined methods to reduce the effects of bias. The Library includes databases of Cochrane and non-Cochrane systematic reviews plus a clinical trials database of over 150,000 entries. Although the database of systematic reviews includes unpublished reports and information not available on MEDLINE, it does not yet cover all clinical areas. Nevertheless, perinatal medicine and many topics in women's health are well represented. The Cochrane Library is available through the Internet (via Ovid's Evidence-Based Medicine Reviews or after subscribing at http://www.ovid.com/) and on CD-ROM from Update Software in Oxford, England, the BMJ Publishing Group in London.

Sources of Evidence

For some questions and clinical problems, systematic reviews or meta-analyses may not be available. In such cases, the searcher will have to identify individual studies, rate these studies for quality, and then synthesize the best available evidence. The largest available source of medical literature is the National Library of Medicine's MEDLINE, a bibliographic database covering materials from 1966 to the present. Facilitated access to millions of articles from more than 3,000 journals has led the way to specialized databases. MEDLINE can be obtained in libraries or purchased through commercial vendors; it is available on-line. Members of ACOG can access MEDLINE through ACOGNET. MEDLINE is also free on the Internet (http://www.ncbi.nlm.nih.gov/pubmed). If one intends to use MEDLINE as a standalone resource, it is generally most expedient to go directly to PubMed. Also, for clinical questions, there is a special screen that provides more evidence-based, clinically relevant searches: http://www.ncbi.nlm.nih.gov:80entrez/query/static/clinical.html — the search, for example, takes about 10 seconds and one of the references identified is the current Cochrane Review.

Example We also conduct a separate search on the MEDLINE main search screen which takes longer to locate publications under the text words “corticosteroids” and “preterm”. Because MEDLINE contains millions of articles and the Cochrane Library contains only systematic reviews, the Cochrane Library, in this case, provides the best available evidence more efficiently. ACOG has a Web site accessible to its members. In addition to MEDLINE, publications of ACOG, including evidence-based *Practice Bulletins*, are available on-line. Similarly, the American College of Physicians (ACP) has a database—directed mainly to internists—derived from structured abstracts and clinical commentaries based on a preestablished methodology that screens out poor evidence (http://www.acpjc.org/). Consensus guidelines offer another potential source of evidence. However, consensus guidelines often provide summaries of evidence without clearly stating how the evidence was obtained and evaluated. The National Institutes of Health (NIH) has a Web site that makes available its consensus guidelines and workshop proceedings (http://odp.od.nih.gov/consensus). The National Guideline Clearinghouse (http://www.guideline.gov/index.asp) includes a broader range of guidelines.
Example Through the Internet, we identify two NIH consensus reports on the use of corticosteroids to reduce morbidity from prematurity. The most recent consensus panel addresses changes in practice from single-dose therapy to multiple-dose therapy. However, the basis for the first NIH report was the Cochrane Library systematic review. A search of the National Guideline Clearinghouse on “preterm and corticosteroids” provides one relevant guideline, “Management of preterm labour” from the Singapore Ministry of Health/National Medical Research Council (Singapore Ministry of Health)/Chapter of Obstetricians and Gynaecologists, Academy of Medicine, Singapore, May 2001.

Task 3. Appraise the Evidence

Once we complete our search for the evidence, we assess both the importance and the validity of the evidence for use of corticosteroids to accelerate fetal lung maturity.

Example The Cochrane systematic review “Corticosteroids prior to preterm delivery” included 18 randomized trials that are of acceptable quality (i.e., meet specified criteria for the elimination of bias, as described in the *Cochrane Collaboration Handbook*, which is included in the Cochrane Library) and that report clinically relevant outcomes. Thus, we found strong evidence on the general subject of using corticosteroids prior to preterm delivery. Our specific question, however, dealt with the use of corticosteroids in the presence of ruptured membranes. The description of study methods in the review was sufficiently detailed to determine that women with preterm, premature rupture of the membranes were not subjects in two of the 18 studies included in the systematic review. We obtain copies of the other 16 reports and determine that five have data on the risk of neonatal respiratory distress syndrome for women with preterm, premature rupture of the membranes at 31 weeks gestation and who had corticosteroids administered without other interventions. We used SAS to calculate the relative risks. Together, these five reports provide support for use of corticosteroids among such women. The summary risk estimate of neonatal respiratory distress syndrome for women who had corticosteroids administered relative to the risk in women who did not have corticosteroids administered is 0.58 (95% confidence interval, range: 0.44–0.76) (Table 59.3). Because the 95% confidence interval does not overlap 1.0, the reduction in risk for women who had corticosteroids administered is tatistically significant.

TABLE 59.3. *Selected studies [a] of the effect of corticosteroids after prelabor rupture of the membranes on respiratory distress syndrome*

While reading the Cochrane review, we find that randomized trials with long-term infant follow-up are available to assess the likelihood of late sequelae of steroid therapy. While reviewing the NIH consensus panel report from 2000, we also note that several of these trials may have included multiple-dose therapy. The NIH consensus panel report from 2000 discusses the practices of single-dose versus multiple-dose therapy and notes that there is not adequate, unbiased evidence to support multiple doses of antenatal steroids. Evidence from randomized trials, several of which are underway, is needed to resolve ongoing questions about the benefits and risks of multiple-dose therapy. Ongoing clinical trials funded by the NIH can be accessed at http://www.clinicaltrials.gov/.

Assessing Importance and Validity

The task of appraising the evidence includes assessing both the importance and the validity of the evidence. Some clinicians choose to determine validity before evaluating importance, and others reverse the order. No matter what the order, when the first step is promising, the other must be completed.

An assessment of the importance of a study finding focuses both on the strength of the association between the factor under investigation and the study outcome and on the number of people potentially affected by the finding. Measures commonly used to assess the strength of association in epidemiologic studies are the odds ratio (OR) (Fig. 59.2) and the relative risk (RR) (Fig. 59.3). As discussed subsequently, a properly conducted randomized controlled trial provides the highest quality of evidence; the RR is the measure of association commonly used in such trials and provides a result that is easier for most clinicians to interpret, especially when the rate of events is high (when the event rates are low, the OR and RR are very close numerically).

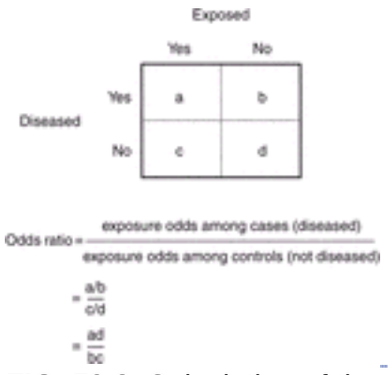

FIG. 59.2. Calculation of the odds ratio using the 2 × 2 table. The values a, b, c, and d represent the numbers of people in each of four possible combinations of exposure and disease status.

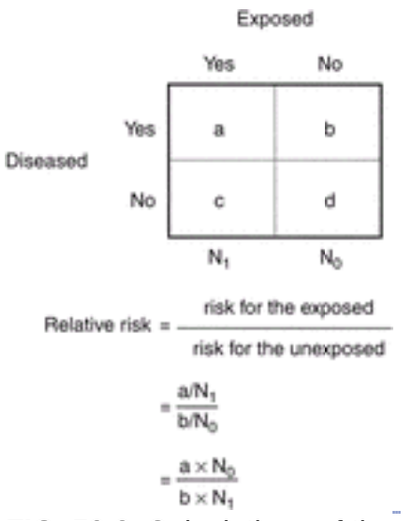

FIG. 59.3. Calculations of the relative risk using the 2 × 2 table. The values a, b, c, and d represent the numbers of people in each of four possible combinations of exposure and disease (N_1, total number exposed; N_0, total number unexposed).

The obstetrician-gynecologist assessing validity is searching for biases. Sackett and colleagues ([10]) have provided questions that may aid in an assessment of validity including those adapted for Table 59.2 and included in Table 59.4. Biases are systematic errors, either in design or analysis, that could lead to an incorrect conclusion. Biases can result from the way study participants were selected (selection bias), from the way information was collected from study participants (information bias), and from failure to adjust for factors that influence the study outcome but that are extraneous to the study's question (confounders). Biases may distort the measure of study outcomes so greatly that study data may suggest a strong association (a potentially important effect) when, in fact, no association exists. Conversely, the data may suggest no association when a strong one is present. In other words, biases may lead to a distortion of the truth.

The main questions to answer:
1. Was the assignment of patients to treatments randomized? and was the randomization list concealed?
2. Were all patients who entered the trial accounted for at its conclusion? and were they analyzed in the groups to which they were randomized?
And, some finer points to address:
1. Were patients and clinicians kept "blind" to which treatment was being received?
2. Aside from the experimental treatment, were the groups treated equally?
3. Were the groups similar at the start of the trial?

TABLE 59.4. *Are the results of this single study valid?*

When a recent systematic review of randomized controlled trials (such as those available from the Cochrane Library) is available, the obstetrician-gynecologist can accept the conclusions of the reviewer, critically appraise the quality of the review by using criteria such as those in Table 59.2 and Table 59.4, or conduct an independent search and review of the evidence. When a recent systematic review is not available, the obstetrician-gynecologist must track down and critically appraise the available evidence.

The system for evaluating the quality of evidence proposed by the Canadian Task Force on Periodic Health Examination and adopted by the U.S. Preventive Services Task Force (Table 59.5) is a useful framework for assessing the relative strengths and weaknesses of different types of epidemiologic studies.

I	Evidence obtained from at least one properly randomized controlled trial.
II-1	Evidence obtained from well-designed controlled trials without randomization.
II-2	Evidence obtained from well-designed cohort or case-control analytic studies, preferably from more than one center or research group.
II-3	Evidence obtained from multiple time series with or without the intervention. Dramatic results in uncontrolled experiments (such as the results of the introduction of penicillin treatment in the 1940s) could also be regarded as this type of evidence.
III	Opinions of respected authorities, based on clinical experience; descriptive studies and case reports; or reports of expert committees.

TABLE 59.5. *System for evaluating quality of evidence proposed by the Canadian Task Force on Periodic Health Examination*

Types of Epidemiologic Studies

A basic understanding of epidemiologic methods is necessary for intelligent appraisal of medical evidence. Brief reviews of epidemiologic methods are available, as is a series of articles in the *Journal of the American Medical Association* (free on the Internet, available at http://www.cche.net/usersguides/main.asp) specifically intended to help clinicians critically appraise the medical literature. Standard texts of clinical epidemiology are also helpful.

Most of the studies in the medical literature that will be relevant to clinical decision making in obstetrics and gynecology are epidemiologic studies. The goal of an epidemiologic study is to accurately measure the relationship between an exposure of interest (e.g., steroid therapy) and an outcome of interest (e.g., neonatal morbidity and mortality from respiratory distress syndrome). The two basic types of epidemiologic studies are experimental and observational.

In experimental studies (e.g., randomized controlled trials), the exposure is manipulated and the effect of that manipulation on the outcome is measured directly. When properly conducted, these studies provide the strongest evidence because they are least likely to be affected by bias and, thus, are most likely to obtain an accurate measure. However, randomized trials are of varying quality. A poorly conducted randomized trial may be of little or no value. The U. S. Preventive Services Task Force requires that randomized trials be “properly conducted” to be considered high-quality evidence (see Table 59.5). Other guidelines for evaluating the quality of randomized trials (The CONSORT statement, http://www.consort-statement.org/) are also available.

In observational studies (e.g., cohort, case-control, and cross-sectional studies), the exposure is observed rather than manipulated. Observational studies provide a wide range of quality of evidence. The quality of evidence from cohort (follow-up) studies, in which study participants are classified as exposed or unexposed to the factor of interest and then followed over time to see whether they develop the outcome of interest, depends on the strength of the study design and analysis. Case-control studies, in which study participants are classified as having or not having the outcome of interest (typically a disease), then assessed to determine whether they were exposed to a factor of interest in the past, have the same potential range of quality. Although prospective studies (including cohort studies) are often thought to be methodologically superior to retrospective (including case-control) studies, theoretically, a perfectly conducted cohort study will provide the same level of evidence as a perfectly conducted case-control study. In practice, however, retrospective (including case-control) studies are generally more susceptible to bias than are prospective (including cohort) studies.

Cross-sectional studies warrant special mention for the lack of evidence they typically provide. Cross-sectional studies can be regarded as a snapshot of individuals that provides information about whether the individuals have been exposed to the factor of interest and whether they have the outcome of interest at that moment. In these studies, the quality of evidence is typically very low because little information is available about whether the exposure caused the outcome. In fact, in many cross-sectional studies it is impossible to determine whether the outcome preceded the exposure.

An example concerning the use of condoms for human immunodeficiency virus (HIV) prevention may be helpful for distinguishing the four types of epidemiologic studies discussed here:

- *Randomized controlled trial:* Men at risk for acquiring HIV infection are randomized to use or nonuse of latex condoms and then followed over time to determine whether they become infected. Although, it would be unethical to assign one study group a known effective strategy for preventing a deadly disease and leaving the other group at risk, a randomized trial of a behavioral intervention to encourage men to use condoms could potentially be conducted without ethical proscriptions.
- *Cohort (follow-up) study:* Men at risk for HIV infection who choose to use latex condoms consistently and men who choose not to are followed over time to determine whether they become infected. Important differences between men who do and do not use condoms that influence the risk of acquiring HIV infection may bias the estimate of the effect of condom use.
- *Case-control study:* Men with and without HIV infection are selected for study and then asked to provide a detailed record of prior condom use. Men with HIV infection may be more or less likely than uninfected men to recall condom use accurately; differences in recall (a type of information bias) may bias study findings. In the cohort study design, men would be asked to prospectively chart condom use which would likely lead to a better measure of condom use than reliance on memory alone.
- *Cross-sectional study:* Men with and without HIV infection are asked about current or recent condom use. It is impossible, however, to determine whether the condom use preceded or followed infection with HIV.

Task 4: Apply the Evidence

Once the importance and validity of the evidence have been assessed, the evidence has to be applied to an individual patient. The smaller the number of randomized controlled trials available to assess the safety and effectiveness of treatment and the narrower the variety of clinical circumstances studied, the more the obstetrician-gynecologist will need to rely on clinical expertise to determine how the available evidence applies to a particular patient. One approach to this task is asking, “Would my patient satisfy the eligibility criteria for the trial?” ([10]) or, “Is my patient so different from those in the trial that the results don't apply to her?”

Evidence-based medicine also considers the values and preferences of each patient. The values and preferences of the patient may well tip the scale toward or away from a given treatment, particularly in instances where the balance of risks and benefits of treatment are unclear or there are competing options with similar balances of somewhat different benefits and risks.

Example Our review of the evidence indicates that single-dose corticosteroids are safe and effective to use for preterm, premature rupture of membranes. The findings applied to a broad range of gestational ages of less than 35 weeks, male and female infants, and across races. No adverse consequences for any subgroups were identified. Thus, there is good evidence that our patient is an appropriate candidate for corticosteroid therapy. Because the benefits are substantial and there are no documented risks, the patient will likely agree to steroid therapy.

SUMMARY POINTS

- Evidence-based medicine is neither “cookbook” medicine nor “cost-cutting” medicine. Rather, it is the use of the best available evidence in caring for an individual.
- The practice of evidence-based medicine brings into play three components: Clinical state and circumstance; patients' preferences and actions; and research evidence. Depending on the circumstances, one component may play a greater role than another.
- Obstetrician-gynecologists can practice evidence-based medicine by using evidence-based medical summaries, systematic reviews, or evidence-based practice protocols.
- Obstetrician-gynecologists can also learn to practice evidence-based medicine independently by becoming proficient at four tasks:
  - framing a researchable question
  - conducting a search for evidence to address the question
  - critically appraising the evidence
  - applying the evidence to the individual patient.
