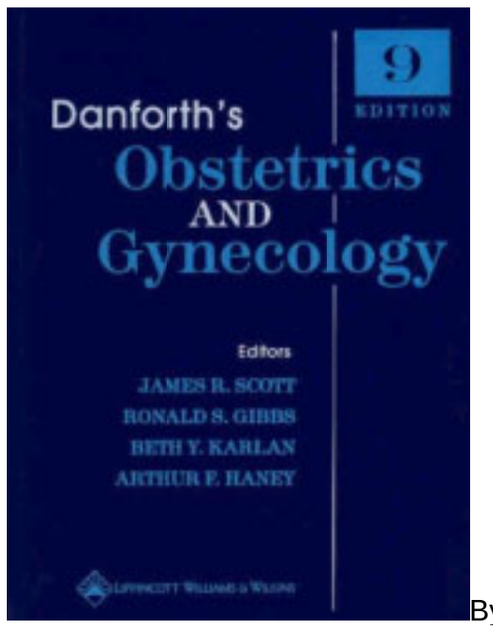
Danforth's Obstetrics and Gynecology, 9th Ed: James R., Md. Scott, Ronald S., Md. Gibbs, Beth Y., Md. Karlan, Arthur F., Md. Haney, David N. Danforth By Lippincott Williams & Wilkins Publishers; 9th edition (August 2003)



By OkDoKeY

Danforth's Obstetrics and Gynecology

CONTENTS

Editors

Contributors

Preface

Farewell

Chapter 1 Prenatal Care
Vern L. Katz

Chapter 2 Normal Labor, Delivery, Newborn Care, and Puerperium
Dwight J. Rouse and Elaine St. John

Chapter 3 Obstetric Analgesia and Anesthesia
Joy L. Hawkins

Chapter 4 Early Pregnancy Loss
D. Ware Branch and James R. Scott

Chapter 5 Ectopic Pregnancy
Michael J. Heard and John E. Buster

Chapter 6 Genetics and Prenatal Diagnosis
Kenneth Ward

Chapter 7 Drugs in Pregnancy
Jerome Yankowitz

Chapter 8 Ultrasound in Obstetrics
Keith H. Nelson and Lewis H. Nelson, III

Chapter 9 Fetal Monitoring
Catherine Y. Spong

Chapter 10 Preterm Labor and Delivery
Debra A. Guinn and Ronald S. Gibbs

Chapter 11 Premature Rupture of the Membranes
Ronald S. Gibbs

Chapter 12 Intrauterine Growth Restriction
Henry L. Galan and John C. Hobbins

Chapter 13 Prolonged Pregnancy
Lisa Moore and James N. Martin, Jr.

Chapter 14 Multiple Gestation
Roger B. Newman

Chapter 15 Diabetes Mellitus and Pregnancy
E. Albert Reece and Carol J. Homko

Chapter 16 Hypertensive Disorders of Pregnancy
Julie S. Moldenhauer and Baha M. Sibai

Chapter 17 Medical and Surgical Complications of Pregnancy
Maureen P. Malee

Chapter 18 Immunologic Disorders in Pregnancy
T. Flint Porter, Morgan Peltier, and D. Ware Branch

Chapter 19 Obstetric and Perinatal Infections
Howard L. Minkoff and Ronald S. Gibbs

Chapter 20 Placenta Previa and Abruption
Helen H. Kay

Chapter 21 Breech, Other Malpresentations, and Umbilical Cord Complications
Dwight P. Cruikshank

Chapter 22 Complications of Labor
Donald J. Dudley

Chapter 23 Operative Vaginal Delivery
Michael A. Belfort

Chapter 24 Cesarean Delivery
T. Flint Porter and James R. Scott

Chapter 25 Critical Care Obstetrics
Steven L. Clark

Chapter 26 Office Gynecology
William R. Keye, Jr. and Marian D. Damewood

Chapter 27 Office Surgical Procedures
Deborah Manzi-Smith and Charles C. Coddington, III

Chapter 28 Gynecologic Ultrasound
Frederick Larsen

Chapter 29 Pediatric and Adolescent Gynecology
Ann J. Davis

Chapter 30 Contraception
Herbert B. Peterson, Kathryn M. Curtis, Olav Meirik, and Catherine d'Arcangues

Chapter 31 Induced Abortion
Suzanne R. Trupin

Chapter 32 Pelvic Infections and Sexually Transmitted Diseases
David A. Eschenbach

Chapter 33 Benign Vulvovaginal Disorders

Edward J. Wilkinson

Chapter 34 Amenorrhea
Marc A. Fritz

Chapter 35 Abnormal Uterine Bleeding
Steve N. London

Chapter 36 Premenstrual Syndrome
Robert L. Reid

Chapter 37 Androgen Excess Disorders
Richard S. Legro and Ricardo Azziz

Chapter 38 Infertility
Julia Johnson

Chapter 39 Assisted Reproductive Technology
Spencer S. Richlin, Aida Shanti, and Ana A. Murphy

Chapter 40 Endometriosis
Robert S. Schenken

Chapter 41 Menopause
Marcelle I. Cedars and Michele Evans

Chapter 42 Human Sexuality and Female Sexual Dysfunction
Laurie Jane McKenzie and Sandra Ann Carson

Chapter 43 Chronic Pelvic Pain
Howard T. Sharp

Chapter 44 Perioperative Evaluation
F. Joseph Kelly, Phillip Y. Roland, and James W. Orr, Jr.

Chapter 45 Pelvic Organ Prolapse
John O.L. DeLancey and Kris Strohbehn

Chapter 46 Laparoscopic Surgery
Joseph S. Sanfilippo and Lisa M. Roberts

Chapter 47 Hysteroscopic Surgery
R. Stanford Williams

Chapter 48 Incontinence
Dee E. Fenner

Chapter 49 Leiomyomata
Arthur F. Haney

Chapter 50 Disorders of the Breast
Mary L. Gemignani

Chapter 51 Vulvar and Vaginal Cancer
Natalie S. Gould, Joan L. Walker, and Robert S. Mannel

Chapter 52 Cervical Cancer
Robert E. Bristow

Chapter 53 Management of the Abnormal Pap Smear
Ellen E. Sheets

Chapter 54 Uterine Cancer
David G. Mutch

Chapter 55 Neoplasms of the Ovary and Fallopian Tube
Ilana Cass and Beth Y. Karlan

Chapter 56 Management of the Adnexal Mass
Linda Van Le

Chapter 57 Gestational Trophoblastic Neoplasms
Andrew J. Li and Beth Y. Karlan

Chapter 58 Medical Ethics
Frank A. Chervenak and Laurence B. McCullough

Chapter 59 Evidence-Based Approach to Obstetrics and Gynecology
Herbert B. Peterson, Susan F. Meikle, and R. Brian Haynes

Appendix 1 Color Plate

Preface

Now in its ninth edition, **Danforth's Obstetrics and Gynecology** has been widely recognized as a standard textbook for practicing physicians, residents, medical students, and nurses. It is gratifying that previous editions have been translated into several languages and have enjoyed worldwide acceptance. For many practitioners, this text has been the basis of learning and an essential reference in our beloved specialty.

The ninth edition has a new look. Three of the four editors of the eighth edition (Drs. DiSaia, Hammond, and Spellacy) have now turned over the reins to new editors. We are delighted that Jim Scott has continued to serve as an editor for the ninth edition to bring perspective, experience, and continuity. In planning this edition, we carefully reviewed the topic of each chapter and its contents. Consisting of 59 chapters, the ninth edition is now focused to provide a practical, clinically-useful text that covers all of obstetrics and gynecology in one volume. In previous editions, basic science chapters were free standing. In the ninth edition, the basic science concepts have been incorporated into pertinent, more clinically oriented chapters. We have strived to incorporate evidence-based medicine in each of the chapters and have strengthened each of the component chapters. We are also pleased to welcome new contributing authors who are all experts in their field and we thank, also, the contributing authors who have updated and revised their previous chapters.

For ready learning, each chapter contains summary points, conveniently placed at the end of the chapter. In addition, rather than using a heavily referenced format, each author has included a concise list of up-to-date suggested readings at the end of each chapter.

The editors are most grateful for the contributions of the administrative staff at our respective universities: Jane Cook and Barb Carpenter at the University of Colorado; Sheryl Martin at the University of Utah; and Phyllis Lopez at Cedars Sinai Medical Center. We also wish to thank Lisa McAllister, Sonya Seigafuse, and Jenny Kim at Lippincott Williams & Wilkins for their great editorial assistance, support, encouragement—and patience during the gestation of this work.

Beth Y. Karlan, MD

Arthur F. Haney, MD

Farewell

With this ninth edition, I end my editorship of Danforth's Obstetrics and Gynecology. When Dr. Danforth first asked me almost 20 years ago to serve as co-editor for the fifth edition, it was only after careful thought and preparation that I was willing to take on such a monumental task. We also added three co-editors I considered to be the leading authorities in each subspecialty: Drs. Philip DiSaia (Gynecologic Oncology), Charles Hammond (Reproductive Endocrinology), and William Spellacy (Maternal-Fetal Medicine). It was a privilege and pleasure to work with them as we edited the sixth, seventh and eighth editions. Now it is time for a transition. As Sparky Anderson once said as he stepped down as manager of the Detroit Tigers after 17 seasons, “It's just time.” Dr. Ronald Gibbs has served as the lead editor for this edition, and Drs. Beth Karlan and Arthur Haney are the other new editors. Each was carefully chosen as a highly respected and nationally recognized expert in his/her subspecialty. They have done a superb job, and I am confident that the book is in good hands for future editions. Dr. Danforth would have agreed.

James R. Scott, MD

Appendix I
Appendix II
Appendix III

This chapter reviews the principles and specifics of prenatal care. The time period from the periconceptual visit through labor and delivery is, for most women, the single greatest psychological transition that a woman undergoes. During these months, the obstetrician, family physician, or midwife serves a much larger role than just as health care provider. Our role is not only to assess the health of the mother and fetus, prescribe interventions, and try to influence behaviors, but also to advise and help our patients as they undergo this challenging psychological passage.

Over the three trimesters of pregnancy a woman must develop new aspects of identity. Her self-image develops an additional sense of femininity beyond what was developed at puberty, and a maternal self-concept must develop as well. Reba Rubin, in her works on the maternal experience, describes a new mother's psychological tasks as the woman grows into her new role. These tasks include:

- accepting a new body image, which is often in conflict with accepted societal views of attractiveness
- accepting the child that is growing inside her
- reordering her identity with her mother, her friends, and the father of the pregnancy
- symbolically finding acceptance and safety for her child (i.e., making a new home).

For many women with good social support these tasks are anticipated and desired roles, which bring a sense of fulfillment. For other women, some or all of these tasks are unanticipated and difficult. The obstetrician, in multiple ways, helps the mother through these transitions, while at the same time ensures the physical health of both patients (mother and fetus). Many aspects of prenatal care have grown from their original role of health promotion to ritualized traditions that have acquired symbolic value in helping women and their families adapt to these psychological transitions. For example, studies have found that for women of average weight, the practice of weighing a woman during each visit has minimal medical value. Yet, if the nurse forgets to weigh a patient, that woman usually remarks quite quickly about having her weight taken. Another example is the routine ultrasound. This is now a demand ritual. At this visit, a mother will usually bring several female family members or friends, to see the sonogram. The new mother not only uses the sonogram to bond with her child, but also shows the baby to the other women around her for their acceptance. Throughout the world, cultures and subcultures view prenatal care differently, but most all hold it with respect. A woman might miss her annual Pap smear, but she rarely misses her prenatal visit.

Many authors have commented on the special relationship of obstetrician and mother, and the window of opportunity to affect healthy behaviors, such as smoking cessation or nutrition. Compared to other physician–patient relationships, the time period of pregnancy allows much greater involvement of the physician in the patient's life. It is with this developmental background that prenatal care has evolved in the last century.

In the United States, the first organized prenatal care programs began in 1901 with home nurse visits. The first prenatal clinic was established in 1911. It is not surprising that this focus on maternal and infant health occurred as a direct outgrowth of the women's suffrage movement. The emergence of the physician-obstetrician as the primary caregiver for women of reproductive age also took place during the last century. This role has become one of partnership with allied health care providers, including nurses, nurse midwives, nurse practitioners, nutritionists, and social workers. This team not only may provide advice and medical treatment, but also serves as the patient's advocate.

Our current emphasis on prenatal care stems from historic pronouncements and retrospective analyses that concluded that women who receive prenatal care have less fetal, infant, and maternal morbidity and mortality. However, a conclusive scientific foundation is lacking for the content of prenatal care and the relationship of its components to good outcomes. As technology flourishes and resources dwindle, it has become increasingly important to obtain scientifically based evidence demonstrating which components of prenatal care are clinically appropriate, cost-effective, and deserving of preferential funding. At this time, the optimal content and delivery of prenatal care remain the subject of discussion and debate. Given the increasing number of tools of prenatal assessment, the current consensus is that the best prenatal care is individualized for the specific needs of the mother.

PRIMARY AND PRECONCEPTION CARE

Philosophy

Care of the woman of reproductive age for both preconception and pregnancy is integrated and accessible, focuses on the majority of personal health care needs, represents a sustained partnership between patient and provider, and occurs within the context of family and community. For many women, pregnancy care occurs as a part of the continuum in a long-term relationship with the health care provider.

The first visit may be a preconception visit or may occur after the woman is pregnant. The content of the visits is similar. If a woman is seen for a preconceptual visit, many issues need not be readdressed when she becomes pregnant. This next section focuses on the preconception visit.

Content of the Preconception Visit

The preconception visit is a focused visit for the woman who is planning to or is considering becoming pregnant in the near future. The content of this interval visit includes a history, physical examination, risk assessment and intervention, selected laboratory testing based on the patient's age and the results of the foregoing evaluation, ongoing management of medical conditions, and a plan of care. A purposeful discussion of contraception, sexually transmitted disease prevention, and timing of conception is appropriate. Timely administration of routine immunizations, educational counseling, and advice complete the visit.

Risk Assessment

A goal specific to the preconception interval visit is the systematic identification of potential risks to pregnancy and the implementation of early intervention as necessary. These risks fall into several categories, described in the following sections.

Unalterable Factors These are preexisting factors and cannot at present be altered in any medical way by clinical intervention. These include the patient's height, age, reproductive history, ethnicity, educational level, socioeconomic status, and genetic composition.
Factors Benefiting from Early Intervention Conditions that should or could be modified before pregnancy is attempted include poor nutrition, an underweight or obese body mass index (BMI), and poorly controlled medical diseases such as diabetes mellitus, asthma, epilepsy, phenylketonuria, hypertension, and thyroid disease. Some prescription medications that are known teratogens should be discontinued and appropriate substitutions made. These include medications such as isotretinoin (Accutane), warfarin sodium (Coumadin), certain anticonvulsants, and angiotensin-converting enzyme inhibitors. Many medications are safe and patients may be assured of medications for asthma, most antihistamines, and antidepressants. Determining the status of a patient's immunity to rubella, varicella, and hepatitis is appropriate during the preconception visit. In high-risk populations or endemic geographic areas, patients should be assessed for active tuberculosis with skin testing and chest x-ray.
Social Risk Factors Inquiry should be made regarding occupational hazards involving exposure to toxins such as lead, mercury and other atom heavy metals, and organic solvents (both liquid and vapors). Hazards in the home, such as exposure to toxoplasmosis or toxic chemicals (asbestos, pesticides), are important to identify. If a woman uses well water, it may be assessed for acidity, lead, and copper. Family violence is a particularly important household hazard. Nonjudgmental, open-ended evaluation should be applied. Judith MacFarland has recommended questions such as “Are you in a relationship in which you are being hit, kicked, slapped, or threatened?” “Do you feel threatened?” “Have you been forced to do things against your will?” These questions should be asked again at the first prenatal visit. Some studies have suggested that a written questionnaire, in addition to oral questions, will allow for greater identification of domestic abuse.
Risky Health Habits The use of illicit drugs or abuse of alcohol represents a significant health hazard to pregnancy. Alcohol is a known teratogen. There is no consensus on the correlation between the quantity of alcohol consumed and the manifestation of adverse fetal effects. Therefore, the best advice to women who wish to become pregnant is to stop drinking. The T-A-C-E screen for alcohol abuse has been well studied. The letters stand for four questions asked in a nonjudgmental manner:

1. T—“How much you drink to feel drunk?” (*tolerance*)
2. A—“Does your drinking *annoy* anyone?”
3. C—“Has anyone told you to *cut* down?”
4. E—“Do you drink in the morning to feel better?” (*eye-opener*).

Smoking cigarettes is associated with adverse pregnancy outcomes including low birth weight, premature birth, and perinatal death. Smoking by both the pregnant woman and members of the household should be avoided during pregnancy and, preferably, not resumed postpartum. The relative risk of intrauterine growth restriction (IUGR) among pregnant smokers has been calculated at 2.2 to 4.2. Because of the morbidity associated with smoking, various methods to assist women to quit smoking should be encouraged prior to pregnancy. Numerous interventions are available (Table 1.1). Use of the transdermal nicotine patch in pregnancy is thought to be preferable to smoking. One benefit of using a nicotine patch is the elimination of exposure to other toxins such as carbon monoxide inhaled in cigarette smoke. Its theoretical risk is that it creates a constant blood level of nicotine, as opposed to the vacillations that occur with smoking. Similarly, all illicit drugs have the potential of harming the pregnancy.

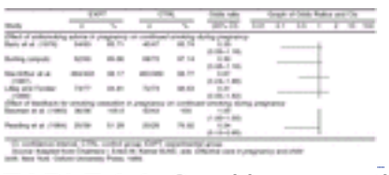

TABLE 1.1. *Smoking cessation in pregnancy*

Other behaviors that should be avoided are those that promote exposure to sexually transmitted and other infectious diseases. These include unprotected sexual intercourse in a nonmonogamous relationship and the sharing of needles between addicts.

Interventions

The final phase of the preconception visit involves specific interventions derived from the information obtained during the history, physical examination, and risk assessment phases. The specific interventions may include immunization against rubella, varicella, or hepatitis, changes in prescribed medications, behavior modification, genetic screening for such conditions as Tay–Sachs disease, cystic fibrosis and sickle cell anemia, and nutritional and physical activity recommendations.

During the physical examination, evaluation of thyroid and breast examinations is important. If a woman is 35 years of age or older, a screening mammogram should be ordered, since as much as two and a half years may pass before she will be able to have one (mammograms have significantly decreased sensitivity during pregnancy and for up to six months after lactation). If a woman has a family history of premenopausal breast cancer, a mammogram may be considered at younger ages. If a Pap smear has not been done within a year, this test should be repeated at this time. Additionally, it is valuable at this visit to examine the patient's skin. The incidence of melanoma is increasing faster than any other malignancy in the United States. The obstetrician has the unique opportunity to assess and teach at this visit regarding this cancer.

Folic acid as a supplement can reduce the occurrence and recurrence of neural tube defects, and may reduce the risk of other birth defects as well. Women who have had a previous pregnancy affected by neural tube defects should take 4 mg of folic acid per day, starting 4 weeks prior to conception through the first trimester. For all other women of reproductive age who have the potential to become pregnant, 1 mg of folic acid should be prescribed.

Approximately 20% of all pregnant women are battered during their pregnancy. About one half of women who are physically abused prior to pregnancy continue to be battered during pregnancy. For some women, the violence begins with pregnancy. All such patients require information regarding their immediate safety and referrals for counseling and support.

Some patients purposely initiate a preconception visit to determine whether or not a preexisting medical condition is an absolute contraindication to pregnancy. Pulmonary hypertension, for example, although rare, is associated with up to a 50% maternal mortality and a greater than 40% fetal mortality. It is possible to obtain epidemiologic studies that provide statistics on the morbidity and mortality for mother and fetus for most disease states. These cannot, however, provide specific data for any one patient with her own unique set of medical, demographic, and social variables. Many patients who make these inquiries will benefit by reading the relevant medical materials themselves and by obtaining more than one opinion. Consultation with other medical specialists may be necessary. For example, women with orthopedic problems often inquire about vaginal delivery. Another common concern is advanced maternal age. Specific risks of increased rates of aneuploidy and

miscarriage should be discussed. Women over 40 have been found to have higher rates of low birth weight, preterm birth, and operative delivery.

It is also important to discuss how and when to discontinue contraceptive measures. Patients using medroxy-progesterone acetate (Depo-Provera) injections may experience a delay of several months in the return of regular ovulatory menstrual cycles. An intrauterine device (IUD) may be removed at any time in the cycle. It should be removed as soon as conception is considered, since removal during pregnancy (although much better than leaving in place) is associated with a higher rate of pregnancy loss. Likewise, birth control pills may be discontinued at any time prior to attempting conception. Many physicians believe that discontinuing the use of oral contraceptives for one cycle allows better growth of the endometrium. Although definitive evidence is lacking, the thought is that there may be better implantation.

The patient should be advised to seek early prenatal care by making an appointment after missed menses or on confirmation of pregnancy by a home pregnancy test. Unfortunately, in the United States, only 75% of pregnant women receive prenatal care beginning in the first trimester. Ongoing barriers to prenatal care access include lack of money or insurance to pay for care, system under-capacity for appointments, and inadequate transportation (Table 1.2).

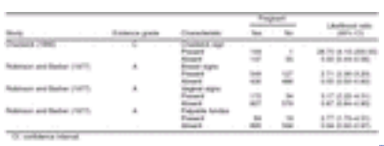

TABLE 1.2. *Probability of pregnancy based on presumptive signs*

INITIAL PRENATAL VISIT

This visit represents the first detailed assessment of the pregnant patient. The optimal timing of this visit may vary. For women who have not undergone the comprehensive preconception visit, prenatal visits should begin as soon as pregnancy is recognized. For these women, much of the content of the preconception visit will need to be addressed at this time—for example, screening for domestic abuse and alcohol use. All other women should be seen by about 8 menstrual weeks (6 weeks after conception) of gestation. For all patients, the appropriate content of prenatal care and the first prenatal visit is contained in the antepartum record published by the American College of Obstetrics and Gynecology (ACOG) (see Appendix I). Identifying data, a menstrual history, and a pregnancy history are obtained. Past medical, surgical, and social history are recorded, along with symptoms of pregnancy. A focused genetic screen, infection history, and risk status evaluation are performed.

Diagnosis of Pregnancy

Evaluation of the signs and symptoms associated with the presumptive diagnosis of pregnancy (see Table 1.2), while a useful adjunct, has been largely superseded by the widely available urine pregnancy test. The detection of greater than 35 mIU of human chorionic gonadotropin (hCG) in the first morning void has a very high specificity for pregnancy. Other tests for confirming the presence of pregnancy include a positive serum ß-hCG and demonstration of the fetal heart by either auscultation or ultrasound. Using a transvaginal probe, fetal cardiac activity should be seen by postconception week 3. Ultrasound imaging is not routinely indicated to diagnose pregnancy but may be used in the evaluation of a patient who is at increased risk for ectopic pregnancy or threatened abortion. In conjunction with early quantitative serum ß-hCG assessments, these conditions can be clearly differentiated from a normal intrauterine pregnancy and timely therapy initiated.

Gestational Age

The Nägele rule is commonly applied in calculating an estimated date of confinement (EDC). Using the date of the patient's last menstrual period minus 3 months, plus 1 week and 1 year, it is based on the assumptions that a normal gestation is 280 days and that all patients have 28-day menstrual cycles. Although several studies have found the average length of gestation for primiparous women to be 282 to 283 days, for convention 280 days is the currently accepted average gestation. After adjustment for a patient's actual cycle length, natality statistics indicate that the majority of pregnancies deliver within 2 weeks before or after this estimated date. During prenatal care, the week of gestation can be obtained based on the calculated EDC. When the last menstrual period is unknown or the cycle is irregular, ultrasound measurements between the 14th and 20th week of gestation provide an accurate determination of gestational age (see Chapter 8).

Physical Examination

A targeted physical examination during the first prenatal visit includes special attention to the patient's BMI, blood pressure, thyroid, skin, breasts, and pelvis. On pelvic examination, the cervix is inspected for anomalies and for the presence of condylomata, neoplasia, or infection. A Pap smear is performed, and cultures for gonorrhea and chlamydia are taken, if indicated. A small amount of bright red bleeding may occur after these manipulations and the patient can be assured that this is normal. On bimanual examination, the cervix is palpated to assess consistency and length, and to detect the presence of cervical motion tenderness. Size, position, and contour of the uterus are noted. The adnexa are palpated to assess for masses. The pelvic examination may include evaluation of the bony pelvis, specifically, the diagonal conjugate, the ischial spines, the sacral hollow, and the arch of the symphysis pubis. This evaluation need only be performed once during the pregnancy.

Laboratory Evaluation

Several laboratory tests are routinely done at the first prenatal visit.

Blood Tests Hematologic testing includes a white blood cell count, hemoglobin, hematocrit, platelet count for women of Asian descent, a serologic test for syphilis (rapid plasma reagin or VDRL), a rubella titer, a hepatitis B surface antigen, a blood group (ABO), and Rh type and antibody screen. Human immunodeficiency virus (HIV) testing should be offered to all pregnant patients and refusal documented in the chart. Routine assessment for toxoplasmosis, cytomegalovirus, and varicella immunity is not necessary, but may be obtained if indicated. The National Institutes of Health and ACOG recommend offering all Caucasian women testing for cystic fibrosis status. Women with histories suggestive of thrombophilia, or a personal or family history for blood clots, should be screened at this time. Women with a history suggestive of thyroid disease should also be evaluated. Appropriate screening for genetic carrier status, if not performed at the preconception visit, includes, but is not limited to, Tay–Sachs disease, Canavan disease in women of Jewish ancestry, a- and ß-thalassemia in women of Asian and Mediterranean descent, and sickle cell disease in women of African descent.
Urine Tests All women should have a clean-catch urine sent for culture. Asymptotic bacteriuria occurs in 5% to 8% of pregnant women. Urinary stasis is present during pregnancy secondary to physiologic changes in the urinary system, including decreased ureteral peristalsis and mechanical uterine compression of the ureter at the pelvic brim as pregnancy progresses. Bacteriuria combined with urinary stasis predisposes the patient to pyelonephritis, the most common nonobstetric cause for hospitalization during pregnancy. Asymptomatic bacteriuria is identified using microscopic urine analysis, urine culture (>100,000 colonies per mL), or a leukocyte esterase–nitrite dipstick on a clean-catch voided urine.
Cultures and Infections The use of routine genital tract cultures in pregnancy is controversial. While it is clear that chlamydiosis, gonorrhea, group B streptococcal disease, herpes infection, and potentially bacterial vaginosis can be detrimental to the ultimate health of the fetus or newborn, the indications for, and timing of, cultures for these infections are not clear. The ACOG recommends assessment for chlamydiosis and gonorrhea at the first prenatal visit for high-risk patients. The high-risk patient is defined as less than 25 years of age with a past history or current evidence of any sexually transmitted disease, a new sexual partner within the preceding 3 months, or multiple sexual partners. Any abnormal discharge should be assessed with a wet prep or Gram stain. Symptomatic patients should be treated. Tuberculosis skin testing in high-risk populations or in certain geographic areas should be done if the patient has not been vaccinated with BCG vaccine. BCG vaccinations are not given in the United States.

Discussion with the Patient

The first prenatal visit is a time for the caregiver and patient to exchange expectations, to answer questions, and to set the stage for what will occur throughout the rest of normal prenatal care. The timing and content of future visits, and the timing and rationale behind further laboratory testing should be explained. The patient should be given authoritative educational resources and materials that are written at the appropriate reading level. She and her partner are encouraged to ask questions about what they will read and to share the concerns they have about the pregnancy. It is important to reinforce that there is no such thing as a meaningless, “dumb”, or trivial question. Emergency and routine phone numbers should be given to the patient in writing. Social services and community resources, such as Women, Infants, and Children (WIC) programs, may be identified for the patient on an as-needed basis. Discussion regarding sexual activities, physical activities, and nutrition are usually initiated at this time. Instructions on safe and unsafe over-the-counter medications (i.e., acetaminophen vs. ibuprofen) are also initiated. Instruction on the use of seat belts and domestic abuse is also recommended here.

Finally, the patient should be made aware of the warning signs and symptoms of infection (fevers, chills, dysuria/hematuria) or threatened pregnancy loss (bleeding,

cramping, passage of tissue). Should any of these occur, the patient should seek immediate medical attention. At the completion of the first visit, the next prenatal appointment is made.

ROUTINE ANTEPARTUM SURVEILLANCE

Rationale for Routine Prenatal Care

Prenatal care involves the following goals for pregnant women:

- to provide continuing, ongoing primary preventive health care
- to maintain or increase maternal health and the capability for self-care and to improve self-image before, during, and after pregnancy
- to reduce the risk of maternal mortality and morbidity, as well as unnecessary pregnancy intervention
- to reduce the risks to health before subsequent pregnancies and beyond the childbearing years
- to promote the development of parenting skills.

The goals of prenatal care for the fetus are as follows:

- to reduce the risk of preterm birth, IUGR, retardation, and congenital anomalies
- to enhance fetal health and reduce the need for extended hospitalization after birth
- to promote healthy growth and development, immunization, and health supervision of the infant
- to reduce the risk of neurologic, developmental, and other morbidities
- to reduce the risk of child abuse and neglect, injuries, and preventable acute and chronic illness.

The goals of prenatal care for the family during pregnancy and the first year of an infant's life are the following:

- to promote family development and positive parent–infant interaction
- to reduce the number of unintended pregnancies
- to identify and treat behavioral disorders that can lead to child neglect and family violence.

Timing and Frequency of Visits

The traditional timing and number of prenatal visits is summarized as follows:

Preconception:	Up to 1 year before conception
First prenatal:	6 to 8 weeks after missed menses
Monthly:	Up to 28 weeks
Bimonthly:	Up to 36 weeks
Weekly:	Until delivery

For the past decade prenatal care has been modified for the number and timing of visits in low-risk patients. Visits may be based on necessary assessments and interventions. A U.S. Public Health Service report delineated the interventions and tests deemed minimally necessary in a normal pregnancy and the suggested the timing for each (Table 1.3). Randomized, controlled prospective trials have evaluated and confirmed the safety of fewer prenatal visits that are modeled around specific times of intervention, such as 16- and 28-week visits. Studies have looked at 6 to 7 visits instead of the usual 13 to 14 and have found similar outcomes. Interestingly, many women reported that they felt dissatisfied with fewer visits.

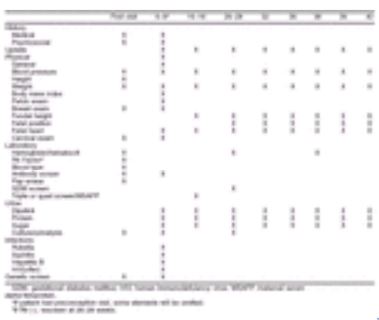

TABLE 1.3. *Timing (in weeks) of prenatal care based on specific interventions*

Content of Subsequent Prenatal Visits

The components of each prenatal visit are the taking of an interval history, assessment of fetal growth and maternal health, risk assessment and identification, intervention as necessary, collection and recording of an ongoing database (see Appendix I), and education, advice and support of the patient and her family.

Interval History Each prenatal visit begins with information gathering. Patients should be asked questions about their general health (see “ Concerns and Questions Particular to Pregnancy” later in the chapter), their diet, sleeping patterns, and fetal movement. Questions regarding warning signs such as bleeding, contractions, leaking of fluid, headache, or visual disturbances are also appropriate. Patients should be given the opportunity to raise their own questions and concerns at each visit, with open-ended inquiries.
Physical Examination The patient is weighed, and total weight gain and trends are evaluated (see “ Nutrition” later in the chapter). The blood pressure is taken and trends are assessed for possible pregnancy-induced hypertension. As blood pressure tends to decrease during the second trimester, increases of 30 mm Hg systolic or 15 mm Hg diastolic over first trimester pressures are considered abnormal. The fundal height is measured with a tape from the top of the symphysis pubis, over the uterine curve, to the top of the fundus (Fig. 1.1 and Fig. 1.2). This technique places an emphasis on change in growth patterns rather than the absolute measurement in centimeters, which can vary between patients. In women who are obese, periodic ultrasound assessments of fetal growth may be necessary. Gestational age is approximately equal to fundal height in centimeters from 16 to 36 weeks gestation. Measurements that are more than 2 cm smaller than expected for week of gestation are suspicious for oligohydramnios, IUGR, fetal anomaly, abnormal fetal lie, or premature fetal descent into the pelvis. Conversely, larger than expected measurements may indicate multiple gestation, polyhydramnios, fetal macrosomia, or leiomyomata. These concerns can be resolved with ultrasound examination.

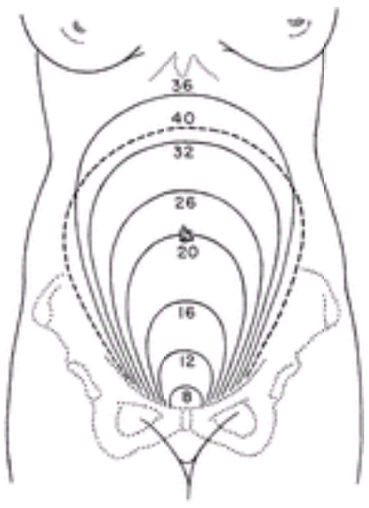

FIG. 1.1. The height of the fundus at comparable gestational dates varies among patients. Those shown are the most common. A convenient rule of thumb is that at 20 weeks gestation, the fundus is at or slightly above the umbilicus.

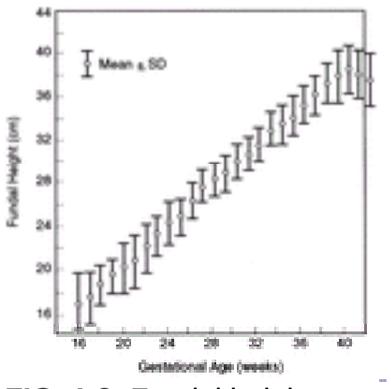

FIG. 1.2. Fundal heights versus gestational age.

Fetal heart rate is auscultated, with care taken to differentiate fetal from maternal rates. The normal fetal heart rate throughout pregnancy is between 120 and 160 beats per minute. Fetal position has been traditionally evaluated with the use of Leopold maneuvers. These are initiated at midpregnancy, when fetal body parts are more clearly identified. The maneuvers consist of four parts; the first three are performed with the examiner standing to one side of the patient and facing her head and the last with the examiner facing the patient's feet.

- The *first maneuver* answers the question, “What fetal part occupies the fundus?” (Fig. 1.3). The examiner palpates the fundal area and differentiates between the irregular, firm breech and the round, hard head.

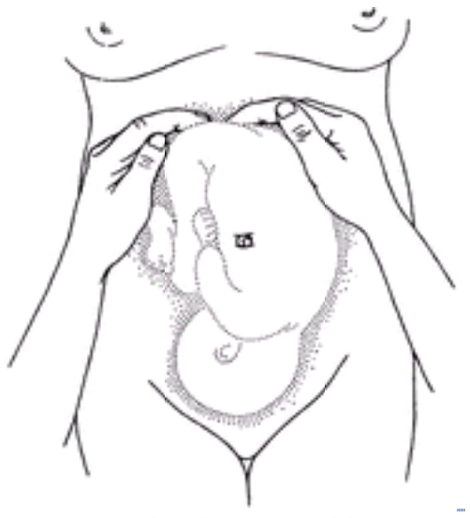

FIG. 1.3. The first Leopold maneuver reveals what fetal part occupies the fundus.

- The *second maneuver* answers the question, “On which side is the fetal back?” (Fig. 1.4). The palms of the hands are placed on either side of the abdomen. On one side, the linear continuous ridge of the back is felt, while on the other side compressible areas and nodular parts are found.

FIG. 1.4. The second Leopold maneuver reveals the position of the fetal back.

- The *third maneuver* answers the question, “What fetal part lies over the pelvic inlet?” (Fig. 1.5). A single examining hand is placed just above the symphysis. The fetal part that overrides the symphysis is grasped between the thumb and third finger. If the head is unengaged, it is readily recognized as a round, hard object that frequently can be displaced upward. After engagement, the back of the head or a shoulder is felt as a relatively fixed, knoblike part. In breech presentations, the irregular, nodular breech is felt in direct continuity with the fetal back.

FIG. 1.5. The third Leopold maneuver reveals what fetal part lies over the pelvic inlet.

- The *fourth maneuver* answers the question, “On which side is the cephalic prominence?” (Fig. 1.6 and Fig. 1.7). This maneuver can be performed only when the head is engaged; if the head is floating, the maneuver is inapplicable. The examiner faces the patient's feet and places a hand on either side of the uterus, just above the pelvic inlet. When pressure is exerted in the direction of the inlet, one hand can descend farther than the other. The part of the fetus that prevents the deep descent of one hand is called the cephalic prominence.

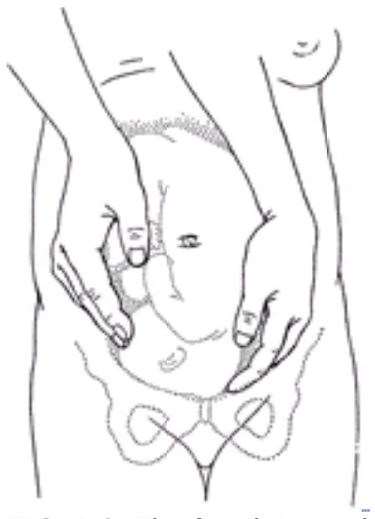

FIG. 1.6. The fourth Leopold maneuver reveals the position of the cephalic prominence. In a flexion attitude, the cephalic prominence is on the same side as the small parts.

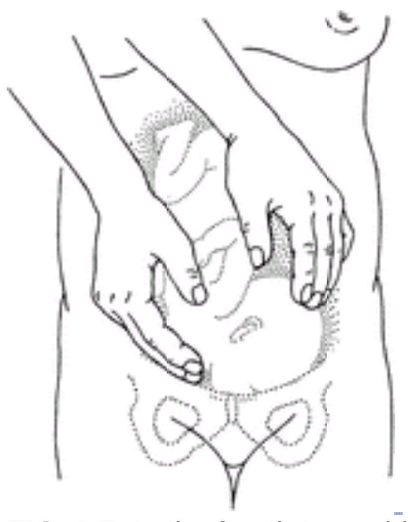

FIG. 1.7. In the fourth Leopold maneuver, in an extension attitude, the cephalic prominence is on the same side as the back.

The routine examination is completed by evaluating the patient for edema. A finding of new-onset edema of the face and hands in association with proteinuria and elevated blood pressure is consistent with preeclampsia. Dependent pitting edema of the ankles and legs in the absence of other findings is normal in late pregnancy. It responds well to resting, with the legs elevated, and therefore is usually absent on rising in the morning. Sudden weight gain in the third trimester to a large extent reflects an increase in edema. The amount of weight gain that is pathologic is not known. However, more than 5 lbs in a week is generally considered problematic. Routine examination of the cervix is not necessary unless the patient is at risk for cervical incompetence or is being evaluated for preterm labor.

Laboratory Evaluation Several laboratory evaluations are offered to all patients. These include screening for neural tube defects and aneuploidy, with alpha-fetoprotein and other serum values (triple or quad screen), screening for gestational diabetes with a glucose challenge, as well as screening for maternal antibodies to fetal blood type.

Maternal Serum Screening Test Screening with maternal serum alpha-fetoprotein (MSAFP) is performed to detect fetal neural tube defects and fetal ventral wall defects. During pregnancy, AFP is produced in sequence by the fetal yolk sac, the fetal gastrointestinal tract, and finally, the fetal liver. Its peak concentration in fetal serum occurs at the end of the first trimester. Excretion of AFP in fetal urine results in high levels of AFP in the amniotic fluid. Transfer of AFP to the maternal serum occurs via the placenta and transamniotically. MSAFP levels continue to rise until approximately 30 weeks gestation (Fig. 1.8). The interpretation of the MSAFP screening test is dependent on gestational age and should be performed at the 15th to 20th menstrual weeks of pregnancy.

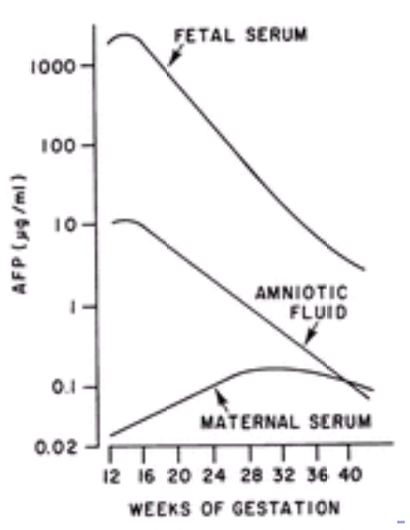

FIG. 1.8. Alpha-fetoprotein concentrations in fetal serum, amniotic fluid, and maternal serum throughout gestation. (From Seppala M, ed. *Amniotic fluid*, second ed. New York: Excerpta Medica, 1978; with permission.)

MSAFP levels are reported as multiples of the median from the database of the individual laboratory. Elevated maternal serum and amniotic fluid levels of AFP detect 85% of open neural tube defects (open spina bifida and anencephaly). Other causes for elevated MSAFP levels include omphalocele, gastroschisis, multiple gestation, fetal demise, incorrect dates, and adverse pregnancy outcomes. Patients with abnormal MSAFP levels require evaluation with targeted fetal ultrasonography (Fig. 1.9)

(see Chapter 6, Chapter 8).

FIG. 1.9. Screening for Down syndrome during pregnancy by measuring markers in maternal serum. (Adapted from Haddow JE, Palomaki GE, Knight, GJ, et al. Prenatal screening for fetal Down syndrome with the use of measurement of maternal serum markers. *N Engl J Med* 1992;327:588.)

The risk of fetal trisomy 21 is related to gestational age/normalized concentrations of MSAFP, total ß-hCG, unconjugated estriol, and inhibin. Thus, these biochemical markers may be used in conjunction with the maternal age-related risk of fetal trisomy 21 to derive a more precise risk of fetal trisomy 21 in a given pregnancy. Called the triple screen or quad screen, this scheme assumes that computed risks for fetal trisomy 21 greater than 1 in 270 (, the mid-trimester risk of fetal trisomy 21 in a 35-year-old woman) should prompt consideration of genetic counseling, targeted ultrasound, and possibly amniocentesis. Using such a scheme, prospective studies show that approximately 60% to 70% of fetal trisomy 21 will be detected, with a false-positive rate of 5%. In women older than age 34 at delivery, the triple marker will detect 80% to 85% of trisomy 21. These women should be offered genetic counseling, as some will opt for amniocentesis or chorionic villus sampling. It is important to counsel a patient about the differences between a screening test and a diagnostic test. The possibility of false-positive and false-negative test results should also be explained. Approximately 60% of trisomy 18 may be detected with biochemical means (triple or quad screen). Many women will opt for first trimester screening, including nuchal thickening and biochemical markers. Early studies hold promise for this type of screening, though precise predictive values are still being estimated.
Screening for Gestational Diabetes The 1-hour, 50-g oral glucose screen is used to detect glucose intolerance in pregnancy. Following an abnormal screen, a 3-hour glucose tolerance test, commencing with a fasting blood sugar, followed by a 100-g Glucola, is currently recommended. Two or more abnormal values on this test are considered diagnostic of gestational diabetes mellitus (GDM). Universal screening is controversial, though most clinicians have opted for a universal approach. Risk factors for GDM include:

- maternal age greater than 30 years
- previous macrosomic, malformed, or stillborn infant
- GDM in a previous pregnancy
- family history of diabetes
- maternal obesity
- persistent glucosuria
- chronic use of certain drugs such as ß-sympathomimetics or corticosteroids.

Proponents of universal screening argue that screening only those patients with risk factors will detect no more than half of patients with glucose intolerance. Opponents argue that the inconvenience and expense of testing are not necessary in patients without these risk factors, because the incidence of frank GDM in this population is so low. Routine screening, if used, is performed on all patients between 26 and 28 weeks gestation. Selective screening based on risks may be performed earlier and repeated as needed, if negative at earlier gestations. A patient may be tested in the fasting or nonfasting state. One hour after administration of a 50-g glucose load, the patient's blood is drawn. A patient with a glucose value greater than 140 mg per dL of serum is a candidate for a 3-hour, 100-g glucose tolerance test. The significance of GDM lies not in an increased risk of fetal loss but in the risk of excessive fetal growth with its attendant birth-related morbidities. In addition, women with GDM have a 60% likelihood of developing overt diabetes mellitus within 16 years.
Rescreening for Rh Antibodies All Rh-negative women who are unsensitized at the beginning of pregnancy should be retested at approximately 26 to 28 weeks gestation. If the antibody screen remains negative, the mother should receive Rh $_0$(D) immune globulin 300 mcg at 28 weeks, to prevent isoimmunization in the third trimester. Approximately 1% of Rh-negative women will become sensitized if not given Rh immune globulins.
Screening for Bacterial Vaginosis Bacterial vaginosis (BV) is a condition in which the normal flora of the vagina (specifically lactobacilli) are reduced in number and replaced by an overgrowth of anaerobic organisms. Studies have linked BV with an increased incidence of preterm labor, endometritis, and premature rupture of the membranes. A simple and effective screen, performed late in the second trimester, consists of a pelvic examination and wet mount to detect BV. A Gram stain is an alternative diagnostic tool. The treatment for women who are positive for BV includes either metronidazole or clindamycin (Cleocin). Because BV is often asymptomatic, a test of cure may be appropriate. Routine screening is not recommended, as studies have not shown that screening and treatment decreases preterm labor and delivery. However, symptomatic women, women with cerclage, or women with preterm dilated cervices should be screened and treated.
Testing for Group B Streptococci Group B streptococci (GBS) are part of the normal vaginal, genitourinary, and gastrointestinal tract flora in up to 30% of healthy women. GBS have been implicated in amnionitis, endometritis, and wound infection in the mother. Vertical transmission during pregnancy, labor, and delivery may result in generalized sepsis in the newborn and related long-term morbidity or neonatal death. Prevention strategies have focused on detection of the bacteria in the mother and early onset of GBS disease in the newborn. The recommended strategy involves routine anogenital cultures of all pregnant women at 35 to 37 weeks gestation. Cultures are obtained from the lower third of the vagina and perianal area. Cervical cultures are not reliable and a speculum is not necessary to obtain an adequate culture sample. Culture-positive women are treated during labor with antibiotic prophylaxis to prevent fetal–neonatal GBS infection. Women with a positive urine culture for GBS should be given antibiotic prophylaxis in labor. These women do not need to be recultured.
Testing Based on Symptoms or Clinical Risk Assessment A part of prenatal care of the normal patient consists of ongoing risk assessment and intervention or referral if a risk is identified. Several clinical signs or symptoms warrant further evaluation. Symptoms suggestive of urinary tract infections should prompt examination of a clean-catch urine specimen and cultures when appropriate. High-risk behaviors, identified during the course of a pregnancy, should prompt a test (or retest) for HIV infection and sexually transmitted diseases (STDs) or performance of a urinary drug screen. Repeated testing of hemoglobin should be done if the patient is symptomatic or at nutritional risk for anemia. Other testing, performed on an as-needed basis, includes ultrasound to detect abnormal fetal growth, antepartum fetal monitoring to assess fetal oxygenation status, or comprehensive targeted ultrasound examinations. A more thorough discussion of antepartum fetal monitoring can be found in Chapter 9.
Discussion with Patients and Families: Answering Questions Patients need the opportunity to engage in dialogue with their health care provider and to feel confident that their concerns are heard. Patients and families will often interact with a nurse or triage person in a physician's office. These individuals need to be trained in careful assessment and evaluation. The value of information ancillary personnel can provide cannot be overemphasized. The prenatal visits are a time to stress the involvement of the entire family in the pregnancy process, including the role of the father and siblings. Therefore, an important part of the prenatal visit is discussion with the patient, her partner, or her family, both to exchange questions and answers, and to provide reassurance and education. The exact content of these discussions will vary from visit to visit. Reaffirming the importance of appropriate social behaviors, such as smoking cessation, is beneficial, as are periodic evaluations of the social support systems and help in the home, both now and after the birth of the infant. Ongoing risk assessment requires that the patient be educated about the signs and symptoms of preterm labor and preeclampsia. The list of warning signs for which an emergent telephone call is warranted includes the following:

- vaginal bleeding
- leaking of fluid from the vagina
- rhythmic cramping pains of more than six per hour
- abdominal pain of a prolonged or increasing nature
- fever or chills
- burning with urination
- prolonged vomiting with inability to hold down liquids or solids for more than 24 hours
- severe continuous headache, visual changes, or generalized edema
- a pronounced decrease in the frequency or intensity of fetal movements.

CONCERNS AND QUESTIONS PARTICULAR TO PREGNANCY

Psychological

Pregnancy is a time of change, expectation, and anticipation. It may also be a time of heightened anxiety, emotionality, concern, and uncertainty. Many symptoms that the nonpregnant patient might view as minor may indicate a cause for alarm during pregnancy. The provision of direct, concise, and accurate information in a

compassionate and reassuring manner will assuage many of these worries and provide direction for day-to-day activities.

Nutrition

The objectives of nutritional assessment and counseling are to develop, in concert with the patient, an analysis of maternal nutritional risk, a goal for total weight gain, and a diet plan that will fit the patient's lifestyle and is ethnically sensitive.

The principle of good nutrition is that there is a positive linear relationship between maternal weight gain and newborn weight *and* that prepregnant maternal BMI can affect fetal weight independently of the amount gained by the mother during pregnancy. Together, initial weight and weight gain have an impact on IUGR and low birth weight. However, for a woman of normal weight and normal nutrition, the relationship between poor weight gain and fetal growth restriction may be an association not a cause and effect.

The BMI is a calculation that relates the patient's weight to her height, thereby providing a more accurate indirect estimate of the patient's body fat distribution than can be obtained by weight alone. The BMI is calculated by dividing weight in kilograms by height in meters squared. If pounds and inches are used, the quotient is multiplied by 700. The BMI of a patient is categorized as underweight, normal weight, overweight, or obese (see Appendix II).

Maternal Weight Gain The ideal weight gain for an individual patient during pregnancy depends on several factors. The most important of these are the prepregnant BMI and the type of gestation (single vs. multiple). It is important to note that weight gain for a normal BMI is 25 to 35 lbs (11 to 16 kg), but the optimal weight gain for an underweight teenager carrying a singleton pregnancy approaches 40 lbs (18.2 kg), or 5 lbs every 4 weeks in the second half of pregnancy (Fig. 1.10). An obese woman, on the other hand, may need to gain no more than 15 lbs (6.8 kg). Figure 1.11 illustrates the components of weight gain in a normal pregnancy. During the first and second trimesters, most of the weight gained reflects maternal changes, primarily an increase in total body water, while fetal growth is most rapid in the last trimester, with the fetus more than tripling its weight. The optimal weight gain for women with twins is usually greater than 40 lbs. Poor weight gain is often a reflection of patients not expanding their intravascular volume. This is associated with low birth weight and greater complications in pregnancy. Having patients “eat more” does not usually help. In contrast, weight gain greater than 30 lbs will often remain as extra weight after delivery. Women should be instructed not to diet during pregnancy. Many women will not gain significant weight until the middle of the second trimester. Patients may be reassured that this is a normal pattern.

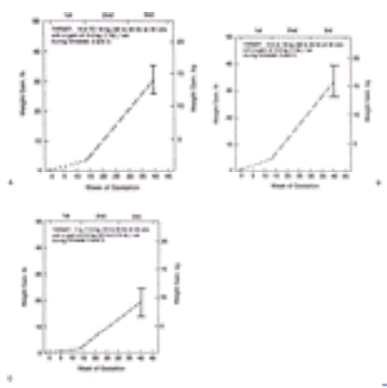

FIG. 1.10. Target weight gains for normal-weight women with body mass index (BMI) of 19.8 to 26, underweight women with a BMI of less than 19.8, and overweight women with a BMI of more than 26 to 29. **A:** A 1.6 kg (3.5 lb) gain in the first trimester and the remaining gain at a rate of 0.44 kg (0.97 lb) per week are assumed. **B:** A 2.3 kg (5 lb) gain in the first trimester and the remaining gain at a rate of 0.49 kg (1.1 lb) per week are assumed. **C:** A 0.9 kg (2 lb) gain in the first trimester and the remaining gain at a rate of 0.3 kg (0.67 lb) per week are assumed.

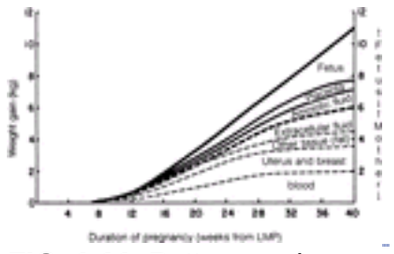

FIG. 1.11. Pattern and components of weight gain during pregnancy (LMP, last menstrual period). (From Pitkin RM. Nutritional support in obstetrics and gynecology. *Clin Obstet Gynecol* 1976;19:489, with permission.)

Maternal Diet While weight gain is an important gauge of caloric intake, the quality of the diet and the frequency of meals may also affect patient and fetal well-being. A diet should be balanced by containing foods from all of the basic food groups. Specifics of a diet will vary considerably according to patient preference, family eating patterns, and cultural and ethnic background. Increased nutritional requirements during pregnancy reflect the needs of the fetus for growth, as well as maternal physiologic needs. To meet the overall increasing energy needs, the average woman must consume an additional 300 kcal per day beyond her baseline needs. The appropriate daily caloric content of a diet required to supply energy needs and achieve appropriate weight gain can be estimated by multiplying the patient's optimal body weight in kilograms by 35 kcal and adding 300 kcal to the total (Table 1.4).

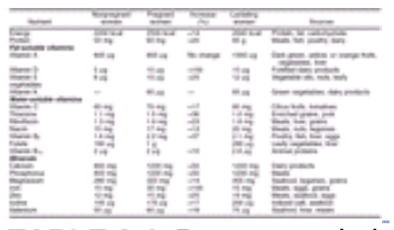

TABLE 1.4. *Recommended dietary allowances for women of reproductive age and for pregnant and lactating women*

Vitamin and Mineral Supplementation Multivitamin supplements are not routinely necessary in a woman eating a well-balanced diet. However, 800 µg of supplemental folic acid daily is necessary because the requirement cannot be met with food alone. Additional folate may be necessary for women with a hemoglobinopathy or MTHFR mutation, for women on antiseizure medications, or for women with a history of neural tube defects. Vitamin D supplementation is not generally required, unless there is inadequate exposure to sunlight. Mineral supplementation is also not needed in healthy women. The exception is iron. The iron requirements of pregnancy total about 1 g. Due to the monthly menses, most women have less than optimal iron stores during their reproductive years. Therefore, supplementation with 30 mg of elemental iron is recommended in the second and third trimesters to prevent anemia and to meet this requirement. One tablet of iron salts per day, ingested between meals or at bedtime, is sufficient to meet this requirement. Women with iron deficiency anemia require 60 to 120 mg of elemental ferrous iron per day. Additional zinc (15 mg) and copper (2 mg) are then needed, as iron inhibits the absorption of these ions. Calcium supplementation is not necessary in women with a diet that includes adequate dairy foods. Absent this, calcium supplementation may be used on an as-needed basis to meet the recommended dietary allowance (RDA) of 1200 to 1500 mg per day during pregnancy and 2000 mg per day with lactation. Zinc is a trace mineral. A zinc deficiency may be teratogenic in humans, although this has not yet been conclusively demonstrated. Zinc levels in amniotic fluid correlate with antimicrobial activity, suggesting that zinc plays a role in protecting against intrauterine infection. Low dietary intake of zinc has been associated with IUGR, although it does not cause IUGR. The RDA for zinc during pregnancy is increased from 15 to 20 mg per day.

Other Dietary Considerations

Vegetarianism Lacto-ovo vegetarians should have no particular nutritional deficiency, with the possible exceptions of iron and zinc, which may be supplemented. The strict vegan, however, must design a diet of sufficient vegetable proteins to provide all of the essential amino acids normally found in animal protein. Due to the decreased protein density of most vegetables, this may cause an unusually high weight gain. Supplementation of zinc, vitamin B_{12}, and iron is necessary.

Food Restriction Dieting and fasting on a chronic basis in an otherwise healthy woman can result in suboptimal fetal growth. Eating disorders such as bulimia and anorexia nervosa reflect extreme forms of food restriction and malnutrition. There are limited data about these disorders in pregnancy, but anorexics in particular place their fetus at risk. Bulimic women may suffer from electrolyte imbalance and a deficit of trace minerals. Many pregnant women in the United States are not eating an optimal diet due to poverty and inadequate resources to purchase food. It is appropriate to inquire about resources in impoverished women and to refer these patients to groups such as WIC and to appropriate agencies providing food stamps.

Pica Pica is the compulsive ingestion of nonfood substances with little or no nutrient value. The practice most commonly involves ice, clay (geophagia), or starch (amylophagia). Although pica is most commonly recognized during pregnancy, it is not specific to the gravid state. Neither the cause nor the medical implications of pica are well understood. It is unusual for pica to cause significant harm if the diet is otherwise nutritionally adequate.

Phenylketonuria Women with phenylketonuria who are not on a phenylalanine-controlled diet are at increased risk of bearing fetuses with microcephaly, growth retardation, and mental retardation. The goal of dietary management is to minimize these adverse fetal outcomes by reducing the maternal serum phenylalanine levels to less than 20 mg per dL before and during the pregnancy. At the first prenatal visit, every pregnant woman should be asked if she was on a special diet as a child.
Megadose Vitamins The misuse of megadose nutrients can be categorized as a fad type of dietary manipulation. Water-soluble vitamins such as vitamin C cannot be consumed in harmful quantities because they are readily excreted in the urine. However, a problem occurs with fat-soluble vitamin A. There is an association between high doses of supplemental vitamin A and birth defects similar to those seen with isotretinoin. Although the minimum teratogenic dose in humans has not been identified, it may be a little as 10,000 IU per day. Beta-carotene is a provitamin of vitamin A, but it does not produce similar toxicity. Most prenatal vitamins contain less than 5000 IU of vitamin A and, until further data are available, this should be considered the maximum safe supplemental dose.
Caffeine Caffeine is contained in numerous foodstuffs such as coffee, tea, chocolate, and cola beverages. A naturally occurring substance, it is the most widely used psychoactive drug in the United States. It is a central nervous system stimulant and is physically and psychologically addictive. Withdrawal symptoms include nausea, lethargy, malaise, and headache. The only evidence for teratogenic effects of caffeine comes from animal studies using doses not compatible with human consumption. Several large human studies have failed to show that caffeine has deleterious effects on the fetus, when ingested in low amounts. However, it is associated with an increased risk of miscarriage when taken in greater than the equivalent of three cups of coffee. Caffeine intake of the equivalent of two to three cups is thus discouraged. Adverse maternal effects of caffeine include insomnia, acid indigestion, reflux, and urinary frequency. As these problems are already exaggerated in pregnancy, moderation in the consumption of caffeine is advisable.

Exercise

Exercise is a routine part of many women's daily activities. For a normal pregnancy, a low-impact exercise regimen may be continued throughout pregnancy. Additionally, studies also show that women may increase their levels of fitness during pregnancy without problems. There are no data to indicate that pregnant women must decrease the intensity of their exercise or lower their target heart rates. However, physiologic changes of pregnancy may alter the effect of various exercises on the body or may limit the body's ability to perform certain types of exercise. Body position as a modulator of cardiac output is particularly important in the third trimester, when either motionless standing or the supine position can result in decreased venous return and cardiac output. In some instances, this will result in hypotension or syncope.

Both oxygen uptake and baseline oxygen consumption are increased during pregnancy. Deep breathing is more difficult, particularly in later pregnancy, due to uterine size and decreased diaphragmatic excursion. These changes combine to make less oxygen available for aerobic activity, thereby decreasing maximum exercise performance.

Exercise is not a means of weight control in pregnancy. Women who seek to exercise to keep from gaining weight or losing their prepregnancy shape should be counseled regarding normal pregnancy body changes.

Data regarding the fetal response to maternal exercise are reassuring. Moderate (submaximal) exercise has never been shown to increase maternal core body temperature and thus, fetal temperature. Studies of the fetus following submaximal maternal exercise (65% to 70% aerobic capacity) have not shown any associated changes in the fetal heart rate. Exercise-induced effects on the fetus, including malformations, increased miscarriage rates, retardation, or growth restriction, have not been demonstrated in human pregnancies. Women who exercise strenuously throughout pregnancy, such as elite athletes, may deliver infants as much as 300 to 400 g smaller in weight than women who do not exercise as strenuously. This, however, is not considered deleterious.

Recommendations Women who exercise regularly before pregnancy may be encouraged to continue. They may be counseled that performance capacity tends to fall, but this is not a sign that they should forgo regular moderate exercise. Indeed, exercise may relieve stress, diminish anxiety, and increase self-esteem. Some studies have also shown that women who exercise regularly have shorter labors. For most women with gestational diabetes, regular exercise has been shown to be helpful for glucose control. Specific exercise regimens should be individualized and patients who have not been physically active prior to pregnancy are advised to proceed slowly. General recommendations include the following:

- Exercise should be regular rather than sporadic and intermittent.
- Exercise should be stopped if signs and symptoms of oxygen deprivation, such as extreme fatigue, dizziness, or extreme shortness of breath, occur.
- To avoid becoming overheated, pregnant women should exercise in a cool area, stay well hydrated, and wear appropriate clothing.
- Exercise that requires prolonged time in the supine position should be avoided during the second and third trimesters.
- The form of exercise chosen should not be one with significant risk of trauma (especially to the abdomen) or falls.
- Caloric intake should be increased in direct proportion to the additional energy requirements of exercise.

Contraindications Relative contraindications to exercise during pregnancy include the following:

- evidence of IUGR
- persistent vaginal bleeding
- incompetent cervix or cervical cerclage placement
- risk factors for preterm labor
- rupture of membranes
- pregnancy-induced hypertension
- chronic medical conditions that might be adversely impacted by vigorous exercise.

Nausea and Vomiting

Recurrent nausea and vomiting during the first trimester occurs in over one half of pregnancies. While the term *morning sickness* is well known, it is a misnomer, as these symptoms can occur at any time throughout the day or night. Symptoms usually begin in weeks 6 to 8, peak during weeks 12 to 14, and are significantly resolved by week 22. The etiology of this problem is not clear. Hormonal, as well as emotional, factors have been investigated without consistent results. Symptoms can be mild or so severe that the patient becomes dehydrated and risks electrolyte imbalance and caloric malnutrition. Nonpharmacologic measures often suffice to alleviate, if not completely relieve, the symptoms. These include avoidance of fatty or spicy foods, eating small, more frequent meals, drinking ginger teas, inhaling peppermint oil vapors, wearing motion sickness bands on the wrists, and increasing rest periods each day. In severe cases of emesis, various pharmacologic agents have been used with varying success. These include pyridoxine, a variety of antihistamines, promethazine, metoclopramide, trimethobenzamide, methylprednisolone, and droperidol. Because supplemental vitamin and mineral preparations may exacerbate symptoms of nausea, they should be stopped until the symptoms have resolved. Women and their families may be reassured that minimal weight gain in the first 18 weeks is common.

Ptyalism

Ptyalism is the increased production of saliva, probably induced by the consumption of starch. There is no cure, although reducing carbohydrate intake may be helpful. The problem is often self-limiting.

Heartburn

Heartburn is usually caused by reflux esophagitis from both mechanical factors (enlarging uterus displacing the stomach above the esophageal sphincter) and hormonal factors (progesterone causing a relative relaxation of the esophageal sphincter). Treatment consists of eliminating acidic and spicy foods, decreasing the amount of food and liquid at each meal, limiting food and liquid intake before bedtime, sleeping in a semi-Fowler position or propped up on pillows, and use of antacids. Liquid forms of antacids and H_2-receptor inhibitors provide the most consistent relief of symptoms. Patients should be cautioned that antacids containing aluminum may cause constipation, while diarrhea may be associated with use of those containing magnesium.

Constipation

Progesterone-induced relaxation of the intestinal smooth muscle slows peristalsis and increases bowel transit time. Dietary management of this common condition includes increased fluids and liberal intake of high-fiber foods. Iron salts may exacerbate the problem. Over-the-counter (OTC) products containing psyllium draw fluid into the intestine and promote a more rapid transit time. Enemas and strong cathartics should be avoided.

Fatigue

Pregnant women will usually have an increased sense of fatigue during pregnancy. This is a normal symptom. A sense of breathlessness is also normal. A significant

increase in fatigue or breathlessness however should alert the clinician to possible pathology.

Varicosities and Hemorrhoids

Varicosities most often occur in the lower extremities but may be seen in the vulva as well. Contributing factors include genetic predisposition, advanced maternal age, increased parity, and prolonged standing. Manifestations can range from mild cosmetic effects to chronic pain and superficial thrombophlebitis. Treatment includes avoidance of garments that constrict at the knee and upper leg, support stockings, and increased periods of rest with the legs elevated.

Hemorrhoids, varicosities of the rectal veins, are due to mechanical compression by the enlarging uterus, as well as from constipation and straining at stool. Treatment includes OTC preparations, witch hazel, topical preparations, cool sitz baths, and stool softeners. If thrombosis of a hemorrhoid occurs, the clot can be excised to relieve pain and swelling.

Leg Cramps

Almost half of all pregnant women suffer from recurrent painful spasms of the muscles of the lower extremities, especially the calves. Leg cramps are more frequent at night and usually occur during the third trimester. Various prophylactic and therapeutic options have been suggested, most notably, calcium lactate and high potassium foods, such as banana, kiwi, or cantaloupe, but there are no data from controlled trials to show benefit over placebo for any of these. Massage, heat, and stretching the affected muscle(s) relieves the cramps when they occur.

Backache

Most pregnant women experience lower backaches as pregnancy progresses. These are usually alleviated by minimizing the amount of time spent standing, by increasing rest, by wearing a specially designed support belt over the lower abdomen, and by taking an analgesic such as acetaminophen. Exercises to increase muscular strength of the back and abdomen are sometimes helpful. Shoes with good support and avoidance of high heels that exaggerate the lordotic posture are essential. Increasingly severe or abrupt-onset back pain requires orthopedic consultation. Rhythmic cramping pains originating in the back may be a sign of preterm labor and necessitate appropriate evaluation.

Round Ligament Pain

This pain most frequently occurs during the second trimester when women report sharp, bilateral, or unilateral groin pain. It has been called “round ligament pain”, though it is not known if round ligament stretch is the true etiology. The pain may be increased with sudden movement or change in position. Resolution of unremitting ligament pain is sometimes achieved by having the patient assume a position on the hands and knees and lower the head to the floor, while keeping the buttocks in the air.

Headache

Generalized headaches are not uncommon during the first trimester of pregnancy. Muscle tension headaches may occur intermittently. The frequency and intensity of migraine headaches may increase or decrease during pregnancy. Headaches during the second and third trimesters are not an expected symptom of pregnancy. Pathologic headaches that occur with preeclampsia are discussed in Chapter 16.

Emotional Changes

Pregnancy is a time of significant psychological stress. Changes in hormonal levels, changes in relationships to partners, family and friends, and changes in body image all lead to increased psychological stress. Increased levels of placental corticotropin-releasing hormone toward the end of pregnancy also affect the maternal hypothalamic–pituitary axis and other brain loci involved in stress responses. There is a corresponding shift in most women toward primary process. Dreams become more vivid and dramatic. Emotional lability is common. It is very helpful to counsel the pregnant woman and her partner about these normal changes. Women with social stressors or with a history of depression may develop signs of atypical depression, necessitating counseling and medications.

Sexual Relations

Coital activity during normal pregnancy need not be restricted. The couple can be counseled regarding changing positions to achieve better comfort. Deep penetration may be more uncomfortable as pregnancy progresses. It is common for women to have changes in sexual desire over the course of gestation. Many women achieve orgasm easier during pregnancy; however libido often decreases in the first and third trimesters. Nipple stimulation, vaginal penetration, and orgasm can cause uterine contractions secondary to the release of prostaglandins and oxytocin. However, there are no proven adverse effects on the fetus or the onset of labor. The question of the effect of coitus in women at risk for preterm labor or early spontaneous pregnancy loss remains unanswered. Couples at risk may prefer to avoid sexual relations to minimize any feelings of guilt or responsibility if a problem occurs subsequently.

There are two concrete interdictions to coitus during pregnancy. The first is that intercourse should not occur after membrane rupture or in the presence of known placenta previa. The second is that forceful introduction of air into the vagina should be avoided because of the risk of fatal air embolism.

Employment

Most patients are able to continue to work throughout their pregnancy. In general, work activities that increase the risk of falls or trauma, especially to the abdomen, should be avoided. Hazardous toxic or chemical exposures should be identified early and avoided. Strenuous physical activity, including repetitive lifting and prolonged standing for more than 5 hours, has been associated with a greater rate of adverse outcomes, and work routines should be modified accordingly.

Urinary Frequency

Patients often experience urinary frequency during the first 3 months of pregnancy, as the enlarging uterus compresses the bladder, and again during the last weeks, as the fetal head descends into the pelvis. If frequency occurs in conjunction with dysuria, hematuria, or urgency/hesitancy, the patient should be evaluated for a urinary tract infection.

Skin Changes

Hair growth has variable patterns in pregnancy, although many women experience increased growth during pregnancy and hair loss postpartum. Skin commonly darkens over the face and median ventral line of the abdomen in many women. Any nevi that change color should be excised.

Leukorrhea

An increase in the amount of vaginal discharge is physiologic and expected during pregnancy. Discharge accompanied by itching or burning, or a malodorous discharge, should be evaluated and treated accordingly. Douching has no place in the treatment or management of leukorrhea in pregnancy. Increased watery discharge may precede preterm labor and should be evaluated.

Syncope

Venous pooling in the lower extremities increases as the pregnancy progresses. This can lead to dizziness or lightheadedness, especially after standing upright abruptly or for long periods of time. Other causes of syncope include dehydration, hypoglycemia, and the shunting of blood flow to the stomach after eating a large meal. Syncope during exercise is a sign of overexertion. In general, syncopal episodes resolve rapidly and should be managed acutely, just as in a nonpregnant patient. Syncope in the supine position is avoidable by resting in the lateral recumbent position, right or left, thereby relieving uterine compression of the vena cava.

X-rays/Ionizing Radiation

The adverse effects on the fetus of ionizing radiation are dose-dependent. While there is no single diagnostic procedure that results in a dose of radiation high enough

to threaten the fetus or embryo, cumulative exposures or multiple procedures should be avoided, especially during the first trimester when the fetus is at highest risk for possible anomalies. Patients may undergo dental x-rays as needed, provided that the abdomen is fully covered by a lead apron. Studies using radioactive isotopes are best avoided. As in all diagnostic procedures, the risks and the potential benefits must be evaluated and individualized for each patient. Exposure to video display terminals is safe in pregnancy.

Travel

Most issues concerning travel involve the comfort of the mother. When prolonged sitting is involved, the patient should try to stretch her legs and walk for 10 minutes every 2 hours to decrease the risk of thrombosis that can occur secondary to the hypercoaguable pregnancy state and mechanical compression of venous blood flow from the extremities. Dependent edema may also be more pronounced after prolonged sitting. If the patient will be away from home for a significant period of time, she should take a copy of her medical record with her. Pregnant women can and should always wear seat belts when riding in a car. Travel in a pressurized airplane presents no additional risk to pregnant women. In traveling abroad, especially to underdeveloped countries, the usual precautions should be taken regarding ingestion of unpurified drinking water and uncooked fruits and vegetables.

Immunizations

Four immunizations using vaccines containing live viruses are relatively contraindicated during pregnancy. These are measles, mumps, rubella, and yellow fever. However, in certain circumstances, risk/benefit assessment may lead to receiving the immunizations. The risks for the fetus from the administration of rabies vaccine are unknown and each case must be considered individually, since the indications for prophylaxis are not altered by pregnancy. Tetanus toxoid, if needed, is acceptable in pregnancy. Flu vaccine is recommended for pregnant women. Women who are receiving hepatitis B vaccine may continue receiving it during pregnancy. Immune globulin for acute exposures to hepatitis A is considered safe also.

PREPARING FOR CHILDBIRTH

Prenatal Education Classes

Few empiric studies have examined the impact of prepared childbirth education on perinatal outcomes, but such education is generally believed to be helpful and valuable. The landmark volume *Birth of a Child* by Grantley Dick-Read, published in 1958, changed the modern face of childbirth education. Formal childbirth classes evolved rapidly in a multiplicity of settings. The goals of these classes are to educate and to answer questions in an environment conducive to the woman's new state of being, so that both the patient and her partner have the opportunity to decrease their anxiety level and increase their knowledge. Classes are designed to be an empowering experience, helping the parent(s) become a part of the process rather than the object of the actions of others. The content of childbirth classes varies but usually includes topics such as normal labor and delivery, anesthesia, breathing and concentration techniques, obstetric complications and interventions, and obstetric operations. Many instructors encourage patients to formulate a “birth plan” and to put this in writing and share it with their clinician. This can facilitate communication between the parents themselves and between patient and caregiver.

Certain decisions are best considered and made prior to delivery. These include issues such as breast-feeding, postpartum contraception, return to work, and circumcision of a male infant. It is helpful if parents are given information in a nonjudgmental, nonthreatening environment so that they may make appropriate, well-considered, and informed decisions.

Signs of Labor

The final element in preparing for childbirth is knowledge of when labor is occurring and when it is appropriate to notify the health care provider. Patients should be given a 24-hour phone number to call for assistance. A course of action should be made clear to the patient and her partner. As has been reinforced throughout pregnancy, any warning signs of potential adverse outcomes mandate an immediate telephone call.

CONCLUSION

The future of effective and efficient prenatal care in the United States depends largely on access, our ability to demonstrate clear benefit for patients and the incorporation of evidence-based data and practices that have well-defined outcomes and use cost-effective methods.

Of equal importance to the content of prenatal care is the manner in which it is delivered. A crucial determinant of effective prenatal care is the clinician–patient relationship. Virtues of trust, honesty, and ethical treatment are integral to achieving the goal of prenatal care, which emphasizes allowing patients to be active in their health care. The skill of a caregiver can prevent the alienating experience of a bad outcome, but caregivers who look for a solution to their own powerlessness in the domination of patients or the domination of natural processes can make good outcomes alienating experiences for their patients. Caregivers must be aware of cultural diversity and assess the care they give, not in terms of their own needs or the needs of a profession or a medical organization, but in terms of those who have entrusted them with care.

SUMMARY POINTS

- Pregnancy is a normal physiologic event in a woman's life and most pregnancies are normal. Pregnancy is a time of significant psychological transitions that are experienced in varied ways by each mother.
- The preconception visit is a focused visit that allows systematic identification of potential risks and the implementation of early interventions.
- The appropriate content of the first prenatal visit and subsequent prenatal care is contained in formalized published forms.
- A firm scientific foundation for the content and timing of prenatal care visits and the relationship of such care to maternal and newborn outcomes is under continued review.
- Pregnancy is a time of change, expectation, anticipation, concern, and uncertainty for many women and their families; the provision of direct, concise, and accurate information in a compassionate and reassuring manner by the clinician is therapeutic.
- Each prenatal visit should evaluate and address interval history, maternal changes, fetal growth, specific interventions, and general patient concerns.

Appendix III

Maternal and child health care currently accounts for a large proportion of health care dollars spent annually in the United States. This is due to the large number of patients and the numerous procedures performed during pregnancy and the first months of life.

The effectiveness of prenatal care is still often measured in terms of finite outcomes such as maternal and infant mortality. While these end points do not take into account such parameters as patient satisfaction, emergency interventions, length of hospitalization, and degree of access, they are used as a crude measure of quality of care of mothers and infants and are often cited in comparisons between states and countries, even when the actual data and methodologies for obtaining them are diverse and incomparable. The definitions currently used by the National Center for Health Statistics when collecting data on maternal and infant mortality and morbidity are given here.

- Live birth: the complete expulsion or extraction from the mother of a product of human conception, regardless of the duration of the pregnancy, that then breathes or shows any other evidence of life, whether or not the umbilical cord has been cut or the placenta is attached.
- Fetal death (stillbirth): death before the complete expulsion or extraction from the mother of a product of human conception, regardless of the duration of the pregnancy. This definition excludes terminations of pregnancy.
- Early neonatal death: death of a live-born infant during the first 7 days of life.
- Late neonatal death: death of an infant after 7 days but before 29 days of life.
- Fetal death rate: the number of stillborn infants per 1000 infants born.
- Neonatal mortality rate:the number of infant deaths before 29 days of life per 1000 live births.
- Perinatal death rate: a combination of fetal and neonatal deaths per 1000 total births.
- Birth rate: the number of births per 1000 members of the population.
- Fertility rate: the number of live births per 1000 female members of the population between the ages of 15 and 44 years.
- Maternal mortality: the death of a woman from any cause related to or aggravated by pregnancy or its management, regardless of duration or site of pregnancy (but not from accidental or incidental causes), occurring during the pregnancy or up to 42 days after the pregnancy. It includes direct and indirect obstetric deaths.
- Direct obstetric death: the death of a woman from obstetric complications of pregnancy, labor, or the puerperium, resulting from interventions, omissions, or treatment, or from a chain of events resulting from any of these.
- Indirect obstetric death: the death of a woman resulting from a previously existing disease or a disease that developed during pregnancy, labor, or the puerperium that was not related to direct obstetric causes, although the physiologic effects of pregnancy were partially responsible for the death.
- Maternal mortality rate: maternal deaths per 100,000 live births.

LABOR

Labor is defined as regular uterine contractions that lead to effacement and dilation of the cervix. If the estimated gestational age is accurate, labor usually begins within 2 weeks of the estimated date of confinement (EDC), which is 280 days (i.e., 40 weeks after the first day of the last menstrual period). However, because only 3% to 5% of patients actually deliver on their EDC, it has been suggested that EDCs be framed in terms of a range (e.g., from 38 to 42 weeks). Conceptualizing EDCs in this manner, it has been argued, might lessen the pressure for date-predicated interventions such as induction of labor.

Prior to the onset of true labor, there is a general softening and stretching of pelvic ligaments and the soft tissues of the vagina. There is also shortening and dilation (ripening) of the cervix. Braxton Hicks contractions (weak, irregular, regional contractions) usually occur for weeks before the onset of actual labor. The normal stimulus for the biochemical cascade that finally results in labor is unknown. Corticotropin-releasing factor (CRF) plays a role. It is released into the maternal circulation early in the second trimester, and its concentration rises exponentially as pregnancy advances. CRF regulates the secretion of adrenal cortisol, which can increase the strength of uterine contractions. CRF also stimulates production of oxytocin by the fetus and prostaglandins by the placenta.

Other factors probably play a role. For instance, progesterone inhibits and estrogen stimulates uterine contractility. Like CRF, estrogen also stimulates the production of oxytocin receptors in the uterus. Thus, as progesterone levels decline near term, estrogen may stimulate myometrial contractility. Mechanical stretch can also increase uterine contractility, as occurs with twin gestations and pregnancies complicated by polyhydramnios. Once labor is initiated, the process is thought to involve multiple positive feedback loops. For instance, contractions stretch the cervix. Stretching of the cervix elicits a reflex contraction by the uterus, pushing the fetal head against the cervix to stretch it more, and so on.

Labor Progress

Clinically recognizable labor is typically divided into three stages, each with statistically derived normative rates and durations. Many normative labor values were derived from the investigations of Emanuel Friedman, who studied thousands of normal and abnormal labors and plotted cervical dilation and fetal descent against time. The resulting graphic labor curve can be used to recognize individual labor patterns which deviate from normal and to guide the nature and timing of interventions. In a World Health Organization study of 35,484 women, use of a partogram (Fig. 2.1) and an agreed upon labor management protocol was associated with a reduction in the percentage of prolonged labors, the proportion of labors requiring augmentation, and postpartum sepsis.

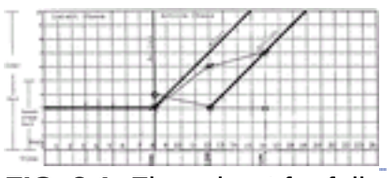

FIG. 2.1. Flow sheet for following labor progress. (From Chua S, Arulkumaran S. Poor prognosis in labor, including augmentation, malpositions and malpresentations. In: James DK, Steer PJ, Weiner CP, Gonik B, eds. High risk pregnancy, second ed. London: Harcourt Brace, 1999:1105; with permission.)

The first stage of labor begins with the onset of regular uterine contractions and ends with complete cervical dilation. This stage is further divided into three phases: latent, active, and deceleration, although the existence of the last phase has been questioned. During the latent phase, contractions become progressively stronger, longer, more frequent, and better coordinated. The mother's discomfort may be minimal or it may be severe. The latent phase is considered prolonged if it lasts longer than 20 hours in a nullipara, or 14 hours in a parous woman. The active phase commences when the slope of cervical dilation reaches its maximum. Typically, and especially in the nullipara, this occurs at 3 to 4 cm of dilation. During the active phase, contractions are usually strong and regular, occurring every 2 to 3 minutes. The active phase ends with complete (10 cm) cervical dilation. This phase of labor is generally quite painful. The length of the active phase is more predictable than the latent, lasting, on average, about 5 hours in nulliparas, and 2 hours in multiparas. Without labor epidural analgesia, respective minimum (fifth percentile) rates of dilation are 1.2 cm per hour and 1.5 cm per hour. With epidural, the rates are slower. Progressive descent of the fetal head into the maternal pelvis occurs to a variable degree during the active phase.

The second stage is defined as the period from complete cervical dilation to complete delivery of the baby. During the second stage, contractions are strong and regular, with a frequency of every 1 to 3 minutes. The baby's head descends more deeply into the pelvis, and in women without regional anesthesia, each contraction stimulates a strong urge to push. In combination, uterine contractions and maternal expulsive efforts effect delivery of the baby. The second stage typically lasts about 50 minutes in nulliparas and 20 minutes in multiparas, but is often longer in women with regional anesthesia. The third stage of labor is defined as the period from delivery of the baby to delivery of the placenta. Regardless of parity, the third stage of labor is usually brief (under 10 minutes). The third stage of labor is prolonged if it persists beyond 30 minutes.

The three classic determinants of the progress of labor are:

- *Power*—uterine contractions and, in the second stage, maternal expulsive efforts
- *Pelvis*—the bony pelvis and the overlying maternal soft tissues
- *Passenger*—the fetus and its lie, presentation, and position.

The power of labor can be assessed clinically by uterine palpation or with the use of an intrauterine pressure catheter. Assessment of the pelvis involves manual

evaluation of the pelvic inlet, midpelvis, and outlet.

- *Pelvic inlet*—The transverse diameter of the pelvic inlet averages 13 cm. It cannot be measured clinically, but a narrow transverse inlet is a very rare cause of abnormal labor progress. The anteroposterior (AP) diameter of the inlet is more important. It is estimated clinically by determining the distance between the lower margin of the symphysis pubis and the sacral promontory (Fig. 2.2). This value is known as the diagonal conjugate. The obstetric conjugate—or true AP diameter—is 1.5 to 2.0 cm shorter. The pelvic inlet is an adequate size for a normal fetus if the diagonal conjugate is 12 cm or greater.

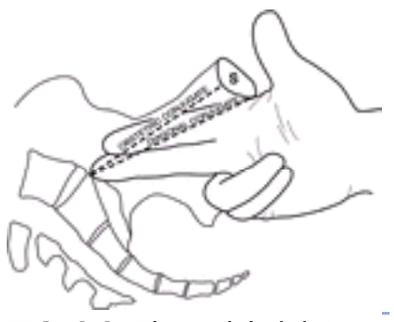

FIG. 2.2. The pelvic inlet anteroposterior diameter is estimated from the diagonal conjugate.

- *Midpelvis*—The specific diameters of the midpelvis cannot be measured clinically. Contraction of the midpelvis is suspected if the ischial spines are quite prominent (or the sacrosciatic notch is less than two fingerbreadths wide), the pubic arch is narrow, the pelvic side walls converge, or the sacral concavity is quite shallow (Fig. 2.3).

FIG. 2.3. The transverse diameter of the midpelvis is estimated by evaluating the distance between the ischial spines.

- *Pelvic outlet*—The transverse diameter of the pelvic outlet should be greater than 8 cm. This diameter can be estimated by placing a fist on the perineum to measure the distance between the ischial tuberosities. The AP diameter is estimated by noting the angle made by the pubic rami. A contracted outlet is rarely the sole cause of dystocia; however, it is often associated with midpelvis contraction.

Consideration of these measurements allows assignment to one of the various pelvic types, and thus an appreciation of how and where labor may be stalled if the pelvis is not favorable for childbirth (Fig. 2.4). Careful evaluation of the midpelvis is most important, as those women found to have a contracted midpelvis are poor candidates for forceps-assisted vaginal delivery. However, because the fetal skull has the ability to mold, borderline pelvimetry is not a contraindication to a trial of labor.

FIG. 2.4. Pelvic types. **A:** Gynecoid pelvis—most common, round to oval inlet, ischial spines not prominent, curved sacrum, wide pubic arch; best suited for childbearing. **B:** Android pelvis—heart-shaped inlet, narrow midpelvis with anterior sacrum, prominent ischial spines, convergent side walls, narrow pubic arch. **C:** Platypelloid pelvis—least common, decreased anteroposterior dimensions at all levels with wide transverse dimensions. **D:** Anthropoid pelvis—narrow inlet, midpelvis, and pubic arch.

From the perspective of the passenger (fetus), labor involves movement progressively downward through the pelvis by the following *cardinal movements* (Fig. 2.5).

FIG. 2.5. Cardinal movements of labor. **A:** Engagement. **B:** Flexion. **C:** Descent and internal rotation. **D, E:** Extension. **F:** External rotation.

- *Engagement* occurs days to weeks prior to labor for primigravidas and at the onset of labor for multigravidas.
- *Flexion* of the neck allows the occiput to lead, thus the smallest possible diameter of the fetal head travels downward through the pelvis.
- *Descent* is progressive as the cervix thins, and the lower uterine segment lengthens.
- *Internal rotation* occurs during descent. The vertex rotates from transverse to either a posterior or anterior position to pass the ischial spines.
- *Extension* occurs as the fetal head distends the perineum and the occiput passes beneath the symphysis.
- *External rotation* of the head after delivery to a transverse position allows the shoulders to rotate internally to an AP position.

MANAGEMENT OF LABOR AND DELIVERY

Antepartum Instructions

All women should be advised of the circumstances that should prompt them to seek evaluation for labor. These include (a) possible rupture of the membranes, (b) regular uterine contractions, (c) bleeding per vagina, and (d) back, pelvic, or abdominal pain greater than they are anticipating. Nulliparas are more likely to confuse false labor or Braxton Hicks contractions with true labor. Although distinguishing the two can be problematic, the contractions of false labor tend to be irregular both in intensity and in interval, and the associated discomfort, if any, is typically limited to the lower abdomen and groin. The contractions of false labor usually abate with time, analgesia, or sedation. With true labor, the contractions progressively increase in intensity. They occur every 2 to 4 minutes and cause discomfort in the abdomen and back with the associated sensation of increasing pelvic pressure. For many women labor will be preceded, by several hours or even days, by the passage of bloody show (a small amount of bloody mucous discharge from the cervix). In 10% of pregnancies, chorioamnion rupture precedes the onset of labor, and amniotic fluid leaks through the cervix and out of the vagina. Optimal management for such women has recently been clarified. A randomized trial of over 5000 women with

prelabor rupture of membranes at term demonstrated that induction of labor with oxytocin (as opposed to expectant management, or induction with prostaglandins) resulted in the lowest rate of neonatal infection and maternal postpartum fever, and did not increase the cesarean delivery rate. In many cases, the only way to confirm the diagnosis of true labor is observation over several hours and examination of the cervix for change.

Admission

If the woman is having contractions, their time of onset and frequency should be recorded. Questions should focus on spontaneous rupture of the membranes, presence or absence of bleeding, and fetal activity. A review of the patient's prenatal record should take specific note of her EDC and its reliability, as well as her past medical and surgical history, and details of previous pregnancies: number, gestation, fetal size, duration of labor, and any complications (e.g., shoulder dystocia). Prenatal laboratory data should be reviewed, including blood type, hematocrit, Rh_0(D) immune globulin requirements, VDRL test, rubella immunity, and hepatitis and human immunodeficiency virus (HIV) status.

The admission physical examination should include vital signs (temperature, pulse, blood pressure), auscultation of the heart and lungs, and a brief neurologic examination. Leopold maneuvers should be performed to assess fetal position (Fig. 2.6), and the uterus should be palpated, or a tocodynamometer employed, to determine the frequency, intensity, and duration of uterine contractions. Fundal height should be evaluated and a clinical assessment of fetal weight should be performed. Fetal heart tones should be assessed, either by auscultation or via electronic monitoring, with specific attention to the response of the fetal heart rate (FHR) to the uterine contractions.

FIG. 2.6. Leopold maneuvers. **First maneuver:** The uterine contour is outlined; the fundus is palpated, allowing identification of the fetal parts. **Second maneuver:** By palpation of the sides of the maternal abdomen, the location of the fetal back is determined. **Third maneuver:** The presenting part is grasped, identified, and evaluated for engagement. **Fourth maneuver:** With palpation toward the pelvis, the identity of the presenting part is confirmed, and flexion or extension of the fetal head is evaluated.

The vulva should be examined for herpetic lesions. If membrane rupture is suspected, it should be confirmed (or ruled out). Several signs support rupture, including pooling of amniotic fluid in the vagina (observed by sterile speculum examination) or direct visualization of fluid leakage through the cervix. The pH of the pooled fluid can be checked with nitrazine paper, which turns blue in the presence of amniotic fluid (but also in the presence of blood), and an air-dried sample (on a slide) of the fluid can be examined under a microscope for the characteristic “fern” pattern that confirms the presence of amniotic fluid (Fig. 2.7). Since cervical mucus and maternal serum can demonstrate a fern pattern, care must be taken in collection of this sample. Palpation of the cervix includes attention to the following:

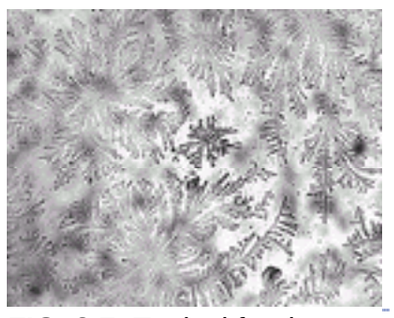

FIG. 2.7. Typical fern pattern of dried amniotic fluid (400×). (Original photo, courtesy of Dr. Dwight Rouse.)

- assessment of consistency (soft or firm)
- degree of effacement (Fig. 2.8)

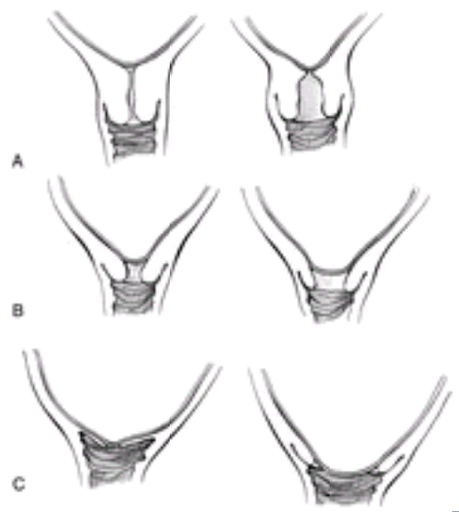

FIG. 2.8. Degree of cervical effacement. **A:** No effacement. **B:** 75% effacement. **C:** 100% effacement.

- dilation of the cervical os
- location of the cervical os with respect to the vaginal axis (posterior, midplane, or anterior).

The presenting part should be identified by palpation. Station is determined by noting the position of the fetal presenting (bony) part relative to the ischial spines (Fig. 2.9). The fetal position is determined by noting the orientation of occiput relative to the maternal pelvis (Fig. 2.10). The attitude of the fetal head is the position of the fetal head relative to the fetal chest and any lateral flexion of the head (Fig. 2.11, Fig. 2.12 and Fig. 2.13). Pelvimetry should be performed as previously described.

FIG. 2.9. Stations of the fetal head. At the 0 station, the fetal head is at the bony ischial spines and fills the maternal sacrum. Positions above the ischial spines are referred to as -1 through -5, referring to the number of centimeters that the head is positioned above the spines. As the head descends past the ischial spines, the stations are referred to as +1 through +5 (head visible at the introitus).

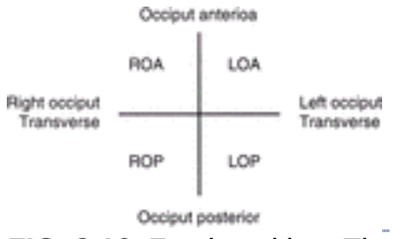

FIG. 2.10. Fetal position. The orientation of the presenting vertex within the maternal pelvis.

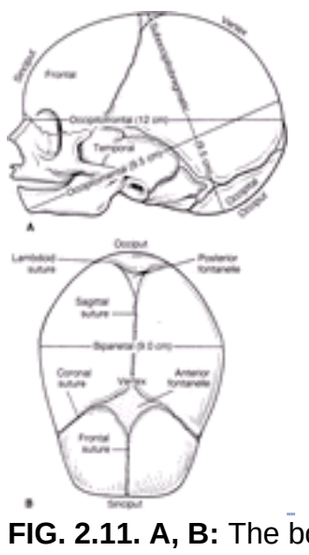

FIG. 2.11. A, B: The bones, sutures, fontanelles, and clinically important diameters of the fetal head.

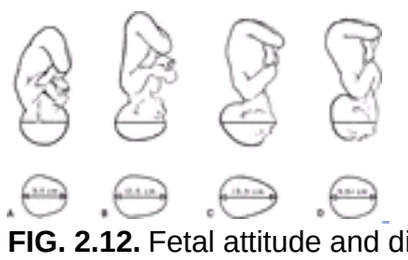

FIG. 2.12. Fetal attitude and dimensions of a term-size fetus. **A:** Full flexion presents the smallest circumference of the fetal head to the narrower planes of the pelvis. **B:** Military attitude usually changes to full flexion with descent into the pelvis. **C:** Brow presentation usually converts to full flexion or a face presentation, as the occipitomental diameter is too large for all except the largest pelves to accommodate. **D:** Face presentation shows dimensions that allow descent through the pelvis, unless the chin is posterior. Persistent mentum posterior must be delivered by cesarean section.

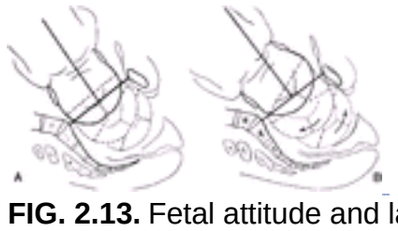

FIG. 2.13. Fetal attitude and lateral flexion of the fetal head. **A:** Synclitism—The plane of the biparietal diameter is parallel to the plane of the inlet. **B:** Asynclitism—Lateral flexion of the fetal head leads to anterior parietal or posterior parietal presentation.

In women at term with rupture of the membranes prior to the onset of labor, it is appropriate to defer digital examination of the cervix until they are in active labor, to decrease the risk of chorioamnionitis. It is important, however, to confirm the baby's presentation, and an ultrasound examination should be performed if the presentation is not clear.

Management of the First Stage of Labor

A variety of management approaches to the first stage of labor have been employed and evaluated, and no single approach is clearly superior. The primary management goals are to monitor fetal well-being, support the woman through what can be a lengthy, uncomfortable period, and offer intervention as it may become appropriate. Support of the woman through labor includes allowing her to assume whatever position is most comfortable (or least uncomfortable) for her. All forms of monitoring, be it intermittent auscultation, external fetal monitoring, or internal monitoring, can be accomplished in a lying, sitting, or upright position. In most normal labors, the only time a healthy woman's movements must be limited is after she has received analgesia and would not be steady on her feet. Uterine blood flow is maximal in the lateral recumbent position, and this should be the initial position adopted if there is concern over fetal well-being. Because of impaired venous return and reduced maternal cardiac output, the supine position is usually best avoided. With these considerations in mind, women should be free to position themselves as they like.

Vital signs should be monitored at least every 4 hours, or more frequently as clinically indicated. By consensus of the Centers for Disease Control and Prevention and the American College of Obstetricians and Gynecologists (ACOG), all women whose 35-37 week rectovaginal group B streptococcus (GBS) culture was positive should receive intrapartum antibiotic prophylaxis for the prevention of early onset neonatal GBS disease. Acceptable prophylactic antibiotic regimens include intravenous penicillin G 5 million units initially, and then 2.5 million units every four hours until delivery, or intravenous ampicillin 2 gm initially, followed by 1 gm every 4 hours until delivery. For women allergic to penicillin, clindamycin, erythromycin, vancomycin, or, in women without a urticarial or anaphylactoid response to penicillin, a first

generation cephalosporin may be substituted.

Irrespective of rectovaginal culture results, women with GBS bacteriuria during the pregnancy and those who have previously delivered an infant with early onset GBS disease should also receive antibiotic prophylaxis. If an appropriate rectovaginal GBS culture was not performed or is not available, prophylaxis should be based on the following risk factors: threatened pre-term delivery (< 37 weeks), GBS bacteriuria at any time in the current pregnancy, fever (= 38.0°C), rupture of membranes for at least 18 hours, or delivery of a prior infant with early onset GBS disease. Separate from the issue of GBS prophylaxis, if a woman develops an intrapartum fever, defined by some authorities as a temperature of at least 37.8°C (100.0°F) and by others as at least 38.0°C (100.4°F), evaluation and treatment for chorioamnionitis may be indicated.

Placement of an intravenous line is not necessary for all women in labor. However, women who are dehydrated may benefit from intravenous hydration. It seems prudent to establish intravenous access for administration of fluids and medication, should they be necessary, in women at increased risk of postpartum hemorrhage (i.e., those with prior postpartum hemorrhage, prolonged labor, or overdistended uterus).

In most women, laboratory evaluation upon presentation in labor can be minimized. Although in many units it is customary to perform routine admission blood type and antibody screen, hemoglobin and hematocrit, and syphilis serology, the necessity and cost-effectiveness of repeating these tests in healthy women who have received adequate prenatal care is debatable. Certainly, if a woman has hypertension on admission, she should be evaluated for possible preeclampsia. In women who have not had any prenatal care, it is advisable to order a hemoglobin and hematocrit, blood type, and Rh status, an antibody screen, a rubella titer, and syphilis, hepatitis, and HIV screens.

The benefits of continuous caregiver support (by nurses, midwives, or laypeople) throughout labor have been established by multiple randomized trials. Salutary effects of such support include reduced pain medication requirements, lowered rates of operative vaginal and cesarean delivery, and a diminution in the frequency of 5-minute Apgar scores below 7. Thus, to the extent possible, all women should have access to continuous caregiver support throughout labor.

No evidence-based criteria are available to direct how often the cervix should be examined during the first stage of labor. In general, frequent examinations in the latent phase of labor serve little purpose. They may unrealistically increase a woman's expectation for progress in labor and in addition, are uncomfortable and increase risk for infectious morbidity. However, during observation, if the membranes rupture, the cervix should be examined and the FHR evaluated if the presenting part was not well applied to the cervix on previous examination. These measures should enhance the detection of umbilical cord prolapse. In the active phase of labor, monitoring the progress of labor with cervical examinations every 2 hours allows identification of those women who are not making normal progress and who should therefore be evaluated for oxytocin augmentation.

During labor, the FHR should be monitored. For most women, both intermittent auscultation and intermittent or continuous electronic monitoring are acceptable (see Chapter 9). While artificial rupture of membranes (amniotomy) may shorten the duration of labor by 1 to 2 hours and reduce the use of oxytocin, it may also increase the risk of cesarean delivery by 25%. Thus, in most women, amniotomy should be reserved for such indications as placement of internal fetal monitoring devices for better assessment of the FHR pattern, or for abnormal labor progress. To avoid umbilical cord prolapse, amniotomy is best performed when the presenting part is well applied to the cervix, and preferably during a contraction (or with fundal pressure) to minimize the chance for dislodging the fetal head. Although typically performed with a thin, plastic, hook-ended tool designed specifically for the purpose, amniotomy may be achieved simply by placing a fetal scalp electrode. In cases of excess amniotic fluid, or when the vertex is not well applied, a spinal or pudendal block needle may be used to create a small opening in the membranes to allow the gradual egress of amniotic fluid, thereby avoiding umbilical cord prolapse or the rapid decompression of the uterus and the associated risk of placental abruption.

Meconium staining of the amniotic fluid occurs in up to one-fifth of deliveries. Meta-analysis of randomized trials performed in settings of standard perinatal surveillance demonstrates that with moderate or severe meconium staining, amnioinfusion of 500 to 1000 mL (or more, depending on the protocol) of sterile saline into the uterus (through an intrauterine catheter) will reduce variable heart rate decelerations and may lower the risk of cesarean delivery. In settings of limited perinatal surveillance, amnioinfusion reduces the risk of meconium aspiration syndrome, neonatal hypoxic ischemic encephalopathy, neonatal ventilation or intensive care unit admission, and perhaps perinatal mortality.

Management of the Second Stage of Labor

The onset of the second stage of labor with complete dilation of the cervix is usually noted by the woman as the presenting part descends into the vagina and she experiences the urge to push with contractions. However, regional anesthesia may partially or completely blunt this urge. The cervix should be examined at this time to confirm complete dilation, and the position and station of the presenting part should be ascertained. Whether nulliparous women with regional anesthesia should begin expulsive efforts in the absence of an urge to push was the subject of a multicenter, randomized clinical trial. In the trial, women allocated to immediate pushing were less likely to have intrapartum fever (4.5% vs. 8.5%). Moreover, their second stages were one hour shorter. However, difficult deliveries (defined as midpelvic operative vaginal deliveries, low-pelvic rotational deliveries, or second stage cesarean delivery) were less common (18% vs. 23%) in the delayed pushing group, who were instructed to not push until the urge was irresistible or the head was on the perineum. Neonatal outcomes were equivalent between the groups. This trial thus supports individualization in the timing of maternal expulsive efforts.

Support of a woman in the second stage involves allowing her to find the most comfortable and effective position for pushing, as well as encouraging her efforts. Preparations for delivery should be made when the presenting part begins to distend the perineum and often sooner for multigravidas. Local or pudendal anesthesia, if necessary, should be administered at this time.

An episiotomy is an incision in the perineum used to facilitate vaginal delivery. It is useful for patients in whom the perineum does not readily stretch and when delivery must be expedited. In the past, routine episiotomy was advocated to prevent subsequent pelvic relaxation; however, there is no evidence that it does so. Meta-analysis of randomized episiotomy trials, in which restrictive episiotomy use (˜ 30% of women underwent episiotomy) was compared to liberal use (˜70% episiotomy rate), reveals the following. Restrictive use of episiotomy lowers the risk of posterior perineal trauma, lessens the need for suturing, and is associated with fewer healing complications. However, restrictive use of episiotomy increases the risk of anterior perineal trauma. There is no difference between the two policies in severe vaginal or perineal trauma, or subsequent dyspareunia, urinary incontinence, or perineal pain.

There are two basic types of episiotomy: midline and mediolateral. The benefits of a midline episiotomy include anatomic end results, easy repair, and lower incidence of postpartum pain or dyspareunia. A mediolateral episiotomy is less likely to extend into the anal sphincter or rectal mucosa, but is generally believed to result in more pain, dyspareunia, and excessive blood loss. Episiotomy should not be performed until delivery is imminent. A midline incision is made with scissors from the midpoint of the posterior fourchette directly backward toward the rectum (Fig. 2.14). The midline episiotomy is subdivided as follows:

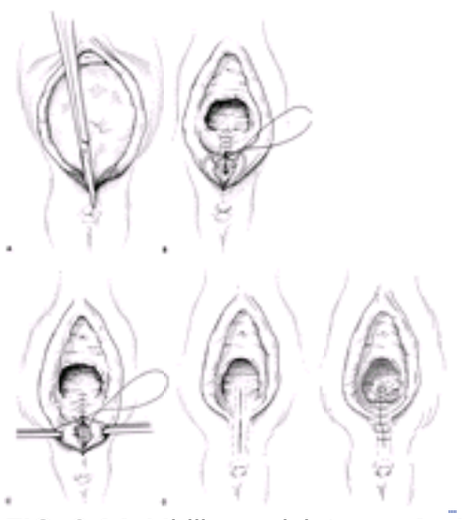

FIG. 2.14. Midline episiotomy. **A:** As the fetal head distends, with the perineum under adequate anesthesia, the episiotomy is cut through the perineal body and the tissues of the vagina and the rectovaginal septum. **B:** The episiotomy is repaired by reapproximating the vaginal mucosa in a running fashion with a delayed absorbable suture. **C:** The submucosal tissue of the vagina and the subcutaneous tissue and fascia of the perineal body are then closed. **D:** The skin is then reapproximated with a running subcuticular suture.

- first degree—through the mucosa only

- second degree—through the mucosa and subcutaneous tissues, including the muscles of the perineal body
- third degree—into or through the anal sphincter
- fourth degree—through the rectal mucosa.

A mediolateral incision is made with scissors from the midpoint of the posterior fourchette at a 45-degree angle laterally on either side.

Regardless of use of an episiotomy, tears and extensions into the rectum are best prevented by keeping the baby's head well flexed until the occiput passes beyond the subpubic arch. As the vertex appears beneath the symphysis, the perineum is supported by direct pressure from a draped hand over the coccygeal region. As the head delivers, it will rotate to a transverse position; the mother should be encouraged to continue to push to achieve delivery of the anterior shoulder. A quick evaluation for the presence of the umbilical cord around the baby's neck (nuchal cord) should be carried out. A nuchal cord can usually be slipped around the baby's head. Occasionally, it must be double-clamped and cut if it is too tight to reduce. Maternal pushing efforts can be assisted by placing gentle downward traction on the baby's head. With delivery of the anterior shoulder, a moment can be taken to bulb suction the baby's nose and mouth. Renewed pushing by the mother in combination with gentle upward traction by the obstetrician will achieve delivery of the posterior shoulder. The baby's body generally delivers easily following the shoulders. Care must be taken to support the baby's head and ensure that the baby does not slip from one's grip. After confirmation of good respiration and normal heart rate (easily checked at the cord insertion at the umbilicus), the baby may be given to the mother to cradle. The cord is then double-clamped and cut, and cord blood collected. The baby should be dried and wrapped soon following delivery to maintain its body temperature.

Management of the Third Stage of Labor

The third stage of labor begins following the delivery of the baby and ends with the delivery of the placenta. Signs of spontaneous placental separation include an apparent lengthening of the umbilical cord, a gush of vaginal bleeding, and a change in shape of the uterus from discoid to globular along with a rise in fundal height. Active management of the third stage of labor, which involves prompt umbilical cord clamping and cutting, administration of an oxytocic agent, and gentle umbilical cord traction, reduces maternal blood loss and the frequency of postpartum hemorrhage, and lessens the risk that the third stage will be prolonged. Cord traction should be used only against fundally applied counter-traction (Fig. 2.15) to lessen the potential for uterine inversion and catastrophic hemorrhage. If at any time heavy bleeding occurs during the third stage of labor or if the placenta is not delivered within 30 minutes of the birth, the placenta should be manually removed. The anesthesiologist should be alerted at this time, as general anesthesia may be required for women who have no regional anesthesia, and curettage may be necessary if the placenta does not readily separate from the uterine wall. Manual removal is accomplished by developing a cleavage plane with the intrauterine hand between the maternal surface of the placenta and the uterine wall, while simultaneously fixing the uterus with the abdominal hand, and progressively peeling the placenta free. To ensure complete placental removal, a 4-inch by 4-inch gauze may be wrapped around the hand and used to abrade the uterine wall. The placenta should then be carefully inspected for cord insertion, confirmation of a three-vessel cord (infants with only two cord vessels have a higher rate of malformations and warrant closer evaluation by the newborn caregiver), and completeness of the placenta and membranes. If any portion of the placenta or the membranes is missing, the uterine cavity should be manually explored. Some advocate routine exploration of the uterine cavity to reduce the risk of infection and bleeding from retained placental fragments. In most women, especially those without regional anesthesia, the benefit of manual exploration is outweighed by the discomfort it causes, as well as the increased risk for uterine infection.

FIG. 2.15. Stage three of labor: delivery of the placenta. **A:** Spontaneous separation of the placenta is confirmed. **B:** With gentle traction on the umbilical cord and suprapubic palpation of the fundus, the placenta and membranes are delivered. **C:** If spontaneous separation of the placenta does not occur or bleeding ensues, the placenta is manually separated from the wall of the uterus and removed.

The uterus should be frequently palpated following delivery of the placenta to ensure that it remains well contracted. Oxytocin, 10 to 20 U administered intramuscularly or as a dilute intravenous solution, has been demonstrated to decrease the incidence of postpartum hemorrhage secondary to uterine atony. The birth canal, including the cervix, vagina, and perineum should be inspected for lacerations requiring repair. During this time, under most circumstances and after drying and swaddling, the baby should be kept with the family and, for women planning to breast-feed, placed to the breast to nurse within the first 10 to 20 minutes after birth. This first suckling not only stimulates endogenous oxytocin release but also begins the process of milk production and successful breast-feeding.

Management of the “Fourth Stage” of Labor

Because many complications of birth occur or become evident during the first hour after delivery, this time has been referred to as the “fourth stage” of labor, though it is not officially defined as a labor stage. The new mother should be seen at least every 15 minutes by a trained labor and delivery nurse to assess vital signs and look for evidence of uterine atony or postpartum hemorrhage. The perineum should be inspected for any signs of hematoma formation, which may be signaled by inordinate vulvar or rectal pain. The newborn should undergo its initial assessment at this time and be observed closely for any signs of compromise.

Postpartum Care

After the first 24 hours, postpartum recovery is rapid. A regular diet can be offered to most women as soon as they request food, sometimes shortly after delivery. Because of their risk to require general anesthesia, it is prudent to delay feeding women who have experienced, or are at risk for, significant postpartum hemorrhage. Full ambulation is encouraged as soon as possible. Exercises to improve tone and strengthen abdominal muscles may be started after 1 day. The perineum should be cleansed with warm water two or three times daily after voiding or bowel movements. Both showers and baths may be taken, but vaginal douching is prohibited during the early puerperium to avoid the risk of introducing infection into the uterus. Pain from an uncomfortable perineal laceration or episiotomy can be relieved with warm sitz baths and an analgesic (e.g., acetaminophen, 650 mg, with or without codeine or ibuprofen, 600 to 800 mg) (Table 2.1).

Oxytocin, 10 U i.m.
Bed rest and vital signs every 15 min for 1 h postpartum then every 4 h
Regular diet
Ambulation as tolerated when stable
Ice pack to the perineum
Tucks to the perineum as required
Sitz baths t.i.d. and at bedtime, as needed
Maintain i.v. line (if present): discontinue when vital signs are stable and uterine bleeding is normal
Urethral catheterization if unable to void in 6 h
Breast binder, ice packs if not nursing
Hemoglobin and hematocrit on postpartum day 1
Type and crossmatch for $Rh_0(D)$ immunoglobulin if indicated
Medications
Vitamins: continue prenatal vitamins; additional ferrous sulfate if anemic
Pain: ibuprofen, 400–600 mg p.o. every 4–6 h, for cramping/pain
Bowels: docusate sodium, 100 mg p.o. BID, milk of magnesia, 30 mL/d p.o., as needed; bisacodyl, 10 mg p.o. or per rectum, as needed

TABLE 2.1. *Examples of orders after routine vaginal delivery: immediately postpartum*

When regional anesthesia is used, care must be taken to avoid problems with urinary retention and bladder overdistention. Women should be encouraged to void every 2 to 3 hours, even if they are not aware of any sensation of bladder fullness, as rapid diuresis may occur following delivery, especially when oxytocin is discontinued.

Prior to discharge, a hemoglobin or hematocrit should be checked if there is any concern that a woman has experienced heavier than normal postpartum bleeding, or if she entered labor significantly anemic. In addition, seronegative women should be immunized against rubella on the day of discharge. If the mother is Rh-negative, is not sensitized, and has an Rh-positive infant, she should be given $Rh_0(D)$ immune globulin to prevent sensitization from occurring. As discharge from the hospital now

occurs anywhere from 12 to 48 hours following an uncomplicated birth, most women have not begun milk production prior to their discharge. To support breast-feeding, it is critical to advise women of the availability of assistance, should they experience any difficulty with nursing. Binding and avoiding any stimulation of the breasts are advised if the mother does not plan to breast-feed. She should also take aspirin, acetaminophen, or ibuprofen if engorgement becomes uncomfortable.

The length of inpatient hospitalization following childbirth has changed remarkably over the past two decades, reflecting the decreasing risk of postpartum complications and changing medical and societal attitudes toward birth, as well as pressures from third-party payors. Numerous reports, including three randomized, controlled trials have shown early discharge, 12 to 24 hours postdelivery, *with* appropriate follow-up in the home results in a low and acceptable rate of readmission of mothers and babies. Several studies show that longer hospital stays improve maternal postpartum adjustment and breast-feeding success. Stays of 12- to 24-hours are only acceptable when patients have adequate help in the home and the community has a home care nursing program with 24-hour coverage, 7 days a week. Home care services, while not always necessary, can be very helpful and appear to increase the safety of early discharge. All women and their babies discharged within 24 hours of birth should be offered a minimum of one home visit or an appointment for outpatient follow-up in the first few days following discharge.

PUERPERIUM

The puerperium is the 6 to 8 weeks following delivery of the placenta, in which the uterus returns to its normal state. Following delivery of the placenta, the uterus rapidly contracts to half of its predelivery size. The involution that then occurs over the next several weeks is most rapid in women who breast-feed their newborns. Postpartum vaginal discharge, or lochia, changes as the uterus involutes. Initially, the discharge is grossly bloody (lochia rubra), persisting for 3 to 4 days. It then decreases in volume and changes to pale brown and becomes thinner (lochia serosa), persisting for 10 to 12 days. Finally, the discharge becomes yellowish white, occasionally tinged with blood (lochia alba), and may persist for several weeks. The total volume of lochia is about 250 mL, and women are usually encouraged to use external pads to absorb it, rather than intravaginal tampons, in order to minimize the risk of infection. When followed closely, a woman's hematocrit may actually rise due to diuresis following delivery and autotransfusion occurring as the uterus involutes. After 1 week, the uterus is firm and nontender and extends to about midway between the symphysis and the umbilicus. By 2 weeks postpartum, the uterus should no longer be palpable abdominally. The contractions of the involuting uterus may be painful, especially during the first few days following delivery. These “after pains” are usually relieved with acetaminophen or ibuprofen.

Prior to discharge, women should receive instructions regarding what they can expect during the puerperium and recommendations for activity. In general, women should be encouraged to rest as they feel necessary and gradually increase their activity following delivery. They do not need to be restricted in terms of ambulation, but should be cautioned that driving in the early postpartum may not be advisable if perineal discomfort is distracting, or would cause a delay in reaction in case of an emergency. Women can resume a regular diet, and, if nursing, should be encouraged to keep well hydrated. Perineal pain should gradually diminish. If it does not, or it worsens, women should be instructed to seek evaluation for possible infection or hematoma. Normal bladder function should resume, but women should be cautioned that they may experience some difficulty with stress and urge incontinence, which can be expected to gradually improve in the months following delivery.

Parents should receive information regarding lochia, expected volume, changes, and duration; activities; care of the breasts, perineum, and bladder; and dietary and, specifically, fluid requirements. The specific signs of complications should be stressed, including fever, chills, leg pain or swelling, episiotomy pain or drainage, and abnormal duration or amount of bleeding.

Couples should be advised that they can safely resume coitus when desired and comfortable; however, abstaining for at least 2 weeks following the birth is often recommended. They should be forewarned of potential discomfort of the perineum and problems with vaginal dryness due to atrophic vaginitis, as well as the potential for transient changes in libido related to pregnancy and delivery.

For women who are breast-feeding, ACOG has summarized hormonal contraceptive options (Table 2.2). Women who are not nursing and desire a combination oral contraceptive can safely have this method initiated 1 to 2 weeks following delivery. Long-acting progestin contraception such as medroxyprogesterone acetate (Depo-Provera) injections or levonorgestrel implants (Norplant System) can be started or placed anytime following delivery. A diaphragm should be fitted only after complete involution of the uterus at 6 to 8 weeks postpartum. In the meantime, condoms and spermicidal foam or jelly should be used. Intrauterine devices can be placed immediately following delivery of the placenta; however, insertion at this time is associated with an increased risk of expulsion. Thus, waiting until 6 to 8 weeks postpartum may be preferable.

◊ Progestin-only oral contraceptives prescribed or dispensed at discharge from the hospital to be started 2–3 wks postpartum (e.g., the first Sunday after the newborn is 2 wks old)
◊ Depot medroxyprogesterone acetate initiated at 6 wks postpartum[a]
◊ Hormonal implants inserted at 6 week postpartum[a]
◊ Combined estrogen–progestin contraceptives, if prescribed, should not be started before 6 wks postpartum, and only when lactation is well established and the infant's nutritional status well-monitored

[a]There are certain clinical situations in which earlier initiation might be considered.

TABLE 2.2. *ACOG recommendations for hormonal contraception if used by breast-feeding women*

In nonlactating women, ovulation usually occurs about 6 weeks postpartum. The first menses following delivery is often an anovulatory cycle; however, conception has been reported as early as 2 weeks postpartum, so contraception must be advised even in the early postpartum period. While women who exclusively breast-feed their babies usually do not ovulate for at least 3 months following delivery, an occasional nursing mother will ovulate early, and thus contraception use should be advised. Women who receive rubella immunization, which is a live vaccine, are advised to delay pregnancy for at least a month. Women should be cautioned about postpartum depression. Instructions from the pediatrician regarding care of the neonate should be reinforced, as well as encouraging follow-up should any problems occur.

Although its value is open to question, it is customary to schedule an office visit 4 to 6 weeks postpartum. At this visit, inquiries should be made regarding breast-feeding, continued bleeding, resumption of sexual intercourse, use of appropriate contraception, and any difficulty with regard to voiding or bowel movements. A focused physical examination can be performed, and a Pap smear obtained, if indicated. Women should be counseled regarding emotional lability in the postpartum period and reassured that intervention is available should she experience clinically significant depression.

Complications of the Puerperium

Puerperal Infection Fever (a temperature of at least 38°C or 100.4°F) is the most commonly observed sign of puerperal infection. The differential diagnosis includes infections of the perineum, vagina, uterus, parametrium, bladder, kidneys, or breast. Noninfectious causes of fever such as thrombophlebitis and breast engorgement must also be considered. After vaginal delivery, endometritis is infrequent but may be presaged by chorioamnionitis. Various obstetric factors increase the risk of endometritis; two of the most consistent are prolonged rupture of the membranes and prolonged labor, both of which are often associated with multiple intrapartum cervical examinations, which also add to the risk. Endometritis is usually caused by normal vaginal flora, including *Escherichia coli*, ß-hemolytic streptococci, facultative organisms such as *Streptococcus faecalis*, and anaerobes such as *Peptostreptoccus, Bacteroides*, and *Prevotella* species. Most infections involve mixed flora, but progression to an anaerobic infection is a particular risk following cesarean delivery. Women suffering with serious puerperal infection of the reproductive tract frequently complain of chills, headache, malaise, and anorexia. Physical examination usually reveals tachycardia and often pallor. If the uterus is involved, it is usually tender and may be large and boggy. Lochia may be diminished if the cervix is blocked, or it may be profuse and malodorous. Parametrial involvement, peritonitis, and pelvic thrombophlebitis may complicate the illness. Endotoxic shock or a virulent puerperal sepsis may develop in a relatively short time and can be fatal. Prompt and aggressive management with broad-spectrum antibiotics—and potentially surgery—is mandatory (see Chapter 19).

Postpartum Hemorrhage Postpartum hemorrhage has been defined as a blood loss of greater than 500 mL during or after the third stage of labor. This definition is somewhat paradoxical, as careful measures of blood loss following delivery indicate that the *average* is approximately 500 mL. After hypertensive disorders and embolism, postpartum hemorrhage is the major cause of maternal mortality for women who reach the second trimester. The major cause of postpartum hemorrhage is uterine atony, or failure of the uterus to contract sufficiently after delivery. This failure inhibits the major hemostatic mechanism of the postpartum uterus—myometrial contraction with constriction of placental bed arteries and veins. Risk factors for uterine atony include prolonged or oxytocin-augmented labor, uterine overdistension (as with polyhydramnios, fetal macrosomia, or multiple gestation), chorioamnionitis, grand multiparity, and a history of postpartum hemorrhage. Halogenated anesthetic agents also inhibit uterine contractility, and very rapid labors have been associated with failure of the uterus to contract adequately after delivery. Additional causes of postpartum hemorrhage are vaginal or cervical lacerations, and retained products of conception. Most serious hemorrhages occur within the first 24 hours after delivery but may occur even weeks after delivery. If hemorrhage occurs, and uterine atony is the presumptive cause, bimanual uterine compression (using a fist in the anterior vaginal fornix and the other hand on the abdomen, open and compressing the posterior uterine wall) should be performed and dilute intravenous oxytocin (40 to 80 units per L) administered. Large bore intravenous access should be secured. If bleeding persists, the vagina and cervix should be inspected for bleeding lacerations, and these should be sutured if found. The uterus should be manually explored for retained placental fragments or membranes. Intramuscular injection of methylergonovine maleate (0.2 mg) or prostaglandin F_2 (0.25 mg) can aid in stimulating contraction of the atonic uterus. Both may exacerbate or provoke

hypertension. Preparation should be made to replace blood and blood products as necessary to prevent the development of a consumptive coagulopathy. If contractions cannot be stimulated in a refractory atonic uterus, laparotomy with uterine artery ligation, hypogastric artery ligation (if a skilled, experienced surgeon is available and the woman is hemodynamically stable) or hysterectomy may be required. If bleeding from a vaginal wall laceration is persistent, packing, angiography, and selective embolization may be helpful.

Depression Many mothers (at least half) feel an emotional letdown during the first few days after delivery. These “maternity blues” are characterized by bouts of sadness, crying, and lability of mood. This state is usually, but not always, short-lived and seldom persists beyond 2 weeks. No specific therapy other than emotional support is indicated. More seriously, up to 20% of women may experience a major postpartum depression, characterized by such symptoms as insomnia, pessimism, lethargy, feelings of inadequacy, inability to cope, and fatigue. In women with these symptoms, it is important to rule out postpartum hypothyroidism. Both counseling and medication (usually with a selective serotonin reuptake inhibitor) may be indicated. Profound, persistent depression or that associated with lack of interest in the infant, suicidal or homicidal thoughts, hallucinations, or psychotic behavior should prompt psychiatric consultation. The recurrence risk for postpartum depression is high, and prophylactic therapy beginning 2 to 3 weeks before delivery may be indicated. An earlier postpartum visit should be considered for women at risk of postpartum depression including those with a prior history of depression not associated with pregnancy. Puerperal psychosis (hallucinations, suicidal impulses) is unusual but may complicate as many as 1 in 500 pregnancies. It is an emergency which should be immediately attended to by a psychiatrist to prevent the mother from harming herself or her infant.

Breast-feeding

Breast-feeding has undergone somewhat of a renaissance in the United States over the past 30 years: in 1971 only one-fourth of mothers breast-fed at hospital discharge, versus almost two thirds in 1998. In 1997, the AAP summarized the manifest benefits of breast-feeding for the infant (Table 2.3).

Research in the United States, Canada, Europe and other developed countries, among predominantly middle-class populations, provides strong evidence that human milk feeding decreases the incidence and/or severity of diarrhea, lower respiratory infection, otitis media, bacteremia, bacterial meningitis, botulism, urinary tract infection, and necrotizing enterocolitis. There are a number of studies that show a possible protective effect of human milk feeding against sudden infant death syndrome, insulin-dependent diabetes mellitus, Crohn's disease, ulcerative colitis, lymphoma, allergic diseases, and other chronic digestive diseases. Breast-feeding has also been related to possible enhancement of cognitive development. (American Academy of Pediatrics, Work Group on Breast-feeding. Breast-feeding and the use of human milk. *Pediatrics* 1997;100:1035–1039 [Paragraph includes 39 citations]).

Source: American College of Obstetricians and Gynecologists. Breast-feeding: maternal and infant aspects. ACOG Educational Bulletin No. 258, July 2000.

TABLE 2.3. *Research on established and potential protective effects of human milk and breast-feeding on infants*

Breast-feeding mothers benefit as well. Suckling-triggered oxytocin release promotes uterine contractions and leads to diminished blood loss. Oxytocin and prolactin levels are elevated in breast-feeding mothers, enhancing feelings of attachment and relaxation. Women who breast-feed face lower risks of ovarian and premenopausal breast cancer, and are less subject to pregnancy-induced obesity. By delaying ovulation, breast-feeding contributes to longer interpregnancy intervals.

Almost all women may breast-feed. However, some women should not. According to the ACOG, these include women who:

- take street drugs or do not control alcohol use
- have an infant with galactosemia
- are infected with HIV
- have active, untreated tuberculosis
- take certain medications
- are undergoing treatment for breast cancer.

Additionally, women with active varicella infections, herpes simplex virus infections of the breast, and active hepatitis A and B (until the infant has been passively and actively vaccinated) should refrain from breast-feeding. The list of medications contraindicated in breast-feeding is not extensive. It includes bromocriptine, cocaine, cyclophosphamide, cyclosporine, doxorubicin, ergotamine, lithium, methotrexate, phencyclidine, phenindione, and radioactive iodine and other radiolabeled elements. Women who want to breast-feed but who receive radioactive elements on a one-time or short-term basis (as for a diagnostic study) can pump and discard their milk until the radioactivity has cleared their bodies.

Premature infants can be breast-fed, but may have special nutritional requirements, especially those born very prematurely. Consultation is necessary to ensure adequate nutrition for such babies. Mothers whose babies are temporarily unable to breast feed may pump their breasts (which is most efficiently done with an electric pump) and the milk may be administered to the baby or stored for later use (frozen unless use is planned within 2 days).

Lack of education and knowledge, both on the part of caregivers and mothers, is the biggest barrier to breast-feeding. To redress this deficiency, ACOG has compiled two lists of resources (Table 2.4, Table 2.5). It is incumbent upon obstetric and pediatric care providers to provide education, support, and assistance to allow women to begin and maintain successful breast-feeding. These activities should begin at the first prenatal visit (or even sooner, e.g., routine gynecologic health visits) and continue throughout the pregnancy and postpartum period. Hospital protocols and care delivery should be conducive to breast-feeding, and specific practices to support breast-feeding have been enumerated (Table 2.6). Since most women are discharged before their milk comes in, most questions and problems with breast-feeding are handled on an outpatient basis. Therefore, to achieve successful, sustained breast-feeding among their patients, physicians and their office staff must have the ability to field questions and promptly correct problems with nursing.

TABLE 2.5. *References for health care workers and patients seeking in-depth information about breast-feeding*

- Maintain a written breast-feeding policy that is communicated to all health care staff.
- Train all pertinent health care staff in skills necessary to implement this policy.
- Inform all pregnant women about the benefits of breast-feeding.
- Offer all mothers the opportunity to initiate breast-feeding within 1 hour of birth.
- Show breast-feeding mothers how to breastfeed and how to maintain lactation even if they are separated from their infants.
- Give breast-feeding infants only breast milk unless medically indicated.
- Facilitate rooming-in; encourage all mothers and infants to remain together during their hospital stay.
- Encourage unrestricted breast-feeding when baby exhibits hunger cues or signals or on request of mother.
- Encourage exclusive suckling at the breast by providing no pacifiers or artificial nipples.
- Refer mothers to established breast-feeding and mothers' support groups and services, and foster the establishment of those services when they are not available.

[a]The 1994 report of the Healthy Mothers, Healthy Babies National Coalition Expert Work Group recommended that the UNICEF-WHO Baby Friendly Hospital initiative be adapted for use in the United States Breast-feeding Health initiative, using the adapted ten steps above.

TABLE 2.6. *Ten hospital practices to encourage and support breast-feeding* [a]

Women who make an informed decision not to breast-feed should be reassured that milk production will gradually diminish over the first few days after delivery. During this time, a properly fitted bra, ice packs, and oral analgesics should minimize the discomfort of breast engorgement. Medical therapies to hasten this process are no longer advised.

Other than encouraging breast-feeding women to follow a well-balanced, varied diet, and to keep adequately hydrated, no specific dietary modifications are necessary. It is reasonable to recommend a multivitamin with iron supplementation to all nursing women, especially strict vegetarians and those who do not eat dairy products.

Nursing women have a greater delay in resumption of intercourse, compared to those who bottle-feed. In some women, this is clearly attributable to discomfort due to relative vaginal atrophy and decreased lubrication from low estrogen levels. If lubrication during intercourse does not provide relief, women with a well-established milk supply may benefit from vaginal estrogen cream.

Not working, or working part-time, is associated with a longer period of breast-feeding. However, working is rarely the reason given by women for not breast-feeding. The barriers to breast-feeding while working include lack of a flexible or part-time work schedule, inadequate maternity leave and job security, lack of on-site day care, and lack of an appropriate place to pump or breast-feed. Often, the most significant problem facing a mother trying to work and breast-feed is the people around her who do not understand her choice to nurse. Increasingly, however, societal attitudes, and social policies and laws have become more favorable to, and supportive of, breast-feeding.

Nursing Problems

Evaluating problems with nursing requires the observation of the mother and baby while nursing, to which the office setting may not be conducive—and thus the advantage of lay assistance and lactation specialists. Adequate rest is important, and encouragement to rest should accompany almost all calls about problems with nursing.

Concerns about Insufficient Milk Supply The most common reason women give for discontinuing breast-feeding is a concern over insufficient milk supply. Milk letdown can be inhibited by cold, pain, and emotional stress and is sometimes difficult to achieve using a breast pump. A quiet, private setting and pictures of the baby to look at may help. Thus simple supportive measures and environmental modification may be all that is required. If the problem proves refractory, oxytocin in nasal-spray form may be helpful. The spray contains 40 USP units (IU) per milliliter, which is administered into one or both nostrils 2 to 3 minutes prior to nursing or pumping.
Painful Nipples Painful nipples are usually caused by problems with positioning and latching on. For some women, comfort will be gained by leaving their nipples exposed and using either a lamp or hair dryer to dry their nipples after feedings. Additionally, breast shields and purified lanolin cream may help provide relief.
Mastitis One to two percent of breast-feeding women will develop mastitis, which can occur any time, but is most frequent in the first through fifth week of breast-feeding. Typical symptoms are unilateral breast pain, chills, and malaise. Signs include fever, and an erythematous, indurated segment of breast. *Staphylococcus aureus* is the most common agent, although a broad- spectrum of bacteria may be causative. In women not allergic or sensitive to penicillin, a 7- to 10-day course of oral dicloxacillin, 500 mg q.i.d., is usually curative. Oral hydration is advised and antipyretics may lessen discomfort and fever. For penicillin-intolerant women, erythromycin may be substituted. Breast-feeding should continue, as drainage of the breast has therapeutic value. Neglected or recurrent infections and infections with resistant organisms can lead to a breast abscess. Treatment of an abscess usually involves intravenous antibiotics and aspiration or surgical drainage.

NEWBORN CARE

Immediate Assessment and Resuscitation

The transition from fetus to newborn infant is the most dramatic physiologic change that occurs in the human life span. The fetus that received all of its oxygen and nutritional needs via the placenta must now use two entirely different, essentially dormant organ systems to meet these needs. The circulation is rerouted and the pulmonary bypass paths (ductus arteriosus, foramen ovale, and umbilical circulation) are no longer used. The lungs and left side of the heart that once handled about 15% of the circulation must now deal with 100% of the circulation in series with the right heart and remainder of the body. The fluid-filled, unexpanded lungs must be inflated and cleared of fluid to allow gas exchange, as they are now the sole source of oxygen for the infant.

Resuscitation in the delivery room is geared toward helping the infant accomplish this transition. The AAP Neonatal Resuscitation Program (NRP) is a training course that all those specializing in pediatrics complete and is strongly encouraged for all individuals who deliver infants or attend deliveries; in fact, many institutions now require current certification for delivery room personnel. The resuscitation algorithm from the current NRP is shown in Figure 2.16.

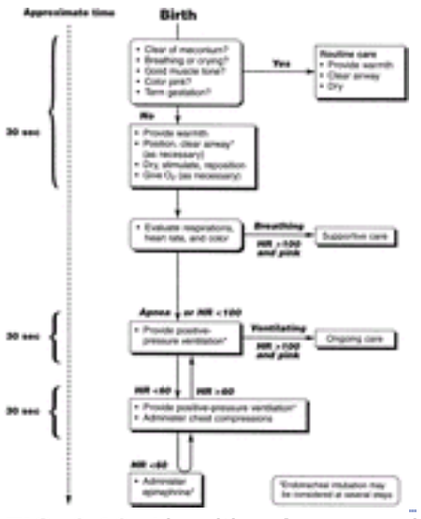

FIG. 2.16. Algorithm for resuscitation of the newly born infant. (From American Academy of Pediatrics © 2000; with permission.)

While every delivery should be attended by personnel trained in newborn resuscitation, the presence of personnel experienced in resuscitation is most desirable for deliveries where the need for resuscitation is more likely. Examples of these situations are summarized in Table 2.7.

TABLE 2.7. *Antepartum factors and intrapartum factors*

Meconium

Meconium passage prior to birth occurs in up to 20% of term deliveries and is a common reason for neonatal resuscitation. In the 1970s it was recognized that early suctioning by the obstetrician or pediatrician decreased the incidence of meconium aspiration syndrome (MAS). In the 1980s, routine suctioning of the oropharynx at the perineum or endotracheal suctioning were standard practice; however, it became clear that not all cases of MAS could be prevented and that aspiration in utero could occur. In the 1990s, many neonatologists were concerned that vigorous babies with thin meconium had a very low risk of MAS, and might actually do better if not intubated for tracheal suctioning. Unfortunately, the majority of studies pertinent to this issue have not been prospective, randomized, or controlled. The most recent Cochrane Library review concluded that until further evidence is available, endotracheal suctioning for meconium should be reserved for those infants who are depressed or have respiratory difficulties.

The Apgar Score

In 1952, Dr. Virginia Apgar devised a 0 to 10 scale scoring system intended to focus attention on the newborn and allow the systematic assessment of its condition and immediate needs (Table 2.8). Since that time, Apgar scores have become a mainstay in immediate newborn assessment. The Apgar score is a useful tool to guide those charged with assessment and care of the newborn. It provides an overall picture of infant status, and has been used in clinical research to correlate later outcomes with initial appearance. It cannot be used to predict neurologic outcome without other tests or examinations, nor is it a validated tool for determining asphyxia. Moreover, it was never intended for use in premature infants. Scores are assigned at 1 minute of age, and every 5 minutes thereafter until the score is over 7, or until 20 minutes of age. Clearly, resuscitation should begin if necessary prior to the 1-minute score.

TABLE 2.8. *Apgar mnemonic*

General Evaluation and Treatment

Every newborn infant should have a thorough physical examination. The newborn exam is focused on identification of congenital abnormalities, birth trauma, and signs of transitional difficulties (Table 2.9). Although infants of 35 or more weeks and over 2 kg will generally be able to maintain their temperature and feed successfully, all infants born prior to 37 weeks may require more frequent monitoring of temperature and blood glucose. Infants who are large or small for their delivery dates are at higher risk for hypoglycemia. If dates are uncertain, a Dubowitz or Ballard examination may be performed, ideally between 24 to 48 hours of age. In addition to monitoring blood sugar prior to established feeding, routine laboratory work often includes blood type, Coombs test, and hematocrit. A positive Coombs test can be caused by Rh or ABO incompatibility. Hematocrit levels between 40% to 65% are acceptable. Most states screen for phenylketonuria (PKU) and congenital hypothyroidism. Other tests used by some states include screens for congenital adrenal hyperplasia, cystic fibrosis, and other inborn errors of metabolism. These tests may be initiated prior to discharge according to state mandates. Infants born in U.S. hospitals are given either dilute silver nitrate drops or erythromycin ophthalmic ointment to prevent *Neisseria gonorrhoeae* conjunctivitis, which was once the most common cause of congenital blindness. Vitamin K is administered intramuscularly to prevent vitamin K deficiency bleeding (VKDB). Factors that can contribute to this deficiency include low vitamin K stores at birth, poor placental transfer of vitamin K, low levels of vitamin K in breast milk, and sterility of the gut. Because standard commercial infant formulas contain supplemental vitamin K, VKDB is almost exclusively a problem of breast-fed infants. The most common sites of bleeding are the umbilicus, mucous membranes, gastrointestinal tract, the penis after circumcision, and skin (from venipuncture). Intracranial bleeding can occur and is the main cause of mortality and long-term morbidity. In the United States, all infants are actively immunized against hepatitis B, the initial dose of which is generally given on the day of birth. If the mother is positive for hepatitis B surface antigen or if her status cannot be determined within a few days, the infant should also receive passive immunization within 7 days in the form of hepatitis B immune globulin.

TABLE 2.9. *Examination of the newborn*

Early Onset Sepsis

One of the most serious problems encountered in the immediate newborn period is early onset sepsis, defined as occurring in the first 5 days after birth. The current estimated rate in the United States is 1 to 2 per 1000 live births. Group B streptococci (GBS) remain the most common causal organisms, but with the routine use of intrapartum antibiotic prophylaxis for GBS, *Escherichia coli* now constitutes a larger proportion of causative organisms. The symptoms of neonatal sepsis include respiratory distress, lethargy, poor feeding, hypotonia, seizures, and shock. The management of infants with symptoms of sepsis includes blood and, if indicated, cerebrospinal fluid cultures, followed by the administration of broad-spectrum intravenous antibiotics, generally a penicillin in combination with an aminoglycoside. The management of asymptomatic infants of mothers with risk factors for neonatal sepsis is less clear and has become a topic of considerable debate since the routine use of intrapartum GBS chemoprophylaxis. Based on expert opinion and limited data the following general approach has been recommended. Because of an increased risk for early-onset GBS septicemia and greater difficulty in assessing symptoms, asymptomatic infants born prior to 35 weeks gestation should be evaluated with a complete blood count and blood culture, and observed in the hospital without empirical antimicrobial therapy for at least 48 hours. In infants born at and beyond 35 weeks, clinical assessment is more dependable. Routine laboratory evaluation is not recommended in these infants. They should, however, be observed in-hospital for at least 48 hours.

Hyperbilirubinemia and Discharge Planning

Timing of newborn discharge has been a topic of controversy for nearly 20 years. Prior to and during much of this time, the traditional stay was 3 days for a vaginally delivered baby and 5 days for those delivered by cesarean (due to the mother's extended stay). This minimum of 3 days allowed detection of the most common serious problems of the newborn, such as ductal-dependant congenital heart disease, early onset sepsis, hyperbilirubinemia, and failure to establish adequate breast-feeding. Discharges at 24 hours (or less) became popular in the late 1980s, a practice driven largely by third-party payors. While numerous small studies were performed to assess the safety of early discharge, most suffered from insufficient numbers to rule out an increase in adverse outcomes that, individually, are relatively uncommon. Bilirubin encephalopathy, a disorder rarely seen for the past 30 to 40 years, has recently been reported to be on the rise. Bilirubin peaks at 5 days in formula-fed infants but may peak as late as 7 to 10 days in breast-fed infants. Breast milk production is minimal in the first 48 hours after delivery and does not reach 80% of full volume until 4 days postpartum. Because of this time frame, it is not easy to predict at 3 days of age which breast-fed infants with a negative Coombs test will be at risk of dangerously high bilirubin levels (>25 mg/dL), and it is nearly impossible to do so at less than 48 hours. In recognition of these issues, the pendulum appears to be swinging back to a 3-day stay for most breast-fed infants. Infants readmitted after discharge prior to 48 hours are most likely breast-fed and jaundice is the most common reason for admission. In addition to insufficient breast milk intake, hyperbilirubinemia can result from relative polycythemia, bruising, cephalohematoma, or be idiopathic. The current AAP guidelines for management of term infants with nonhemolytic jaundice are given in Table 2.10.

TABLE 2.10. *American Academy of Pediatrics hyperbilirubinemia treatment guidelines: total serum bilirubin (mg/dL)*

SUMMARY POINTS

- Labor is defined as regular uterine contractions that lead to effacement and dilation of the cervix.
- Labor can be conceptualized as depending on the *Power*, the *Passage*, and the *Passenger*.
- A variety of management approaches to labor have been employed and evaluated, and no single approach is clearly superior.
- Both infection and hemorrhage can complicate normal labor and delivery, and caregivers must be vigilant for these complications and competent in their management.
- Encouraging and providing support for breast-feeding has significant benefits for both infants and mothers.
- Every delivery should be attended by personnel trained in newborn resuscitation.
- Newborn hospital stays shorter than 3 days may compromise the detection of hyperbilirubinemia in breast-fed infants.

REFERENCES

The purpose of this chapter is to acquaint the obstetrician with the various techniques of obstetric analgesia (pain relief) and anesthesia (for surgical procedures) and to describe their indications, advantages, disadvantages, and complications. The technical aspects, including the methods of administration, will not be described in detail. Readers seeking specific information on how to perform the various obstetric anesthetic techniques are referred to one of the basic obstetric anesthesia textbooks ([1]).

Obstetric analgesia or anesthesia refers to the multiple techniques useful for the alleviation of the pain associated with labor, delivery, or surgery. The choice of an appropriate analgesic technique must be made by the patient, the obstetrician, and the anesthesiologist and should take into consideration the patient's anatomy and physiology, the status of her fetus, the obstetric plan for delivery, and the pharmacology of the drugs to be employed ([2]). Most women now request some form of analgesia during childbirth (Table 3.1).

PAIN OF PARTURITION

Increasing dilation of the cervix, contraction and distention of the uterus, and distention or tearing of the vagina, vulva, and perineum causes the pain that occurs during labor and delivery. Pain may be generated through stretching or application of pressure to adjacent pelvic organs.

The pain that occurs in the first stage of labor increases in severity as the cervix becomes more dilated. The onset of pain lags approximately 15 to 30 seconds behind the onset of the uterine contraction and is first perceived when the intraamniotic pressure reaches 15 mm Hg above that of resting tonus. In the second stage of labor, sharp pain occurs as the tissues of the vagina and perineum are stretched. Stretching stimulates the second, third, and fourth sacral nerve roots, which carry nociceptive information to the spinal cord through the sensory fibers of the pudendal nerve. Adnexal pressure and traction on the bladder, urethra, rectum, and peritoneum also contribute to the pain of parturition. Compression of the lumbosacral plexus by the fetal head, particularly in the occiput posterior position, may cause pain even before the onset of labor.

The pain of uterine contractions is conducted through small sensory nerve fibers of the paracervical and inferior hypogastric plexuses to join the sympathetic nerve chain at L2-3. The ascending fibers enter the spinal cord through the nerve roots of T-10 to T-12, with a variable contribution from L-1 (Fig. 3.1). Because the cutaneous branches of the lower thoracic and upper lumbar nerves migrate caudally for a considerable distance before they innervate the skin, the pain of uterine contractions is often referred to the area over the upper sacrum and the lower lumbar spine.

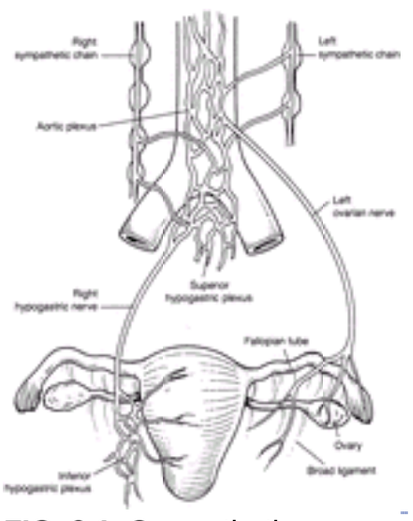

FIG. 3.1. Sympathetic nerve supply of the uterus from the pelvic and abdominal distribution. The uterine nerves arise from the upper part of the uterus (i.e., upper uterine segment), the contraction of which contributes to pain; from the lower part of the uterus (i.e., lower uterine segment), the distention of which contributes to pain; and from the cervix, the dilation of which contributes to pain. The ovarian nerve supplies the ovary, fallopian tube, broad ligament, round ligament, and the side of the uterus, and it communicates with the uterine plexus. The sympathetic efferent and afferent fibers are shown together. (Adapted from Abouleish E. *Pain control in*

obstetrics. Philadelphia: JB Lippincott Co, 1977.)

Pain from the uterus and cervix is transmitted through the small-diameter myelinated d-A fibers and unmyelinated C fibers. Because there are relatively fewer nociceptive afferent nerves from visceral structures than from somatic structures, visceral pain is perceived as being diffuse and difficult to localize. These visceral afferents also synapse on and excite the same dorsal horn neurons as afferents from somatic structures. This arrangement is responsible for the phenomenon of referred pain.

The gate theory of Melzack and Wall holds that stimulation of the large cutaneous ß-A nerve fibers closes a “gate” in the substantia gelatinosa of the spinal cord, preventing pain impulses from being carried rostrally by the d-A and C nerve fibers. This theory forms the basis for the use of acupuncture, transcutaneous electrical nerve stimulation, and intracutaneous nerve stimulation with sterile water injections for the relief of pain associated with parturition.

Pregnancy appears to reduce anesthetic requirements. It has been postulated that high progesterone levels lead to increased quantities of endogenous endorphins, which may increase the maternal threshold to pain. One study correlated pain intensity during labor and plasma levels of ß-endorphin. The lowest endorphin levels were found after abolition of labor pain by epidural analgesia. The highest concentrations were observed in the first few minutes after delivery, immediately after cessation of the severe pain of expulsive labor.

The nature of the pain of labor varies in intensity with the stages of labor. The intensity of pain is related to physical factors such as the strength and duration of uterine contractions, the rapidity of cervical dilation, the degree of distention of the vaginal and perineal tissues, the requirement for operative delivery, and the size, presentation, and position of the infant. Augmentation of labor with oxytocin increases the strength and pain of uterine contractions. The primiparous woman may perceive greater pain than the multipara who enters labor with more advanced cervical dilation and who may also be more psychologically prepared (Fig. 3.2). Exhaustion, psychological factors, and protracted nausea and vomiting may also increase the parturient's perception of labor pain.

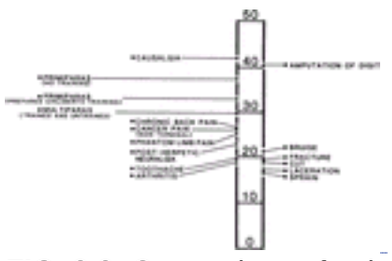

FIG. 3.2. Comparison of pain scores obtained from women during labor and from patients in a general hospital pain clinic or emergency department using the McGill pain questionnaire. (From Melzack R. The myth of painless childbirth. *Pain* 1984;19:321–37.)

Pain management is an important part of modern obstetric care. The obstetrician should appreciate the importance of providing pain relief during labor through the use of nonpharmacologic techniques, systemic analgesics, or regional block analgesia. During the second stage of labor, additional analgesia may also be needed through perineal extension of a segmental epidural or through the use of pudendal or spinal blocks.

SYSTEMIC ANALGESIA AND SEDATION

In the management of labor pain, systemic narcotics are usually considered to be the first step beyond the less invasive or “natural” methods such as massage, water baths, and birth attendants (doulas). They may also be necessary for patients who are not candidates for regional analgesia. Research indicates the analgesic effects of parenteral agents used in labor is limited and the primary mechanism of action is heavy sedation ([3]). Although narcotics may be effective for some patients in relieving the pain of labor, their side effects prohibit the use of large doses. The physician must balance maternal and neonatal respiratory depression with effective relief of the pain of labor. Because the pain of labor occurs intermittently with contractions, maternal hyperventilation during a contraction leads to hypoventilation for the 2 to 3 minutes between contractions, especially when narcotics have depressed the carbon dioxide response curve. There are advantages and disadvantages of all available narcotics, and a drug should be chosen with knowledge of its side effects and pharmacokinetics (Table 3.2).

TABLE 3.2. *Parenteral medications for labor analgesia*

Use of Systemic Medications

Because the use of systemic narcotics and tranquilizers does not require special training or the availability of anesthesia personnel, they are used extensively in the United States to provide labor analgesia (see Table 3.1). These compounds do not induce fetal heart rate (FHR) abnormalities other than changes in variability and rarely sinusoidal heart rate patterns, nor do they cause fetal acidosis. The drug-related adverse maternal effects of narcotics can include nausea, vomiting, pruritus, sedation, decreased gastric motility, loss of protective airway reflexes, and hypoxia due to respiratory depression. The adverse neonatal effects of these agents include central nervous system (CNS) depression, respiratory depression, impaired early breast-feeding, altered neuroadaptive behavior, and decreased ability to regulate body temperature. To minimize these side effects, the lowest effective dosage should be employed, and the timing with respect to delivery must be carefully considered. Resuscitation equipment should be kept at hand, and naloxone, used to antagonize opioids, should be readily available. Benzodiazepine effects may be reversed with flumazenil (Romazicon).

Systemic Narcotics

Meperidine Meperidine (Demerol) has achieved wide popularity for systemic analgesia during labor. It is preferred over morphine because it produces less emesis and does not depress the newborn carbon dioxide response curve as much as morphine. It can be administered intravenously or intramuscularly during labor. Current usage most often consists of small, incremental intravenous doses of 25 to 50 mg. Small doses can also be used to treat shivering. Placental transfer of meperidine occurs rapidly. Maximal depression of the infant occurs when delivery takes place 2 to 4 hours after maternal intravenous or intramuscular administration. Delivery of the infant within 1 hour of administration produces little evidence of newborn depression. A study using meperidine for labor analgesia by a patient-controlled infusion device found 5% of infants required naloxone at delivery ([4]). Meperidine has as its principal metabolite the compound normeperidine, which is equipotent with meperidine in its ability to produce respiratory depression and can also cause seizures. Repeated intravenous administration of small doses of meperidine leads to increasing maternal and fetal levels of normeperidine. Meperidine has an elimination half-life in neonatal blood of 22.7 hours, and that of normeperidine is measured in days, reflected in abnormal neurobehavioral scores for up to 3 days.

Morphine Morphine is pharmacologically more potent than meperidine by a factor of approximately 10. Morphine depresses the newborn carbon dioxide response curve more than meperidine, perhaps due to greater permeability of the infant brain to morphine. Because of this reputation, morphine has virtually disappeared from the armamentarium of analgesic drugs used by the obstetrician for the management of labor.

Fentanyl Fentanyl (Sublimaze) is a potent synthetic narcotic with analgesic activity approximately 100 times that of morphine. Its onset of action is rapid, and its duration of activity is short (i.e., 20–30 minutes) because of its rapid distribution from plasma. The terminal drug elimination half-life after a single small dose is 1 to 2 hours. Fentanyl is highly bound to protein, which may limit its placental transfer. It has no active metabolites. Fetal–maternal blood concentration ratios average 0.31 over the first 10 minutes after intravenous administration. Fentanyl produces moderate analgesia and mild sedation. There may be a brief period of decreased FHR variability, but no other disturbing FHR patterns have been reported. Comparative studies with meperidine indicate that the need for newborn naloxone (Narcan) administration is greater after use of meperidine than after administration of fentanyl.

Nalbuphine Nalbuphine (Nubain) is a potent narcotic agonist–antagonist agent which, at equianalgesic doses, produces respiratory depression equivalent to that of morphine. The advantage and disadvantage of nalbuphine is that as the dosage is increased, a ceiling effect is seen for respiratory depression, and unfortunately also for analgesia. Maximal respiratory depression occurs with a dose of 30 mg in a 70-kg adult. Sedation and dysphoric reactions may also occur. Reversal of other opioid effects may precipitate withdrawal in a susceptible patient. A possible transient depressive effect of nalbuphine on the fetal CNS has been identified.
Butorphanol Butorphanol (Stadol) is another synthetic narcotic with agonist–antagonist properties. It is five times more potent than morphine and 40 times more potent than meperidine. It has achieved moderate popularity in the United States in the management of the pain of the first stage of labor. It is usually administered intravenously in doses of 1 to 2 mg. Butorphanol exhibits the same ceiling effect for analgesia and respiratory depression as nalbuphine. Maternal side effects may include sedation, dysphoric reactions, and reversal of other opioid effects.
Newer Opioids Sufentanil and remifentanil, the newer synthetic opioids, have not been studied extensively for systemic analgesia during labor.

Patient-controlled Intravenous Analgesia

Intravenous patient-controlled analgesia (PCA) is widely available and provides pain relief through self-administration of intravenous opioids. Fentanyl, remifentanil, and meperidine are the analgesics most commonly employed with this technique. The infusion pump is programmed so that the patient receives an incremental dose when she pushes the button, followed by a lockout interval when additional requests by the patient will not be administered. An hourly maximum may also be programmed. A basal infusion is rarely used in labor because of the risk of respiratory depression between contractions. The actual settings are dictated by the pharmacokinetics of the narcotic chosen. The main advantage of PCA is improved patient satisfaction due to a feeling of control and not having to wait for a nurse to bring pain medication. Use of PCA may also decrease nursing staffing requirements.

In a study by Rosenblatt and colleagues ([5]), metoclopramide (Reglan) was used as an analgesic adjunct to PCA for patients undergoing prostaglandin induction of labor for second-trimester termination of pregnancy. Patients were given intravenous metoclopramide, 10 mg, or saline placebo followed by PCA-administered morphine. Those receiving metoclopramide used 54% less morphine and had lower pain scores.

Narcotic Antagonists

Naloxone Because all narcotics cross the placenta and can produce respiratory depression in the neonate, availability of an effective antagonist is essential. Naloxone reverses opioid-induced respiratory depression without producing side effects of its own. Because it also reverses analgesia, its prophylactic use is not advised. Naloxone may be administered to the parturient as an intravenous bolus of 0.1 to 0.4 mg to treat maternal respiratory depression. Care must be taken to *titrate* naloxone to the desired effect, since large doses have been implicated in the causation of myocardial infarction, pulmonary edema, and severe hypertension. Naloxone, 0.01 mg per kg, may also be administered intravenously, intramuscularly, or through the endotracheal tube to the newborn to reverse the respiratory depressant effects of placentally transferred narcotics. The effect is usually apparent within a few minutes and persists for as long as 2 hours. The neonate must be carefully observed for evidence of renarcotization, because the half-life of naloxone is less than that of most narcotics.

Sedative Drugs

Benzodiazepines The principal benzodiazepine drugs are diazepam (Valium) and midazolam (Versed). Diazepam has been used extensively in other parts of the world for seizure prophylaxis in patients with severe preeclampsia. However, because of its side effects on the newborn, it has found little favor in the United States. Newborns exposed to diazepam characteristically exhibit hypotonicity, hypoactivity, and impaired temperature regulation and metabolic response to cold stress. Midazolam is a newer benzodiazepine anxiolytic, a sedative drug with significant amnestic properties. It is five times more potent than diazepam and is soluble in water, a property that reduces pain associated with intravenous administration. Midazolam crosses the sheep placenta, achieving a fetal–maternal concentration ratio of 0.15. Its metabolites are inactive, and the drug is excreted more rapidly than diazepam. Midazolam has been used as an induction agent for cesarean delivery, but because of its ability to cross the placenta, it has produced neonatal respiratory depression and decreased body tone and temperature. Midazolam has not been recommended for use as a tranquilizer-sedative in labor, because its amnestic properties are unacceptable to most parturients.
Barbiturates Barbiturates may be used in the latent phase of labor. Although they cause maternal sedation and decreased anxiety, barbiturates lack analgesic properties and may increase the perception of pain when given without concomitant administration of a narcotic. Most barbiturates have long elimination half-lives and readily cross the placenta. Prolonged neonatal effects have led to the virtual elimination of these drugs from use during labor.
Other Sedatives Phenothiazine derivatives, such as promethazine (Phenergan), have been used in obstetrics and provide sedation and decrease nausea. Hydroxyzine, although not a phenothiazine, has similar properties when used in combination with narcotics. Maternal sedation is achieved without significant maternal or newborn side effects. It is important to remember that none of these drugs provide analgesia, and some parturients may object to the heavy sedation they cause. In addition, both medications are very painful intramuscular injections. They should have little place in the management of labor analgesia. Ketamine (Ketalar), when administered intermittently at low doses (10–15 mg), can produce analgesia in parturients without causing maternal loss of consciousness or neonatal respiratory depression. An improvement on this technique using low-dose ketamine infusion has been described by Maroof and associates ([6]). In this study, patients were given an intravenous bolus of ketamine, 0.5 mg per kg, upon achieving 4 cm of cervical dilation. This was followed by an infusion of ketamine at 0.25 mg per kg per hour. Patients served as their own controls, evaluating labor with and without the benefit of ketamine. Pain scores were significantly better with ketamine. The authors concluded that ketamine infusion produced acceptable analgesia throughout labor and was not associated with delirium or loss of consciousness in any patient. In addition, neonatal respiratory depression was not noted. The profound amnesia and potential for dysphoria or other psychomimetic effects when using ketamine limit its general use for labor analgesia. It is most useful for short painful procedures such as urgent forceps delivery or manual removal of the placenta.

Inhalational Agents

Nitrous oxide can be inhaled periodically with contractions in a 50% mixture with oxygen. During a painful contraction, the mother breathes from a mask connected to the regulator valve of a breathing circuit. A scavenging system is required by the Occupational Safety and Health Administration (OSHA) to eliminate exhaled waste anesthetic gases. Unfortunately, when it is breathed at the onset of a contraction, maximal analgesia is achieved only after the contraction has ended. When nitrous oxide is used in conjunction with narcotics, maternal oxygen saturation may decrease. Use of a pulse oximeter to ensure adequate maternal oxygenation is recommended. In practical terms, since almost all deliveries in the United States now take place outside the operating room, an anesthesia machine will probably not be available to safely administer inhalational agents.

REGIONAL ANALGESIA

Local Anesthetic Agents

Most local anesthetic agents share a common structure consisting of a hydrophilic amino group connected by an intermediate chain to a lipophilic aromatic residue. Their presumed mechanism of action is to block exchange of sodium and potassium ions across the cell membrane, probably through mechanical interruption of ion flow through cell wall channels.

Local anesthetic drugs are manufactured as chloride salts. The nonionized base is able to diffuse across tissues, while the ionized form is actually the active component. The amounts of nonionized (mobile) and ionized (active) drug depend on the pK_a of the local anesthetic and tissue pH.

After injection of lidocaine (Xylocaine), the sensory nerve action potential decreases more sharply in pregnant women than in nonpregnant women. This implies that pregnant women have an increased susceptibility to the effects of local anesthetic agents ([7]).

Local anesthetics belong principally to two groups, those of ester and amide configurations. Ester drugs are generally characterized by their rapid onset of action, short duration, and low toxicity. Chloroprocaine (Nesacaine) is a representative of this group. It is rapidly metabolized by serum pseudocholinesterase, forming paraaminobenzoic acid. Lidocaine, bupivacaine, ropivacaine, and levobupivacaine are representatives of the amide group. These drugs are more highly bound to protein and have a slower onset and a longer duration of action. They are metabolized in the liver. Toxicity is usually greater for amides than for drugs of the ester group (Table 3.3).

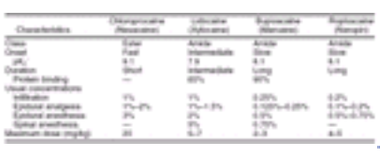

TABLE 3.3. *Characteristics of local anesthetics commonly used in obstetric anesthesia*

Local anesthetic drugs are absorbed systemically. Distribution to the fetus depends on maternal tissue uptake, maternal blood concentration, uterine blood flow, and maternal and fetal metabolism and excretion. Fetal-tissue drug distribution is also affected by asphyxia. Fetal asphyxia leads to increased P_aCO_2, which results in cerebral and coronary vessel dilation and increased brain and myocardial blood flow. The increased perfusion of these organs with anesthetic drug leads to greater toxicity. The decrease in pH seen with fetal asphyxia results in increased ionized (active) drug in the fetal circulation and tissues, a phenomenon referred to as ion trapping. The clinical significance of this is unclear.

Side Effects of Local Anesthetic Drugs

Systemic Toxicity Systemic complications involving the use of local anesthetics include toxic blood levels of the drug and allergic reactions, as well as reactions due to epinephrine that is often added to local anesthetic solutions to retard systemic absorption and prolong duration of action. Maximal safe doses for healthy young adults are 7 mg per kg (300 mg) of lidocaine, 2 to 3 mg per kg (175 mg) of bupivacaine, and 20 mg per kg (1000 mg) of chloroprocaine (see Table 3.3). The most common reason for high blood levels of local anesthetic drugs is accidental intravascular injection. This most commonly occurs when an epidural catheter has been placed or migrated into a vein. To minimize accidental intravenous injection, gentle aspiration should be undertaken before each injection. Injection should be done slowly and incrementally with only 2 to 5 mL of local anesthetic drug to reduce the chance of a sudden increase in plasma levels. A marker such as epinephrine may be added to the local anesthetic solution so that intravascular injection will manifest as tachycardia. The infiltration of a local anesthetic agent into an area rich in vessels, such as the region of the uterine artery (e.g., paracervical block), pudendal vessels, or the epidural space may be associated with absorption of the drug through blood vessel walls. The serum levels tend to rise slowly, and toxic manifestations usually occur only after multiple injections. Repeated injections of slowly metabolized local anesthetic drugs, such as the amides, may lead to accumulation in the serum such that toxic levels are achieved. This phenomenon does not occur readily with esters such as chloroprocaine, which are rapidly metabolized (maternal serum half-life of 21 seconds and fetal serum half-life of 43 seconds for chloroprocaine). To minimize the likelihood of producing high serum levels, care should be taken to record the amount and concentration of local anesthetic solution and to limit use to approximately 25% less than the maximal safe dose. Signs and symptoms of local anesthetic drug toxicity include, in order of their appearance, a relaxed feeling, drowsiness, lightheadedness, tinnitus, circumoral paresthesias, metallic taste, slurred speech, blurred vision, unconsciousness, convulsions, and cardiac dysrhythmias and arrest. In 1983, the U.S. Food and Drug Administration issued an advisory, warning that 0.75% bupivacaine should no longer be used in obstetrics because of reports of bupivacaine-induced cardiac arrest occurring at blood levels of only 3 to 5 µg per mL. The advisory stated that the resuscitation in these cases had been “difficult or impossible despite apparently adequate preparation and appropriate management.” Inadvertent intravascular injection causes high serum levels, which produce cardiac arrest through blockade of the cardiac sodium channels, inhibiting repolarization of the nerve cell membranes of the conduction system of the heart. Bupivacaine has been found to bind avidly to nonspecific cardiac protein–binding sites, slowing the conduction of impulses arising in pacemaker cells and causing a dose-dependent reduction in the strength of myocardial contractility, leading to cardiac arrest. Management is best accomplished through prevention, as described previously. Therapy is symptomatic. Initial treatment includes the use of mask oxygen, a reliable intravenous line, and measures to ensure and protect the airway. These include use of cricoid pressure to occlude the esophagus, the availability of adequate suction, and the capability to perform endotracheal intubation, if needed. Adequacy of respirations must be ensured, if necessary by means of positive pressure ventilation with 100% inspired oxygen. The patient should be hyperventilated to help correct metabolic acidosis caused by seizure activity and decreased cardiac output. CNS hyperreactivity and convulsions are treated with thiopental (Pentothal) in small, incremental doses of 25 to 50 mg given intravenously, or with 1 to 5 mg of midazolam given intravenously. In the event of cardiovascular depression, elevate the lower extremities and verify left uterine displacement. Vasoactive drugs such as ephedrine, phenylephrine, epinephrine, and calcium may be employed to support the circulation. If cardiopulmonary resuscitation is indicated, the fetus should be delivered within 5 minutes to relieve maternal central venous compression and advanced cardiac life support (ACLS) protocols should be followed.

Use of Regional Anesthetic Blocks

Local Infiltration of the Perineum Local infiltration of the perineum is commonly performed when an episiotomy is needed and time or fetal head position does not allow a pudendal block to be administered. An average of 10 to 20 mL of local anesthetic solution is employed. The preferred drugs are lidocaine 1% or chloroprocaine 2%.

Pudendal Block The pudendal block provides analgesia of the vaginal introitus and perineum. There are several advantages of this analgesic technique. Because the elapsed time between administration and delivery is short, there is relatively little systemic absorption and therefore little opportunity for the drug to directly affect the fetus. The block is easy to accomplish and provides analgesia of the perineum only. The disadvantages include the need for large drug doses (i.e., 10 mL on each side) and the potential for local anesthetic toxicity, hematoma, and the possibility of infection leading to retropsoas or subgluteal abscess. With the transvaginal approach, the ischial spine must first be identified. Through a guide, a needle is inserted into the vagina and directed laterally and posteriorly to the ischial spine. A submucosal wheal is made, and the needle is advanced into the sacrospinous ligament, where resistance is felt. As the needle passes the ligament, a loss of resistance is felt. The needle has now entered the pudendal canal, which contains the pudendal nerve and associated vessels (Fig. 3.3). After aspirating the needle for blood, 3 to 5 mL of local anesthetic solution (usually lidocaine 1%) is injected, and the needle is advanced another 0.5 to 1 cm. If aspiration is again negative, 5 to 7 mL of solution is injected. A total of 10 mL is injected on each side. Approximately 10 minutes are required for anesthesia to occur. Chloroprocaine 1% to 2% may also be used for this block. Analgesia with chloroprocaine lasts less than 1 hour, but lidocaine analgesia is more prolonged.

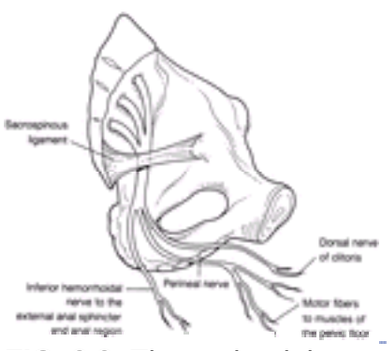

FIG. 3.3. The pudendal nerve and its branches. The inferior hemorrhoidal nerve can arise higher up from the pudendal nerve or separately from the sacral plexus. (Adapted from Abouleish E. *Pain control in obstetrics.* Philadelphia: JB Lippincott Co, 1977.)

Paracervical Block Paracervical block (PCB) anesthesia may be used when the active phase of labor begins, and it can be employed until approximately 8 cm of dilation has been achieved. Although formerly popular, this block has fallen into relative disuse since the description of bradycardia after PCB and its proven association with fetal acidosis. The PCB is useful when anesthesia personnel are unavailable and parenteral narcotics are inadequate. The PCB relieves the pain associated with uterine contractions, but it is not effective for pain associated with distention of the pelvic floor. The two drugs of choice are chloroprocaine and lidocaine in 1% concentrations. Typically, 6 mL of drug is administered superficially, just under the vaginal mucosa, at the 4- and 8-o'clock positions (Fig. 3.4). In this way, bradycardia, which occurs in 10% to 30% of cases, is less likely to appear. The landmark study by Baxi and colleagues ([8]), using a transcutaneous oxygen electrode attached to the fetal scalp, demonstrated that bradycardia is related to decreasing fetal oxygenation, which becomes marginal approximately 10 minutes after injection. This research has been corroborated by the study of isolated human uterine artery segments and by work in animals, indicating that direct uterine artery vasoconstriction and uterine hypertonus in response to the injection of a local anesthetic drug diminish uterine blood flow and fetal oxygenation.

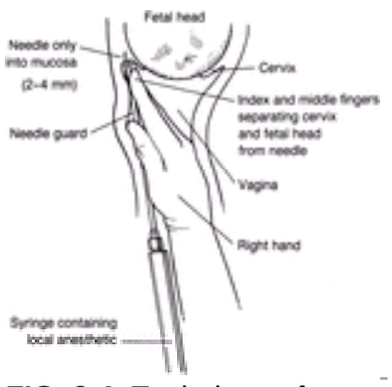

FIG. 3.4. Technique of paracervical block. Notice the position of the hand and fingers in relation to the cervix and fetal head and the shallow depth of the needle insertion. No undue pressure is applied at the vaginal fornix by the fingers or needle guide. (Adapted from Abouleish E. *Pain control in obstetrics.* Philadelphia: JB Lippincott Co, 1977.)

Lumbar Epidural Analgesia

Standard Technique Lumbar epidural analgesia was first performed in 1884 by Corning, who recognized that analgesia could still occur when attempted spinal analgesia failed. In 1921, Pages applied the technique to surgery. Obstetric applications were made by Graffagnino and Seyler in 1935. The most commonly used

anesthetic agents for lumbar epidural analgesia for labor are bupivacaine 0.0625% to 0.25% and ropivacaine 0.1% to 0.2%. The technique of lumbar epidural analgesia involves the insertion of a 17- or 18-gauge hollow-bore needle through the ligamentum flavum into the epidural space at the L4-5, L3-4, or L2-3 interspace. Although the hanging-drop technique for identification of the epidural space is generally effective, most physicians prefer the loss-of-resistance technique as the one that affords the least risk of penetration of the dura. Use of air or saline may be used to identify the epidural space. A 20-gauge catheter is passed through the epidural needle for a distance of 3 to 5 cm within the epidural space. This catheter is securely taped in place and serves as an avenue for intermittent or continuous infusion of local anesthetic agents or opioids.

Combined Spinal–Epidural Analgesia The combined spinal–epidural (CSE) technique adds a subarachnoid injection of an opioid with or without a small dose of local anesthetic in a needle-through-needle technique to provide a faster onset with a smaller dose of medication than is possible using epidural medications alone ([9]). The epidural catheter is still available for additional analgesia. A prospective, double-blinded, randomized study compared CSE analgesia with standard epidural analgesia in spontaneously laboring nulliparous parturients. There was no difference in the rate of progress of labor, the amount of epidural local anesthetic required, and the incidence of instrumental deliveries between the CSE and the standard epidural analgesia groups. However, analgesia was more complete and there was higher patient satisfaction in the CSE group than in the epidural analgesia group.

Patient-controlled Epidural Analgesia Patient-controlled epidural analgesia (PCEA) is a technique by which the patient self-administers on-demand doses of an analgesic mixture via an epidural catheter, whenever she perceives discomfort. To avoid overdosage, a lockout period follows each self-administration. This technique is associated with a decreased use of local anesthetic solution and less demand on staff time compared to continuous epidural infusion (CEI). Most studies have found patients will self-administer less local anesthetic solution than continuous infusions provide and that anesthesia workforce needs are reduced by about 40% ([10]). Quality of analgesia, complications, and amount of motor block are similar between the two techniques.

Epidural Medications in Labor Epidural injection of opioids alone has been shown to be of limited value for the relief of labor pain. High doses of morphine (7.5 mg) have provided satisfactory analgesia, but only during the first stage of labor. Because of its slow onset of action (often 1 hour or more) and high incidence of side effects (nausea and pruritus), morphine is not a satisfactory agent for this use. Fentanyl and sufentanil used alone can provide analgesia for early labor, but require high doses—100 µg fentanyl or 30 µg sufentanil. In contrast, *spinal* injection of opioids alone provides excellent, although time-limited analgesia for labor in small doses—10 to 25 µg fentanyl or 5 to 10 µg sufentanil. Fortunately, the addition of opioids to dilute concentrations of epidural local anesthetics has been proven to be quite effective in the relief of labor pain. The combination is a rational one because local anesthetic solutions relieve somatic pain preferentially, whereas opioids are more effective in relieving visceral pain. By combining a lipid-soluble opioid such as fentanyl or sufentanil to bupivacaine or ropivacaine, the concentration of local anesthetic can be dramatically decreased and motor block can be minimized. The addition of fentanyl or sufentanil approximately doubles the analgesic efficacy of any concentration of bupivacaine or ropivacaine, while shortening the time to complete analgesia. *Opioid and Chloroprocaine Mixtures*. Mixtures of morphine with chloroprocaine have not been shown to be useful, as chloroprocaine appears to antagonize the analgesic effects of the opioid, while increasing its side effects, particularly nausea and pruritus. The mechanism of this unfavorable interaction is unknown. Chloroprocaine may also prolong the onset of morphine analgesia and decrease the effectiveness of bupivacaine if used before these agents. The most satisfactory analgesia appears to be produced when opioids are combined with amide local anesthetics. The beneficial effects of epidural opioids in labor appear to be the following:

- reduction in motor block, allowing improved mobility of the patient
- reduction in shivering
- decreased incidence of hypotension
- use of lower doses of local anesthetic agents
- greater maternal satisfaction with the analgesia that they provide.

Effects of Epidural Analgesia on Uterine Blood Flow Studies investigating changes in intervillous blood flow and mean arterial pressure with lumbar epidural analgesia in adequately preloaded patients have demonstrated only a negligible reduction in these parameters with the onset of effective analgesia. Well-hydrated patients with preeclampsia have experienced improvement in intervillous blood flow along with a slight decrease in blood pressure.

Advantages and Disadvantages of Lumbar Epidural Analgesia There are three principal advantages of lumbar epidural analgesia:

- the parturient remains awake and cooperative.
- the incidence of complications is very low when the technique is used correctly.
- once an epidural catheter is in place, it can be used to provide analgesia or anesthesia for a vaginal or cesarean delivery.

The disadvantages of lumbar epidural analgesia include:

- the possibility of poor perineal analgesia
- the presence of “hot spots”, where analgesia is insufficient
- delayed onset of action
- technical difficulty
- intravascular injection
- accidental dural puncture
- hypotension. Technical failure occurs in approximately 4% of cases.

Indications and Contraindications for Lumbar Epidural Analgesia Indications for lumbar epidural analgesia include pain in labor, management of the patient with preeclampsia who does not have a coagulation abnormality, management of labor in patients with certain cardiac lesions, and management of breech delivery. A joint statement by the American College of Obstetricians and Gynecologists (ACOG) and the American Society of Anesthesiologists (ASA) ([11]) notes that: “Labor results in severe pain for many women. There is no other circumstance in which it is considered acceptable for a person to experience untreated severe pain, amenable to safe intervention, while under a physician's care. In the absence of a medical contraindication, maternal request is a sufficient medical indication for pain relief during labor. Of the various pharmacologic methods of pain relief used in labor and delivery, regional analgesia techniques—spinal, epidural and combined spinal epidural (CSE) are the most flexible, effective, and least depressing to the CNS, allowing for an alert, participating mother and an alert neonate.” There are absolute and relative contraindications to the induction of lumbar epidural analgesia. Absolute contraindications include the following: patient refusal, hemodynamic instability, infection at the anticipated site of puncture, and absence of resuscitation equipment. Relative contraindications may include fever, preexisting CNS disease, hypovolemia, hypotension, lack of experience by the anesthetist, and blood coagulation defects. Although an arbitrary platelet count of 100,000 per mm ^{3} has been advocated as the lower limit for safe lumbar epidural analgesia, successful blocks without epidural bleeding complications have been obtained with platelet counts as low as 50,000 per mm ^{3}. In one report, Beilin and colleagues ([12]) described a study of 80 women who presented for labor and delivery and had platelet counts less than 100,000 per mm ^{3} during the peripartum period. Of these 80, 30 were given an epidural anesthetic. The range of platelet counts was 69,000 to 98,000 per mm ^{3}. No patient had any documented neurologic complication. These authors concluded that regional anesthesia should not necessarily be withheld when the platelet count is less than 100,000 per mm ^{3}. However, given that the risk of epidural hematoma is extremely rare, a study this small would be unlikely to reveal a problem. The underlying cause of the thrombocytopenia is also important and must be considered along with any absolute number. For example, the patient with idiopathic thrombocytopenic purpura or gestational thrombocytopenia is much less likely to bleed at a low platelet count than the patient with HELLP (hemolysis, elevated liver enzymes, low platelet count) syndrome. The best indicator of potential bleeding is a patient history of bruises, contusions, petechiae, bleeding from the gums, and so on.

Subarachnoid Analgesia Subarachnoid or spinal analgesia for labor has become increasingly popular. The major advantages of spinal analgesia include (a) use of a very low dose of local anesthetic or narcotic analgesic drug and (b) the excellent analgesia provided. Onset of action is rapid, and uterine activity is not affected. The disadvantages include (a) the possibility of postdural puncture headache (PDPH) which is increasingly rare with the use of pencil-point needles and (b) the time-limited nature of a single-shot technique. For this reason spinal analgesia is commonly combined with an epidural catheter as a CSE technique. Indications and contraindications are similar to epidural analgesia. Morphine and fentanyl can provided analgesia during labor when administered intrathecally in small doses. Labor analgesia usually lasts for 4 to 8 hours and is not accompanied by motor block. The major disadvantages include pruritus and nausea. Pruritus can be antagonized with small doses of intravenous naloxone or oral naltrexone. PDPH can be minimized through the use of 22- to 27-gauge Whitacre, Sprotte, or other pencil-point needles. A 28-gauge microcatheter can be passed through 22-gauge spinal needles, permitting the use of continuous spinal analgesia in labor and surgery. These catheters were withdrawn from the market because of associated cauda equina syndrome, probably related to local anesthetic neurotoxicity.

Complications of Regional Block Analgesia

Hypotension Hypotension is common, occurring in 10% to 20% of patients undergoing epidural analgesia for labor and 50% to 80% for cesarean delivery. It often occurs despite left uterine displacement and administration of an adequate vascular preload. Treatment should consist of the following steps:

1. Ensure or verify left uterine displacement.
2. Increase intravenous fluid infusion to the maximal available rate.
3. Administer oxygen by facemask.
4. If hypotension does not immediately resolve, administer ephedrine intravenously in 5- to 10-mg increments until hypotension resolves.

Phenylephrine, an a-agonist, has been avoided in the past because of concerns about compromising uterine blood flow, but more recent work has shown no adverse clinical effects and higher fetal pH values than ephedrine alone ([13]).

Postdural Puncture Headache When a large-bore epidural needle (e.g., 18-gauge Tuohy) penetrates the dura and arachnoid membranes, the incidence of PDPH is greater than 50%. Other factors governing the incidence of PDPH include the number of times the dura has been punctured, the direction of the bevel, and the type of needle used. PDPH occurs because a decrease in cerebrospinal fluid (CSF) volume causes compensatory cerebral vasodilation and traction on the pain-sensitive blood vessels and meninges. Assumption of the erect position increases traction on these structures and aggravates the pain. Therefore, the main diagnostic criterion of PDPH is that it is postural. Ocular and auditory symptoms, such as vertigo, ataxia, and sixth cranial nerve palsy may be associated with PDPH. Many different treatment regimens have been employed for this condition, including administration of saline through the epidural catheter, the use of abdominal binders, the administration of intravenous or oral caffeine (as a cerebral vasoconstrictor), bed rest, analgesics, and epidural blood patches. The most effective of these is the epidural blood patch. Evidence suggests that prophylactic epidural blood patch can substantially reduce the incidence and severity of PDPH. In a study by Lowinwirt and associates ([14]), patients with accidental dural puncture with 16- or 17-gauge needles were randomized and allocated to two treatment groups. In one group, patients received 15 to 20 mL of autologous blood through the indwelling epidural catheter at least 5 hours following the last dose of local anesthetic and just before catheter removal. Patients in the control group were managed conservatively with intravenous hydration, bed rest, theophylline, or caffeine. Eighty-three percent of patients receiving the prophylactic epidural blood patch avoided PDPH. Only 4% of patients treated conservatively avoided PDPH. Use of a prophylactic epidural blood patch was not associated with any complications.

Chronic Back Pain Low-back pain is a common complaint in the postpartum period. A controversy exists as to the role that epidural analgesia for labor and delivery might play in the subsequent development of low-back pain. Whereas several retrospective studies have demonstrated an association, other prospective studies have shown no increased risk of acute low-back pain after epidural use. A study by Loughnan and colleagues ([15]) examined the risk of low-back pain 6 months after delivery in patients who received epidural analgesia, as compared with those who did not. This prospective follow-up study showed no difference in the prevalence of low-back pain at 6 months after delivery. Therefore, it seems unlikely that epidural analgesia makes any significant contribution to the 19% to 33% prevalence of low-back pain among postpartum women.

Neurologic Complications Neurologic complications of epidural and spinal analgesia are rare, occurring in about 1 per 10,000 blocks. Many postpartum neurologic sequelae are related to intraoperative positioning problems. An example is foot drop associated with pressure on the lateral popliteal nerve and caused by an improperly placed stirrup. In the lithotomy position, pressure applied on the femoral cutaneous nerve by the inguinal ligament may cause pain and numbness in the lateral thigh. Pain and numbness in the distribution of the sciatic nerve may result from forceps delivery or passage of the baby's head through the pelvis. Spinal nerve root neuropathy may be caused by traumatic insertion of a spinal needle or an epidural needle or catheter. In this case, pain and paresthesias along the distribution of the nerve are perceived immediately, but they tend to disappear when the needle or catheter is removed. Rarely, symptoms may appear as long as 2 days after the procedure. Recovery usually occurs in 1 to 2 weeks, but injury can be permanent. Accidental injection of an irritant solution (e.g., thiopental) or a prep solution into the CSF may produce adhesive arachnoiditis, which can cause permanent loss of spinal cord function. Epidural abscess usually is caused by hematogenous spread and not by injection of contaminated anesthetic solutions. Epidural hematoma is a serious complication that, although rare, may occur in conjunction with coagulopathy. A hematoma should be suspected if recovery from the block is slow or absent or if neurologic function worsens after a period of initial recovery. The primary symptoms are pain and weakness, which may progress rapidly to paralysis. Early surgical drainage provides the only chance for recovery of neurologic function.

Effects of Epidural Analgesia on Progress of Labor Whether use of regional analgesic techniques is associated with an increased risk of cesarean delivery remains controversial, but that concern is mainly based on results from small retrospective studies. There is definitely an *association* between use of epidural analgesia for labor and cesarean delivery, but the problem is that nulliparous women with longer and more painful labors are the patients more likely to choose epidural analgesia, and they are also those who are at higher risk to have a cesarean delivery regardless of their choice of labor analgesia. The presence of severe pain during early labor signals an increased risk for prolonged labor and operative delivery ([16]). Also, regional analgesia is often recommended to women in whom operative or instrumental delivery is thought to be likely. Designing a study to remove that bias or association has proven difficult, both for the ethical reason you cannot refuse a treatment available to a patient if requested (i.e., if a patient is randomized to receive “no epidural” but she later requests it because of inadequate pain relief she must be allowed to cross over) and because there is no other form of pain relief to offer that provides equivalent analgesia (i.e., a “control group”). For this reason, many studies done prior to the last decade were methodologically flawed. More recent studies have attempted to control for the fact that women already at increased risk for an operative delivery are more likely to choose epidural analgesia, and have *not* found regional analgesia to be associated with cesarean delivery ([17]). There are different methodological ways to accomplish this. Several retrospective, population-based studies have found that the introduction of an epidural analgesia service or the increased use of epidural analgesia did not increase the cesarean delivery rate. In a “natural” experiment, a military hospital went from a 1% to 84% epidural analgesia rate in one year while other conditions remained unchanged ([18]). A review of singleton, nulliparous, term patients in spontaneous labor before and after the change found no differences in rates of cesarean delivery overall and for dystocia, no change in instrumental delivery rates, no change in duration of first and active stages of labor, but an increase in the second stage of labor by about 25 minutes. At the National Maternity Hospital in Dublin, the epidural rate increased from 10% to 57% over 3 years with no effect on cesarean delivery rates ([19]). These clinicians suggested use of active management of labor and use of oxytocin in the second stage of labor to overcome increases in instrumental vaginal delivery rates. Other studies have used generous doses of narcotics in the control group to prevent crossover to the epidural analgesia group. A review of 802 nulliparous patients randomized to epidural analgesia or intramuscular meperidine using standardized labor management found similar cesarean delivery rates in an intent-to-treat analysis ([20]). The spontaneous vaginal delivery rate was also similar between groups. A randomized trial of 715 women who received epidural analgesia or patient-controlled meperidine found no difference in cesarean delivery rates and lower pain scores in the epidural group ([4]). Pain relief is a worthy goal unto itself! Obstetric management must also influence the cesarean delivery rate. Even randomized trials cannot blind the obstetrician to the type of analgesia being used, and the obstetrician makes the decision regarding the need for cesarean delivery. If epidural analgesia has an influence on the risk of cesarean delivery, then those obstetricians with a higher use should have a higher cesarean delivery rate. In contrast, a review of 110 obstetricians in a single hospital practice found no relationship between frequency of epidural analgesia use and rate of cesarean section for dystocia across practitioners ($R^2 = 0.019$) ([21]). They concluded that after accounting for a number of known patient risk factors, obstetric practice style appears to be a major determinant of rates of cesarean delivery. As noted earlier, the intensity of labor pain may be predictive of an increased risk of cesarean delivery for dystocia. A secondary analysis of women randomized to receive patient-controlled intravenous meperidine analgesia for labor found that those who required higher doses of narcotic had higher pain scores initially, longer labors (9 vs. 5 hours), and more cesarean deliveries for dystocia (14% vs. 1.4%) ([22]). Thus, it would appear that there are many variables with the potential to affect the risk of cesarean delivery besides choice of analgesia during labor. These would include patient-related factors such as parity, induction, level of pain, labor pattern, and oxytocin use, as well as obstetrician-related factors such as active or passive management. An editorial suggested that “Perhaps the time has now come to look at the problem in a different way and to ask why labor is prolonged and spontaneous delivery less likely in some units than in others. The realization that labor with regional analgesia is not the same as that without and that management must be modified will hopefully result in improvements in outcome” ([23]). Chestnut ([24]) has made some astute comments on the current state of affairs regarding anesthesia in labor:

1. Use of dilute solutions of local anesthetics in labor may be less likely to have an effect on progress of labor.
2. Administration of epidural analgesia should be delayed until labor is well established; however, it is unnecessary to wait until an arbitrary cervical dilation, such as 5 cm.
3. Studies on patients attempting vaginal birth after cesarean delivery have not shown an increase in cesarean delivery rates when epidural analgesia is used, and good analgesia may encourage some women to attempt vaginal delivery.
4. Use of epidural analgesia during labor may decrease the use of general anesthesia with its attendant risks if emergency cesarean delivery is required.
5. Maternal administration of high doses of narcotics may result in substantial neonatal effects such as respiratory depression ([25]).
6. Maternal–fetal factors and obstetric management, not epidural analgesia, are the most important determinants of the cesarean delivery rate.

OTHER METHODS OF PAIN RELIEF

Prepared Childbirth

Prepared childbirth techniques are based on the belief that pain can be eliminated or reduced by conditioned reflexes of controlled relaxation and that education about the birth process can diminish the pain resulting from fear of the unknown. Parturients and significant others are offered a series of five to ten weekly lectures and are educated about pregnancy, labor, and the delivery process. The parturient is taught how to relax and engages in exercises to strengthen her back and abdominal muscles. She also learns specific breathing patterns to be used while she experiences the discomfort of uterine contractions. All parturients should have access to emotional support, whether by her husband, a family member, a birth attendant (doula), or professional hospital staff. Insurance companies are beginning to pay for doulas as the literature has supported the beneficial effect on decreasing interventions ([26]). Effective courses also teach pregnant women that additional methods of pain relief are available and that these do not cause harm to the fetus. The pregnant woman should be advised that to ask for these other methods does not imply that she is a failure.

Hypnosis

Hypnosis is a state of altered consciousness that requires deep concentration. The patient is not asleep, but she initiates a trance as labor begins and continues it until delivery is completed. The patient must undergo a time-consuming series of training sessions with a hypnotist, and this technique is not always successful ([27]).

Acupuncture

Acupuncture has been used to help control labor pain in China and the Far East for many years. Since the early 1970s, mixed reports of its efficacy have been published in the West. Some studies indicate that acupuncture can significantly lower pain scores and may decrease the duration of the first stage of labor. Although enthusiasm for the technique varies in Western countries, the Chinese continue to report 99% rates of excellent and good success. When acupuncture is used for

cesarean section in conjunction with intravenous meperidine and local anesthetic infiltration, blood pressure, pulse rate, and respirations are stable, and the degree of patient acceptance is reported to be high.

Biofeedback

Biofeedback is provided by a portable electromyographic device through an audible sound and visual monitor. Electrodes placed over the maternal abdomen monitor tension of the abdominal musculature. This technique may be helpful during the first stage of labor and may reduce its duration.

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) analgesia is based on the observation that application of a mild electric current to the skin can result in reduction of pain. Activation based on the gate theory and release of enkephalins are possible modes of action. Studies evaluating the effectiveness of TENS suggested that, although the method does no harm, it probably does little good and should not be advocated for widespread use for labor analgesia ([28]).

Intracutaneous Nerve Stimulation

Trolle and colleagues ([29]) evaluated the analgesic effect of intradermal sterile water blocks in women complaining of severe low-back pain during labor. Saline solution was used as a control. Sterile water or saline (0.1 mL) was injected at four different spots in the low-back area, approximately corresponding to the borders of the sacrum. Eighty-nine percent of women in the sterile water group reported an analgesic effect, compared with 45% in the saline group. However, meperidine use in the two groups was similar, as were the rates for oxytocin use and dystocia. The cesarean section rate in the sterile water group was significantly lower due to more cephalopelvic disproportion and malposition of the occiput in the saline group. This technique is free of adverse effects and enjoys a high degree of patient acceptance although the mechanism is unclear.

ANESTHESIA FOR CESAREAN DELIVERY

There are three anesthetic choices for cesarean delivery. Selection of one over the others depends on the patient's desires, medical status, and the urgency of the operation. Regional anesthesia is strongly preferred in the United States (Table 3.4).

	≥1500 Births			<500 Births		
	1981	1992	1997	1981	1992	1997
Epidural (%)	29	54	43	12	29	29
Spinal (%)	33	35	49	37	49	63
General (%)	35	12	8	46	22	8

TABLE 3.4. *Types of cesarean anesthesia provided by size of hospital in three time periods*

Epidural Anesthesia

Epidural anesthesia accounts for approximately 40% of anesthetics used for cesarean section. It offers the advantages of unlimited duration, minimizing the risks of airway management, and providing a route for postoperative pain management.

To carry out a cesarean delivery, a sensory dermatome level of at least T-4 is required. Anesthesia to this level eliminates proprioception from the respiratory muscles of the chest wall, and the parturient may experience a subjective sensation of dyspnea. Reassurance will usually allay this fear. The patient should be placed on the operating table with the uterus displaced laterally through elevation of the right hip or by tilting of the operating table, to prevent aortocaval compression.

A vascular preload of 1000 to 1500 mL of a non–glucose-containing crystalloid solution should be administered before dosing of the epidural needle or catheter with the anesthetizing solution. A surgical concentration of a local anesthetic (often 2% lidocaine) with or without added opioid is administered through the catheter in 3- to 5-mL increments. The patient should be given oxygen by nasal cannula or by mask. One study failed to reveal any differences in the clinical condition of neonates, as assessed by Apgar scores and blood gas analyses, when oxygen administration by these two modalities was compared.

Epidural opioids have been useful for relieving pain of visceral origin, which affects as many as one-third of the women who have cesarean sections under epidural anesthesia. Visceral pain occurs primarily during bladder retraction, exteriorization of the uterus, and suturing of the peritoneum. The addition of fentanyl or sufentanil to the local anesthetic reduces the time of onset of analgesia, decreases the incidence of nausea, and increases the quality of analgesia without depressing the neurobehavioral status of the newborn.

Studies of fentanyl concentrations in neonates demonstrate that fentanyl crosses the placenta. Even high maternal doses (e.g., 100 µg) of fentanyl yield safe levels in the newborn. Morphine 2 to 4 mg is often administered through the epidural catheter after delivery to provide 12 to 24 hours of postoperative analgesia, although the incidence of associated pruritus and nausea can be high. Use of epidural morphine may reactivate herpetic labialis (herpes simplex virus-1) infections ([30]).

There are several advantages to using epidural analgesia for cesarean section delivery:

- if an epidural catheter is already in place, it can be used expeditiously for the cesarean section delivery.
- maternal hypotension may be less pronounced and slower in onset with epidural than with spinal anesthesia.
- headache is usually avoided, unless the patient sustains an accidental dural puncture.
- the length of anesthesia is controllable in case surgery is prolonged.
- the technique is adaptable for postoperative pain relief.

The disadvantages include:

- the slower onset of analgesia
- the requirement for a larger amount of anesthetic solution with its attendant increased risk of systemic toxicity
- the lower success rate than that experienced with subarachnoid block.

An unexpectedly high level of anesthetic block may be achieved with epidural or spinal anesthesia and, as a result, this should be monitored. The likelihood of inadvertent spinal anesthesia while attempting epidural block can be minimized through gentle aspiration of the catheter combined with using a test dose of sufficiently small volume that it is unlikely to produce a high block. A total spinal block generally occurs within 90 seconds after injection, but it may be delayed for as long as 20 minutes. Dyspnea, hypotension, unconsciousness, and apnea are signs and symptoms of total spinal block. Treatment includes ventilation through an endotracheal tube and, if needed, circulatory support.

Subarachnoid or Spinal Anesthesia

A subarachnoid block provides excellent anesthesia for cesarean section delivery. Over 50% of cesarean deliveries are performed using this technique (see Table 3.4). Prehydration is administered with 1500 to 2000 mL of a non–glucose-containing crystalloid solution. A 22- to 27-gauge pencil-point spinal needle is inserted into the subarachnoid space, which is identified by the characteristic feel of the needle penetrating the dura and observing CSF in the needle. Bupivacaine 0.75%, 10 to 12 mg, with dextrose, is most commonly used. Analgesia of shorter duration is obtained with the use of lidocaine 5% in 7.5% dextrose.

Opioids may also be administered intrathecally to improve quality of analgesia, decrease nausea, and improve cardiovascular stability by allowing a lower dose of local anesthetic. Spinal (as well as epidural) narcotics are associated with a high incidence of pruritus, as well as the rare but real potential for delayed respiratory depression. Fentanyl may be administered to improve intraoperative analgesia while the addition of morphine can provide postoperative analgesia that may last for 18 to 24 hours.

Contraindications to spinal anesthesia are the same as for epidural anesthesia and include patient refusal, septicemia, infection of the puncture site, acute or chronic hypovolemia, and abnormal clotting parameters. Spinal anesthesia is usually avoided in pregnant women with acute CNS disease.

The most common complication of spinal anesthesia is hypotension. This should be treated promptly with fluid administration and intravenous ephedrine (5- to 10-mg bolus). Oxygen should be given, and the parturient's oxygen saturation should be monitored with a pulse oximeter. In the event of a high spinal block which compromises ventilation or airway control, cricoid pressure should be applied and endotracheal intubation performed to prevent aspiration of gastric contents.

With the increasing use of spinal and epidural narcotics, pruritus is becoming a commonplace adverse effect. Its incidence approaches 60% when spinal or epidural morphine is employed. The cause seems to be related to stimulation of opioid receptors rather than to release of histamine. Naloxone can be used to control pruritus, but the dose must be titrated carefully to avoid antagonism of analgesia. Nalbuphine may also be used and is less likely to antagonize analgesia.

Approximately 23% of women experience shivering during normal labor and delivery, and the rate increases to approximately 68% with epidural analgesia. Shivering can be diminished or abolished through epidural injection of opioids (e.g., fentanyl 100 µg) or small intravenous doses of meperidine (e.g., 12.5 mg).

General Anesthesia

General anesthesia is used for cesarean delivery when the patient refuses regional analgesia or has a contraindication to regional analgesia, or when a need exists for rapid delivery because of fetal distress, cord prolapse, shoulder dystocia, or maternal hemorrhage.

The American College of Obstetricians and Gynecologists in the fifth edition of *Guidelines for Perinatal Care*, cites the risk factors for failed intubation and urges obstetricians to be alert to the presence of the factors that place parturients at increased risk for complications from emergency general anesthesia. Among these are marked obesity, severe facial and neck edema, extremely short stature, short neck, difficulty opening the mouth, a small mandible, protuberant teeth, arthritis of the neck, anatomic abnormalities of the face or mouth, a large thyroid gland, asthma, serious medical or obstetric complications, and a history of problems with anesthetics. If any of these factors is identified, a member of the anesthesia team should be consulted to prepare for the unexpected need to induce general anesthesia. If the anesthesiologist has concerns about his or her ability to intubate the patient, early placement of a regional anesthetic should be planned or arrangements for an awake intubation should be made.

Pneumonitis resulting from aspiration of gastric contents has long been feared as a complication of general anesthesia for obstetrics, but is extremely rare. One review compared the incidence of aspiration in obstetric and gynecological patients ([31]). The incidence of clinically significant aspiration was 0.11% in women undergoing cesarean delivery compared to 0.01% in gynecology inpatients. No patient died, but morbidity was significant. The prudent anesthetist administers a nonparticulate oral antacid, such as sodium citrate, given prophylactically to increase the gastric pH. If time allows, an H_2-blocker (e.g., ranitidine 50 mg intravenously) should be administered. Intravenous metoclopramide, 10 mg, hastens gastric emptying, increases gastroesophageal sphincter tone, and may decrease nausea.

Before induction of anesthesia, the patient should be preoxygenated with 100% oxygen by mask for at least 3 minutes. Induction is commonly carried out using thiopental (3–4 mg per kg i.v.). Propofol (Diprivan) has also been used. Propofol is associated with a blunted hypertensive response to endotracheal intubation and has yielded similar and satisfactory Apgar scores, neurologic and adaptive capacity scores, and umbilical cord blood gas analyses. If propofol infusion is used for maintenance of anesthesia for a prolonged time before delivery, neonatal blood levels are high, and neurologic and adaptive capacity scores may be impaired. If the patient is hemodynamically unstable, ketamine 1 mg per kg or etomidate 0.3 mg per kg may be used.

Intubation is facilitated by use of succinylcholine. Cricoid pressure is maintained during induction of anesthesia until the endotracheal tube is in place, the cuff has been inflated, respirations have been auscultated, and end-tidal carbon dioxide has been seen. After successful intubation, a mixture of equal parts of nitrous oxide and oxygen may be administered, and a low dose of an inhalational agent, such as desflurane 3%, sevoflurane 1% or isoflurane 0.75%, is administered to optimize maternal analgesia and amnesia. These low concentrations have minimal effects on uterine contractility and are not associated with postpartum hemorrhage. After delivery of the infant, the nitrous oxide concentration may be increased to 70%, and narcotics may be given intravenously to supplement the anesthesia. Midazolam may be used to decrease the risk of maternal recall.

The advantages of general anesthesia include:

- reliability of the technique
- rapidity of induction of anesthesia
- avoidance of sympathetic blockade and hypotension.

The disadvantages include:

- the risks of maternal aspiration of gastric contents
- failed intubation
- maternal awareness
- hypertension during manipulation of the larynx.

If the cords are poorly visualized during laryngoscopy, no more than three attempts at endotracheal intubation should be made before beginning a failed intubation drill ([32]). The initial maneuver in the failed intubation drill depends on the obstetric indication for cesarean section. If the operation is not emergent, the patient should be awakened and an epidural or spinal block performed. If a regional anesthetic cannot be accomplished, an awake fiberoptic intubation should be considered. In an obstetric emergency where surgery must proceed, the patient must be ventilated with bag and mask or laryngeal mask airway, and anesthesia may be maintained with inhalational or intravenous agents throughout the remainder of the cesarean section. The continuation of cricoid pressure is important to reduce the maternal risk of aspiration. If it should prove impossible to ventilate the patient with bag and mask, an emergency maneuver such as cricothyroidotomy must be performed. Use of an esophageal gastric tube airway (Combitube) or laryngeal mask may enable adequate ventilation.

Inability to intubate has been estimated to occur seven times more commonly in the obstetric patient than in the general operating room, and continues to contribute significantly to anesthetic causes of maternal mortality ([33]). Anticipation of a difficult intubation allows the anesthesia team to be prepared to avoid general anesthesia or plan an awake intubation.

Analgesia after Cesarean Section

Considerable advances have been made in the management of pain after cesarean section. The availability of spinal and epidural narcotics has enabled the anesthesia team to provide the postsurgical patient with effective, long-term analgesia. Morphine is the most commonly used neuraxial opioid because of its long duration and lack of motor block compared to local anesthetic infusions. The most feared complication is respiratory depression. The rate of analgesia-related respiratory depression is approximately 0.09%. Because this complication is rare, patients receiving postoperative neuraxial opioid analgesia may be safely nursed on the general ward, if the nurses are appropriately educated in monitoring the degree of somnolence and the respiratory rates of their patients. Patients who did not receive regional anesthesia may receive intravenous PCA. Combining narcotics and nonsteroidal antiinflammatory medications such as ketorolac or ibuprofen improves the quality of analgesia and allows reduced doses of narcotics. Naloxone should be readily available to antagonize respiratory depression.

SUMMARY POINTS

- Pain management is an important part of modern obstetric care. Most women will request some form of analgesia during childbirth.
- Parenteral narcotics for labor analgesia may be administered by intermittent injection or patient-controlled intravenous infusion. There are advantages and disadvantages of all opioids.
- High systemic blood levels of local anesthetic caused by intravascular injection or excessive absorption may lead to convulsions and cardiac arrest. Resuscitation equipment must be immediately available whenever regional blocks are used.
- Modern techniques of regional analgesia for labor (dilute concentrations of epidural local anesthetics, combined spinal–epidural analgesia and patient-controlled epidural infusions) emphasize pain relief with minimal motor block. Studies indicate these techniques do not impact progress of labor.
- Although modern anesthetic care for cesarean delivery is extremely safe (anesthesia-related maternal mortality = 1.1 per million live births), general anesthesia complications are more common than regional anesthetic complications because of difficulties with airway management.

SUGGESTED READINGS

The term *spontaneous abortion*, which has a negative connotation to many patients, is gradually being replaced by the word *miscarriage.* Both terms originally defined pregnancy losses prior to 20 weeks gestation, but they are more commonly used by physicians to describe first-trimester losses. These arbitrary time limits have become less useful with advances in developmental biology and diagnostic sonography. The preembryonic period is defined as conception through the first 5 weeks of pregnancy from the first day of the last menstrual period. The embryonic period encompasses 6 to 9 weeks gestation, and the fetal period is from 10 weeks until delivery.

EPIDEMIOLOGY

Human reproduction is relatively inefficient, and miscarriage is the most common complication of pregnancy, with an overall incidence of approximately 15% among clinically recognized pregnancies. The rate of miscarriage is, however, heavily dependent upon the past obstetric history, being higher among women with prior miscarriages and lower among women whose past pregnancy(ies) ended in live births.

Histologically defective ova found in hysterectomy specimens (Fig. 4.1) and data on early pregnancies detected with sensitive ß-human chorionic gonadotropin (ß-hCG) assays indicate that the very early and often unrecognized pregnancy loss rate is two to three times higher than that of recognized pregnancy. The prevalence of miscarriage also increases with maternal age from 12% in women younger than 20 years of age to over 50% in women older than 45 years of age (Fig. 4.2).

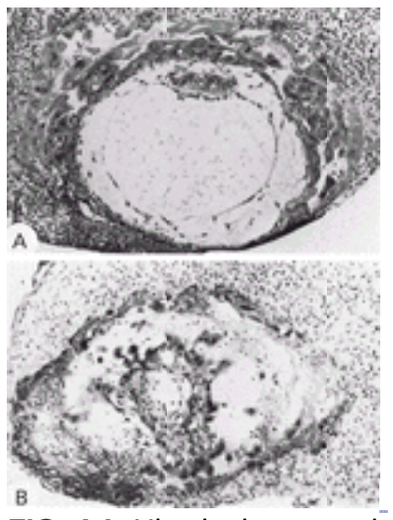

FIG. 4.1. Histologic comparison of **(A)** a morphologically normally implanted human ovum estimated to be about 11 to 12 days of age with **(B)** an abnormal conceptus, showing a defective trophoblast with pathologically large lacunae and an empty chorionic sac that is destined to abort. ETIOLOGY

In view of the complicated genetic, hormonal, immunologic, and cellular events requiring precise integration for fertilization, implantation, and embryonic development, it is remarkable that successful pregnancy occurs so often. When early pregnancy loss occurs, it can be due to a number of embryonic and parental factors.

Embryonic Factors

Most single, sporadic miscarriages are caused by nonrepetitive intrinsic defects in the developing conceptus, such as abnormal germ cells, chromosomal abnormalities in the conceptus, defective implantation, defects in the developing placenta or embryo, accidental injuries to the fetus, and probably other causes as yet unrecognized. Fifty percent of women presenting with spotting or cramping already have a nonviable conceptus by sonogram, and many of these embryos are morphologically abnormal. About one-third of abortus specimens from losses occurring before 9 weeks gestation are anembryonic. Some cases of empty gestational sacs or “blighted ova” actually represent pregnancy failures with subsequent embryonic resorption. The high proportion of abnormal aborted concepti is apparently the result of a selective process that eliminates about 95% of morphologic and cytogenetic errors.

The frequency of chromosomally abnormal spontaneously aborted products of conception in the first trimester is approximately 60% and decreases to 7% by the end of week 24 (Fig. 4.3). The rate of genetic abnormalities is even higher in anembryonic miscarriages. Autosomal trisomies are the most common (51.9%) and arise de novo as a result of meiotic nondisjunction during gametogenesis in parents with normal karyotypes. The relative frequency of each type of trisomy differs considerably.

Trisomy 16, which accounts for about one-third of all trisomic abortions, has not been reported in live-born infants and is therefore uniformly lethal. Trisomy 22 and 21 follow in frequency. The next most common chromosomal abnormalities, in decreasing order, are monosomy 45,X (the single most common karyotypic abnormality), triploidy, tetraploidy, translocations, and mosaicism.

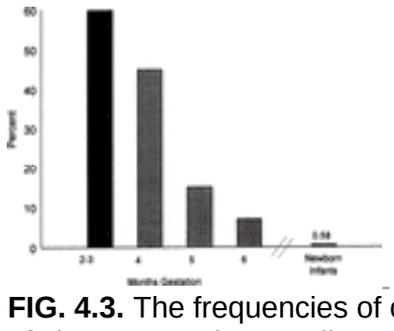

FIG. 4.3. The frequencies of chromosomal anomalies among 3040 spontaneously aborted fetuses related to the duration of pregnancy. For comparison, the frequency of chromosomal anomalies among 54,749 newborn infants is shown. (Data from Shiota K, Uwabe C, Nishimaura H. A cytogenetic study of human spontaneous abortions using banding techniques. *Hum Genet* 1976;31:177.)

Parental Factors

In a small percentage of cases, one member of the couple is the carrier of a balanced translocation, and the offspring of these parents may be repeatedly aborted. Media publicity tends to give the impression that a variety of agents such as infections, video display terminals, cigarette smoking, coffee, ethanol, chemical agents, and drugs (see Chapter 7) markedly increase the risk of miscarriage. In reality, there is little credible evidence that extrinsic factors account for anything other than a very small proportion of early pregnancy loss.

PATHOLOGY

Most miscarriages occur within a few weeks after the death of the embryo or rudimentary analog. Initially, there is hemorrhage into the decidua basalis, with necrosis and inflammation in the region of implantation. The gestational sac is partially or entirely detached. Uterine contractions and dilation of the cervix usually result in expulsion of most or all of the products of conception. When the sac is opened, fluid is often found surrounding a small macerated embryo, or there may be no visible embryo in the sac. Histologically, hydropic degeneration of the placental villi caused by retention of tissue fluid is common.

CLINICAL FEATURES AND TREATMENT

An unrecognized pregnancy episode should always be considered a possibility in any woman of reproductive age with abnormal bleeding or pain. Each new pregnant patient should also be instructed to notify her physician promptly about vaginal bleeding or uterine cramps. Since management depends on a number of factors, it is convenient to consider the clinical aspects of miscarriage under the following subgroups.

Threatened Miscarriage

Any bloody vaginal discharge or uterine bleeding that occurs during the first half of pregnancy has traditionally been assumed to be a threatened miscarriage. Because as many as 25% of pregnant women have some degree of spotting or bleeding during the early months of gestation, it is a common diagnosis.

Bleeding associated with threatened miscarriage is typically scanty, varies from a brownish discharge to bright red bleeding, and may occur repeatedly over the course of many days. It usually precedes uterine cramping or low backache. On pelvic examination, the cervix is closed and uneffaced, and no tissue has passed. The differential diagnosis includes ectopic pregnancy, molar pregnancy, vaginal ulcerations, cervicitis with bleeding, cervical erosions, polyps, and carcinoma.

A viable conceptus can be detected with modern ultrasound as early as 5.5 weeks of gestation. The ability to visualize the embryo and embryonic heart motion has made evaluation and management of threatened miscarriage more precise. However, accurate knowledge of gestational age is necessary for proper interpretation. Ultrasound findings are unreliable at 3 to 4 weeks gestation, and what appears to be an empty uterus can be misinterpreted as an abnormal intrauterine or ectopic pregnancy when it is actually a normal early gestation. If there is any doubt of normalcy, it is best to perform serial ß-hCG measurements and a follow-up sonogram. From 5 to 6 weeks, the yolk sac and gestational sac are visible by transvaginal ultrasound, and the embryo with cardiac activity is seen soon after that. Abnormal gestational sac and yolk sac size, an embryo small for dates, and slow embryonic heart rates suggest impending pregnancy loss. The presence of an appropriately sized embryo with a normal cardiac rate is encouraging, even in the setting of uterine bleeding, and more than two thirds of these will survive. In the absence of signs of miscarriage, more than 95% of pregnancies continue if a live embryo is demonstrated ultrasonically at 8 weeks gestation. These embryos have a very low mortality rate during the next few weeks, and the subsequent pregnancy loss rate is only 1% if a live fetus is seen at 14 to 16 weeks gestation.

Although there is no convincing evidence that any treatment favorably influences the course of threatened miscarriage, a sympathetic attitude by the physician along with continuing support and follow-up are important to patients. This includes a tactful explanation about the pathologic process and favorable prognosis when the pregnancy is viable. An optimistic but cautious approach is prudent, since a few of these women will have a later embryonic or fetal death. It is reasonable to advise patients to remain available to medical care until it can be determined whether the symptoms will persist or cease. Continued observation is indicated as long as bleeding and cramping are mild, the cervix remains closed, quantitative ß-hCG levels are increasing normally, and a normal embryo or fetus is evident on follow-up sonogram. If the bleeding and cramping progressively increase, the prognosis becomes worse. An unfavorable outcome is also associated with negative or falling ß-hCG values, sonographic evidence of an embryo or fetus decreasing in size (Fig. 4.4), a slow heart rate, and a uterus that is not increasing in size on pelvic examination. If careful clinical evaluation indicates that the conceptus is no longer viable, the treatment options are expectant management or evacuation of the uterus. In women with minimal intrauterine tissue by ultrasound, waiting for spontaneous passage of the products of conception is possible. The complication rate may be decreased by elective uterine curettage in patients with significant amounts of tissue (see “ Missed Miscarriage” later in the chapter).

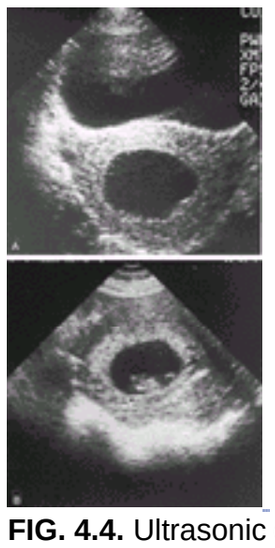

FIG. 4.4. Ultrasonic comparison of **(A)** an anembryonic pregnancy with no fetal tissue that is destined to abort with **(B)** a normal gestational sac with a transonic area, echogenic rim, and fetal pole.

Inevitable and Incomplete Miscarriage

Early pregnancy loss is a process rather than a single event. Previously classified as different entities, inevitable and incomplete miscarriages present a similar clinical picture and are treated in the same way. A miscarriage is inevitable when bleeding or gross rupture of the membranes is accompanied by pain and dilation of the cervix. The miscarriage is incomplete when the products of conception have partially passed from the uterine cavity, are protruding from the external os, or are in the vagina with persistent bleeding and cramping. Placental tissue is more likely to be retained when this occurs in the second trimester. Bleeding can be profuse and occasionally produces hypovolemia. A careful vaginal examination usually establishes the diagnosis. Rarely, one conceptus is aborted, and a normal retained twin proceeds to delivery at term. This unusual situation can be diagnosed by ultrasound at the time of first-trimester bleeding. There is otherwise no fetal survival in inevitable or incomplete miscarriages. Evacuation of the uterus is advisable to prevent maternal complications from further hemorrhage or infection.

In most cases, suction curettage can be performed promptly and safely in an outpatient setting using analgesia, a paracervical block, and an intravenous infusion of normal saline containing 10 to 20 U of oxytocin. Often, the cervix is dilated, and the products of conception can be removed from the cervical canal and lower uterine segment with ring forceps to facilitate uterine contractions and hemostasis. Suction curettage is performed using a plastic curette and vacuum pressure. As the curettage proceeds, tissue can be seen as it flows through the curette and suction tubing. The curette is rotated 360 degrees clockwise as it is withdrawn, and the procedure is repeated in a counterclockwise direction. When a grating sensation is noted and no more tissue is obtained, the endometrial cavity has been emptied.

Preparation is necessary to anticipate any problems such as allergic reactions to medication, uterine atony, uterine perforation, seizure, or cardiac arrest. In selected cases, a hemoglobin level should be obtained, and blood replacement may be necessary if hemorrhage occurs. If measures taken in the emergency room fail to promptly control bleeding, the patient should be transferred to the operating room for an examination under anesthesia and evacuation of the uterus. After curettage, the patient is observed for several hours. When stable, she is discharged and followed as an outpatient.

Medical management of incomplete miscarriage has been explored in well-designed trials. Misoprostol may be used instead of surgical evacuation of the uterus in clinically stable patients, though the need for uterine curettage in the misoprostol-treated patients is high (50%). In spite of this, misoprostol treatment of incomplete miscarriage is associated with lower rates of short- and long-term complications compared to surgical evacuation.

Rh-negative women with miscarriage should receive 50 g (in the first trimester) or the standard 300-g (in the second trimester) dose of Rh immune globulin to prevent Rh immunization. The tissue obtained should be examined to confirm the presence of products of conception and rule out the possibility of ectopic pregnancy.

Complete Miscarriage

Patients followed for a threatened miscarriage are instructed to save all tissue passed, so it can be inspected. When the entire products of conception have passed, pain and bleeding soon cease. If the diagnosis is certain, no further therapy is necessary. In questionable cases, ultrasound is useful to determine that the uterus is empty. In some circumstances, curettage may be necessary to be sure that the uterus is completely evacuated. Removal of remaining necrotic decidua decreases the incidence of bleeding and shortens the recovery time.

Missed Miscarriage

In this situation, expulsion of the conceptus does not occur despite a prolonged period after embryonic death. The reason that some dead embryos do not abort spontaneously is not clear. Typically, the patient's symptoms of pregnancy regress, the pregnancy test becomes negative, and no fetal heart motion is detected by ultrasound. Most patients do eventually abort spontaneously, and coagulation defects due to retention of a dead fetus are rare in the first half of pregnancy. However, expectant management is emotionally trying, and many women prefer to have the uterus evacuated. During the first trimester, this is done by suction curettage preceded by cervical preparation using misoprostol or insertion of laminaria if the cervix is closed. The procedure is often performed in a hospital setting with intravenous fluids and blood available in case significant bleeding occurs.

Evacuation of the uterus by medical means is also an acceptable approach in the first trimester. In one randomized, controlled trial, an 80% complete abortion rate was achieved using 800-µg of misoprostol (four 200-µg tablets) per vagina every four hours, and the need for dilation and curettage (D&C) was reduced to 28%. Most patients responded to the first dose of misoprostol. Combination regimens that include methotrexate or RU-486 with misoprostol appear even more promising, but have not yet been tested in missed abortion.

In the second trimester, the uterus can be emptied by dilation and evacuation (D&E) or induction of labor with intravaginal prostaglandin E_2 (PGE_2) or misoprostol. D&E is an extension of the traditional D&C and vacuum curettage. It is especially appropriate at 13 to 16 weeks gestation, although many proponents use this procedure through 20 weeks. The cervix is usually first prepared using misoprostol or passively dilated with laminaria to avoid trauma, and the fetus and placenta are mechanically removed with suction and instruments.

If induction of labor is chosen, vaginal PGE_2 is used, one 20-mg suppository is placed high in the posterior vaginal vault every 4 hours until the fetus and placenta are expelled. Between 2.5 and 5 mg of diphenoxylate given orally and 10 mg of prochlorperazine given intramuscularly can control diarrhea and nausea, and narcotics or epidural anesthesia can be used to control pain. In this situation, a retained placenta is relatively common and may require manual removal and uterine curettage. Misoprostol, 200-µg tablets placed high in the vagina every 4 hours, is equally effective. This regimen may cause less nausea, vomiting, diarrhea, and fever than PGE_2.

Septic Miscarriage

Septic abortion, once a leading cause of maternal mortality, has become a less frequent occurrence, primarily because changes in abortion laws have made pregnancy terminations by physicians available to women with unwanted pregnancies. However, any type of spontaneous miscarriage can also be complicated by infection. The infection is most commonly endometritis but can progress to parametritis and peritonitis. These patients present with fever, abdominal tenderness, and uterine pain. In severe cases, local infection progresses to septicemia and septic shock. The polymicrobial infection mirrors the endogenous vaginal flora and includes *Escherichia coli* and other aerobic, enteric, Gram-negative rods, group B-hemolytic streptococci, anaerobic streptococci, *Bacteroides* species, staphylococci, and microaerophilic bacteria.

The initial evaluation and management of septic abortion should include several steps:

- physical and pelvic examination
- complete blood cell count and determination of electrolyte, blood urea nitrogen, and creatinine levels
- type and screen or crossmatch of blood
- smears from cervix for Gram stain
- aerobic and anaerobic cultures of endocervix, blood, and available products of conception
- indwelling Foley catheter
- intravenous fluids (e.g., saline, Ringer lactate) through a large-bore angiocatheter
- administration of 0.5 mL of tetanus toxoid, given subcutaneously for immunized patients, or 250 U of tetanus immune globulin, administered deep within the muscle
- supine and upright radiographs of the abdomen to detect free air or foreign bodies.

Optimal therapy consists of evacuation of the uterus and aggressive use of parenteral antibiotics before, during, and after removal of necrotic tissue by curettage (Table 4.1). Prompt removal of the infected tissue is important and should be performed within a few hours after beginning intravenous antibiotics. Numerous antibiotic regimens have been recommended, but high-dose, broad-spectrum coverage as outlined in Table 4.1 is essential. Although most patients with septic abortions respond favorably to treatment, septic shock syndrome is a serious complication that requires aggressive management in an intensive care setting (see Chapter 25).

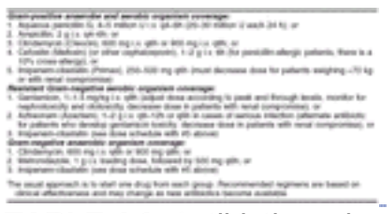

TABLE 4.1. *Antibiotic regimens for septic abortion*

RECURRENT MISCARRIAGE

Recurrent miscarriage (RM), traditionally defined as three or more consecutive first-trimester spontaneous losses, affects up to 1% of couples. Primary recurrent miscarriage is diagnosed in women who have never had a successful pregnancy, and secondary recurrent miscarriage in those whose repetitive losses follow a live birth. There is no specific classification for women who have multiple miscarriages interspersed with normal pregnancies. It is generally agreed that a workup for possible causes of RM is indicated in most patients after two or three consecutive miscarriages.

The management of couples with RM is controversial. This clinical entity has received much attention in the lay and medical literature during the past decade. A definite cause is established in no more than 50% of couples, and several alleged causes of RM are controversial. Despite publicity to the contrary, there is little evidence that poor nutrition, infections, unrecognized diabetes, toxic agents, or psychological trauma are significant etiologic factors. Some alleged experts and Internet sites inappropriately emphasize unproven hypotheses and results from poorly designed clinical studies. Seeking a solution, some patients and physicians may explore less well-accepted etiologies and empirical or alternative treatments. Moreover, new diagnostic tests for RM are continually being proposed to replace those that have been disproved and discarded. For example, antithyroid antibodies, elevated follicular-phase luteinizing hormone levels, circulating maternal embryotoxic factor, and abnormal lymphocyte subset ratios (elevated $CD56^{+}$ levels) have been touted within the last decade. It is beyond the scope of this chapter to critically analyze each new “treatment” or assay, but the mechanism of pregnancy loss and potential relationship to each of these remains largely theoretical. Until effective treatments are identified and proven by properly designed studies, these screening tests have little use in the routine evaluation of patients with RM.

Typically, investigation of anatomic, hormonal, genetic, and infectious factors has been recommended. Even these may be criticized because the derivation of their diagnostic use and treatments advocated are empirical and have come under scrutiny because they were never submitted to properly designed study. Importantly, evidence has mounted that the average women with RM has a fairly good prognosis for a successful next pregnancy without any specific treatment.

Known and Suspected Causes of Recurrent Miscarriage

Structural Uterine Defects Hysterosalpingography, magnetic resonance imaging, hysteroscopy, sonohysteroscopy, and laparoscopy can be used to diagnose septate uterus, other müllerian anomalies, uterine defects associated with diethylstilbestrol exposure, submucous myomas, and intrauterine synechiae. The prognosis for successful pregnancies in patients with müllerian anomalies is related to the type of malformation, with asymmetric fusion defects carrying the worst prognosis and septate, bicornuate, and didelphic uteri carrying increasingly better prognoses. In patients with RM, the prevalence of these anatomic defects is approximately 10% to 15%. The cause of pregnancy loss in women with uterine anomalies is uncertain. A diminished blood supply interfering with normal implantation and placentation and the reduced size of the uterine cavity are often cited as possible causes, but these reasons seem unlikely or insubstantial in the setting of the arcuate uterus. Abdominal metroplasty has been replaced in most cases by the hysteroscopic removal of uterine septa. This procedure can be accomplished in an outpatient setting and eliminates the need for cesarean delivery. Noncontrolled, retrospective studies suggest the subsequent live-birth rate is greater than 80%. Removal of synechiae and submucous myomas can also be performed hysteroscopically (see Chapter 47).

Endocrine Problems The luteal phase defect (LPD) has long been thought to be a cause of spontaneous abortion, but the evidence linking LPD to recurrent abortion is subject to criticism. It is traditionally thought that women with LPD have short menstrual cycles, postovulatory intervals less than 14 days, and secondary infertility. LPD was initially thought to be due to failure of the corpus luteum to make enough progesterone to establish a mature endometrial lining suitable for placentation. This theory has evolved to implicate poor follicular-phase oocyte development, which results in disordered estrogen secretion, inadequate ovarian steroidogenesis, and subsequent maldevelopment of endometrial receptors. In turn, these effects could result from excess luteinizing hormone or hyperandrogenic states. Some investigators claim that LPD accounts for over one fourth of cases of RM, but studies of this disorder have not included concurrently tested controls. Also, there is little agreement on the criteria necessary to make the diagnosis. Endometrial biopsy or luteal-phase serum progesterone levels are the most widely accepted diagnostic tests. Both are timed for the late luteal phase of the cycle. The endometrial biopsy is histologically dated, and a lag greater than 2 to 3 days is considered suspect. However, this should be confirmed by repeat biopsy, because delayed endometrial histology can occur sporadically in women with no reproductive problems. To further confuse the issue, normal women have endometrial histology suggestive of LPD in up to 50% of single menstrual cycles and 25% of sequential cycles. Though the association between LPD and RM remains speculative, many clinicians have treated women with RM with progesterone in their next pregnancy. One commonly advocated treatment is a 25-mg progesterone suppository inserted into the vagina twice a day (morning and night) beginning after ovulation and continuing until menses begin or through the first 8 to 10 weeks of pregnancy. Comparable doses of oral micronized progesterone have also been used. No properly designed studies have evaluated the role of progesterone treatment in women with RM with LPD. Older studies and meta-analyses are difficult to interpret because of marked differences in inclusion criteria and how LPD was diagnosed, the use of various progesterone compounds, and the small number of women studied. In a more recent randomized trial, a subgroup of women with polycystic ovary syndrome (PCOS) and three or more miscarriages were randomized to treatment with either progesterone or placebo pessaries. There was no difference in the pregnancy outcomes. Clomiphene and other ovulatory agents have been tried to improve follicular development and corpus luteum function, but the results have been variable. Human chorionic gonadotropin has been used in an attempt to stimulate the corpus luteum support of pregnancy in women with RM. One placebo-controlled, multicentered trial found no significant difference in the successful pregnancy rates (83% vs. 79%). In summary, the relationship between the LPD and recurrent pregnancy loss remains a subject of controversy. It has not been shown conclusively that progesterone treatment or corpus luteum support influences pregnancy outcome in women with recurrent pregnancy loss. PCOS has been found in one third or more of women with RM. However, the diagnosis of PCOS in women with RM does not predict a worse pregnancy outcome than in women with RM without PCOS. There is no known effective therapy for women with PCOS and RM.

Genetic Abnormalities Parental chromosomal anomalies are found in approximately 3% to 5% of couples with RM. Cytogenetic examination of both partners is helpful to predict recurrence and forms the basis for genetic counseling. Most abnormalities are balanced translocations, with two-thirds being reciprocal translocations and one-third robertsonian translocations. Couples with balanced translocations have spontaneous loss rates ranging from 50% for reciprocal translocations to 25% for robertsonian translocations. All couples with a parental chromosomal abnormality deserve counseling about genetic amniocentesis or chorionic villus sampling in any future pregnancy to exclude a serious fetal chromosomal abnormality. Parental chromosomal abnormalities do not usually preclude further attempts at pregnancy, because most couples eventually have normal offspring. For the rare homologous robertsonian translocation that prevents successful pregnancy, therapeutic possibilities include artificial donor insemination, in vitro fertilization with donor oocytes, and adoption. Chromosomal analysis of the products of conception is also clinically useful, particularly in the evaluation of the reason for failure of a treatment regimen. Molecular mutations that may be shown in the future to cause recurrent miscarriages include lethal, single-point mutations, possibly linked to *MHC* genes; mutations in genes that code for products critical for normal development; mutations in homeobox genes that control transcriptional regulation; mutations that lead to severe metabolic errors and embryonic death; and disorders of protooncogenes and oncogenes. One group has shown that certain polymorphisms of the *HLA-G* gene are associated with significantly higher rates of miscarriage among couples presenting with RM. Also, marked skewing of the normal 50:50 distribution of X chromosome inactivation in the mother, a condition termed *highly skewed X-chromosome inactivation*, may be associated with otherwise unexplained RM. Before testing is recommended, confirmation of these molecular genetic associations in different populations is required. For now, commercially available tests for these conditions are not widely available, and there are no proven treatment options.

Autoimmune Disorders

Antiphospholipid Syndrome Antiphospholipid syndrome (APS) has been recognized as a proven cause of pregnancy loss for over a decade. Approximately 5% to 15% of women with RM have lupus anticoagulant (LA), anticardiolipin (aCL), or both. These acquired antiphospholipid autoantibodies are induced by as yet unknown stimuli in the setting of aberrant immunoregulation. Low levels of immune globulin G or immune globulin M aCL are of questionable significance. Though women with APS may present with RM in the first trimester, fetal death in the second or early third trimesters may be more specific for the condition. Patients with high levels of aCL or a history of prior fetal death are at greatest risk of another fetal loss. The cause of fetal death appears to be a decidual vasculopathy that results in decidual infarction and insufficient blood flow to the placenta. Intervillous thrombosis has also been described. However, these lesions are nonspecific, and the degree of pathology is not always sufficient to explain the fetal death. The mechanisms by which aCL may cause decidual vasculopathy and fetal death are unknown. A number of pathophysiologic mechanisms have been proposed, including an imbalance of local prostacyclin and thromboxane production, enhanced platelet aggregation, decreased activation of protein C, increased tissue factor, and decreased trophoblast annexin V production or availability. Most recently, the complement system has been invoked as having a major role in antiphospholipid syndrome-related pregnancy loss. Maternally administered heparin is widely considered the treatment of choice for APS pregnancies, both to improve embryo-fetal outcome and protect the mother from thrombotic events (Table 4.2). Treatment is usually initiated in the early first trimester after ultrasonographic demonstration of a live embryo. The dose of heparin required for safe and effective treatment, however, is debated. Some experts use relatively low doses of heparin (e.g., 5000 U of standard heparin b.i.d.), particularly when treating women with recurrent preembryonic or embryonic losses. However, higher doses of heparin are recommended for patients with APS with prior thrombosis, and some experts urge full anticoagulation. The optimal dose of heparin is controversial for women whose APS is diagnosed because of prior fetal loss or neonatal death after delivery before 34 weeks gestation due to severe preeclampsia or placental insufficiency, but who do not have a history of thromboembolism. These women are at risk for thromboembolic disease, and it is our opinion that these cases should receive sufficient thromboprophylaxis. Low molecular-weight heparins (LMWHs) are widely used in Europe for the treatment of APS pregnancy, and there is little reason to suspect that the appropriate use of LMWHs differs from that of standard heparin with regard to efficacy. In most case series and trials, daily low-dose aspirin is included in the treatment regimen. One important caveat deserves mention—a small, placebo-controlled trial found that otherwise

healthy women with RM and low titers of antiphospholipid antibodies do not require treatment.

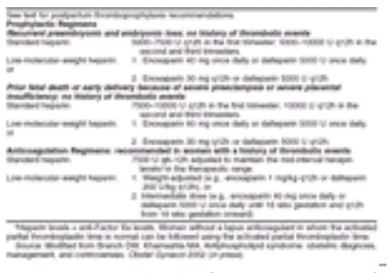

TABLE 4.2. *Subcutaneous heparin regimens used in the treatment of antiphospholipid syndrome during pregnancy*

Intravenous immune globulin has also been used during pregnancy, usually in conjunction with heparin and low-dose aspirin, especially in women with particularly poor past histories or recurrent pregnancy loss during heparin treatment. However, a randomized, controlled, pilot study of intravenous immune globulin treatment during pregnancy in unselected APS cases proved negative. Anticoagulant coverage of the postpartum period in women with APS and prior thrombosis is critical. We prefer switching the patient to warfarin thromboprophylaxis as soon as she is clinically stable from delivery. In most cases, an international normalized ratio of 3.0 is desirable, and postpartum coverage should extend for 6 to 8 weeks after delivery. Because of their risk for thrombosis, the same strategy is recommended in women without prior thrombosis but in whom APS is diagnosed because of prior fetal loss or neonatal death after delivery at or before 34 weeks gestation for severe preeclampsia or placental insufficiency. Both heparin and warfarin are safe for nursing mothers. The need for postpartum anticoagulation in women with primary APS diagnosed solely on the basis of recurrent preembryonic and embryonic losses is unclear.

Other Autoimmune Disorders Autoantibodies to thyroid antigens are associated with a modest increased rate of pregnancy loss if identified in early pregnancy or immediately before pregnancy. Some investigators have found a significant proportion of women with RM to have antithyroid antibodies; others have not. Even if antithyroid antibodies are associated with RM, no treatment options have proven beneficial. Approximately 15% of women with RM have detectable antinuclear antibodies (ANA). Subsequent pregnancy outcomes among women with a positive ANA test result are similar to those among women with a negative ANA test result. A randomized treatment trial of women with recurrent pregnancy loss and a positive autoantibody result, including ANA, found no benefit to treatment with prednisone and low-dose aspirin and treatment with placebo. Thus, currently available data do not support testing women with recurrent pregnancy loss for ANA.

Thrombophilic Disorders The relationship between inherited thrombophilic disorders and recurrent miscarriage has been the subject of intense study within the last several years. The most common inherited thrombophilic disorders are factor V Leiden and prothrombin G20210A mutation, found in approximately 8% and 3%, respectively, of Caucasian women in the United States. These mutations are associated with approximately 25% of isolated thrombotic events and approximately 50% of familial thrombosis. Other less common thrombophilias include deficiencies of the anticoagulants protein C, protein S, and antithrombin III. Hyperhomocysteinemia, most commonly due to the C677T polymorphism of the methylenetetrahydrofolate reductase (MTHFR) gene, is also associated with venous thrombosis. Data regarding the association of these thrombophilic abnormalities and RM do not allow clear and consistent conclusions. The rather obvious fact that most women with common thrombophilic mutations, such as factor V Leiden, the prothrombin G20210A mutation, or the MTHFR C677T mutation, do *not* have RM further confounds the picture. One prospective study of next pregnancies in women with RM found a significantly lower successful pregnancy rate among those with the factor V Leiden mutation compared to those without (37.5% vs. 69.3%). Various studies are more consistent in finding an association between thrombophilias and second- or third-trimester fetal loss. The odds ratio for stillbirth is significantly higher in women with combined thrombophilic defects. Some women with RM have evidence of ongoing, perhaps chronic, thrombin generation or the formation of thrombosis-related microparticles. These studies underscore the potential importance of prothrombotic states to pregnancy loss, but more research is required to bring the current findings into the clinical realm. Despite the recent interest in this field, no treatment trials have been performed. Thus, which therapy, if any, is effective in promoting successful pregnancy among women with recurrent pregnancy loss and thrombophilia is uncertain.

Cervical Incompetence Incompetent cervix, also called premature cervical dilation, is an important cause of second-trimester pregnancy loss. It is characterized by gradual, painless dilation of the cervix with bulging and rupture of the membranes and subsequent expulsion of a fetus too immature to survive. Pregnancy loss from this cervical abnormality usually occurs in the second trimester and is thought to be an entirely different and distinct entity from a first-trimester miscarriage or premature labor in the third trimester. It results from different factors, presents a distinctive clinical picture, and requires different management. Moreover, miscarriage and premature labor are common, but mid-trimester premature cervical dilation is relatively rare. Unlike the rest of the uterus, the cervix is fundamentally a connective tissue structure. The cause of cervical incompetence is obscure, and various etiologic factors have been proposed. Previous surgery or trauma to the cervix, such as D&C, amputation, conization, cauterization, loop electrosurgical excision procedure (LEEP), or traumatic delivery, seem to be factors in some cases. In other instances, congenital cervical structural defects, uterine anomalies, or abnormal cervical development associated with in utero diethylstilbestrol exposure appear to play a role. Little agreement can be found regarding the diagnosis of cervical incompetence, except that it is one of exclusion that requires careful evaluation to rule out other potential causes of mid-trimester pregnancy loss. Other causes of very early delivery include abruptio placentae, chorioamnionitis, and uterine anomalies, but they usually present different clinical pictures. Whether or not the condition can be diagnosed during the nonpregnant state by methods designed to calibrate the diameter of the endocervical canal or during early pregnancy by sonographic findings is questionable. The absolute diagnosis of cervical incompetence can be made only by seeing the fetal membranes bulging through the partially dilated cervix of a patient in the second trimester of pregnancy who is not in labor. More typically, a presumptive diagnosis is made from the characteristic history of apparently silent dilation of the cervix followed by rupture of the membranes and a relatively painless, rapid labor with delivery of an immature infant. Also, the fetus is typically alive at the time of presentation to the hospital; delivery of a dead, macerated fetus makes the diagnosis of cervical competence questionable. Upon inspection in the nonpregnant state, the cervix may be shortened with a patulous os or may be deformed with lacerations that sometimes extend to the vaginal fornix. Although bed rest, various intravaginal devices, and pharmacologic agents have been used with some success, the generally accepted treatment for incompetent cervix is surgical. Various methods have been described, but the McDonald or Shirodkar procedures (Fig. 4.5) are most commonly employed prophylactically. These are techniques performed vaginally, usually under regional anesthesia, designed to reinforce the cervix close to the level of the internal os. If there is insufficient cervical tissue to allow placement of a cerclage vaginally, an abdominal approach is sometimes used. The reinforcement suture is usually placed toward the end of the first trimester after ultrasound documentation of a live fetus, after the risk of miscarriage has passed, and before the cervix starts to dilate.

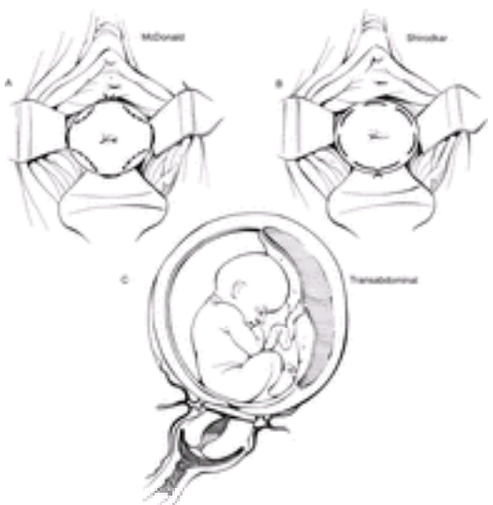

FIG. 4.5. Incompetent cervix can be treated by three procedures. **A:** In the McDonald cerclage procedure, a multiple-bite suture using large, monofilament nylon is placed around the cervix and tied securely to reduce the diameter of the cervical canal to a few millimeters. **B:** In the Shirodkar procedure, Merseline tape encircling the cervix is passed under the mucosa and anchored to the cervix anteriorly and posteriorly with interrupted sutures. **C:** With transabdominal cervicoisthmic cerclage, a Merseline band is placed in an avascular space medial to the uterine vessels at the level of the cervicouterine junction.

Placement of the cerclage in the second trimester after cervical change has occurred is sometimes necessary but appears less effective. The procedure should not be used if the diagnosis is in doubt, if membranes are ruptured, or if vaginal bleeding and cramping are part of the clinical picture. There is no evidence that postoperative antibiotics, progesterone, or tocolytic agents are useful adjuvants. If membranes rupture or labor ensues at any time, removal of the cerclage should be strongly considered to prevent chorioamnionitis, sepsis, cervical laceration, and rupture of the uterus. Otherwise, the suture is removed when fetal maturity is achieved, usually after 37 weeks gestation, which is often followed by the onset of labor and a relatively rapid delivery. If the patient desires further pregnancies, some physicians leave the cerclage in place and deliver by cesarean section. Often, the history is not typical, and it is difficult to determine whether or not premature cervical dilation will occur in a subsequent pregnancy. These patients are usually followed with frequent vaginal examinations and serial sonograms to diagnose potential cervical changes. Transvaginal ultrasound can be used to accurately assess cervical length and may be useful in deciding for or against cerclage in women with an unclear history. The effectiveness of cerclage has often been questioned, even in women with a classic clinical picture. Nevertheless, when patients are carefully selected, this type of management is 80% to 90% successful in preventing delivery of an immature fetus. There is little difference in the fetal survival rates between the McDonald and Shirodkar techniques. The procedure has also been used prophylactically for patients with previous preterm deliveries with less convincing evidence for cervical incompetence. Results from prospective randomized studies have led to conflicting conclusions.

Idiopathic Causes Because most cases of RM have no discernible cause, alloimmune factors have long been suspected. These have yet to be proven, largely because little is known about the mechanisms that prevent immunologic rejection of the conceptus in successful pregnancies (see Chapter 18). Early reports proposed that HLA compatibility between couples, the absence of maternal leukocytotoxic antibodies, or the absence of maternal blocking antibodies were related to RM. The

importance of these factors has not been substantiated, and these expensive tests are no longer clinically indicated. Contemporary research is focused on local decidual or trophoblast immunosuppressive factors such as cytokines, growth factors, hormones, enzymes, and endometrial proteins. Some of these immunoactive factors appear to be necessary for implantation and growth and development of the early placenta and embryo, and others may cause abortion, when expressed. There are, however, no practical clinical tests available for these factors and no proven treatment if they were found abnormal. Although no alloimmune mechanism has been unequivocally shown to cause RM in humans, several types of immunotherapy have been advocated. Originally, the attempt to improve maternal immunotolerance in recurrent aborters was based on evidence that pretransplant blood transfusions decreased rejection of organ allografts and that the rate of resorptions or abortions in animal models was reduced by prior immunization with spleen cells from a paternally related strain. The most popular regimen involves injections of the father's leukocytes. Though proponents persist, this treatment is questionable at best and harmful at worst. Most randomized trials have proven negative, and the largest and only multicenter randomized trial found that treated pregnancy outcomes were worse in the women who received leukocyte immunization. Based largely on this trial, the U.S. Food and Drug Administration has stated that the administration of this therapy for RM may only be done as part of a clinical investigation, and then only if there is an investigational new drug application in effect. Participating women should be counseled that immunization using viable leukocytes carries the risks of any blood transfusion, such as hepatitis, human immunodeficiency virus, and cytomegalovirus infections. Reactions have been uncommon but include soreness and redness at the injection site, cutaneous graft-versus-hostlike reaction, fever, maternal platelet and leukocyte alloimmunization, and blood group sensitization. Intravenous immune globulin has been proposed as an alternative therapy in patients with idiopathic RM. A number of randomized trials have been reported, and the results are conflicting. Nevertheless, this treatment seems to be no more successful than paternal cell immunization, and intravenous immune globulin is not recommended outside of a research protocol by either the American College of Obstetricians and Gynecologists or the American Society of Reproductive Medicine. It is imperative for physicians to recognize that the prognosis for idiopathic RM is by no means dismal. Numerous studies and several meta-analyses indicate that the average next pregnancy live-birth rate for placebo-treated women with idiopathic RM is 60% to 70%. Many couples see this modestly favorable prognosis in a somewhat positive light, and it compares favorably with the prognosis for conditions such as APS or parental karyotype abnormalities. Understanding this prognosis may allow the couple to choose against an expensive unproven treatment. One caveat—as expected, increasing maternal age and increasing number of miscarriages are negative variables.

Recommendations for Recurrent Miscarriage

The scheme for a reasonable and cost-effective evaluation of women with RM shown in Table 4.3 is based on current guidelines published by the American College of Obstetricians and Gynecologists and the Royal College of Obstetricians and Gynaecologists. A sympathetic attitude by the physician is crucial—establishment of trust and rapport and a sincere appreciation of the distress and grief experienced by these couples permit tactful and thorough discussions with patient and partner. It is reasonable to institute an evaluation after two consecutive miscarriages in anxious women or if the patient has few reproductive years remaining or has had an infertility problem. Couples interested in an investigational protocol are perhaps best referred to legitimate research centers.

History
Determine pattern and trimester of pregnancy losses and whether a live fetus was present; clues suggestive of autoimmune disease; unusual exposure to environmental toxins, drugs, infections; previous gynecologic disorders or surgery, including dilation and curettage; and previous diagnostic tests and treatments.
Physical
Abnormalities on pelvic examination, including findings suggesting abnormal cervix, diethylstilbestrol exposure, or uterine anomalies.
Tests
Lupus anticoagulant and anticardiolipin antibodies
Parental chromosome analyses (father and mother)
Evaluation of uterine cavity and shape by hysterosalpingogram, hysteroscopy, or other appropriate imaging studies
Chromosome analysis of products of conception
Other laboratory tests if suggested by history and physical examination

TABLE 4.3. *Proposed evaluation for recurrent miscarriage*

SUMMARY POINTS

- Miscarriage is the most common complication of pregnancy, and the most frequent etiology is a chromosomal abnormality of the conceptus.
- Ultrasound is helpful in determining whether or not the embryo is viable, and appropriate modern management may be either observation or evacuation of the uterus.
- Recurrent early pregnancy loss is sometimes associated with underlying maternal abnormalities that can be detected with standard tests. Physicians should be aware of unproven tests and controversial treatments in order to best counsel their patients.

Ectopic Pregnancy and Assisted Reproductive Technology

Management of ectopic pregnancy is changing dramatically. Although ectopic pregnancy remains a leading cause of life-threatening first-trimester morbidity, informed clinical suspicion and modern diagnostic procedures now routinely lead to diagnosis and treatment before there are symptoms. Medical therapy with systemic methotrexate, an intervention targeted specifically toward proliferating trophoblasts, is now preferred to surgery as standard first-line therapy. Surgery remains the first choice for hemorrhage, medical failures, neglected cases, and cases where medical therapy is contraindicated. In the wake of these changes, the United States has seen a considerable drop in maternal morbidity and mortality from this disease.

Optimal dosing for methotrexate remains controversial. Rules for timing and technique for surgical intervention during medical failures are empirical. Early diagnosis and selection of optimal therapy are key to prevention of complications, preservation of fertility, control of costs, and elimination of mortality. Using an evidence-based approach to diagnosis and treatment for ectopic pregnancy, this chapter provides a comprehensive examination of the standard of care for this serious gynecologic disease.

INCIDENCE

The incidence of ectopic pregnancy in the United States is not known precisely. Recent attempts at the Centers for Disease Control and Prevention (CDC) to estimate the incidence of this disease have been thwarted, because many cases are treated medically in outpatient facilities and are not recorded in hospital registries. Where hospital records were used, a relentless increase in ectopic pregnancies from 4.5 per 1,000 in 1970 to 16.8 per 1,000 in 1989 to 19.7 per 1,000 (108,000 cases) in 1992 has been reported. The current incidence will probably prove much higher once the CDC is able to make estimates including outpatient records. Certain epidemiologic trends make this likely. First, there is a continued increase in risk factors (Table 5.1) in a society with unprecedented sexual liberties. Second, there is increased ascertainment of ectopics from use of more sensitive and specific diagnostic methods that detect many cases that, in the past, would have resolved spontaneously without diagnosis. Third, with the increasing use of assisted reproductive technology (ART) for treatment of infertility, there is an increase risk of ectopics which comprise up to 5% of pregnancies achieved by using ART. Not surprisingly, heterotopics also are being reported with increasing frequency in ART pregnancies. Between 1979 and 1986, 13% of maternal deaths were secondary to ectopic pregnancy; by 1992, this dropped to 9%. However, ectopic pregnancies continue to be the leading cause of maternal death in the first trimester accounting for 5% to 6% of all maternal deaths in the United States. Ninety percent of these deaths were due to hemorrhagic complications.

Factors identifying patients at increased risk for ectopic pregnancy. Patients at increased risk need aggressive monitoring of their pregnancies immediately after first missed menses.

Risk Factor	Odds Ratio[a]
High Risk	
Tubal surgery	21.0
Tubal ligation	9.3
Previous ectopic pregnancy	8.3
In utero exposure to DES	5.6
Use of IUD	4.2–45.0
Tubal pathology	3.8–21.0
Assisted reproduction	4.0
Morning-after pill	High
Moderate Risk	
Infertility	2.5–21.0
Previous genital infections	2.5–3.7
Multiple sexual partners	2.1
Salpingitis isthmica nodosa	1.5
Low Risk	
Previous pelvic infection	0.9–3.8
Cigarette smoking	2.3–2.5
Vaginal douching	1.1–3.1
First intercourse <18 yr	1.6

TABLE 5.1. *Risk factors associated with ectopic pregnancy*

PATHOGENESIS

Any event that impairs the ability of the tube to transport gametes or embryos will predispose to ectopic implantation. The clinical picture is determined by the site of ectopic implantation. The most common site of ectopic pregnancy is the fallopian tube, which accounts for 98.3% of all ectopic gestations. Implantation in the ampulla is observed in 79.6% of tubal ectopic pregnancies; 12.3% are in the isthmus, 6.2% are in the fimbrial end, and the remaining 1.9% occur in the interstitial (cornual) region. Ectopic nidation outside the fallopian tubes is rare; only 1.4% of ectopic pregnancies are abdominal pregnancies, 0.15% ovarian, and 0.15% cervical (Fig. 5.1).

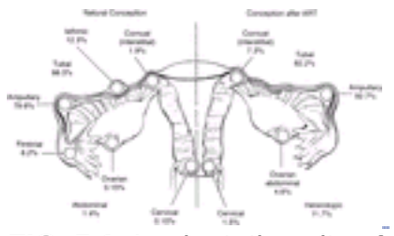

FIG. 5.1. Implantation sites for ectopic pregnancy following natural cycles and assisted reproductive technology.

In most tubal implantations, the proliferating trophoblasts invade the tubal wall. The degree of trophoblastic invasion of maternal tissues, the viability of the pregnancy, and the site of implantation determine the sequence of clinical events. As the trophoblasts proliferate, the growth may extend from the luminal mucosa, into the muscularis and lamina propria, into the serosa and, ultimately, full thickness even into large blood vessels in the broad ligament. With vascular invasion, bleeding takes place which distorts the tube, stretches the serosa, and causes pain. The embryo is abnormal and degenerates in about 80% of cases. Spontaneous tubal abortion occurs in about 50% of tubal ectopic pregnancies and is often clinically silent. Spontaneous tubal abortion with hemorrhage can occur with bleeding that is self-limited. Tubal rupture usually is associated with significant hemorrhage. This complication is most likely to occur in the isthmic part of the tube, which has limited distensibility. Chronic tubal rupture with extension into the broad ligament can produce a pelvic hematoma that can last for several weeks. Unruptured ectopic pregnancies can produce a chronic course, with persistently elevated ß-human chorionic gonadotropin (ß-hCG) levels that may last for weeks.

RISK FACTORS

Ectopic pregnancy most often is associated with risk factors leading to tubal epithelial damage, which alters gamete and embryo transport. Meta-analyses identify the risk factors listed in Table 5.1 as the most influential.

Tubal Damage and Infection

Documented tubal pathology carries a 3.5-fold common adjusted odds ratio for ectopic pregnancy. Patients with a previous ectopic pregnancy are 6 to 8 times more likely to experience another ectopic pregnancy, and 8% to 14% of patients experience more than one ectopic pregnancy. Patients with a history of tubal surgery have a 21-fold common adjusted odds ratio of ectopic pregnancy.

Tubal pathology frequently results from pelvic infections. Patients with a history of pelvic infections, including gonorrhea, serologically confirmed chlamydia, and nonspecific pelvic inflammatory disease, have a two-fold to four-fold higher risk of developing an ectopic pregnancy. The ectopic pregnancy rate is 4% in women with laparoscopically proven salpingitis, compared with 0.7% in women with normal tubes. In evaluating histologic specimens of ectopic pregnancy, microscopic evidence of inflammatory disease is present in 38% of cases. Recurrent episodes of pelvic infections increase the likelihood of tubal occlusions: 12.8% after one infection, 35.5% after two infections, and 75% in patients with three or more infections.

Salpingitis Isthmica Nodosa

Salpingitis isthmica nodosa is a disease defined by an anatomic thickening of the proximal portion of the fallopian tubes with multiple luminal diverticula. This pattern of tubal pathology increases the incidence of ectopic pregnancy by 52% in age- and race-matched controls.

Diethylstilbestrol

In utero exposure to diethylstilbestrol (DES) alters fallopian tubal morphology, resulting in absent or minimal fimbrial tissue, a small tubal os, and decreased length and caliber of the tube. Abnormal tubal anatomy accounts for the five-fold increase in the risk for ectopic pregnancy.

Cigarette Smoking

Patients who smoke cigarettes are at a slightly increased risk for ectopic pregnancy. It is difficult to conceptualize the link between ectopic pregnancy and cigarettes. Theories include impaired immunity in smokers predisposing them to pelvic infections, alterations in tubal motility, or a representation of certain lifestyles associated with increased risk of tubal injection.

Contraception

Intrauterine devices (IUDs) have been associated with ectopic pregnancy. A multicenter case-control study conducted by the World Health Organization in ten countries found an odds ratio of 6.4 for ectopic pregnancy in current IUD users compared with pregnant controls, whereas the odds ratio was only 0.5 when the comparison was made with nonpregnant controls. Similarly, in the Oxford Study of 17,032 contraceptive users, the proportion of unplanned pregnancies that were ectopic was higher in women using IUDs compared with women taking oral contraceptives. Thus, IUDs effectively prevent pregnancy, but if pregnancy occurs in a woman using an IUD, there is increased likelihood that the pregnancy will be ectopic.

Tubal ligation carries a similar risk for ectopic pregnancy to what is observed with current IUD use. A meta-analysis using case-control studies found the odds ratio for tubal sterilization to be 9.3 when compared with pregnant controls and 0.52 when compared with nonpregnant controls, a finding confirmed by two additional multicenter case-control trials. As with the IUD, tubal ligations effectively prevent pregnancy, but if pregnancy does occur, the suspicion for an ectopic pregnancy should be high.

Electrocoagulation procedures are associated with higher ectopic pregnancy risk than other forms of tubal sterilization, possibly resulting from tubal recanalization or uteroperitoneal fistula formation. Uteroperitoneal fistulas have been found in up to 75% of hysterectomy specimens from women with previous tubal ligations in which the tubes were cauterized flush with the uterus.

Oral contraceptives are associated with a reduced risk of ectopic pregnancy when compared with nonpregnant controls but with elevated risk when compared with pregnant controls. This protection is presumably due to the suppression of ovulation by oral contraceptives. It is therefore not surprising that patients who take emergency contraception, such as oral contraceptives after fertilization, are at substantial risk for an ectopic pregnancy. This has been attributed to altered tubal motility.

Barrier contraception (condoms, spermicides, and diaphragms) also reduces the odds ratio of ectopic pregnancy. An additional advantage may be attributed to the decreased risk of sexually transmitted diseases in women using barrier methods.

Evidence-based Recommendation

Women with a previous ectopic pregnancy, tubal surgery, tubal pathology, or in utero DES exposure are at high risk for ectopic pregnancy. Women who have experienced genital infections, infertility, or more than one sexual partner have a moderate risk of ectopic pregnancy. Previous pelvic or abdominal surgery, smoking,

vaginal douching, or an early age of first sexual intercourse have only a slightly increased risk of ectopic pregnancy.

Contraception, if used properly, is an effective way of reducing pregnancy, both intrauterine and extrauterine. If pregnancy occurs in women with an IUD, after tubal ligation, or following emergency contraception, suspicion for ectopic pregnancy should be high. (Strength of recommendation: A.)

SIGNS AND SYMPTOMS

Today, many ectopic pregnancies never produce symptoms; rather, they are timely diagnosed and treated because the patient is identified as high risk. Table 5.1 summarizes and weighs risk factors that should be examined in every woman who has just been identified as being pregnant. If the diagnosis is delayed, some patients may develop the classic triad of amenorrhea, irregular vaginal bleeding, and lower abdominal pain. Early diagnosis, unfortunately, is not always achievable. Sudden, severe, lower abdominal pain is the most common complaint in 90% to 100% of women with symptoms of an ectopic pregnancy. Pain radiating to the shoulder, syncope, and shock as a result of hemoperitoneum occur in up to 20% of patients.

The most common signs are detected upon abdominal examination. Abdominal tenderness is present in 90% of patients and rebound tenderness in 70%. The pelvic examination is usually nonspecific; cervical motion tenderness is present in up to two thirds of patients, while a tender adnexal mass is present in 50%.

DIAGNOSIS

Ectopic pregnancy can be diagnosed as early as 4.5 weeks gestation. Unfortunately, visualizing an ectopic pregnancy this early is frequently not possible. More importantly, traditional laparoscopic visualization (Fig. 5.2, Fig. 5.3, Fig. 5.5) is now rarely necessary. Routine diagnostic tests are serial measurements of ß-hCG, ultrasonography, serum progesterone levels, and uterine curettage.

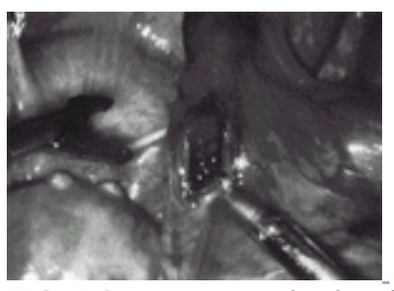

FIG. 5.2. Laparoscopic visualization of an isthmic ectopic pregnancy.

FIG. 5.3. Laparoscopic visualization of an ampullary ectopic pregnancy.

FIG. 5.5. Ultrasonogram of free fluid noted under the liver edge above the right kidney. Confirmed to be blood from a ruptured ectopic pregnancy at the time of surgery. (Courtesy of R. Mangal, M.D., Obstetrics/Gynecologic Associates, Houston, TX.)

Outpatient diagnosis of ectopic pregnancy using various algorithms has been shown to be safe and effective without need for hospitalization even when the diagnosis is equivocal. The clinical algorithm in Figure 5.4 is highly efficacious in diagnosing ectopic pregnancy.

FIG. 5.4. Diagnostic algorithm for ectopic pregnancy.

Serial ß-Human Chorionic Gonadotropin Determinations

ß-hCG determinations used today are based on the enzyme-linked immunosorbent assay (ELISA), detecting low ß-hCG concentrations in urine and serum, 20 mIU/mL down to 1 mIU/mL, respectively. The ß-hCG, produced by trophoblastic cells in normal pregnancy, rises at least 66% and up to two-fold every 2 days. This generally applies to ß-hCG values below 10,000 mIU/mL. Eight-five percent of abnormal pregnancies, whether intrauterine or ectopic, have impaired ß-hCG production with a prolonged doubling time. ß-hCG levels that plateau or fail to rise normally along with a low serum progesterone value should be considered nonviable. If a viable intrauterine gestation is not visible by transvaginal ultrasonography when the ß-hCG is above 2,000 mIU/mL (First International Reference Preparation [IRP]) and no fetal heartbeat can be visualized in the adnexa, uterine curettage can be performed. In this situation, treatment of a nonviable intrauterine pregnancy is performed or ectopic pregnancy is diagnosed when the ß-hCG levels do not fall. These ß-hCG thresholds are not universal, and each institution must identify its own values to avoid terminating normal intrauterine pregnancies.

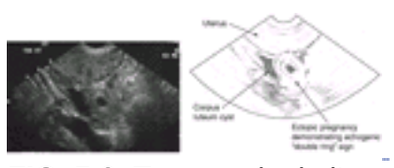

FIG. 5.6. Transvaginal ultrasonographic illustration of tubal ectopic gestation.

ß-hCG determinations are further employed for diagnosis after uterine curettage. If the ß-hCG fails to decline by 15% from a level drawn immediately before surgery, the pregnancy is presumed ectopic and treatment should be initiated.

Ultrasonography

Although the uterus and adnexa may be evaluated abdominally or vaginally, transvaginal ultrasonography reliably detects intrauterine gestations when the ß-hCG levels are between 1,000 and 2,000 mIU/mL (First IRP), as early as 1 week after missed menses. An intrauterine gestation should almost always be visualized when the ß-hCG level is greater than 2,000 mIU/mL.

Diagnosis of an ectopic pregnancy can be made with 100% specificity but with low sensitivity (15%–20%) if an extrauterine gestational sac containing a yolk sac or embryo is identified. A complex adnexal mass without an intrauterine pregnancy improves sensitivity to 21% to 84% at the expense of lower specificity (93.0%–99.5%). In reviewing the literature, the presence of any noncystic, extraovarian adnexal mass in the absence of an intrauterine gestation was diagnostic of an ectopic pregnancy with 98.9% specificity, 96.3% positive predictive value, 84.4% sensitivity, and a 94.8% negative predictive value. Despite the high resolution of transvaginal ultrasonography, an adnexal mass will not be found in 15% to 35% of patients with an ectopic pregnancy, particularly in early stages. Some sonographic images, such as the pseudogestational sac, may mislead even an experienced examiner to falsely diagnose a gestational sac.

Serial ß-hCG concentrations and transvaginal ultrasonography predict ectopic pregnancy with a positive predictive value of 95%. Diagnosis is made routinely by the absence of an intrauterine pregnancy (i.e., gestational sac) at a designated ß-hCG concentration. The vast majority of viable intrauterine pregnancies can be identified by ultrasonography when the ß-hCG is greater than 1,500 mIU/mL (First IRP). However, in those patients with an “indeterminate” ultrasonogram, one fourth have an ectopic pregnancy. Therefore, serial hCG and ultrasonography alone cannot diagnose all ectopic pregnancies.

Uterine Curettage

Uterine curettage is necessary when a transvaginal ultrasonogram and a rising or plateauing ß-hCG level below the cutoff value are not sufficient for diagnosis. A decrease in the ß-hCG level of 15% or more 8 to 12 hours after curettage is diagnostic of a complete abortion. If the ß-hCG titer plateaus or rises and the trophoblast was not removed by curettage, an ectopic pregnancy is likely.

Evidence-based Recommendation

Serial ß-hCG determinations, transvaginal ultrasonography, and uterine curettage allow for definitive diagnosis of ectopic pregnancy. A confirmatory laparoscopy is rarely necessary. (Strength of recommendation: A.)

TREATMENT FOR ECTOPIC PREGNANCY

Medical Management

Methotrexate therapy of ectopic pregnancy has been used successfully over the last two decades. A folic acid antagonist, methotrexate inhibits de novo synthesis of purines and pyrimidines, interfering with DNA synthesis and cell multiplication. Rapidly proliferating trophoblasts are particularly vulnerable to methotrexate and this differential sensitivity forms the basis of the therapy. When methotrexate is administered to pregnant women undergoing planned termination, a single dose of 50 mg/m^2 significantly blunts the hCG increment over the following 7 days and has been associated with a drop in circulating progesterone and 17a-hydroxyprogesterone concentrations prior to abortion. It appears that methotrexate directly impairs trophoblastic production of hCG with a secondary decrement of corpus luteum progestin secretion. Hemodynamically stable patients with unruptured ectopic pregnancy measuring less than or equal to 4 cm by ultrasonography are eligible for methotrexate therapy. Patients with larger masses or evidence of acute intraabdominal bleeding should undergo surgical treatment. The two commonly employed methotrexate treatment regimens are shown in Table 5.2.

Single-dose methotrexate protocol		
Day 1:	Baseline studies	
	Methotrexate	50 mg/m^2 i.m.
Day 4:	hCG titer	
Day 7:	hCG titer	
	CBC and platelet count	
	Liver and renal function tests	
Weekly:	hCG titer until negative	
Multiple-dose methotrexate protocol		
Treatment is discontinued when a decline is observed in two consecutive daily hCG titers, or after 4 doses of methotrexate.		
Day 1:	Baseline studies	
	Methotrexate	1.0 mg/kg i.m.
Day 2:	Citrovorum	0.1 mg/kg i.m.
Day 3:	Methotrexate	1.0 mg/kg i.m.
Day 4:	Citrovorum	0.1 mg/kg i.m.
	hCG titer	
Day 5:	Methotrexate	1.0 mg/kg i.m.
	hCG titer	
Day 6:	Citrovorum	0.1 mg/kg i.m.
	hCG titer	
Day 7:	Methotrexate	1.0 mg/kg i.m.
	hCG titer	
Day 8:	Citrovorum	0.1 mg/kg i.m.
	hCG titer	
	CBC and platelet count	
	Renal and liver function tests	
Weekly:	hCG titer until negative	

hCG, human chorionic gonadotropin; CBC, complete blood count.

TABLE 5.2. *Methotrexate protocols: single versus multiple*

Multiple-dose Methotrexate Multiple-dose methotrexate therapy is tailored to the patient's weight and ectopic pregnancy responsiveness. Outcomes of 12 studies comparing multiple-dose systemic methotrexate with laparoscopic salpingostomy are presented in Table 5.3. Between 1982 and 1997, this tabulation shows 325 cases of ectopic pregnancy treated with multiple-dose methotrexate. Of these cases, 93.8% were treated successfully with multiple-dose systemic methotrexate (no subsequent therapy was required), and 78.9% of the women tested had patent fallopian tubes; in addition, of the women desiring pregnancy, 57.9% had a subsequent intrauterine pregnancy and 7.4% developed a repeat ectopic pregnancy. These rates all compare favorably with conservative surgical management.

TABLE 5.3. *Outcome of different treatments for ectopic pregnancy*

There is one randomized clinical trial comparing laparoscopic salpingostomy with systemic multiple dose methotrexate. In it, 100 patients with laparoscopy-confirmed ectopic pregnancy were randomly treated with systemic methotrexate or laparoscopic salpingostomy. In the 51 patients treated with methotrexate, three (8%) required surgical intervention for active bleeding or tubal rupture. An additional course of methotrexate was required in two patients (5%) for persistent trophoblast, basal on ß-hCG secretion. Of the 44 patients in the salpingostomy group, two patients (5%) failed and required salpingectomies, and eight patients (22%) required treatment with methotrexate for persistent trophoblast. Tubal patency was present in 67% of the patients in the methotrexate group and in 61% in the salpingostomy group. This randomized study and previous meta-analysis have demonstrated the effectiveness of systemic methotrexate therapy as equal to laparoscopic salpingostomy.

Single-dose Methotrexate Single-dose methotrexate, although more convenient, is not as efficacious as multiple-dose methotrexate. The high success rates in the initial studies using single-dose methotrexate was most likely due to the inclusion of spontaneously aborting intrauterine pregnancies. Subsequent studies of single-dose methotrexate therapy involving 304 patients are presented in Table 5.3. Although overall success of treatment, measured as no surgical intervention, is 87.2%, 11.5% additional patients required more than one dose of methotrexate. Of the patients considered successfully treated (with one or more doses), tubal patency was found in 81.3% of the women evaluated. The subsequent intrauterine pregnancy rate was 61%, and for ectopic pregnancies 7.8%, in the patients desiring future fertility in the same group (those treated with either one or more doses of methotrexate). Based on the clinical evidence presently available, the routine use of methotrexate as a single-dose intramuscular regimen is probably not as effective as multiple dosage. However, single-dose therapy remains a standard according to publications of the American College of Obstetricians and Gynecologists. With this background, a recent meta-analysis of 26 studies evaluating methotrexate dosing for ectopic pregnancy by Barnhart et al. showed an odds ratio of 1.96 higher likelihood of rupture with use of single-dose methotrexate over multidose therapy. This failure rate was even higher when controlling for baseline ß-hCG values.

Safeguards and Counseling During methotrexate therapy, a patient should be examined by a single examiner only once. The physician and the patient must recognize that transient pain (“separating” or “tearing pain”) is common. Transient pelvic pain from resolution tubal bleeding of the ectopic pregnancy frequently occurs

3 to 7 days after the start of therapy, lasts 4 to 12 hours, and is presumably due to tubal abortion. Perhaps the most difficult aspect of methotrexate therapy is learning to distinguish the transient abdominal pain of successful therapy from that of a rupturing ectopic pregnancy. Isthmic ectopic pregnancies are probably at high risk for rupture, and there is simply no way to identify these in advance. A review of ectopic ruptures after methotrexate therapy revealed a high prevalence of isthmic (47%) ectopic pregnancies that was unexpected. These ectopic pregnancies have an early normal doubling time and rise in ß-hCG titers after methotrexate dosing. Physicians must therefore carefully observe for clinical indications that an operation is necessary (Table 5.4 and Table 5.5). Thus, surgical intervention is required when pain is worsening and persistent beyond 12 hours. Orthostatic hypotension or a falling hematocrit should lead to immediate surgery. Sometimes it is necessary to hospitalize the patient with pain for observation (usually about 24 hours). In addition, colicky abdominal pain is common during the first 2 or 3 days of methotrexate therapy, and the woman should avoid gas-producing foods, such as leeks and cabbage. Finally, the patient should avoid exposure to the sun, because photosensitivity can be a complication of methotrexate.

Indications for systemic methotrexate for uncomplicated ectopic pregnancy
Indications for Methotrexate:
◊ No rupture
◊ UTZ size ≤4 cm
◊ hCG ≤10,000 mIU/mL
◊ Positive fetal heartbeat: proceed with caution

UTZ, ultrasound; hCG, human chorionic gonadotropin.

TABLE 5.4. *Treatment with multiple-dose methotrexate*

Dealing with methotrexate failure
Operate when:
◊ Pain is severe and persistent
◊ Falling hematocrit
◊ Orthostatic hypotension

TABLE 5.5. *Methotrexate failure*

Methotrexate by Direct Injection In 1987, Feichtinger and Kemeter instilled 1 mL (10 mg) of methotrexate into an ectopic gestational sac under transvaginal ultrasonography, and resolution occurred within 2 weeks. Direct injection delivers concentrations of methotrexate to the site of implantation at higher concentrations than those achieved with systemic administration. Less systemic distribution of the drug should decrease the overall toxicity. However, this approach has the substantial disadvantage of requiring laparoscopic or ultrasound needle guidance. Outcomes in 21 studies involving direct injection of methotrexate with either laparoscopic or transvaginal ultrasound guidance are presented in Table 5.3. Between 1989 and 1997, 75.1% of 668 cases of ectopic pregnancy were treated successfully with methotrexate by direct injection, and some patients required more than one injection. Tubal patency and subsequent pregnancy rates were comparable to conservative laparoscopic surgery and systemic methotrexate: 80.2% of the women tested had patent oviducts and, of the women desiring pregnancy, 57.2% had a subsequent intrauterine pregnancy and 5.9% developed a recurrent ectopic pregnancy. Randomized, controlled trials have demonstrated successful treatment with methotrexate by direct injection in 86.2% of the patients. Again, successful therapy included some patients who received more than one injection. Tubal patency was present in 85.1% of the women evaluated, and intrauterine pregnancy occurred in 73.1% of the women desiring subsequent fertility. One of the earlier randomized, controlled trials was discontinued because three of seven patients assigned to laparoscopic injection of methotrexate required additional laparoscopic surgery. Even with the higher success rate in the randomized trials, this technique is more cumbersome than systemic methotrexate.
Side Effects High doses of methotrexate can cause bone marrow suppression, hepatotoxicity, stomatitis, pulmonary fibrosis, alopecia, and photosensitivity. These side effects are infrequent in the short treatment schedules used in ectopic pregnancy and can be attenuated by the administration of leucovorin (citrovorum factor). The side effects of methotrexate resolve within 3 to 4 days after the therapy is discontinued. Impaired liver function is the most common side effect. Other side effects include stomatitis, gastritis and enteritis, and bone marrow suppression. Local therapy by direct injection of methotrexate into the ectopic gestation resulted in fewer side effects, likely because of less systemic absorption. Even with local injection, impaired liver function tests, gastritis and enteritis, and bone marrow suppression can occur. Additional case reports exist in the literature. Cases of life-threatening neutropenia and febrile morbidity can occur after single or multidose intramuscular methotrexate, requiring hospitalization. Cases of transient pneumonitis from methotrexate therapy for ectopic pregnancy have been observed. Reversible alopecia (a loss of 33–50% of the scalp hair) on two separate occasions following single-dose therapy for an ectopic pregnancy has also been reported. Rarely, hematosalpinx and pelvic hematoceles have been noted as late sequelae of methotrexate following the normalization of ß-hCG levels. These patients have pelvic pain, abnormal bleeding, and a pelvic mass, requiring surgical intervention, 3 to 5 months after therapy. Methotrexate remains the first choice before surgical therapy.
Direct Injection of Cytotoxic Agents Prostaglandins, hyperosmolar glucose, potassium chloride, and saline by direct injection have been tried as therapeutic alternatives to methotrexate. The limited experience with prostaglandins and hypertonic glucose, poor success rates, and the need for laparoscopic or transvaginal aspiration makes these treatment alternatives unattractive.
Evidence-based Recommendation Multiple-dose systemic methotrexate is the medical treatment of first choice for ectopic pregnancy. (Strength of recommendation: A.)

Surgical Treatment

Since the first successful salpingectomy performed by Tait in 1884, ectopic pregnancies traditionally have been treated by salpingectomy during laparotomy. Historically, ectopic pregnancies were diagnosed at the time of emergency surgery, when concern for the patient's life superseded any concerns for her future fertility. It was not until 1953, when Stromme performed the first conservative procedure (salpingostomy) for ectopic pregnancy, that subsequent successful pregnancy outcomes were reported, confirming the potential for fertility preservation after salpingostomy. Subsequently, other conservative surgical procedures, such as manual fimbrial expression and segmental tubal resection with later reanastomosis, have been performed to preserve fertility. These surgical techniques have been modified for the laparoscope.

Ruptured Ectopic Pregnancy Early diagnosis and treatment of ectopic pregnancy avoids rupture in most cases. In the 1970s, 13.5% to 17.8% of patients with ectopic pregnancies arrived for treatment in hypovolemic shock, whereas in the early 1980s, only 4.4% of patients arrived in this condition. Today, either laparotomy or laparoscopy with salpingectomy is the first choice for rupture. Once contraindicated over concern of decreased venous return from intraperitoneal insufflation, laparoscopic salpingectomy is successful in patients in hypovolemic shock. Nearly all patients in hypovolemic shock require blood transfusions. In the hands of a skilled laparoscopist, with adequate cardiac monitoring and anesthesia, laparoscopic salpingectomy is an acceptable alternative to laparotomy. At present, it is the surgeon's choice of laparoscopy or laparotomy for ruptured ectopic pregnancy.
Stable Ectopic Pregnancy If methotrexate is contraindicated, laparoscopic salpingostomy is the first surgical choice. Salpingectomy can be performed either during laparotomy or laparoscopy using cautery or sutures (laparoscopic or endo-loops). Subsequent to salpingostomy, 53% of patients have intrauterine pregnancies, compared with 49.3% after salpingectomy. Recurrent ectopic pregnancy rates were slightly higher after conservative surgery, 14.8% compared with 9.9%. Laparoscopic salpingectomy is preferred over salpingostomy in cases of uncontrollable bleeding not resolving with conservative measures when extensive tubal damage is present, if the ectopic pregnancy is in the same tube, and if sterilization is desired. The recommended conservative surgical procedure for an ampullary ectopic pregnancy is linear salpingostomy, because the ectopic nidation typically is located between the endosalpinx and serosa rather than in the tubal lumen. A linear salpingostomy is created through a longitudinal incision by electrocautery, scissors, or laser over the bulging antimesenteric border of the fallopian tube. The products of conception are removed with forceps or gentle flushing or suction. After maintaining hemostasis, the incision is closed primarily or left to heal by secondary intention. Isthmic pregnancies routinely are treated with segmental excision, followed by intraoperative or delayed microsurgical anastomosis. The tubal lumen is narrower and the muscularis is thicker in the isthmus than in the ampulla, predisposing the isthmus to greater damage after salpingostomy and greater rates of proximal tubal obstruction. Manual fimbrial expression, also known as *milking*, should be used only when the trophoblastic tissue is already aborting spontaneously through the fimbriae. Laparoscopy has several advantages over laparotomy, including less blood loss, decreased need for analgesia, and improved postoperative recovery, as measured by shorter hospitalizations and length of time to resume normal activity. In addition, cost analysis has demonstrated significant savings in randomized trials. Laparoscopic salpingostomy and fimbrial expression have been evaluated in 32 studies and are presented in Table 5.1. Of the 1,614 patients treated between 1980 and 1997, treatment was successful in 93.4% (required no additional therapy). Of the patients evaluated for tubal patency using either hysterosalpingography or laparoscopy, 77.8% had patent tubes. Of the women desiring subsequent fertility, 56.6% had an intrauterine pregnancy and 13.4% developed another ectopic pregnancy. When evaluating subsequent fertility, intrauterine pregnancy rates are comparable for laparoscopy and laparotomy, as are rates of recurrent ectopic pregnancy.

PERSISTENT ECTOPIC PREGNANCY FOLLOWING SALPINGOSTOMY

Persistent ectopic pregnancy is diagnosed by a plateauing or rising ß-hCG concentration following conservative surgical therapy. Although the number of reported cases is small, women with persistent ectopic pregnancies are treated successfully using single-dose systemic methotrexate.

The increased rate of persistent ectopic pregnancies has been a criticism of conservative laparoscopic therapy when compared with laparotomy. A decision analysis that compared prophylactic methotrexate with linear salpingostomy against no methotrexate in a group of 1,000 women concluded that prophylactic methotrexate at the time of surgery was preferable if certain conditions are met as follows: (a) the incidence of persistent ectopic pregnancy is greater than 9% with observation alone after salpingostomy, (b) the incidence of persistence is less than 5% when prophylactic methotrexate is given, (c) the probability of ectopic pregnancy rupture is greater than 7.3% with a persistent ectopic pregnancy, and (d) the complication rate associated with prophylactic methotrexate is less than 18%. Because the great majority of

clinical circumstances meet these recommendations, prophylactic methotrexate administration is recommended.

Evidence-based Recommendation

Due to lower morbidity and equal efficacy, laparoscopic surgery is preferable to laparotomy in the treatment of bleeding or complicated ectopic pregnancy. Salpingectomy by laparotomy is reserved for ectopic ruptures with a hemodynamically unstable patient. (Strength of recommendation: A.)

ECTOPIC PREGNANCY AND ASSISTED REPRODUCTIVE TECHNOLOGY (ART)

Incidence

The risk of ectopic pregnancy is increased in patients undergoing an ART procedure. This increased risk has been attributed to the cause of infertility for which most patients seek treatment, that is, tubal factor infertility. Information on ectopic pregnancies resulting from ART comes from data obtained from institutions in the United States and Canada reporting to the Society for Assisted Reproductive Technology. The rate of pregnancies that resulted in ectopic pregnancies after in vitro fertilization (IVF) in 1999 was 3%. This included outcome of ART cycles using fresh, nondonor eggs or embryos in approximately 53,000 embryo transfers. This lower percentage likely reflected the trend toward performing salpingectomies when hydrosalpinges are present to improve the success of ART.

Location

As in naturally occurring ectopic pregnancies, the fallopian tube is the most common site for ectopic pregnancies following IVF. Data obtained from three case-control studies reveal that 82.2% of ectopic pregnancies were tubal. When tubal location was specified, 92.7% were ampullary and 7.3% interstitial. Extratubal ectopic nidations were as follows: 4.6% ovarian or abdominal, 1.5% cervical, and 11.7% heterotopic pregnancies (see Fig. 5.1).

Tubal Pathology

The most important predisposing factor for ectopic pregnancy in patients undergoing IVF is tubal pathology. Ectopic pregnancies are 4 times higher in patients with tubal factor infertility compared with patients with normal tubes. Hydrosalpinges are associated more commonly with ectopic pregnancy than other types of tubal pathology. Prior tubal reconstructive surgery (salpingostomy) increases the risk of ectopic pregnancy by 10% above that in patients with tubal factor infertility without prior surgery.

Thus, it is not surprising that patients with previous pelvic inflammatory disease have a six-fold increase in ectopic pregnancy after IVF. However, a history of prior ectopic pregnancy does not seem as important a risk factor in IVF cycles as in natural cycles.

Salpingectomy, particularly with hydrosalpinx, has been shown to decrease risks of ectopic pregnancy while increasing pregnancy rates after IVF. Meta-analysis has demonstrated that the presence of hydrosalpinges decreases the chance for viable pregnancy by approximately 50% when compared with patients with tubal disease but without hydrosalpinges.

The implantation rate was also noted to be 50% lower with a higher chance of miscarriage and ectopic gestation. The ultimate conclusion is that when a hydrosalpinx is present there is a decreased pregnancy rate with resultant decreased delivery rate following IVF.

In addition, patients who undergo salpingectomy or proximal tubal occlusion prior to oocyte retrieval and transfer are at decreased risk for pelvic infection as well as future ectopic pregnancy.

Ovulation Induction

Hormone alterations during ovulation induction theoretically alter tubal function. In animal models, estrogen administration results in functional tubal blockage and embryo arrest in the fallopian tube. In humans, steroid hormones alter tubal function and contractility, thus affecting tubal peristalsis. There remains controversy as to whether ovulation-inducing agents, including clomiphene citrate, increase ectopic pregnancy rates.

Embryo Transfer

Knutzen et al. injected 50 µL of radiopaque fluid in mock embryo transfers and found that the material entered the tubes either partially or totally in 44% of subjects, suggesting misplacement of embryos into the fallopian tubes leads to ectopic pregnancy. Embryo catheter placement was implicated also in the increased risk of ectopic pregnancies, which occurred more frequently in patients who underwent deep fundal transfer versus midcavity placement. Although transfer techniques may increase the chances of embryos reaching the fallopian tubes, ectopic pregnancies may result from tubal pathology preventing the embryos from moving back into the uterus.

Heterotopic Pregnancy

Heterotopic pregnancies occur in 1% to 3% of pregnancies following an ART procedure and usually are diagnosed incidentally on routine follow-up ultrasonographic studies. This increased prevalence of heterotopic pregnancies following ART may be related to ovarian hyperstimulation and multiple ovum development. Of 111 reported heterotopic pregnancies following ART, 88.3% were tubal, 6.3% cornual, 2.7% abdominal, 1.8% cervical, and 0.9% ovarian.

Evidence-based Recommendation

Heterotopic and extratubal ectopic pregnancies are more frequent following ART than with natural cycles. Salpingectomy or proximal tubal occlusion of a preexisting hydrosalpinx prior to IVF helps prevent tubal ectopic pregnancies while increasing pregnancy rates following ART. (Strength of recommendation: B.)

EXPECTANT MANAGEMENT

Ectopic pregnancies may resolve spontaneously. In a cavalier experiment in 1955, Lund hospitalized 119 women with ectopic pregnancy for observation. All were at least 6 weeks gestation. Some required multiple blood transfusions, and many were hemodynamically unstable. However, 68 resolved without surgery. Twelve additional studies reported in the literature since Lund's study found similar results (Table 5.3). Of the ectopic pregnancies, 67.2% resolved without surgery. Thus, both conservative medical and surgical therapy overtreats at least 50% of women with ectopic pregnancy. Falling ß-hCG levels under 1,000 mIU/mL have been followed with conservative expectant management. Although patients with an equivocal diagnosis of ectopic pregnancy may be treated in this fashion, there are no data to support expectant management in clinical practice.

Evidence-based Recommendation

Expectant management of ectopic pregnancy may be considered an appropriate conservative therapy for some patients with low initial (1,000 mIU/mL) and falling hCG levels.

COST ANALYSIS

In 1990, total costs for ectopic pregnancies were estimated to be $1.1 billion. Direct costs, expenditures for health care, accounted for 77% of the total costs, and the remainder were incurred as a result of lost wages or household responsibilities not performed due to illness (indirect costs). Direct costs from hospital charges were estimated at $6,079 per case, with hospital accommodations (mean length of stay, 3.47 days) and operating room charges accounting for the majority of the hospital expense, 36% and 40%, respectively. An additional $3,254 for professional fees increased inpatient charges to $9,333, and $149 for postoperative follow-up visits increased the total direct cost to $9,482 per case. Indirect costs for a 28-day disability were estimated at $250.5 million, 67% as a result of lost wages and the remainder from lost household duties.

Laparoscopic surgery was less expensive than laparotomy. Surgical management generally has been directed toward laparoscopy. The cost of laparoscopic conservative surgery or salpingectomy was estimated at $2,125 and $1,872, respectively. Costs for conservative treatment or salpingectomy via laparotomy were

estimated to be higher, $3,420 and $3,490, respectively. Systemic methotrexate therapy is even more cost efficient.

Charges for patients successfully treated with methotrexate average $1,563 (range, $1,169 to $2,300). Patients requiring laparotomy, due to hemodynamic instability, incur a higher average charge of $8,001 (range, $3,171 to $22,082). The average length of stay following laparotomy was 5.2 days.

A study, undertaken to compare the costs of systemic methotrexate with surgery, concluded that there would be a reduction in overall costs if patients were treated without confirmatory laparoscopy when hCG levels were below 3,000 mIU/mL; otherwise, there was not a substantial cost saving over surgery. Because a confirmatory laparoscopy no longer is required for diagnosis, the lower cost for medical therapy is more realistic. Compared with the cost of a laparoscopic salpingostomy, methotrexate results in a 20% decrease in the cost of treatment.

Evidence-based Recommendation

Systemic methotrexate for unruptured ectopic pregnancy is less expensive than surgery, and direct costs are decreased substantially with methotrexate therapy. In addition to its cost effectiveness, systemic methotrexate does not subject patients to surgery and the complications associated with it. This cost benefit, however, diminishes with higher hCG titers and even disappears with levels greater than 3,000 mIU/mL, because of treatment failures and increased complications. (Strength of recommendation: B.)

RARE TYPES OF ECTOPIC PREGNANCY

Abdominal Pregnancy

The incidence of abdominal pregnancy is estimated at 1 in 8,000 births and represents 1.4% of all ectopic pregnancies. The prognosis is poor, with an estimated maternal mortality rate of 5.1 per 1,000 cases. The risk of dying from an abdominal pregnancy is 7.7 times higher than from other forms of ectopic pregnancy. The high rate of morbidity and mortality from abdominal pregnancy often results from a delay in diagnosis.

Abdominal pregnancies can be categorized as primary or secondary. These ectopic pregnancies may become apparent throughout gestation, from the first trimester to fetal viability. Symptoms may vary from those considered normal for pregnancy to severe abdominal pain, intraabdominal hemorrhage, and hemodynamic instability. Primary abdominal pregnancies are rare and are thought to occur as a result of primary peritoneal implantation. They usually abort early in the first trimester due to hemorrhagic disruption of the implantation site and hemoperitoneum. Secondary abdominal pregnancies occur with reimplantation after a partial tubal abortion or intraligamentary extension following tubal rupture. Historical criteria to distinguish between primary and secondary abdominal pregnancies are moot, because treatment is directed by the clinical picture.

Ultrasonography is the diagnostic tool of choice and usually can identify the empty uterus along with the extrauteral products of conception. If the fetus is near viability, hospitalization is recommended. If time permits, bowel preparation, administration of prophylactic antibiotics, and adequate blood replacement should be made available prior to an operative delivery. Unless the placenta is implanted on major vessels or vital structures, it should be removed. Although complications may occur, including sepsis, abscess formation, secondary hemorrhage, intestinal obstruction, wound dehiscence, amniotic fluid cyst formation, hypofibrinogenemia, and preeclampsia, the placenta can be left in place to prevent further hemorrhage at the time of surgery. In contrast to the typical tubal ectopic pregnancy, methotrexate is unlikely to accelerate retained placental absorption, because the trophoblastic cells are no longer actively dividing.

Ovarian Pregnancy

Ovarian pregnancy, the most common form of abdominal pregnancy, is rare, accounting for less than 3% of all ectopic gestations. Clinical findings are similar to those of tubal ectopic gestations: abdominal pain, amenorrhea, and abnormal vaginal bleeding. In addition, hemodynamic instability as a result of rupture occurs in 30% of patients.

Women with ovarian pregnancies are usually young and multiparous, but the factors leading to ovarian pregnancies are not clear.

The diagnosis usually is made by the pathologist, because many ovarian pregnancies are mistaken for a ruptured corpus luteum or other ovarian tumors. Only 28% of cases were diagnosed correctly at time of laparotomy. The recommended treatment is cystectomy, wedge resection, or oophorectomy during laparotomy, although laparoscopic removal has been successful.

Cornual Pregnancy

Cornual or interstitial pregnancy accounts for 4.7% of ectopic gestations and carries a 2.2% maternal mortality. Almost all cases are diagnosed after the patient is symptomatic. The most frequent symptoms are menstrual aberration, abdominal pain, abnormal vaginal bleeding, and shock, resulting from the brisk hemorrhage associated with uterine rupture. Due to myometrial distensibility, rupture is usually delayed, occurring at 9 to 12 weeks gestation.

A unique risk factor for interstitial pregnancy is previous salpingectomy, present in about 25% of patients.

Only a high index of suspicion and repeated ultrasonographic examination with Doppler flow studies allows early diagnosis. With a timely early diagnosis, alternatives to the traditional cornual resection during laparotomy have been performed successfully. These include laparoscopic cornual resection, systemic methotrexate administration, local injection of methotrexate, potassium chloride injection, and removal by hysteroscopy. Regardless of the initial treatment attempted, if uncontrolled hemorrhage occurs, immediate hysterectomy is warranted.

Cervical Pregnancy

The incidence of cervical pregnancy ranges from 1 in 2,500 to 1 in 12,422 pregnancies. The most common predisposing factor is a prior dilation and curettage, present in 68.6% of patients. Interestingly, 31% of these were performed for termination of pregnancy. Other predisposing factors implicated in cervical pregnancies are previous cesarean delivery and IVF.

The most common initial symptom of cervical pregnancy is painless vaginal bleeding. These ectopics usually are diagnosed incidentally during routine ultrasonography or at the time of surgery for a suspected abortion in progress. In reported cases, 91% of patients sought treatment for vaginal bleeding, and 29.2% had massive bleeding. Not surprisingly, abdominal pain occurred with vaginal bleeding in only 25.8% of cases. The cervix is usually enlarged, globular, or distended. On occasion, it appears cyanotic, hyperemic, and soft in consistency. Sonography and magnetic resonance imaging have improved diagnosis of cervical pregnancy. Up to 81.8% of patients have been diagnosed correctly with ultrasonographic identification of the gestational sac in the cervix below a closed internal cervical os, with trophoblastic invasion into the endocervical tissue.

When the patient is hemodynamically stable, conservative therapy commonly is employed. There are no large studies, only several case series. These have shown that use of methotrexate and uterine artery embolization are safe and effective for treatment in the stable patient with a cervical pregnancy. Systemic and local treatment with various agents carries an overall success rate of 81.3%. Unfortunately, massive hemorrhage may occur despite conservative measures, and hysterectomy is warranted.

Heterotopic Pregnancy

Heterotopic pregnancy is the coexistence of an intrauterine and ectopic gestation. In 1948, the spontaneous heterotopic pregnancy rate was calculated as 1 in 30,000 pregnancies, based on an ectopic pregnancy incidence of 0.37% and dizygous twinning rate of 0.8%. In the 1980s, the calculation rose to 1 in 10,000 due to an increased ectopic pregnancy rate. Today, heterotopic pregnancies occur in 1 in 3,889 to 1 in 6,778 pregnancies. In a review of 66 heterotopic pregnancies by Reece et al., 93.9% were tubal and 6.1% ovarian.

Simultaneous existence of intra- and extrauterine pregnancies poses several diagnostic pitfalls. Heterotopic pregnancies are diagnosed in most cases after clinical signs and symptoms develop, and 50% of patients are admitted for emergency surgery following rupture. The delay in diagnosis is secondary to the finding of an intrauterine pregnancy, with the assumption that any symptoms will be self-limited.

Similar to tubal ectopic pregnancies, the most common complaint is lower abdominal pain. Routine ultrasonography detects only about 50% of tubal heterotopic

pregnancies, and the remainder are diagnosed during laparoscopy or laparotomy when patients become symptomatic. Serial levels of the ß subunit of hCG are not helpful due to the effect of the intrauterine pregnancy.

If patients are hemodynamically unstable, exploratory laparotomy is warranted. If the diagnosis is suspected or the patient is symptomatic but hemodynamically stable, laparoscopy can be performed. Expectant management is not recommended, because ß-hCG levels cannot be monitored adequately. Systemic methotrexate is contraindicated if a viable intrauterine pregnancy is present and desired. Local injection of methotrexate with potassium chloride has been noted successful in a small case series.

SUMMARY POINTS

- In most circumstances, ectopic pregnancy can be diagnosed before symptoms develop and treated definitively with few complications.
- Quantitative ß-hCG testing, ultrasonography, and curettage allow early diagnosis of ectopic pregnancy and use of medical therapy as the initial therapy option.
- Conservative surgical therapy and medical therapy for ectopic pregnancy are comparable in terms of success rates and subsequent fertility. Medical therapy is the preferred choice because of the freedom from surgical complications and lower cost.
- Surgery is the treatment of choice for hemorrhage, medical failures, neglected cases, and when medical therapy is contraindicated.
- Multiple-dose methotrexate is preferable to single-dose methotrexate, direct injection, or tubal cannulation and is the first choice for unruptured, uncomplicated ectopic pregnancy.
- Laparoscopic salpingostomy or salpingectomy is favored for cases of intraabdominal hemorrhage, medical failure, neglected cases, and complex cases when medical therapy is contraindicated.
- Prophylactic postoperative systemic methotrexate (a single dose) can prevent virtually all cases of persistent ectopic pregnancy following salpingostomy.
- Salpingectomy prior to IVF decreases ectopic pregnancy incidence while increasing pregnancy rates in select patients with preexisting tubal disease.

Genetic screening has become an important component of prenatal care. Recent discoveries have expanded the indications for cytogenetic or molecular genetic tests performed on chorionic villi, amniocytes, and fetal blood. Soon first-trimester DNA-based prenatal diagnosis will become possible for thousands of additional conditions. New technologies such as flow cytometry, fluorescent in situ hybridization, and DNA amplification with the polymerase chain reaction (PCR) enable testing of a single cell for chromosomal or Mendelian problems. This approach already has allowed preimplantation testing of embryos and minimally invasive diagnosis using the small population of fetal cells in the maternal circulation. Over the next decade, gene therapy will be applied prenatally for the treatment of inborn errors and postnatally for the treatment of genetic diseases. This will provide additional impetus for genetic evaluation.

Genetic principles are central to understanding the pathophysiology of many of the conditions for which obstetrician-gynecologists provide care (Table 6.1). More than 20 million Americans have a diagnosed genetic disease. One percent of all newborns have a recognizable Mendelian disorder, 0.5% have a chromosomal syndrome, and many more have a polygenic, multifactorial disorder. Most pregnancy losses and most congenital anomalies have genetic causes. Genes also play an important role in common gynecologic disorders such as leiomyomata, endometriosis, gynecologic cancers, and infertility. Genetic variants are responsible for tendencies to have multiple gestations, preeclampsia, gestational diabetes, and other pregnancy complications. Susceptibilities to infectious or teratogenic agents are determined genetically. Our rapidly expanded knowledge of the human genome will revolutionize obstetric and gynecologic practice.

One in twenty newborns has a detectable genetic defect at birth.
Over 20 million Americans have a diagnosed genetic disease.
Life-years lost to genetic diseases are estimated at 6.5 times greater than years lost to heart disease—the nation's number one killer.
Thirty percent of pediatric hospital admissions and 10% of adult admissions are for disorders that are wholly or partly genetic.
All cancers have somatic or inherited genetic changes.

TABLE 6.1. *The burden of genetic disease*

Recognizing that a condition is genetic enables us to find the gene responsible for the illness, which can lead to improved means of classification, diagnosis, prevention, and treatment. Correlation of the phenotype with the genotype often provides specific predictive insights. Because any DNA test can be performed prenatally, discovery of the gene that causes a particular disease can give at-risk couples the necessary information to prepare for having an affected child, to consider prenatal therapy if available, or to choose to end the pregnancy.

Patients often have genetic illnesses that will affect pregnancy or their gynecologic care, illnesses that may remain undiagnosed unless physicians are thorough in their evaluation of unusual signs or symptoms. For example, a new obstetric patient has a wasted facial appearance, generalized weakness, and difficulty releasing her grip when shaking the physician's hand. Hopefully, this patient has already been evaluated and correctly diagnosed. If not, it is the obstetrician's responsibility to refer a patient with unusual signs and symptoms for evaluation. In this case, the patient has the classic signs of myotonic dystrophy, an autosomal dominant disorder. Formerly, myotonic dystrophy was a difficult diagnosis to establish in some patients, but the diagnosis can be made easily using DNA analysis of her blood. The physician and this woman need to know that she is at significant risk for developing polyhydramnios, which could result in preterm labor; her fetus may have positional deformities and is at risk for a severe, often fatal, neonatal form of myotonia; her labor is likely to be prolonged, and she may be unable to push during the second stage. If she requires cesarean section, she may have undiagnosed cardiac problems that place her at higher risk for anesthesia. If failure to recognize these risks results in a bad outcome, a lawsuit claiming negligence might be brought.

PATTERNS OF INHERITANCE

Single Gene Disorders

The observation that “like begets like” has been stated throughout recorded history, but current theories describing how genetic traits and illnesses are inherited are just over 100 years old. In the late 1800s, Mendel described how individual genetic traits were passed on from generation to generation. Single gene disorders (i.e., mendelian disorders) are conditions caused by a mutation at a single site in the DNA and inherited in the proportions predicted by Mendel's laws. These disorders can be dominant conditions in which the phenotype is expressed even when only one chromosome of a pair has a defect, or recessive conditions which are expressed only if the defect exists on both chromosomes. Classically, these different modes of inheritance are revealed by pedigree analysis (Fig. 6.1 and Fig. 6.2).

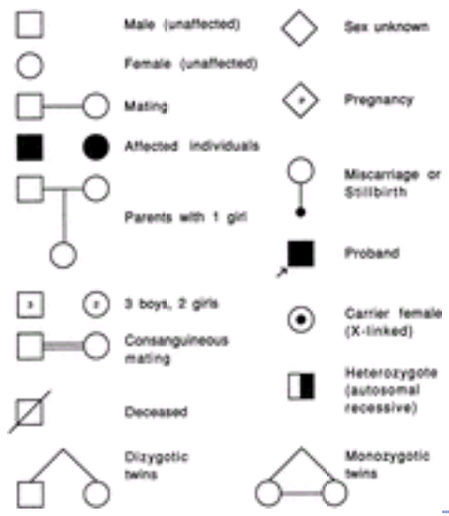

FIG. 6.1. Symbols used to draw a pedigree.

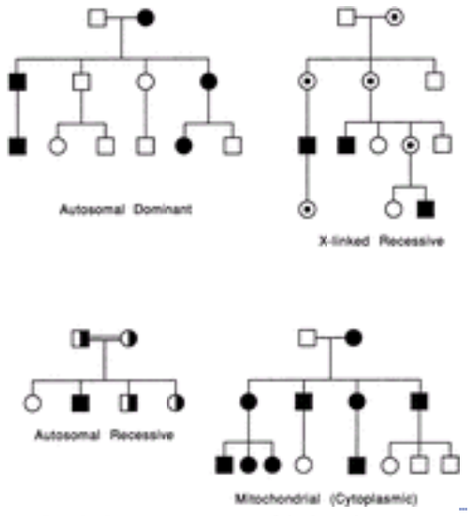

FIG. 6.2. Patterns of inheritance.

As we learn more about the tremendous variation that occurs at every locus, the distinctions between dominant and recessive conditions have become blurred. Dominance and recessiveness are attributes of the phenotype, not attributes of the gene or allele. They are empirical terms, and they depend on the sensitivity of the method used to describe the phenotype. The researchers must specify particular phenotypic features when describing inheritance. For instance, sickle cell anemia is a recessive disease only if the full-blown disease is considered, but it is a codominant condition if the hemoglobin is being analyzed by electrophoresis. The ABO blood group is an example of a trait in which both codominant and recessive inheritance is seen. The retinoblastoma gene is a recessive tumor suppressor gene at the cellular level, but abnormalities in the gene are responsible for the autosomal dominant tendency to develop retinoblastomas and osteosarcomas.

In autosomal dominant conditions, the disease is expressed in persons who are heterozygous for the disease-causing mutation. McKusick's catalog of mendelian disorders describes more than 3,000 dominant conditions. Marfan syndrome, myotonic dystrophy, neurofibromatosis, achondroplasia, and Huntington disease are examples of autosomal dominant disorders. The probability of an affected person transmitting the abnormal gene to the children is 50% with each pregnancy. Typically, autosomal dominant conditions have less than 100% penetrance, and fewer than 50% of the offspring show signs of the disorder. Male and female offspring usually are affected with equal frequency and severity. The trait passes through one parental line only, and father-to-son transmission can occur. For highly penetrant, autosomal dominant conditions, the gene is expressed in each generation (i.e., vertical transmission). New mutations are relatively common and, on average, paternal age is advanced when isolated, sporadic, or new mutation cases appear. Autosomal dominant phenotypes often involve isolated or multiple *structural* defects. They can be extremely variable and the onset of clinical features is often age dependent. Dominant disorders tend to be less severe than recessive diseases, but they are usually lethal in the rare persons who are homozygous for a dominant disease.

Autosomal recessive conditions are expressed only in persons in whom both versions (i.e., alleles) of the involved gene are abnormal. More than 1,500 autosomal recessive conditions have been described. Cystic fibrosis (CF), sickle cell anemia, Tay-Sachs disease, and phenylketonuria are examples of autosomal recessive disorders. Male and female offspring are affected with equal frequency and severity. Each parent is a heterozygous carrier, and abnormal genes are inherited from both parents. Each offspring of two carrier parents has a 25% chance of being affected, a 50% chance of being a carrier, and a 25% chance of being neither a carrier nor affected. If the recessive phenotype is extremely rare, consanguinity usually is found in the pedigree. Affected persons rarely have affected children; autosomal recessive inheritance shows a “horizontal” pattern in a pedigree, with typically only a single generation of siblings affected. Affected persons who mate with unaffected persons who are not carriers have only unaffected, carrier offspring. Most autosomal recessive phenotypes are biochemical or enzymatic in nature, and they tend to be less variable and more severe than dominant conditions.

X-linked inheritance occurs when a trait is carried on the X chromosome. Boys are hemizygous for X chromosome genes, but girls can be homozygous or heterozygous. Of the 300 X-linked recessive diseases that are recognized, the hemophilias and Duchenne muscular dystrophy are the best known. Characteristics of X-linked recessive inheritance include a higher incidence of the disorder in male than in female offspring. The mutant gene or disease never is transmitted directly from father to son, and all the daughters of an affected man are carriers. The trait is transmitted through carrier females, and affected males in the same kindred are related to one another through the females. X-linked dominant diseases are much rarer; examples include Alport syndrome, vitamin D-resistant rickets, and incontinentia pigmenti. They appear twice as often in female as in male offspring. All daughters of an affected man have the disorder, but no sons are affected. Heterozygous affected women transmit the mutant allele at a rate of 50% to progeny of both sexes. If the affected woman is homozygous, all of her children will be affected.

Y-linked or holandric inheritance occurs when a trait is carried on the Y chromosome. Only male offspring are affected, and there is only male-to-male transmission. No known disease genes are inherited in this fashion, but genes for gender determination, tooth size, and height occur on the Y chromosome.

Mitochondrial inheritance is a more recently described mode of inheritance, causing traits and disorders that are inherited through the mitochondrial chromosome. Unique patterns are seen in affected families. Mitochondria are inherited exclusively with the cytoplasm of the egg; a woman who carries a disease will pass the disease to 100% of her offspring. Male carriers will pass the disorder to none of their offspring. Leber optic atrophy and certain rare myopathies are inherited in this fashion.

Polygenic, Multifactorial Disorders

Multifactorial or polygenic inheritance is the most common form of inheritance. Even in the classic mendelian disorders described above, there can be tremendous quantitative and qualitative differences in the phenotype among persons who have the same allele or the same genetic mutation. This variability can be evident as nonpenetrance of certain features (or the entire phenotype) and as differences in the severity of features, the frequency of cyclic or episodic events, or the age of onset of the first clinical sign of the disorder. Genetic variability can be caused by the underlying genetic background of the affected person, including gender influences and limitations. The phenotype may be influenced further by maternal factors such as cytoplasmic inheritance, the intrauterine environment, or imprinting. X-linked disorders can be altered by variations in X inactivation or lionization. Each genotype undergoes subtle changes through somatic mutation, gene amplification, or transpositions and positional effects over time. Exogenous factors such as the environment, teratogens, medical intervention, and chance also influence variability.

Most congenital anomalies reflect multifactorial inheritance (Table 6.2). A common error some obstetricians make is to counsel a patient that rare conditions will not occur repetitively in her family. If the birth defect in question has a strong genetic component or if there is an identifiable environmental or teratogenic component which would recur in subsequent pregnancy, the risks may remain high for that patient (Table 6.3). The rates may be even higher if a mendelian or chromosomal condition has gone unrecognized in the affected child. Before counseling patients about the recurrence risk of any birth defect, it is pertinent to review which syndromes are associated with that birth defect and ask whether any member of the family has those syndromes. When this requires skill or knowledge beyond the usual expertise of an obstetrician-gynecologist, referral to a medical geneticist is appropriate.

Anomaly is a structural feature that departs from the normal.
Syndrome is a recognizable pattern of structural defects, often with a predictable natural history that can be identified on several patients, thus allowing diagnosis and classification.
Sequence is a pattern of defects that results from a single event early in pregnancy.
Association is a grouping of anomalies that frequently occur together but are not actual syndromes.
Malformation is a morphologic defect resulting from abnormal development.
Disruption is morphologic defect resulting from extrinsic breakdown or interference with normal development.
Deformation is an abnormal form, shape, or position caused by mechanical forces.

TABLE 6.2. *Types of birth defects*

TABLE 6.3. *Empiric recurrence risks for common congenital anomalies*

Multifactorial inheritance usually works according to a threshold model. Several factors must collaborate to cause a bodily function to go awry, and only after these factors reach some critical point is the phenotypic effect seen. Many different factors can affect the observed recurrence risk. The intrinsic heritability “or geneticness” of the condition is frequently the most important factor. This usually is determined by examining whether monozygotic twins are concordant for a particular condition relative to dizygotic twins. For instance, neonatal seizures show a very high heritability rate, with 85% to 90% concordance in monozygotic twins verses 10% to 15% concordance in dizygotic twins. The population incidence of the condition is another important variable. The recurrence risk is higher for common disorders or within populations with a high incidence of the disorder. In disorders with a relatively high heritability, the recurrence risk of the disorder approximates the square root of the population incidence. There can be marked variation in the population frequency of different disorders and different ethnic groups. For instance, cleft lip occurs commonly in Native Americans, but African Americans have a nine-fold lower incidence of cleft lip than the general population.

If the incidence of a congenital anomaly shows a sex bias, the recurrence risk is higher in the offspring (and other relatives) if the parent is of the less frequently affected sex. For example, pyloric stenosis affects 5 times as many male as female offspring, and empirical data show that there is a 25% chance of producing an affected child if the mother had pyloric stenosis at birth and only a 4% risk if the father is the affected parent. Similarly, the recurrence risk is higher when the gender of the affected child is the less frequently affected. Again, the risk of having another child with pyloric stenosis is 3.2% if the first-affected sibling is a boy and 6.5% if the affected sibling is a girl. Hirschsprung disease, clubfoot, and cleft lip are examples of anomalies which are more common in male infants. Cleft palate, anencephaly, hip dysplasia, and scoliosis are more common in female infants.

The number of affected individuals in a kindred can affect the recurrence risk. The greater the number of family members who have already been affected with a multifactorial condition, the more likely it is that the genetic background is favorable for expression of this condition. After a couple has one affected child with cleft lip and palate, there is a 4% empirical recurrence risk. After two affected children, the risk rises to 10%. Consanguinity also increases the risk of recurrence because of the greater likelihood of deleterious genes being shared, but a more distant relationship from an affected person decreases the risk of recurrence.

The severity of the disorder often predicts the recurrence risk. An illustration of this is found in Hirschsprung disease. The recurrence risk is proportional to the length of the aganglionic segment of the colon. Neural tube defects are the most notable exception to this rule, because the recurrence risk for any neural tube defect appears to be the same whether the first-affected child had anencephaly or a small spina bifida lesion.

Cytogenetic Disorders

Cytogenetic disorders are changes in the genome visible under a light microscope. These gross lesions involve the loss or duplication of a large number of genes; multiple malformations and dysfunctions usually are observed clinically. Diagnostic clues for a cytogenetic disorder can range from subtle dysmorphic features to major structural malformations, particularly craniofacial, skeletal, cardiac, and genitourinary malformations. No individual anomaly is pathognomonic for a particular chromosomal syndrome, rather it is the pattern that can be distinctive. There is tremendous overlap between patterns and because nonchromosomal syndromes can mimic chromosomal abnormalities, obtaining a karyotype is always necessary to confirm the diagnosis. Cytogenetic disorders usually are associated with some degree of mental retardation and growth deficiency. Most have an increased rate of perinatal loss and premature mortality of live-born neonates. The rate of chromosome abnormalities is at least 40% to 60% in first-trimester abortuses, and the rates of abnormalities also are elevated in fetal deaths and preterm and post-term deliveries (Table 6.4 and Table 6.5). About 1 in 160 babies is born with a genetic defect detectable by ordinary cytogenetic means (Table 6.6).

Gestational age in weeks	With chromosomal abnormalities (%)
<8	72.1
8–11	53.5
12–15	47.9

TABLE 6.6. *Incidence of chromosomal aberrations seen in newborn surveys*

Cytogenetic studies have been used clinically for approximately 40 years. In the late 1950s, it was determined that humans have 46 chromosomes and that many of the recognized birth defect syndromes, such as Down syndrome, Turner syndrome, and Klinefelter syndrome, have abnormalities of chromosome number or structure. Normally, the nucleus of most human cells contains two sets of chromosomes, with one set contributed by each parent. Each set has 22 autosomes and either an X or a Y sex chromosome (Fig. 6.3).

FIG. 6.3. Normal human karyotype (46,XY).

Metaphase chromosome preparations can be prepared from any cell undergoing mitosis. Typically, in order to obtain adequate numbers of cells, mitosis is induced artificially using a mitogenic chemical such as phytohemagglutinin. The cells are then incubated in a dilute solution of an agent that poisons the mitotic spindle. The chromosomes are swollen using a hypotonic salt solution, fixed on a slide, and dried for staining. The stained chromosomes can be observed by light microscopy.

The dyes used to stain chromosome preparations reveal patterns of light and dark bands that reflect regional variations in the molecular composition of each chromosome. Giemsa is the most commonly used dye. Q-banding is a fluorescence technique that gives results similar to the G-banding (i.e., Giemsa banding), while R-banding (i.e., reverse banding) gives a pattern opposite to that with G- or Q-banding. T-banding specifically stains the telemetric regions of chromosomes, which can help to screen for missing regions at the ends of the chromosomes, and C-banding primarily stains the centromeric region of the chromosomes.

Differences in the size of the chromosomes, the banding pattern, and the centromere position allow the 24 chromosomes to be differentiated from each other in an analysis called a karyotype. The most common features looked for on a karyotype include aneuploidy (i.e., abnormal number of chromosomes) or structural chromosome abnormalities such as deletions, inversions, insertions, or translocations (Table 6.7) (Fig. 6.4).

p	Short ("petite") arm of a chromosome
q	Long arm of a chromosome
del	Deletion of a chromosomal segment
der	Derivative chromosome resulting from a structural rearrangement
dup	Duplication of a chromosome segment
i	Isochromosome
ins	Insertion of a chromosomal segment into another chromosome
inv	Inversion of a chromosomal segment
r	Ring chromosome
rob	Robertsonian translocation
t	Translocation
ter	Terminal segment of chromosome (pter, terminal short arm; qter, terminal long arm)
/	Diagonal hash-line indicates mosaicism (46,XX/45,X indicates a mosaic patient with cell lines containing 46 chromosomes and 45 chromosomes respectively, i.e., mosaic Turner syndrome)
+ or –	When appears before a chromosome indicates the addition or loss of that whole chromosome (i.e., +21 indicated trisomy 21, Down syndrome); when appears after a chromosome, indicates the addition or loss of a part of a chromosome (i.e., 8q- indicates the loss of part of the long arm of chromosome 8)

TABLE 6.7. *Chromosomal nomenclature*

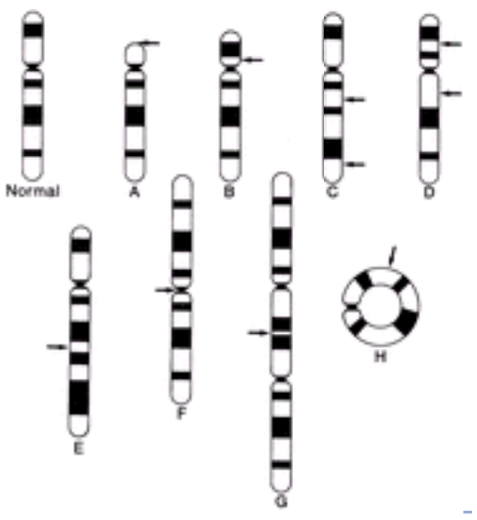

FIG. 6.4. Types of chromosomal abnormalities. A, terminal deletion; B, interstitial deletion; C, paracentric inversion; D, pericentric inversion; E, translocation (additional material from a different chromosome); F, isochromosome; G, dicentric chromosome; H, ring chromosome. The *arrows* indicate the sites of chromosomal breaks where rearrangement occurs.

Because the technology to study cytogenetic disorders is well established, there is greater clinical experience with this than with other types of genetic testing. There are several well-defined indications for obtaining a fetal karyotype analysis (Table 6.8). Pregnant women who are 35 years or older routinely are offered a fetal karyotype analysis, because trisomy tends to occur more commonly with advancing maternal age (Table 6.9). Other indications for obtaining a fetal karyotype include having a previous child with an abnormal karyotype, parental chromosomal rearrangements, unexplained intrauterine growth retardation, and an abnormally low level of maternal serum a-fetoprotein. In addition, many fetal anomalies associated with karyotypic abnormalities can now be visualized using high-resolution ultrasonography (Table 6.10). A fetal structural abnormality detected by ultrasonography is another frequent indication for obtaining a fetal karyotype.

Advanced maternal age
Previous child with an abnormal karyotype
Parental chromosome rearrangements
Fetal structural abnormality on ultrasonography
Unexplained intrauterine growth retardation
Abnormally low MSAFP

MSAFP, maternal serum α-fetoprotein.

TABLE 6.10. *Risk of a chromosomal abnormality with selected sonographic findings*

A variety of genetic defects, including the common trisomies and many chromosomal translocations, can be detected by routine karyotype analysis. Recent modifications, including chromosome painting that allows a particular chromosome to be identified directly, or fluorescent in situ hybridization (FISH) that allows specific sites along the chromosome to be identified, have greatly extended the capabilities of the cytogenetics laboratory. However, there are molecular and single gene rearrangements that cannot be observed by light microscopy and require molecular genetic technology for evaluation.

FISH is a cytogenetic technique in which a specific DNA probe with a fluorescent label is bound to homologous DNA in a clinical sample. FISH can be performed either on a metaphase chromosome spread to detect microdeletions and microduplications, and during interphase to detect a larger chromosomal region in a nondividing cell. Interphase FISH can be performed on cultured cells, tissue sections, and on cytologic smears. FISH has been used to detect common aneuploidies, such as trisomy 21, trisomy 18, trisomy 13, and the sex chromosome aneuploidies, in prenatal diagnosis.

Because uncultured amniocytes can be used, the FISH technique can offer more rapid detection of chromosome aneuploidies. In one of the first large studies, FISH was performed as an adjunct to conventional cytogenetics in 4,500 patients. Region-specific DNA probes to chromosomes 13, 18, 21,X, and Y were used to determine ploidy by analysis of signal number in hybridized nuclei. A sample was considered to be euploid when all autosomal probes generated two hybridization signals and when a normal sex chromosome pattern was observed in greater than or equal to 80% of hybridized nuclei. A sample was considered to be aneuploid when 70% or more of hybridized nuclei displayed the same abnormal hybridization pattern for a specific probe. The accuracy of all *informative* FISH results, euploid and aneuploid, was 99.8%, and the specificity was 99.9%.

Current prenatal FISH protocols are not designed to detect all chromosome abnormalities and should be used only as an adjunctive test to cytogenetics. FISH can provide rapid and accurate clinical information in pregnancies when fetal abnormalities have been observed by ultrasonography.

Future improvements are likely. FISH protocols, which would allow the simultaneous and unequivocal discernment of all human chromosomes, are under development. Each chromosome is labeled in a unique way using several different colors. A “spectral karyotype” can be generated, which allows visualization of a unique, defined emission spectra for each human chromosome. Computerized analysis may allow automatic and rapid analysis, with resolution approaching routine G-banding.

Parent of Origin Effects

Genomic imprinting refers to the differential expression of genes based on the parent of origin of the gene. Imprinting usually is mediated by differential methylation of the alleles involved. Most experimental evidence regarding imprinting comes from animal studies, but some naturally occurring human analogs exist. The paternal genetic contribution appears to be essential for the development and function of the placenta and extraembryonic tissues, but the maternal contribution is required for embryonic development. Ovarian teratoma, the most common benign pelvic tumor in women of reproductive age, is characterized by a diploid karyotype, in which both haploid sets of chromosomes are maternal in origin. Complete hydatidiform moles, which show failure of normal embryonic and fetal development, are usually diploid with two paternal haploid chromosome sets and no maternally derived chromosomes.

The differential function of parental chromosomal contributions in development is also evident when studying human triploidy. In an android conception (i.e., two paternal, one maternal chromosome set), the fetus is severely growth retarded, with a disproportionately large head and syndactyly of digits of the hand. The placenta is usually very large and hydropic. Survival into the second trimester or occasionally into the third trimester is possible but usually requires the presence of mosaicism with a diploid cell line. When the chromosomal constitution is gynoid (i.e., two maternal, one paternal set), the conceptus is underdeveloped and the placenta is small and cystic; such pregnancies rarely continue beyond the first trimester.

In some persons with an apparently normal karyotype, both versions of a pair of homologous chromosomes were inherited from one parent, a phenomenon called uniparental disomy. This can give rise to abnormalities if genomic imprinting causes regions of both chromosomes to be inactivated or overexpressed.

THE MOLECULAR GENETICS REVOLUTION

In the mid 1950s, there were only two “facts” known about the human genome. It was thought that humans had 48 chromosomes and that X-chromosome inactivation in humans occurred by the same mechanism as had been observed in fruit flies. Both of these observations have been proven to be in error. In the past few decades,

there has been an explosion of knowledge about the human genome, largely attributed to advances in molecular biology.

Deoxyribonucleic Acid

Genes are the instructions required for building structural proteins and enzymes and peptide hormones, and the complete set of genetic instructions for any organism is called its genome (Table 6.11). The human genome has 46 chromosomes, including 22 pairs of autosomes and two sex chromosomes. The genome is made up of three billion base pairs, somewhere between 40,000 and 100,000 genes. The functions of approximately 10,000 human genes have been characterized, and in 2003 the first draft of the human genome sequence will be completed.

46 chromosomes including
22 pairs of autosomes
2 sex chromosomes
40–70,000 genes
2,900,000,000 base pairs

TABLE 6.11. *The human genome*

In 1944, Avery and colleagues demonstrated that DNA is the chemical that carries genetic instructions. Roughly equal parts of DNA and its supporting proteins make up the 46 chromosomes. If the strands of DNA in the nucleus of a single cell could be unwound and spliced together, the resulting DNA molecule would stretch more than 1.5 meters long, but it would be only 20 trillionths of a centimeter wide.

The genetic code is spelled out with the four nitrogenous bases: adenine, thiamine, cytosine, and guanine (Fig. 6.5). The purine and pyrimidine bases are arranged in a ladderlike, double helix arrangement that is very stable (i.e., theoretic dissociation constant = 10 - 23). During cell division, DNA is duplicated with extremely high fidelity by synthesis of a new strand of one side of the molecular ladder.

DNA	CAG—CGG—GGT
RNA	GUC—GCC—CCA
Protein	Valine—Alanine—Proline

FIG. 6.5. Genetic code. The DNA code consists of four characters and is read three characters at a time. It is translated into an RNA message, which instructs cells in how to assemble proteins from amino acid building blocks.

The human genome consists of at least 40,000 genes, but the genes comprise only one tenth of the encoded information. Most of the genome is of unknown function, but it probably codes for the proper spacing, alignment, and punctuation of the genetic instructions. About 99.8% of the DNA sequence is identical from one person to the next. Stated another way, there are many minor differences between any two persons; on average, there is a variation of one nucleotide for every 200 to 500 base pairs. When these sequence differences occur within genes, they can lead to genetic diseases or genetic variation. Most of the minor differences have no observable effect because they occur in the noncoding regions of the genome, regions of DNA that do not contain genes. These otherwise unimportant differences have been the basis of the current explosion of genetic knowledge, because much of our ability to study genes or diagnose genetic illness exploits differences (i.e., DNA sequence polymorphisms) in these regions to track or find neighboring genes.

The DNA sequence is read by cellular enzymes three bases at a time, and each triplet directs the positioning of a particular amino acid within the structure of a protein (see Fig. 6.5). The protein coding instructions are transmitted to the cellular machinery through messenger RNA, a transient, intermediary molecule that is similar to a single strand of DNA (Fig. 6.6). The RNA strand is transcribed from the DNA template in the nucleus and has an opposite or complementary genetic sequence. Messenger RNA moves from the nucleus into the cytoplasm, where the protein manufacturing organelles build a protein. Analysis of messenger RNA molecules is extremely useful in the laboratory for detecting genes.

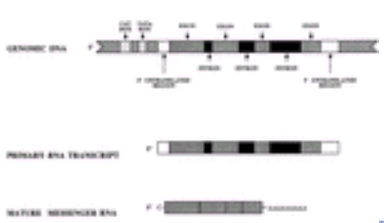

FIG. 6.6. Anatomy of a gene. Regulatory regions are present in the 5' region. Introns are spliced out of the final messenger RNA.

Several advances in molecular biology have enabled the molecular genetics revolution to take place. The first was the discovery of restriction enzymes, which are bacterial proteins that can cut DNA molecules at specific sites by recognizing the DNA sequence at those sites. Over 400 restriction enzymes have been discovered, many are commercially available, and about 25 are used commonly. Restriction fragment length polymorphisms (RFLPs) occur because of minor sequence changes (usually single base substitutions) that abolish or create a recognition site, altering the length of a digestion fragment. Restriction sites occur frequently, and several restriction sites can occur in the vicinity of any given gene. When these RFLPs are polymorphic, they become useful markers for linkage studies, diagnostic testing, and paternity testing (Fig. 6.7). RFLPs and other DNA polymorphisms provide the landmarks for genetic maps.

FIG. 6.7. Linkage study using restriction fragment length polymorphisms. Each lane represents the genotype of one family member. *M*, mother; *F*, father; *D*, daughter; *S*, son. In this example, the disease allele is associated with the upper band passed from the mother to the son.

Scientists have gained a greater understanding of how to manipulate the physical conditions, such as pH, salt concentration, and temperature, of in vitro DNA reactions. These skills—combined with the use of restrictions enzymes—allowed the development of recombinant DNA or new combinations of DNA engineered in the laboratory. Recombinant DNA technology has made possible the development of gene probes (pieces of DNA usually radioactively labeled) that recognize and bind specifically to a homologous sequence in another sample of DNA. These technologies also underlie cloning—the copying of DNA segments in lower animals and the

manufacturing of human proteins using bacteria or cell cultures.

Various blotting technologies are used commonly to study DNA. With blotting, biologically relevant molecules undergo electrophoresis and are transferred to a stable membrane for repeated experiments. Blots are called Southern blots if DNA is being analyzed, Northern blots if RNA is being analyzed, and Western blots if proteins are being analyzed.

DNA testing is clinically applicable to many disorders and can be performed in one of several ways (Table 6.12). When the molecular basis of a disease is known, direct mutation testing can provide a yes or no answer on any DNA sample. For instance, in CF, hundreds of mutations have been discovered. A battery of mutations can be tested for using various methods such as dot blots, which are simple to interpret (Fig. 6.8).

TABLE 6.12. *Common conditions for which DNA testing is available*

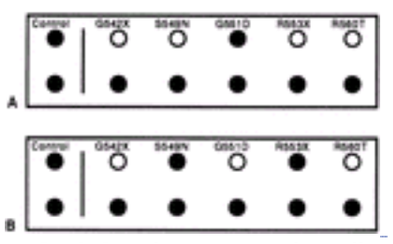

FIG. 6.8. Direct mutation diagram. Direct detection of cystic fibrosis mutations using reverse dot blots. In this example, five mutations in exon 11 of the cystic fibrosis gene (G542X, S549N, G551D, R553X, R560T), are tested for using a simple YES/NO assay. Exon 11 is amplified using the polymerase chain reaction. The product of the reaction is labeled to allow its detection and is placed on a membrane. The membrane has been prepared with oligonucleotide probes, which detect either the normal or the abnormal sequence. **A:** results from a known cystic fibrosis carrier. **B:** results from a child with cystic fibrosis.

Similarly, fragile X syndrome is usually the result of an expansion of a triplet sequence within the gene. Normal persons usually have only 5 to 50 copies of this triplet repeat, but affected patients have hundreds or thousands of copies of the triplet repeat. Similar triplet expansions cause myotonic dystrophy, Huntington disease, and Kennedy disease. The region containing the triplet can be amplified using the PCR, which produces millions of copies of the small region of DNA from the X chromosome that contains the fragile X repeat. Specificity is achieved by directing the reaction using two complementary primers on either side of the region of interest. Once amplified, the size of the product can be measured to evaluate the number of triplets, determining whether the mutation exists (Fig. 6.9).

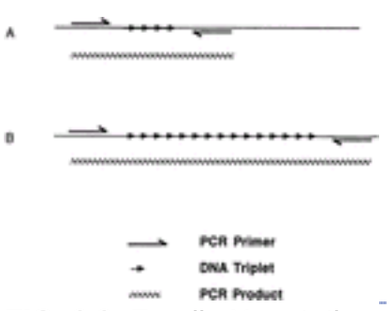

FIG. 6.9. Fragile X mutation detection. In patient A, a shorter polymerase chain reaction product corresponds with a smaller number of triplet repeats. Patient B exhibits an expanded number of repeats. Affected patients typically have hundreds or even thousands of copies of the triplet.

For families with unusual mutations or with diseases for which the molecular basis is unknown, linkage testing can be performed. Linkage tests compare DNA polymorphisms close to the disease-causing gene in family members known to have or carry the disease with those of unaffected and at-risk family members. Indirect assessments can be made about whether at-risk persons have the disease allele. The accuracy of these predictions depends on correct diagnosis and relationships of the family members, and the genetic distance between the polymorphism tested and the disease allele. For some families, linkage testing an be uninformative (Fig. 6.10).

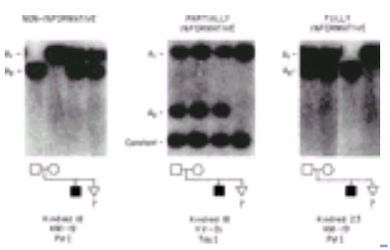

FIG. 6.10. Informativeness of linkage testing for cystic fibrosis. Marker KM-19 in kindred 18 is “not informative”-the disease alleles can not be distinguished in the parents.

The Genome Project

The Human Genome Project promises to be the single most important project in biology; genetics and genomics are now the central sciences of medicine. An understanding of the relationship between genetic variation and disease risk will alter the future prevention and treatment of common illnesses.

The full human sequence will be completed in 2003, but a very accurate draft is available now for over 95% of the genome. Disease gene identifications that formerly required years of chromosome walking and jumping, cloning, physical mapping, sequencing, and sequence assembly can now be completed in weeks. Industrialized sequencing technologies using capillary electrophoresis, micro arrays, and others developed for the genome project are now widely used for genotyping and sequencing.

We also now have a tremendous catalog of individual sequence variation in humans. Tens of thousands of micro-satellite markers are available for linkage analysis and hundreds of thousands of SNPs (single nucleotide polymorphisms) for genetic association studies. The tools are now well developed for doing these functional studies to find which variations and mutations cause individuals to be at risk for numerous medically important, genetically complex human diseases. The genome project has delivered improved cDNA resources, better predictive software, and additional knowledge about the non-protein coding regions of the genome. Remarkable technologies are commercially available for comprehensive analysis of gene expression in single cells, tissues, or whole organisms.

Advances in gene knockout technology, antisense technology, gene transfer, and gene transfection allow greater in vitro insights using appropriate model systems, including both cell culture and whole organisms. The complete sequence of the *Escherichia coli*, yeast, nematode, fruit fly, and mouse genomes provide important evolutionary clues to gene function and extend the range of experiments possible.

At the same time there have been parallel improvements in the technology for global protein analysis. Gene expression is played out at the protein level—elegant techniques are now available to examine spatial and temporal patterns of protein expression, protein-ligand interactions, and protein modifications.

Finally, the genome project occurred at the same time as the information technology revolution. Tremendous bioinformatics and computational software is now available for gene discovery, expression profiling, understanding gene-environment interactions, and so on. Suffice it to say, better tools are now available for making advances in women's health care than ever before in human history.

At least 3% of the annual budget of the project is going to the Ethical, Legal, and Social Issues section of the enterprise. This amount of early attention to societal impact is unprecedented for a science and technology project. Grant-funded programs have examined privacy issues, genetic discrimination in insurance and employment, and the role of coercion. Genetic discoveries may challenge long-held beliefs about equality, predetermination, and free will as we learn about genes that have a major role in personality, creativity, intelligence, and mental illness. The safety, efficacy, and utility of new gene tests should be evaluated, especially before treatment is available.

GENETIC EVALUATION

Genetic History and Physical Examination

Important details are being learned about many rare disorders which practitioners may see only once in their careers. In the past, many practitioners have had a “laissez-faire” attitude about genetic disorders, because “you can't do anything about your genes.” However, it is important to detect genetic conditions so that the patient can have adequate counseling about the condition and the risk to offspring. For severe conditions, patients often are interested in prenatal diagnosis, so they can consider pregnancy termination or prepare for the birth of an affected child. Our new predictive powers have led to an expanded medicolegal duty to warn patients of risks of which they may not have been aware. Failure to provide accurate and timely reproductive counseling has resulted in a host of lawsuits. Genetic diagnosis becomes even more critical as more treatment options become available for the child with a severe genetic disease.

In light of these expanding obligations to screen, what is expected of the general obstetrician-gynecologist? As with any medical diagnosis, the history is the most important part of the genetic evaluation. Important aspects of a genetic history, such as the patient's age, menstrual history, and obstetric history, are queried routinely as part of any routine obstetric or gynecologic history. In addition, it is important to ask about the patient and her partner's ethnicity (Table 6.13). The family history should extend to third-degree relatives (i.e., cousins). A minimal familial history can usually be elicited using the following questions:

TABLE 6.13. *Single gene disorders with an ethnic predilection*

- Do you have a family history of diabetes, hypertension, cancer, or twins?
- Are there any diseases that seem to run in your family?
- Is there a history of genetic disease like cystic fibrosis, hemophilia, or muscular dystrophy?
- Is there anyone with mental retardation or any kind of birth defect?
- Have any of your sisters, cousins, or other relatives had problems with their pregnancies?
- Are your parents alive? Are they healthy?
- As far as you know, are you and your husband or partner related by blood?
- Do you know your ethnic background? (Do you know where your relatives are originally from?)
- Is there any reason you are especially concerned that you might have trouble with your pregnancy or that your baby may be born with a birth defect or other medical problem?

It takes only a few minutes to ask these questions of a new patient. The final, open-ended question is often the most revealing. Alternatively, many practitioners find it helpful to ask similar questions using a patient-completed questionnaire. I use a form similar to the one suggested by the American College of Obstetricians and Gynecologists (ACOG) (Fig. 6.11). It is designed so that only “yes” responses need to be dealt with further. Including a form such as this one in the patient's chart clearly documents that a genetic history was obtained for medicolegal purposes. More than one fifth of healthy obstetric patients affirmatively answer at least one important question on the form.

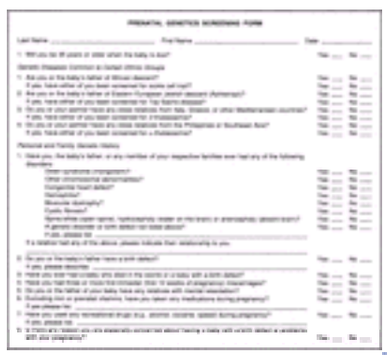

FIG. 6.11. Genetic screening questionnaires.

The physician should suspect genetic factors if a patient has an unusual problem and other people in her family have the same disorder. Similarly, if a patient reports a positive family history, it is important to decide whether the patient unknowingly has the same disease. When a patient reports an unfamiliar genetic condition or a rare illness, the physician should seek information about the genetics of this condition. Is she at risk of passing the condition to her offspring? Is prenatal diagnosis available? Is prenatal treatment available? For instance, consider a patient whose first child died of methylmalonic aciduria. In a subsequent pregnancy, her obstetrician noted this history on his prenatal record but did not inform the patient that there was a one-in-four risk that her current fetus could be affected. The obstetrician was unaware that prenatal diagnosis is available and, more importantly, that a simple treatment (i.e., giving the mother supplemental vitamin B_{12}) could prevent much of the morbidity of this particular form of methylmalonic aciduria. The child was born severely damaged and died at 2 years of age. The patient was very angry that she was not informed about prenatal therapy, and a lawsuit was initiated. Obstetricians cannot be expected to be expert in every rare enzymopathy, but this case illustrates how important it is to seek out additional information about rare conditions through a literature search or by consultation with a genetics center. Fortunately, helpful computerized databases are available on the internet such as OMIM (Online Mendelian Inheritance in Man) and Gene Tests (a directory of DNA diagnostic laboratories).

The general physical examination may reveal dysmorphic features or a distinctive physical finding that frequently is associated with genetic problems. For instance, a dislocated lens found on funduscopic examination of the eye is a distinctive feature consistent with Marfan syndrome or homocystinuria. If the patient has no history of severe ocular trauma, she probably has one of these conditions. Obstetricians cannot be as good at detecting such clues as an expert medical geneticist, because “the eye cannot see what the mind does not know.”

Genetic Counseling

Genetic counseling is a communication process which deals with the occurrence or risk of occurrence of a genetic disorder in a family. As our abilities to learn about the fetus have increased, more couples have an indication for prenatal diagnosis or a need to discuss reproductive options. Although every obstetrician has a role in providing genetic counseling, many practitioners find that genetic counselors—persons with advanced degrees and who are specially trained in the educational, psychological, and administrative aspects of medical genetics—are helpful consultants. Genetic counselors are experienced in obtaining and interpreting a thorough family history; often counselors are involved in the establishment or confirmation of a diagnosis. When presented with a prenatal diagnosis, they can obtain and interpret the history of a current pregnancy, explaining fetal risks and discussing the options available. Genetic counselors can provide the detailed counseling that is necessary regarding fetal chromosomal abnormalities of consanguinity, recurrence risks of multifactorial disorders, fetal abnormalities identified by ultrasonography, or infertility and habitual abortion. They are trained extensively about genetic screening for diseases that are common in various ethnic groups. Genetic counselors play a central role in the discussions regarding the option of aborting a genetically abnormal fetus. This type of counseling is traditionally informational and nondirective.

Pregnancy Termination

Pregnancy termination for genetic reasons can be particularly heart wrenching for a couple because the pregnancy usually is a desired pregnancy. Patients should be encouraged to involve their doctors, genetic counselors, clergy, other support persons, and family in these difficult decisions.

It is the physician's responsibility to explain the fetal diagnosis and prognosis. If a woman decides to have a pregnancy termination, the physician should explain the termination procedure, options if there are any, and the relative risks of the different procedures. The cost of the procedure is discussed and whether the procedure is covered by public funding or insurance. The physician should explain the benefits of diagnostic examination of the fetus by DNA, metabolic, or chromosomal analysis or by dysmorphologic examination. The disposition of the fetal remains should be discussed. The possibility that a fetus may live for a short period after induced labor termination is discussed. With late second-trimester or third-trimester inductions, it is often appropriate to encourage patients to see or hold the baby, and to name their baby. Patients are advised that lactation may occur after the delivery, and they are told about the options available to reduce lactation. With late terminations, the option of having a memorial service or in some way commemorating the baby's existence should be discussed. Physicians and counselors help couples decide what information to tell other children and family members, friends, and acquaintances.

It is important to reinforce that the genetic defect is not caused by the patient. The woman who is carrying the pregnancy and undergoes the termination may grieve in different ways than may the father of the baby. Referral to local support groups and counselors is often appreciated. Six to eight weeks after the procedure, a follow-up visit should be scheduled to summarize the diagnostic findings, review recurrence risks, and discuss prenatal diagnosis or therapy options for future pregnancies.

Laboratory Screening

Laboratory studies play an important role in the diagnosis of genetic disorders. A genetic illness is sometimes first discovered as an incidental finding on blood studies or an ultrasonographic examination. For instance, a low mean corpuscular volume on an automated complete blood count suggests thalassemia. In some instances, a positive family history prompts laboratory studies that clarify a patient's risk. Some programs have evolved to screen entire populations for genetic conditions using laboratory assays. Just as we currently perform a history and physical examination or a cholesterol screen to identify disease risk, soon there will be a DNA screen to detect mutations in dozens of important genes involved in cancer, cardiovascular disorders, and metabolic disease.

Population screening is appropriate when a defined subset of the population is at risk, and an accurate and inexpensive heterozygote test is available (Table 6.14). It is optimal if prenatal diagnosis is available, as well (e.g., sickle cell anemia, Tay–Sachs disease, thalassemia). The goals of screening programs are early diagnosis to allow better treatment of affected persons and identification of at-risk matings between persons who are heterozygotes or carriers of recessive disease. Neonatal screening programs for phenylketonuria, galactosemia, and hypothyroidism are carried out in most states. Successful carrier screening for Tay–Sachs disease has been achieved in several Jewish populations. The cost effectiveness of the screening program is often a primary concern in deciding whether to proceed with population screening. Equally important issues include the ability to manage minor variants which do not require action, stigmatization of carriers, and responsibility for decisions not to screen.

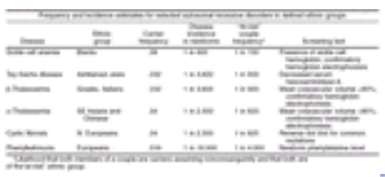

TABLE 6.14. *Population screening*

PRENATAL DIAGNOSIS

Limited but important information about the fetus can be gained using the traditional diagnostic techniques of history, auscultation, and palpation. It is important to consider the onset of fetal movement and the assumption of the vertex position as developmental milestones that the fetus does or does not achieve. Experienced examiners can assess fetal size, size or dates discordance, fetal positioning, and fetal heart rate abnormalities.

Maternal Serum Screening

Screening for fetal genetic conditions can be achieved by testing maternal serum. The first such program involved the use of maternal serum a-fetoprotein (MSAFP) levels to test for neural tube defects, an etiologically heterogenous group of conditions characterized by failure of embryonic closure of the neural tube. A cause for a neural tube defect can be identified in only 5% to 20% of cases, and most cases are thought to be polygenic or multifactorial. Between 90% and 95% of all infants with neural tube defects are born to women with no history of a child with neural tube defect.

There is substantial evidence for genetic predispositions to neural tube defects, including racial and ethnic variations in incidence, the increased incidence when a couple is consanguineous, gender bias, and increased monozygotic twin concordance. There is also strong evidence for environmental factors including maternal folate deficiency, previous spontaneous abortion or stillbirth, and the seasonal incidence. Mendelian disorders associated with neural tube defects include Meckel syndrome, in which affected individuals have a posterior encephalocele. Chromosomal syndromes, such as trisomy 18, trisomy 13, and triploidy, and sporadic syndromes such as OEIS complex (i.e., *o*mphalocele, *e*xtrophy, *i*mperforate anus, *s*pinal defect) can result in neural tube defects. Other well-described environmental causes of neural tube defects include amniotic band disruption sequence, maternal diabetes, maternal use of valproic acid, and hyperthermia. Forty-five percent of fetuses with neural tube defects have anencephaly, 45% have spina bifida, 5% have an encephalocele, and the remaining 5% have iniencephaly or exencephaly.

The incidence of neural tube defects is high (approximately 1%) in Ireland, Wales, Alexandria, and the Punjab. The rate is between 1 in 1,000 and 2,000 in the United States. Across the United States, the incidence is higher in the east than in the west, and highest in the Appalachian region. In the United States, if a person has previously had one child with neural tube defect, the recurrence risk is 2% to 3%. If there have been two affected children, it is 6.4%, and with three affected children, it may be as high as 25%. For patients at high risk for neural tube defect, prenatal diagnosis can be performed by targeted ultrasonography and an amniocentesis for amniotic fluid a-fetoprotein and acetylcholinesterase at approximately 16 weeks of gestation. The peak concentration of a-fetoprotein in the amniotic fluid occurs between 12 and 14 weeks, the widest margin between abnormal and normal distributions at approximately 16 to 18 weeks. A cutoff of 2.5 multiples of the median again yields a 98% detection rate, with a 0.8% false-positive rate. Acetylcholinesterase level determinations in amniotic fluid do not depend on gestational age. Amniotic fluid a-fetoprotein and acetylcholinesterase levels are normal in the 5% to 10% of cases of neural tube defects that are closed. Other open fetal defects, such as omphalocele and gastroschisis, can cause a rise in amniotic fluid a-fetoprotein.

MSAFP screening was introduced for assessing fetuses of women with no known risk factors for neural tube defects in the 1980s. Like all screening tests, the predictive value of the test depends on the population prevalence and particular cutoff used for setting the limits of normal and abnormal. In the United States, a cutoff of 2.5 multiples of the median frequently is used, meaning that 5% of those tested will have positive results. With this cutoff, more than 95% of anencephalic fetuses, 80% of fetuses with open spina bifida, and approximately 5% of fetuses with closed spina bifida are detected, for an overall detection rate of approximately 64%. MSAFP screening is most accurate from week 16 to 18. MSAFP starts to increase at approximately 13 weeks and peaks at 32 weeks gestation. An inaccurate gestational age determination is the most common reason for an abnormal MSAFP result.

It is important to correct MSAFP values for maternal weight, race, diabetes, and multiple gestation. There is a negative correlation between maternal weight and MSAFP. Blacks have approximately 1.1 times the MSAFP level of Caucasians, and Asians have an intermediate level between blacks and Caucasians. In insulin-dependent diabetics, the MSAFP level is approximately 60% of nondiabetic controls, and it is inversely correlated with the hemoglobin A_{1C} levels. Between 1% and 2% of infants of diabetic mothers have babies with neural tube defects. In multiple gestation, the median twin MSAFP level from 16 to 20 weeks is about 2.5 multiples of the median for a singleton pregnancy.

Low MSAFP levels have been associated with Down syndrome. One fifth to one third of these fetuses' mothers exhibit low MSAFP levels, with a median MSAFP of 0.7. Additional assays, such as unconjugated estriol, can provide more information about risk. Estradiol levels are low in cases of trisomy 21, very low in trisomy 18, and normal with spina bifida. Human chorionic gonadotropin levels are high in trisomy 21, very low in trisomy 18, and low in anencephaly.

For some couples, MSAFP screening raises anxiety, because the results are available around the time they feel that miscarriage is not going to occur and after the pregnant woman already feels fetal movement. When counseling patients about MSAFP screening, it is important to stress that it is a screening rather than a diagnostic test. The physician should explain the possible reasons for a high or low result, discuss the evaluation that would be recommended in that case, and stress that most babies of mothers with an abnormal screening result are normal. Frequently, discussions about a-fetoprotein screening bring out other issues the couple are worried about with respect to birth defects. This discussion is also an opportunity to educate the couple about the background incidence of birth defects.

The search is on for new biochemical markers which would improve the sensitivity and specificity of maternal serum screening. Retrospective studies suggest that maternal serum levels of dimeric inhibin A may be highly predictive. When the fetus is affected by Down syndrome, the maternal serum inhibin A concentrations are 2.1 times the median value in controls. Serum concentrations of inhibin A in Down syndrome pregnancies do not rise above normal until the end of the first trimester. The levels were not significantly different in the women with fetuses affected by trisomy 18.

Small retrospective studies also have examined the feasibility of first-trimester screening for Down syndrome. Earlier screening for Down syndrome would allow more time for intervention in the event of a positive test result. For women who choose pregnancy termination, the procedure can be carried out at a time when it is medically, psychologically, and perhaps morally less problematic. On the other hand, earlier tests will find many Down syndrome fetuses that would have aborted spontaneously. The follow-up diagnostic tests carry a greater risk of miscarriage (of normal pregnancies) at these earlier gestational ages. Serum a-fetoprotein screening for neural tube defects (NTDs) is impossible during the first trimester.

Initial studies show that maternal serum free ß-human chorionic gonadotropin and pregnancy-associated plasma protein A are useful markers. The “free-ß” chorionic gonadotropin levels are approximately one half the median, and pregnancy-associated plasma protein A levels are twice the median control levels in Down syndrome pregnancies. Urinary markers are being evaluated also. Large, prospective studies are needed to further assess first-trimester screening. Eventually, sorting fetal cells from maternal blood may prove to be the most sensitive and specific screening test.

Fetal Imaging

For many years, the fetus could be seen before birth only by using x-ray films. Radiographic examinations have limited prenatal indications because of concerns about fetal radiation exposure and because the information obtained by radiographs is limited to inspection of the calcified structures. Today, fetal radiography is used mostly for the differential diagnosis of skeletal dysplasias in the third trimester. In the past, attempts to gain information about the fetal soft tissues involved injecting into the amniotic fluid a water-soluble dye to outline the fetal gastrointestinal tract or a fat-soluble dye to outline the fetal skin. Modern high-resolution ultrasonography has revolutionized fetal imaging, giving clinicians a noninvasive way to get information about the internal and external features of the fetus.

Newer imaging methods serve as a useful adjunct to ultrasonographic examination for the prenatal diagnosis of certain conditions. Computed tomography (CT) uses low doses of radiation and computerized processing to obtain cross-sectional images. Magnetic resonance imaging (MRI) is based on detection of moving hydrogen atoms when tissues are subjected to a strong magnetic field. Both methods are expensive, but they are noninvasive and do not exhibit the shadowing phenomena seen with ultrasonography. CT and MRI are most useful for suspected central nervous system anomalies, particularly if ultrasonographic imaging is limited by reverberation artifacts caused by the fetal skull. They also are useful for cases of oligohydramnios; decreased amniotic fluid makes ultrasonographic imaging difficult, but the condition holds the fetus still for CT or MRI.

Fetal movement is a major limiting factor with CT and MRI, but the newer ultrafast scanners can produce an image within fractions of a second. Prenatal studies do not necessarily require maternal sedation or fetal paralysis with an intrauterine, intramuscular injection of a muscle relaxant such as curare. Fast CT scans have slightly lower resolution but an even lower dose of radiation compared with conventional CT. Another advantage of CT is the ability to use contrast agents. For instance, CT amniography can differentiate cyst adenomatoid malformation of the lung and diaphragmatic hernia by demonstrating the location of fetal stomach and small bowel. MRI allows differentiation in tissue densities and is exceptionally useful for differentiating white and gray matter in the central nervous system, fat, and flowing blood. MRI computers can construct images in any plane desired. Although there are no known biologic hazards with MRI, there are also no clear indications for use of MRI in the first trimester. Because the teratogenic risk is unknown, MRI use should be limited to the second and third trimesters.

Direct visualization of the fetus is indicated only in certain clinical situations and can be performed using a small-bore, fiberoptic endoscope. The trocar for the most commonly used fetoscope is 2.2 mm in diameter; the scope, itself, is 1.7 mm in diameter. The narrow field of view and the short focal length give a limited view of a small portion of the fetus. Fetoscopy may reemerge as an important adjunct to amniocentesis and fetal blood sampling as narrower scopes are developed. Scopes small enough to fit through the shaft of a 20-gauge needle have been developed, but it is not yet possible to get enough light inside the uterus to allow visualization with such a narrow scope. Embryoscopy has been used during the first trimester to visualize the embryo or early fetus through the membranes. This is accomplished by passing the endoscope through the cervix and up against the membranes. Neither fetoscopy nor embryoscopy may be possible in many cases because of the placental position or cloudy amniotic fluid.

Fetal Sampling for Prenatal Diagnosis

Amniocentesis Amniocentesis was introduced to the United States in the 1960s, and it is the most extensively used fetal sampling technique. Genetic amniocentesis is performed routinely at approximately 15 weeks of gestation when the amniotic fluid volume is approximately 200 mL. At this gestational age, ultrasonographic examination cannot detail all of the fetal anatomy, but it can reliably ascertain dates or rule out multiple gestations. Typically, 20 mL of fluid is removed with a 20- to 22-gauge needle using a transabdominal approach with ultrasound guidance (Fig. 6.12). Biochemical testing can be performed on the fluid as indicated. Amniotic fluid a-fetoprotein levels are obtained routinely to screen for open fetal defects, and fetal cells can be grown for karyotype determination or for DNA assays. DNA assays that use the PCR to amplify small amounts of DNA allow direct analysis of amniotic fluid. Roughly one third of the amniocenteses must be performed transplacentally. In most operators' experience, this has not been associated with substantially increased risk if care is taken to avoid major fetal vessels. The transplacental approach is associated with a slightly higher incidence of Rh sensitization. With either approach, it is imperative that Rh-negative women who may be carrying an Rh-positive fetus receive RhoGAM.

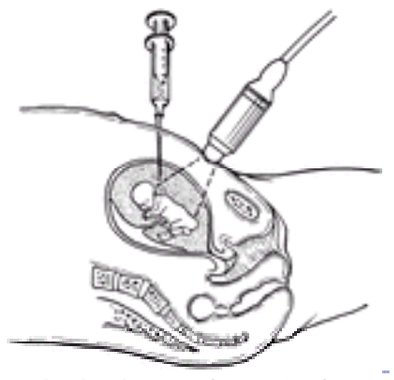

FIG. 6.12. Amniocentesis.

With multiple gestations, it is usually possible to sample each of the gestations. Indigo carmine dye can be placed in the sac after the amniocentesis is completed to prevent tapping the same sac twice. Biochemical assays of amniotic fluid are somewhat harder to interpret in multiple gestations, because many biologic molecules can diffuse from one sac into the other. Few women describe amniocentesis as terribly painful. Those who do frequently experience a uterine contraction at the time the needle is inserted. It is not unusual to have some cramping or a bruised feeling at the site after the procedure. Vaginal spotting or amniotic fluid leakage occurs in 1% to 2% of cases. After a routine amniocentesis, the fluid usually stops leaking within 2 to 3 days. Even when the amniotic fluid volume becomes markedly decreased, miscarriage is not inevitable, because the membranes usually seal and the amniotic fluid can reaccumulate within a week, allowing the pregnancy to progress normally. As ultrasonographic equipment has improved, the maternal risk incurred with amniocentesis has decreased. Symptomatic amnionitis occurs in fewer than 1 of 1,000

patients. Serious maternal bowel or vascular injuries are extremely rare. The procedure-related rate of fetal loss after amniocentesis generally is quoted as 0.5% (1 in 200), but many centers are reporting lower rates.

Chorionic Villus Sampling Chorionic villus sampling (CVS) is a diagnostic technique that was introduced to the United States in the mid-1980s. With this technique, a small sample of the chorionic villi is taken for examination of chromosomal status, biochemical assays, or DNA tests. Assays depending on analysis of amniotic fluid such as a-fetoprotein cannot be performed on a chorionic villus sample. CVS usually is accomplished by the transcervical or transabdominal route. Occasionally a transvaginal CVS is performed with the uterus extremely retroflexed. A transcervical CVS usually is performed between 9 and 12 weeks of gestation, at which time a plastic catheter, approximately 1.5 mm in diameter, is passed through the cervix and then directed toward the placental mass under continuous ultrasound guidance (Fig. 6.13). Between 10 and 20 mg of villi are aspirated through this catheter by negative pressure using a syringe. Transabdominal CVS is performed using an 18- to 20-gauge spinal needle passed into the thickest portion of the placenta that is readily assessable (Fig. 6.14). Villi are aspirated into a syringe. This procedure can be performed throughout gestation.

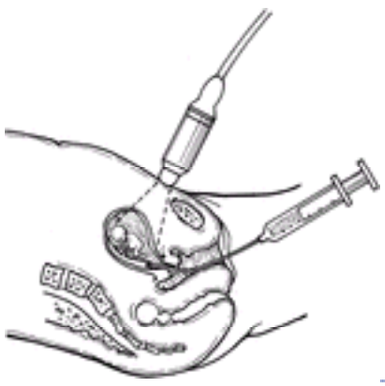

FIG. 6.13. Transvaginal chorionic villus sampling.

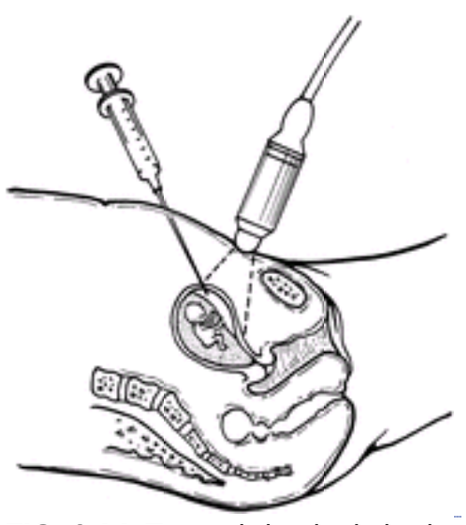

FIG. 6.14. Transabdominal chorionic villus sampling.

Transabdominal CVS is considered easier to learn and safer, but patient acceptance appears to be lower. Theoretically, transcervical CVS would have a greater risk of infection, although this has not been borne out by large surveys. In most series, a larger sample is obtained with transcervical CVS, but more passes are required to obtain this sample. Transcervical procedures require more uterine manipulation, and bleeding or leakage of fluid is more common during and after the procedure. Most laboratories report a greater level of maternal cell contamination with transcervical CVS, although this is rarely a clinically important issue. Those performing CVS should be facile with both techniques, because patient anatomy frequently dictates which is the optimal technique. CVS compares favorably with amniocentesis with regard to safety. Two large National Institutes of Health cooperative trials found a procedure-related loss rate of approximately 0.8%. In approximately 2% of first-trimester chorionic villus samples, a discrepancy is found between the cytogenetic analysis of the placenta and that of the fetus. Frequently, a second invasive procedure, usually amniocentesis or fetal blood sampling, is required to determine whether the fetus is affected. This phenomenon is called confined placental mosaicism. Pregnancies in which confined placental mosaicism is found by CVS may be at risk for spontaneous abortion, perinatal loss, or intrauterine growth retardation. The reported rates of loss have ranged from 3.6% to 16.7%. In chromosomally abnormal conceptuses, a mosaic normal cell line in the placenta may be the factor that allows prolonged survival of aneuploid fetuses. Kalousek studied 14 placentas from live-born or from terminated pregnancies with trisomy 13 or 18, and found the placentas were all mosaic for, or contained only, diploid cells. There have been several reports of increased incidents of limb anomalies when fetuses have undergone very early CVS using the transabdominal approach. These reports are of concern, because the affected children have a relatively distinctive pattern of malformation, and it is biologically plausible that their anomalies may be related to CVS. The absolute number of fetuses with this problem is small, but the publicity regarding these findings has caused many women to avoid CVS. The Centers for Disease Control performed a multistate case-control study to assess and quantify the risk for specific limb deficiencies associated with CVS. Between 1988 and 1992, 131 infants with nonsyndromic limb deficiency, born to mothers 34 years of age or older, were reported in seven population-based birth defect surveillance programs. Control subjects were 131 infants with other birth defects. They found that exposure to CVS was associated with a six-fold increase in risk for transverse digital deficiency (odds ratio = 6.4; 95% confidence interval, 1.1 to 38.6). The data showed a significant trend toward increased risk with earlier gestational exposure. The CDC estimates that the absolute risk for transverse digital deficiency in infants after CVS is approximately 1 per 3,000. Most feel that the actual risk is significantly lower and that there is minimal to no risk when CVS is performed after 70 days of gestation. Further studies are needed to determine whether the problem is specific to CVS or whether the same risk affects other invasive first-trimester diagnostic manipulations.

Fetal Blood Sampling and Fetal Biopsy Originally, fetal blood was sampled by inserting a needle into the placenta; the blood obtained was usually a mixture of fetal and maternal blood, which limited its usefulness. In 1977, fetoscopy came into use, allowing a needle to be placed in a cord vessel under direct sonographic visualization. Pure fetal samples could be obtained, but fetoscopy requires special equipment and expertise, and the procedure-related loss rate was between 3% and 7%. With improvement in ultrasonographic imaging during the mid-1980s, cordocentesis can be performed in a manner similar to amniocentesis (Fig. 6.15).

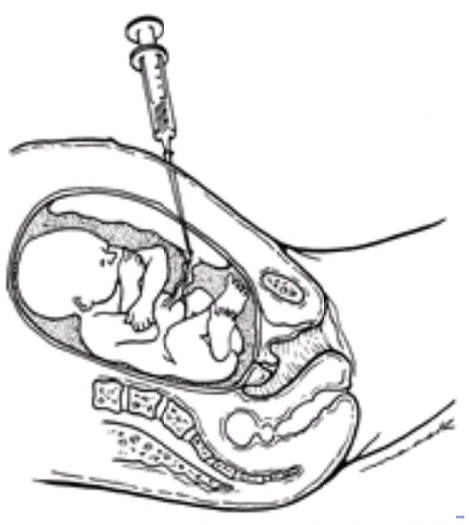

FIG. 6.15. Cordocentesis (fetal blood sampling).

A transplacental route usually is preferred, and a spinal needle is advanced under ultrasound guidance into a vessel with cord insertion into the placenta. Cordocentesis usually is not performed until after 17 weeks gestation. Depending on the indication, procedure-related loss rates of as low as 1% have been reported with no observed increase in the rate of preterm delivery. Typically, no maternal sedation or antibiotics are required. In most cases, a fetal sample can be obtained on the first attempt, usually in less than 10 minutes, and any substance measurable in adult blood can be assayed in fetal blood. Most cordocenteses are performed to obtain a fetal karyotype because of fetal anomalies or to determine the fetal hematocrit to assess isoimmunization or severe fetal anemia. Fetal platelet counts, acid-base status, antibody levels, and blood chemistries can be assayed as indicated. Hematologic values are checked routinely (particularly the mean corpuscular volume which is higher in fetus than mother) to be certain that the blood obtained is fetal. A Kleihauer test can be performed to check for maternal blood contamination. A variety of other tissues, particularly fetal skin, liver, and muscle, have been sampled prenatally to diagnose a genetic disorder using either electron microscopy or biochemical analysis. Such biopsies are necessary if a genetic abnormality is expressed only in certain tissues and the causative gene is unknown. Now that the molecular basis of many of these disorders is known, simpler DNA assays using villi, amniocytes, or blood usually obviate the need for tissue biopsy. Initially, fetal

biopsies were performed using fetoscopy, but they now are performed under ultrasound guidance. Typically, local anesthesia, maternal sedation (with or without fetal paralysis), and prophylactic antibiotics are used for tissue biopsy procedures. As with any invasive procedure, RhoGAM is necessary for the nonsensitized Rh-negative mother who may be carrying an Rh-positive fetus.

Early Amniocentesis Early amniocentesis is similar to amniocentesis at the “traditional” gestational age, except that the procedure is performed at 10 to 12 weeks of gestation. Early amniocentesis was proposed as an alternative first-trimester prenatal diagnostic technique, but a large Canadian prospective study demonstrated an unacceptable rate of procedure-related malformations in the exposed pregnancies.

Preimplantation Diagnosis Various methods of diagnosis before a pregnancy is formally established are becoming available in the 1990s. Someday these extremely early diagnoses may be necessary to allow initiation of genetic therapy treatments. For many couples, preimplantation diagnosis provides an alternative to selective pregnancy termination, allowing them to avoid the moral issues and the psychological trauma that accompanies termination of a wanted pregnancy. For most genetic conditions, carriers have both normal and abnormal gametes, and chance determines whether an abnormal gamete is incorporated into the conceptus. Aided by the rapid progress in assisted reproductive technologies and molecular diagnostic techniques, it has become possible to test gametes in vitro and select healthy gametes for fertilization. Sperm sorting has been accomplished using molecular probes tagged with laser-activated dyes and using separation techniques such as flow cytometry, but current approaches usually cause unacceptable damage to the sperm. Greater success has been possible in genotyping oocytes, which are larger and more resistant to damage. Oocyte diagnosis takes advantage of the unique properties of female meiosis; unlike sperm, oocytes conveniently discard their unused genetic material in the form of polar bodies. For a heterozygous woman, the discarded genetic material can be tested to see whether it contains the abnormal allele. If it does, then the oocyte must contain the normal allele. Conversely, if the polar body tests positive for the normal allele, the oocyte must contain the abnormal allele. Only the normal oocytes are then fertilized. Contamination with cumulus cells adherent to the exterior surface of the zona pellucida can lead to errors. Polar body biopsy can be performed only in conjunction with in vitro fertilization. The first polar body has no essential function and contains no embryonic material; it is small and relatively easy to remove using micromanipulation techniques (Fig. 6.16). Theoretically, DNA testing results can be obtained before fertilization, leaving a long period for confirmatory studies before implantation. Aneuploidy screening can be incorporated as well, at least for maternal meiosis I nondisjunction. The main disadvantages are that polar body biopsy is an indirect assay of the oocyte and that it can be used only for maternal carriers. In addition, the further away from the centromere the gene is located, the more likely recombination is to occur, making polar body biopsy results indeterminate. Polar bodies that are heterozygous need to be discarded or the oocytes biopsied again to remove the second polar body.

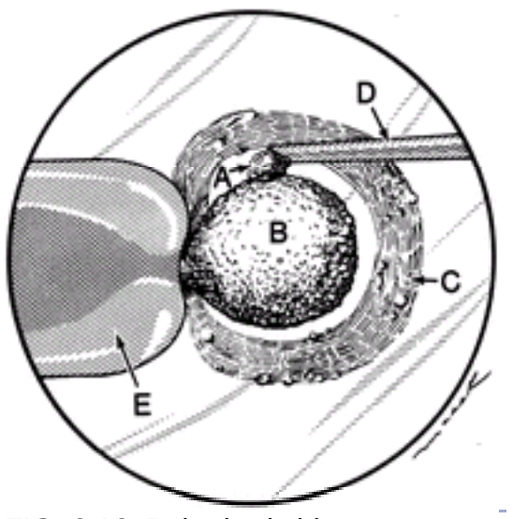

FIG. 6.16. Polar body biopsy.

Initial success has been greater with “selective implantation” protocols in which the diagnosis is made during the first week after fertilization but before implantation. Preimplantation embryos can be grown in vitro and biopsies obtained after the first few cleavage divisions. There is much experience with this technique in animal research, and embryo splitting at this stage has been used extensively for diagnosis in the cattle and sheep industry. The eight-cell preembryo is probably at the ideal stage for biopsy. Cells are still independent and totipotent, they have not developed gap junctions which will make them adherent, and damage is tolerated relatively well. By this stage, some of the embryonic genes have begun to function, and it may become possible to perform some biochemical microassays. This technique is limited by the difficulty in removing blastomeres, which are larger than polar bodies, and the short time to work with the sample before the chance of successful implantation begins to lessen. It has proved difficult to freeze spare embryos after biopsies and, as with other preimplantation techniques, there is the possibility of sperm or cumulus cell contamination. Attempts have also been made to perform testing 5 days after fertilization, when the preembryo has reached the blastocyst stage. The blastocyst consists of roughly 120 cells that are mostly trophoblastic tissue, but the inner cell mass that eventually becomes the embryo is clearly visible. Only the best laboratories have had any success culturing human preembryos to this developmental stage in vitro. As an alternative, investigators have tried to lavage naturally conceived blastocysts from the uterus during the 2 to 3 days when the conceptus is normally free-floating in the endometrial cavity before implantation. Unfortunately, it has proved exceedingly difficult to obtain multiple blastocysts by lavage after superovulation. Various methods of sampling blastocyst cells have shown success in animal models including bisection, aspiration of the cavity, and excision of cells herniating through the zona pellucida. The latter is achieved after mechanical disruption of the zona to cause premature herniation or after spontaneous hatching. The advantages of blastocyst biopsy include the relative differentiation of the cells, greater cell number, better transfer efficiency, and self-selection of the healthiest embryos. Lavage of naturally conceived blastocysts offers a potentially “low-tech” approach to preimplantation diagnosis. Perhaps contrary to expectations, disruption of zona pellucida may enhance hatching. Technical limitations include the small number of blastocysts available and their limited incubation time. The cells are very adherent to each other, increasing the risk of damage to the inner cell mass. As with CVS mosaicism, there is the possibility that the trophectoderm does not reflect the fetal karyotype or biochemical status.

Fetal Cells in Maternal Circulation The newest fetal sampling technique that shows promise involves separating fetal cells that occur naturally in the maternal circulation. Nucleated erythrocytes, fetal leukocytes, and syncytiotrophoblast cells are found in the maternal circulation during most pregnancies, from as early as 6 weeks gestation. It is possible to use a separation technique such as flow cytometry to establish an enriched population of fetal cells and then assay these cells for fetal mutations using a technique such as DNA amplification. Certain cell types have a long life span in the maternal circulation, allowing persistence of cells from prior pregnancies, and confusing results are possible. “Vanished” abnormal co-twins can lead to diagnostic errors. Ultimately, this method may provide a noninvasive, reliable screen for aneuploidy that is inexpensive enough to use in low-risk populations.

Cystic Fibrosis Screening The *CFTR* gene was discovered in 1989, and more than 1,000 mutations which can lead to CF have been identified. Couples who both carry the CF gene would have a 1 in 4 chance of delivering a child with CF. Cystic fibrosis causes pulmonary and gastrointestinal disease of varying severity. Most patients with CF have substantial illness and shortened life span and require lifelong medical care. Screening is now widely available for the most frequent CF mutations. Recently ACOG advised that DNA screening for CF should be made available to *all* couples seeking preconception or prenatal care. The ACOG/American College of Medical Genetics publication entitled *Cystic Fibrosis Carrier Testing: the Decision is Yours* can be helpful for this purpose. Because Caucasians have a higher rate of CF (particularly European or Ashkenazi Jewish), obstetric care providers are advised to offer screening specifically to these couples and to record in the medical record the couple's decision on whether to be screened (Table 6.15.).

Caucasians	1 in 29
Hispanic Americans	1 in 46
African Americans	1 in 65
Asian Americans	1 in 90

Prenatal Treatment and Gene Therapy

As we begin to understand the molecular mechanisms by which genes cause disease, we will have the opportunity to design and apply preventive, health maintaining measures. Some genetic conditions can be treated by giving patients the protein they are missing or by stimulating a function that is not performing properly (e.g., growth hormone deficiency, diabetes).

More sophisticated gene therapies are being tested. Finding the CF gene enabled the disease to be “cured” in the test tube and improved in animal models. Scientists may be able to design proteins or antisense RNAs that can be used as a drug to block the effect of abnormal genes or kill cancer cells. Modified viruses may be used to insert corrected genetic instructions. Prenatal gene therapy with stem cell transplantation has been attempted for severe combined immunodeficiency with some preliminary success.

Many genetic conditions need to be treated prenatally. Although in utero treatment is experimental, prenatal treatment of disorders with vitamin-dependent or responsive cofactors has been successful. For instance, prenatal treatment of the vitamin B_{12}-responsive form of methylmalonic acidemia by administration of 10 mg per day of vitamin B_{12} has improved the biochemical defect. Similarly, infants with biotin-responsive multiple carboxylase deficiency have been aided by maternal biotin supplementation. In these rare disorders, prenatal treatment can mean the difference between life and death for affected infants. Dietary restriction of galactose in mothers who are at risk of delivering a galactosemic infant, and dietary restriction of phenylalanine in mothers who themselves have phenylketonuria, are helpful means of preventing the devastating effects of these metabolic conditions. Gene therapy and prenatal tissue transplantation are likely to rapidly expand the therapeutic

options for treating and preventing metabolic disease.

GENETICS IN GYNECOLOGIC DISORDERS

Genes play an important role in the pathogenesis of many common gynecologic disorders. Molecular genetic investigations of persons with gonadal dysgenesis and pseudohermaphroditism have defined many aspects of human sexual differentiation. Because it is the smallest chromosome, the Y chromosome became the first human chromosome to be mapped completely.

Genetic testing for susceptibility to ovarian cancer is rapidly becoming part of routine practice. Most cancer is clonal in origin, meaning it arises from a single aberrant cell. Cytogenetic or molecular alterations are observed uniformly in malignant cells. Although some of these changes appear to be random events occurring in rapidly dividing cells, other specific genetic changes play an etiologic role in development of certain cancers. Particular mutations may be either germinal (i.e., inherited) or somatic (i.e., acquired). Either can be seen in familial cancer clusters: germinal because of segregation within the family of a cancer-causing mutation and somatic because of shared environmental exposures to carcinogens. Mendelian transmission of cancer predisposition usually is observed as multifocal and early-onset disease. Typically, cancer-predisposing mutations are found to overexpress protooncogenes that normally drive important cell functions or to inactivate tumor suppressor genes that normally exert a protective effect.

Genetic testing for BRCA1 and BRCA2 mutations is now recommended to most women with invasive ovarian cancer. Approximately 10% of patients with ovarian cancer will have a positive test result, including 4% of women without a family history of ovarian cancer. Women with the BRCA mutation have better ovarian cancer survival rates than women without the mutation, possibly due to enhanced susceptibility to chemotherapy. A variety of strategies for prevention of ovarian cancer in relatives at risk, including chemoprevention and prophylactic oophorectomy, have shown some efficacy.

Common gynecologic diseases such as endometriosis and polycystic ovary syndrome are familial, and genes involved in these conditions are likely to be discovered over the next few years. Age at menopause, susceptibility to hot flushes and osteoporosis, susceptibility to pelvic relaxation, and susceptibility to chronic vaginitis are likely to have genetic components, as well. Disease gene discoveries related to these conditions may suggest novel diagnostic and therapeutic approaches.

TRENDS

The genome project promises to provide us with the most important information in human biology. Technologies developed for the genome project and the genomic sequence, itself, will provide the basis for much of biomedical research in the next century. The possibilities for understanding normal development, disease predisposition, and cancer are staggering. The ability to obtain an accurate prenatal diagnosis will expand exponentially over the next few decades. Gene therapy is becoming a reality faster than anyone thought possible. The challenge is for the obstetrician-gynecologist to stay abreast of all these developments and to educate patients about developments that can influence their care.

SUMMARY POINTS

- Most obstetric and gynecologic diseases show a polygenic, multifactorial pattern of inheritance. One in twenty newborns has a diagnosable genetic disorder.
- A thorough family history is currently the most important part of a genetic evaluation, but laboratory screening of the general population is becoming available for an increasing number of genetic conditions.
- Accurate prenatal diagnosis is now possible for hundreds of genetic conditions through ultrasonographic and genetic testing.
- The Human Genome Project is providing new information each month, making it difficult for care providers to keep abreast of all the new developments, especially for rarer diseases. Reference to current on-line data and liberal referral to genetic counselors and geneticists is necessary when encountering rare conditions.
- Over the next decade, genetic testing will continue to become less invasive, and there will be greater opportunities to prevent the morbidity of genetic disease through prenatal and presymptomatic treatments.

PRINCIPLES OF TERATOLOGY

Anything a pregnant woman ingests or is exposed to could affect her fetus. This is problematic for the health care provider who must treat a wide variety of illnesses during pregnancy. In fact, over 60% of American women receive a prescription for at least one medication during pregnancy. This figure is about 99% for women in France and over 70% for Hungarian women. The most common conditions for which medications are prescribed include gastrointestinal, dermatologic, psychological, and psychiatric disorders and pain.

Generally, whatever medication would be given to a nonpregnant women is the appropriate choice in pregnancy. Awareness of the few exceptions and how to choose from available options requires a knowledge of teratology and alterations in drug metabolism related to pregnancy. Teratology is the study of abnormal development or the production of defects in the fetus. Birth defects affect 2% to 3% of all neonates. With longer follow-up, at least 5% of individuals are found to be affected by a birth defect. Exogenous causes of birth defects, including drugs or chemical exposures, account for almost 10% of birth defects. Thus, at least 0.2% to 0.3% of pregnancies are affected by teratogenesis.

The Food and Drug Administration (FDA) introduced a drug classification system in 1979 to discourage nonessential use of medication during pregnancy. Drugs are classified as either A, B, C, D, or X, with the latter being the most teratogenic. There has been growing perception that the FDA classification has led to excessive maternal anxiety and unnecessary pregnancy termination. The FDA is evaluating a revised labeling system for drugs and biologic agents that will include a description of the drugs based on clinical management, summary of risk assessment, and discussion of data.

How much drug the fetus will be exposed to is determined by a complex interaction of many factors, including how the agent is absorbed, the volume of distribution, metabolism, and excretion. Absorption is via the gastrointestinal tract, skin, lungs, or after parenteral administration. Pregnancy alters absorption in a variety of ways, including prolongation of gastric emptying time by the increased progesterone. The volume of distribution is generally increased during pregnancy. Estrogen and progesterone alter hepatic enzyme activity with varying effects on drug metabolism and clearance, depending on the precise pathway. Renal excretion is generally increased during pregnancy. Other factors affect precisely how much drug crosses the placenta. Passage of drugs across the placenta is influenced by several factors. Lipid-soluble substances readily cross the placenta, and water-soluble substances pass less well. Those with greater molecular weight also cross the placenta less easily. The degree to which a drug is bound to plasma protein influences the amount of drug that is free to cross. Virtually all drugs cross the placenta to some degree, with the exception of large organic ions such as heparin and insulin. Active placental transfer must be considered, also.

Other concepts related to teratology include specificity, timing, dosage, maternal physiology, embryology, and genetics. Specificity indicates that a substance may be teratogenic in some species but not others. For example, thalidomide produces phocomelia in primates but not rodents. Often, animal data of safety or teratogenic effect is not necessarily applicable to humans. Timing is also critical. When administered between 35 and 37 days gestation, thalidomide produces ear malformations, but between 41 and 44 days, amelia or phocomelia. Dosage is also important. In most cases, administration of a low dose will result in no effect while malformations occur at intermediate doses and death at higher doses. Death may cause organ-specific teratogenic action to go unnoticed. The route of administration, possibly secondary to absorption, is also important. Small doses over several days may have an effect different than the same total dose given at once. Sequential dosing, as opposed to a bolus, may induce an enzyme to metabolize the substance that potentially causes less damage. Constant exposure may destroy cells that would have catabolized the drug if administered in periodic doses. As noted above for thalidomide, timing of exposure relative to embryologic events is important. Teratogen exposure in the first 2 to 3 weeks after conception is generally thought to have no effect or to result in spontaneous loss (all-or-nothing phenomenon). The period of susceptibility to teratogenic agents is during the period of organogenesis, which occurs primarily at 3 to 8 weeks postconception (35-70 days after the last menstrual period or LMP) or to 10 weeks from the LMP. After this period, embryonic development is characterized primarily by increasing organ size (10-12 weeks); thus, the principal effect of exposure will be growth restriction or effects on the nervous system and gonadal tissue. These systems continue to develop throughout pregnancy. During organogenesis each organ system will have different critical periods of sensitivity. A teratogen can act by causing cell death, altering tissue growth (hyperplasia, hypoplasia, or asynchronous growth), or interfering with cellular differentiation or other basic morphogenic processes.

The genetic make-up of the mother and fetus can affect individual susceptibility to a drug. Fetuses with low levels of the enzyme epoxide hydrolase may be more likely to manifest the fetal hydantoin syndrome than those with normal levels of epoxide hydrolase. Combinations of agents may produce different degrees of malformation or growth restriction than if given individually. Fetuses whose mothers are on combination antiepileptic agents are at the highest risk for malformations, including neural tube defects and facial dysmorphic features.

Most drug therapy does not require cessation of nursing because the amount excreted into breast milk is small enough to be pharmacologically insignificant.

ANTIBIOTICS AND OTHER ANTIINFECTIVE AGENTS

Antibiotics are used widely during pregnancy to treat a variety of disorders including upper respiratory tract infections, urinary tract infections, and others (Table 7.1). Pregnant patients are particularly susceptible to vaginal yeast infections. This is one reason that antibiotics should be used only when clearly indicated. Therapy with antifungal agents may be necessary after the course of antibiotic therapy.

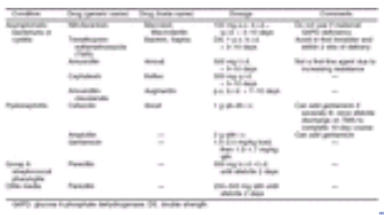

TABLE 7.1. *Antibiotics used for common infections in pregnancy*

Antibiotics

Penicillins Penicillin derivatives, including amoxicillin and ampicillin, have a wide margin of safety and lack toxicity for both the woman and her fetus. Penicillin is a ß-lactam that inhibits bacterial cell wall synthesis and can be administered orally, intramuscularly, and intravenously. It is the drug of choice for the treatment of a wide variety of bacterial infections including group A streptococcal pharyngitis, otitis media, and mild *Streptococcus pneumoniae* pneumonia. Penicillin is the drug of choice to treat syphilis. Pregnant women with allergy to penicillin should be desensitized to receive their full course when being treated for a syphilis infection. Ampicillin and amoxicillin are good choices for enterococcal urinary tract infections, but many other pathogens are resistant, so they should be used selectively.
Amoxicillin-clavulanate (Augmentin) combines the ß-lactam with a ß-lactamase inhibitor that expands the spectrum of activity. This combination can be used for sinusitis and urinary tract infections. The extended spectrum penicillins are also safe, but they are much more expensive and generally not used as first-line agents for most disorders during pregnancy. The cephalosporins are safe and used for urinary tract infections, including pyelonephritis, and for gonorrhea. The penicillins can be used safely during breast-feeding.
Clindamycin Clindamycin is a macrolide and acts on the bacterial ribosome preventing transcription. It can be used to treat bacterial vaginosis, although metronidazole is the first-line medication. It generally is reserved for anaerobic infections that are not sensitive to other agents. Up to 10% of patients will develop pseudomembranous colitis. Clindamycin is safe during breast-feeding.
Metronidazole Metronidazole inhibits bacterial protein synthesis. It is used to treat trichomonas and bacterial vaginosis. This agent was found to be positive in the Ames test but has not been proven to be carcinogenic in humans, nor has it been shown to produce birth defects. Although some authorities suggest deferring use past the first trimester, there are no data supporting this suggestion. This medication is safe in breast-feeding, although the American Academy of Pediatrics recommends interrupting breast-feeding for 12 to 24 hours following a 2-gram dose.
Aminoglycosides Aminoglycosides inhibit bacterial protein synthesis. They can be used to treat pyelonephritis but should be used only when serious gram-negative infection is suspected. Maternal administration has been associated with ototoxicity in the fetus leading to hearing loss. Breast-feeding is safe, because little drug passes to the neonate via the breast milk.
Trimethoprim-sulfamethoxazole This combination (Bactrim or Septra) inhibits folic acid metabolism and is very active against many organisms that cause urinary tract infections. No definite teratogenic effects have been described, but in 2,296 Michigan Medicaid recipients, first-trimester trimethoprim exposure was associated with a slightly increased risk of birth defects, particularly cardiovascular, and in a retrospective study, the odds ratio was 2.3. Given this and the mechanism of action via the folate pathway, avoidance in the first trimester is prudent. It displaces bilirubin from its protein binding sites in the neonate, potentially contributing to an increased risk of hyperbilirubinemia or kernicterus in newborns. Therefore, it should not be used close to delivery. This theoretic effect has not been substantiated in clinical trials. Trimethoprim-sulfamethoxazole has been used to treat otitis, sinusitis, *Shigella* colitis, and *Pneumocystis carinii* infections, in addition to both asymptomatic bacteriuria and acute cystitis. Use of this medication is safe during breast-feeding.
Nitrofurantoin Nitrofurantoin inhibits bacterial protein and cell wall synthesis. It is eliminated by excretion, and this bactericidal activity makes it highly effective in treating uncomplicated lower urinary tract infections. It can induce hemolytic anemia in patients with glucose 6-phosphate dehydrogenase deficiency and, because the newborn's red blood cells are deficient in reduced glutathione, the label carries a warning against use of the drug at term. However, hemolytic anemia in the newborn after exposure before birth has not been reported. This medication is compatible with breast-feeding.
Erythromycin Erythromycin and azithromycin inhibit bacterial protein synthesis. They often are used as an alternative to the penicillins and are first-line treatment for mycoplasma and chlamydia infections. These medications also are useful in treating community-acquired pneumonia or severe bronchitis. Use of both erythromycin and azithromycin are compatible with breast-feeding.
Antiviral Agents The emergence of the human immunodeficiency virus and acquired immunodeficiency syndrome has resulted in development of many antiviral agents. Previously, herpes was one of the few viral infections for which pregnant women might be exposed to treatment (Table 7.2).

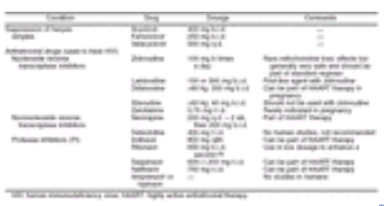

TABLE 7.2. *Antiviral agents in pregnancy*

Acyclovir and Valacyclovir Acyclovir (Zovirax) has resulted in no fetal abnormalities in 601 exposures reported. The Centers for Disease Control and Prevention recommends that pregnant women with disseminated infection (e.g., herpes, hepatitis, or varicella pneumonia) be treated with acyclovir. No human studies during pregnancy have been carried out with famciclovir.
Human Immunodeficiency Virus Treatment A variety of agents may be used to treat patients with human immunodeficiency virus infection. The medications generally fall into three categories, the nucleoside reverse transcriptase inhibitors (nRTIs), the nonnucleoside analog reverse transcriptase inhibitors (NNRTIs), and the protease inhibitors (PIs). Zidovudine is the most widely studied nRTI, and no adverse effects have been seen over 4 years of follow-up. In the same class of medications, didanosine, stavudine, and lamivudine also seem to be safe. Nevirapine, an NNRTI, has had no reported adverse effects. The PI class has not been as extensively studied.

UPPER RESPIRATORY TRACT COMPLAINTS

The common cold is the most frequent acute illness, and most are self-diagnosed and treated. Medicine used to treat symptoms associated with the common cold are among the most commonly used drugs in pregnancy. Most patients complain of fatigue, malaise, rhinorrhea, nasal congestion, cough, and sore throat. The cold can be caused by a variety of viruses, rhinoviruses, coronaviruses, respiratory syncytial virus, adenovirus, parainfluenza and influenza viruses, and others. Therefore, in the absence of a complicating superinfection with bacteria, antibiotic treatment is not appropriate.

The most common treatments are used to alleviate the symptoms listed above and include antihistamines, decongestants, and cough remedies.

Antihistamines

Most antihistamines are safe during pregnancy. Brompheniramine (Bromfed) was associated with an increased relative risk of malformations in the Collaborative Perinatal Project but not the Boston Collaborative Drug Surveillance Program. Other safe antihistamines include chlorpheniramine, clemastine, diphenhydramine, and doxylamine.

There are newer antihistamines with little or no data in pregnancy and are best used as second-line therapy. These include astemizole (Hismanal), cetirizine (Zyrtec), loratadine (Claritin), and fexofenadine (Allegra).

Decongestants

The most common oral decongestants are all sympathomimetic agents and include pseudoephedrine, phenylephrine, and phenylpropanolamine. There have been some reports of an association with gastroschisis and first-trimester maternal exposure to pseudoephedrine. In the first trimester, an alternative would be to try use of topical preparations, including the nasal decongestants oxymetazoline (Afrin) and phenylephrine (Neo-Synephrine).

Cough Suppressants

Codeine and dextromethorphan are the most common cough suppressants. Neither has been associated with a teratogenic effect.

Most cold treatments including the antihistamines, decongestants, and cough suppressants are safe during breast-feeding.

ASTHMA TREATMENT

Although the cold is the most common acute illness during pregnancy, asthma is the most common chronic respiratory condition. About 5% of pregnancies are complicated by asthma, and it may cause increases in preterm birth, low birth weight, and other complications. Whether aggressive and active management reduces these risks to the background level is a controversial issue. Asthma is characterized by airway inflammation and hyperreactivity.

Treatment of the asthmatic should start with reduction of environmental factors that worsen the disease. All patients should receive the influenza vaccination yearly. Allergens should be avoided, as should both active and passive exposures to cigarette smoke. For patients who do not respond optimally to these environmental alterations, a variety of pharmacologic treatments are available (Table 7.3).

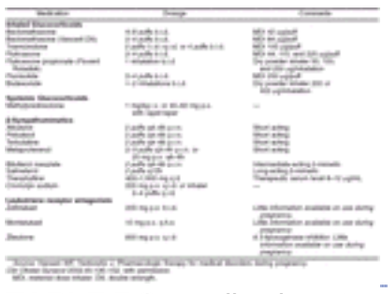

TABLE 7.3. *Medications to treat asthma*

ß-Sympathomimetic Agents

The short-acting ß-sympathomimetic agents are the first-line treatment for acute asthma exacerbations. Albuterol inhalers (Proventil, Ventolin) are commonly used. Terbutaline and metaproterenol inhalers are acceptable alternatives. No teratogenic risks have been ascribed to these medications and all are compatible with breast-feeding. For longer term treatment salmeterol, a long-acting ß-sympathomimetic agent, is available and safe.

All of the ß-sympathomimetic agents can cause tachycardia and other cardiovascular effects. These are usually mild and self-limited.

Glucocorticoids

Inhaled glucocorticoids are also first-line therapy. They act by reducing inflammation. Agents include beclomethasone, fluticasone, and others. No teratogenicity for inhaled steroids has been seen, and they are compatible with lactation.

Systemic glucocorticoids also can be used for acute exacerbations but may increase the risk for cleft lip and palate up to five-fold.

Theophylline

Theophylline was at one time a first-line agent for treatment of asthma, but with the emergence of the ß-agonists and inhaled glucocorticoids, its role has been reduced markedly. This agent can be administered intravenously for acute asthma or orally for chronic suppression. The narrow therapeutic window has contributed to this medication falling out of favor. Used for many years, theophylline has shown no evidence of teratogenicity, and it can be used during breast-feeding.

Cromolyn Sodium

Cromolyn sodium is used for long-term therapy in patients with atopy, functioning as a mast cell stabilizer. Administered by inhaler, there are no known teratogenic or lactation concerns.

Leukotriene Receptor Antagonists and Lipoxygenase Inhibitors

The leukotriene receptor antagonists (zafirlukast, montelukast) and the 5-lipoxygenase inhibitors affect the inflammatory pathways. These agents are new, and human data are few to none. Given sparse data, if these agents can be avoided during pregnancy and lactation, other drugs should be used.

GASTROINTESTINAL DISORDERS

Gastrointestinal problems are extremely common in pregnancy and include nausea, vomiting, hyperemesis gravidarum, gastroesophageal reflux, intrahepatic cholestasis of pregnancy, and inflammatory bowel disease. The clinical picture of several serious disorders may be altered or overlooked during pregnancy and include appendicitis, cholecystitis, pancreatitis, hepatitis, and carcinoma of the gastrointestinal tract.

Nausea and vomiting, or morning sickness, occurs in as many as 90% of pregnancies. Nonpharmacologic treatment can include acupressure at the Neiguan point (2 inches proximal to the wrist crease between the tendons of the flexor carpi radialis and palmaris longus muscles), which may be of benefit. Ingestion of ginger appears to reduce nausea and vomiting in pregnancy. Pyridoxine, vitamin B_6, also appears to reduce symptoms. Pharmacologic treatment can include use of antihistamines, antidopaminergics, and other agents (Table 7.4).

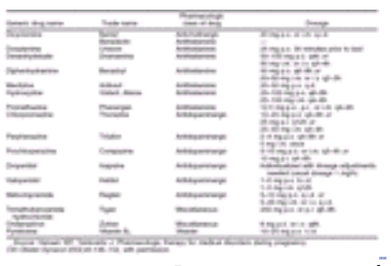

TABLE 7.4. *Drugs commonly used for management of nausea, vomiting, and hyperemesis gravidarum*

Antihistamines

Doxylamine (Unisom) is an antihistamine that was a component of Bendectin (doxylamine and pyridoxine). An effective treatment for the nausea and vomiting of pregnancy, Bendectin was withdrawn from the American market in 1983 because of unproved allegations that it increased the risk of malformations. Doxylamine can be combined with pyridoxine, reconstituting the two active ingredients of Bendectin. Other commonly used antihistamines include dimenhydrinate (Dramamine); diphenhydramine (Benadryl); hydroxyzine (Vistaril, Atarax), which has both antianxiety and antihistamine properties; and promethazine (Phenergan), which has a central cholinergic blocking activity.

Antidopaminergic Agents

Several antidopaminergic agents have been used in pregnancy and are probably safe. The list includes prochlorperazine (Compazine), metoclopramide (Reglan), chlorpromazine (Thorazine), perphenazine (Trilafon), droperidol (Inapsine), and haloperidol (Haldol). There tend to me more maternal side effects with these medications than with the antihistaminic agents. There are also some conflicting data about possible minimal increased risks of birth defects with the latter members of

the group. I tend to suggest use of the prochlorperazine or metoclopramide as first-choice agents in this class. These agents are probably safe in breast-feeding, but some require observing the neonate for sedation.

Other Agents

Trimethobenzamide (Tigan), which provides nausea inhibition at the chemoreceptor level, and ondansetron (Zofran) have been used, but there is less experience with these agents, and certainly the latter is much more expensive with no greater efficacy than standard antihistamines.

Reflux or heartburn is a common complaint during pregnancy, particularly in later gestation. Up to 80% of women may have some symptoms of reflux or heartburn. As with hyperemesis, starting with the least invasive environmental or lifestyle changes is prudent. Advice includes elevation of the head of the bed while sleeping, wearing loose clothing, eating frequent small meals that are low in fat, and cessation of smoking. Antacids would then be the first-line therapy (Table 7.5) and are not known to be associated with any fetal risk. The next class of agents is the histamine receptor antagonists, which can have a reduced bioavailability following antacid use. Therefore, the antacids and the histamine receptor antagonists should be given at least 1 hour apart. The histamine antagonists include cimetidine (Tagamet), famotidine (Pepcid), ranitidine (Zantac), and nizatidine (Axid). There are limited data concerning nizatidine, so the first three would be initial choices. All are compatible with breast-feeding. Promotility drugs can be used and include metoclopramide (described above) and cisapride (Propulsid), about which little has been reported. Sucralfate (Carafate) inhibits pepsin activity and may improve symptoms. The proton pump inhibitors are relatively new agents and, therefore, I would not recommend them. Misoprostol, a prostaglandin E_1 analog, is contraindicated in pregnancy.

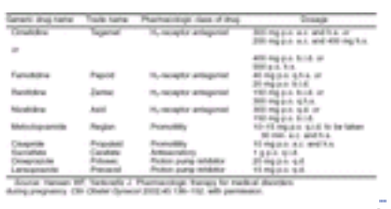

TABLE 7.5. *Drugs commonly used for gastroesophageal reflux in pregnancy*

Intrahepatic cholestasis of pregnancy causes itching of the extremities, trunk, palms, and soles. The pruritus can worsen at night and become severe. In the past, cholestyramine (Questran) was the treatment of choice. Cholestyramine is a nonabsorbable anion exchange resin that binds bile acids, which are elevated in cholestasis. There is now some evidence that ursodeoxycholic acid (UDCA, ursodiol), a minor, naturally occurring hydrophilic bile salt, both reduces maternal pruritus and improves biochemical abnormalities without obvious adverse effects on the newborn. Evidence is accumulating from controlled clinical trials that UDCA is safe. When intrahepatic cholestasis is diagnosed, UDCA coupled with close maternal fetal surveillance is indicated due to potential increases in spontaneous preterm delivery, fetal distress with meconium staining of amniotic fluid, and fetal death.

Inflammatory bowel disease in the form of ulcerative colitis and Crohn disease occur commonly during the reproductive years. Sulfasalazine (Azulfidine) is used for the treatment of both ulcerative colitis and Crohn disease. It is composed of 5-aminosalicylic acid and sulfapyridine. It is poorly absorbed from the gastrointestinal tract and is therefore safe in pregnancy. There is a potential for side effects if used during breast-feeding, so the American Academy of Pediatrics cautions women about use of sulfasalazine during lactation. Mesalamine (Asacol) also can be used during pregnancy and may have fewer maternal side effects than the sulfasalazine. Azathioprine is an immunosuppressant and appears safe to use during pregnancy.

ANALGESIC USE

Analgesics, both by prescription and over-the-counter purchase, are among the most commonly used medicines in pregnancy. This class of drugs basically falls into two categories, the nonsteroidal antiinflammatory agents and the opioid family.

Nonsteroidal Antiinflammatory Drugs

Aspirin is one of the nonsteroidal antiinflammatory drugs (NSAIDs) and acts by irreversible inhibition of enzymes in the prostaglandin synthesis pathway. Caution certainly should be advised in use of aspirin beyond the lowest daily dosages, because this drug readily crosses the placenta. First-trimester use has been associated with an increased risk of gastroschisis. Although dosages at or below 100 mg per day have been studied to determine whether there is a reduction in preeclampsia or intrauterine growth restriction without complications, higher dosages have been associated with increased risk of placental abruption. The World Health Organization Working Group on Human Lactation and the American Academy of Pediatrics Committee on Drugs both raise concern about maternal use of aspirin while breast-feeding.

Indomethacin and ibuprofen are commonly used NSAIDs that cause competitive and reversible inhibition of prostaglandin synthesis. These NSAIDs can cause constriction of the fetal ductus arteriosus as gestational age progresses and, therefore, their use is not suggested after about 32 weeks gestation. They have not been shown to cause malformations, but use beyond the first trimester can cause oligo- or anhydramnios secondary to direct renal effects. Both indomethacin and ibuprofen are considered compatible with breast-feeding.

Acetaminophen is widely used in pregnancy. It crosses the placenta but is considered safe in the usual dosages. It can be used routinely in all trimesters to relieve pain and lower fevers. It is usually the analgesic of choice for a wide variety of aches, pains, and headaches. It is compatible with breast-feeding.

Opioid Analgesics

Many narcotic preparations are available and are used during pregnancy. They all cross the placenta but have not been associated with malformations when used in usual dosages. Use close to delivery can result in neonatal depression. The common narcotics, codeine, meperidine, and oxycodone, are all compatible with breast-feeding.

PSYCHIATRIC DISORDERS

Major depression (15% incidence) and schizophrenia (8%-10% incidence) are very common during the reproductive years. As with any medication, there are concerns about teratogenesis, neonatal withdrawal, or long-term neurobehavioral effects, but these issues must be balanced by the risks to the mother and fetus or infant of withdrawing the necessary medication (Table 7.6).

Medication	Dosage
Amitriptyline	25–50 mg q.h.s.
Chlorpromazine	100 mg q.d. or b.i.d.
Desipramine	25–50 mg q.h.s.
Fluoxetine	10–20 mg q.h.s.
Haloperidol	5–10 mg/d
Imipramine	25–50 mg q.h.s.
Lithium	0.6–2.1 g/d in 3 divided doses
Nortriptyline	10–25 mg q.h.s.

Source: Hansen WF, Yankowitz J. Pharmacologic therapy for medical disorders during pregnancy. *Clin Obstet Gynecol* 2002;45:136–152, with permission.

TABLE 7.6. *Starting dosages for psychotropic medications in pregnancy*

The tricyclic agents have been widely used to treat depression and also anxiety, obsessive compulsive disorders, migraines, and other problems. None of the tricyclics has been associated with malformations. If needed, it would be prudent to use the agents with the most accumulated experience, including nortriptyline, desipramine, amitriptyline, and imipramine. There is no evidence to date of clear adverse neonatal effects during breast-feeding, but the American Academy of Pediatrics considers the effects of amitriptyline and imipramine unknown but of concern for the nursing infant.

The selective serotonin reuptake inhibitors (SSRIs) include fluoxetine and the newer agents, fluvoxamine, paroxetine, and sertraline. Extensive experience with

fluoxetine shows no clear increased risk of malformations. There is much less experience with the newer agents, but none of the data indicates a teratogenic effect. The effects on the infant of the group of drugs that includes fluoxetine are unknown but may be of concern in relation to breast-feeding. The patient should weigh the strength of her desire to breast feed and the benefits of breast-feeding against the potential effects of continued SSRI use.

Other agents are prescribed for depression. Monoamine oxidase inhibitors have not been studied sufficiently to draw a conclusion about their safety. The psychostimulants may cause problems following in utero exposure and are best avoided. St. John's wort, an extract of the plant *Hypericum perforatum*, has been touted for antidepressant properties, but recent studies have not proven efficacy, so this medication should also be avoided.

The mood stabilizers, specifically lithium, valproic acid, and carbamazepine, have all been identified as teratogens. The data on lithium causing malformations have weakened with additional studies. Initial reports found a 5% to 10% risk of malformations with a markedly increased risk of Ebstein anomaly. More recent reports show little, if any, increased risk of malformation and have failed to confirm the specific association with Ebstein anomaly. For the patient with a first-trimester exposure to lithium, targeted ultrasonography in the second trimester is warranted. Lithium also has been associated with hydramnios, possibly secondary to fetal diabetes insipidus. Although there is little data, the American Academy of Pediatrics considers lithium to be contraindicated during lactation.

Valproic acid and carbamazepine are both associated with an increased risk of neural tube defects, so second-trimester serum screening for a-fetoprotein and targeted ultrasonography are warranted. Yet many of the neural tube defects are closed and difficult to detect.

The antianxiety agents generally fall into the benzodiazepine family. There have been reports of an increased risk of cleft lip after exposure not substantiated in other reports. Although the odds ratio may have been increased, the absolute rate of clefting would still be low given a rate of only 0.06% in the normal population. The American Academy of Pediatrics states that the effects on the neonate during lactation are unknown but may be of concern.

The antipsychotic agents include the butyrophenones (including haloperidol) and phenothiazines. No clear teratogenic effect has been seen with either group. Haloperidol is classified as having an unknown but possibly concerning effect if used during lactation.

VITAMIN AND MINERAL USE

Prenatal use of multivitamins, often with additional iron, is commonly advocated by many health care providers for pregnant women. There is clear evidence that the folate component reduces the first occurrence and recurrence rate of neural tube defects. Other studies point to possible reduction in cardiac and urinary tract abnormalities. For the woman who eats a balanced diet, most of the recommended daily allowances should be obtained except for folate and iron. However, there are multiple at-risk populations that may not attain the goals, including those patients with eating disorders, vegetarians, the poor, substance abusers, women carrying multiple gestations, and so on.

The only clear teratogenic vitamin is vitamin A which, when used at over 10,000 IU per day, can cause cranial neural crest anomalies. It would be prudent to not exceed 5,000 IU per day in supplementation.

Supplementation of iron can improve hematocrit at the time of delivery and 6 weeks postpartum. Some studies have shown a benefit of calcium in reducing the risk of gestational hypertension and preeclampsia, although other studies fail to confirm this finding. Zinc may increase birth weight and head circumference in populations with zinc deficiency, but probably not in the United States.

RECREATIONAL DRUG USE

Recreational drug use is a major problem in the United States. Anonymous testing studies have found rates of positivity from 7.5% to over 13% in a variety of populations, the drugs found including opiates, cocaine, or cannabinoids.

As concerning as the illicit drugs are, the effects of tobacco also are well described and of great impact. Some studies suggest that one sixth of low birth weight incidence could be prevented if women stopped smoking during pregnancy. Nicotine reduces uteroplacental blood flow and increases the risk of preterm birth, low birth weight, and sudden infant death syndrome.

Maternal alcohol use can cause the fetal alcohol syndrome characterized by craniofacial changes and impaired cognitive development. Although the full-blown picture can be seen with excessive consumption, no safe level of alcohol use has been established.

The effects of recreational opioid use appear to be confined to an increased risk of growth restriction, intrauterine fetal death, and neonatal withdrawal. No clear long-term effects have been proven.

Marijuana use during pregnancy has not been linked with any clear teratogenic effect or long-term developmental consequences.

Cocaine use has been associated with an increased risk of placental abruption, preterm premature rupture of membranes, and low birth weight. A variety of congenital abnormalities have been described with maternal cocaine use, but no definite connection has been established. A variety of neurobehavioral effects have been described also, but long-term problems are not clear.

Amphetamine, described as a stimulant for depressed patients, is becoming a commonly abused drug. Although no clear pattern of malformations has been seen, increases in cleft lip and palate have been seen in some, but not all, studies. Concern has been raised about impact on long-term physical growth and intellectual and behavorial development.

ANTICONVULSANT AGENTS

Epilepsy is the most common neurologic disorder in pregnancy. Five percent of the population report having had a seizure at some point in their lives. All antiepileptic drugs (AEDs) cross the placenta and, therefore, have potential for teratogenicity (Table 7.7). Given the incidence of epilepsy, 1 in 250 fetuses is exposed to an AED. Recent studies are making it clear that the AEDs are responsible for the congenital malformations found in the offspring of pregnant women with epilepsy, not the epilepsy, itself, as has been conjectured in the past.

Drug	Dosage and comments
Phenytoin (Dilantin)	300–600 mg/d in divided doses, therapeutic level: 10–20 μg/mL
Carbamazepine (Tegretol)	200–1,200 mg/d, therapeutic level: 4–12 μg/mL
Phenobarbital	60–240 mg/d, therapeutic level:10–40 μg/mL
Valproic acid (Depakote)	10–15 mg/kg per day, therapeutic level: 50–100 μg/mL
Ethosuximide (Zarontin)	500–2,000 mg/d in divided doses, therapeutic level: 40–100 μg/mL
Clonazepam (Klonopin)	1.5–20 mg/d
Gabapentin (Neurontin)	New agent
Lamotrigine (Lamictal)	New agent

Source: Hansen WF, Yankowitz J. Pharmacologic therapy for medical disorders during pregnancy. *Clin Obstet Gynecol* 2002;45:136–152, with permission.

TABLE 7.7. *Anticonvulsants*

Phenytoin (Dilantin) is a hydantoin AED. The fetal hydantoin syndrome includes a constellation of anomalies including craniofacial, limb, and neonatal growth and performance delays. The risk of teratogenicity is about 2 times the background risk. Phenytoin is compatible with breast-feeding.

Carbamazepine (Tegretol) causes a group of defects similar to the fetal hydantoin syndrome, in addition to the increased risk of spina bifida. The risk of spina bifida is about 0.5% to 1.0%. Carbamazepine is compatible with breast-feeding.

Phenobarbital is in the barbiturate class. It has been associated with findings similar to the hydantoin syndrome, as well as with congenital heart defects and orofacial

clefting. Breast-feeding is acceptable unless the infant becomes sedated, in which case breast-feeding should be discontinued.

Valproic acid (Depakote) has a 1% to 2% risk of causing spina bifida. These neural tube defects tend to be in the lumbosacral area. Valproic acid use also has been associated with cardiac defects, orofacial clefting, and genitourinary anomalies. There is a fetal valproate syndrome that includes facial, central nervous system, and limb anomalies. Breast-feeding is permissible while using this medication.

Several newer AEDs have been developed and include felbamate, gabapentin, lamotrigine, and others. Many patients make their first visits to prenatal clinics while taking these medications and having completed the first trimester. We counsel them that, at present, there is no evidence of teratogenicity but that little information is available.

HEADACHES

Headache is a very common problem in pregnancy. Evaluation of headaches requires categorizing the headache as primary or secondary. Secondary headache is due to another condition such as flu, while in the primary category the headache, itself, is the disorder. Primary headaches include migraine, tension-type headache, and cluster headache. Criteria have been developed for differentiating these categories and include frequency, degree of pain, and location of pain.

Sumatriptan is a selective serotonin receptor agonist. There is no evidence that it is a human teratogen, based on limited numbers of patients reported to the Sumatriptan Pregnancy Registry maintained by GlaxoWellcome and patients who contacted a teratogen hotline. Even less data is available about three newer drugs in this class: naratriptan, zolmitriptan, and rizatriptan.

ß-Adrenergic blockers, such as propranolol have been used as preventive therapy. ß-Blockers, calcium channel blockers, and many of the antidepressants discussed earlier have been used as preventive therapy and appear safe in pregnancy and lactation.

ANTINEOPLASTIC AGENTS

Cancer is relatively common during pregnancy, complicating 1 in 1,000 to 1 in 1,500 pregnancies. The most common malignancies include carcinoma of the cervix and breast, lymphoma, melanoma, leukemia, and carcinoma of the ovary and colon. Chemotherapeutic agents act on rapidly dividing cells and are, therefore, potentially harmful to the fetal tissue. The trimester of exposure is, of course, critically important to what potential effect the drug may have. Teratogenesis is a concern in the first trimester, but impact on the continued development of the brain in the second and third trimester is of import. Delivery planning is also important, because both maternal and neonatal blood counts may be adversely affected by the chemotherapy. For the most part, chemotherapeutic drugs are secreted into the breast milk, making breast-feeding contraindicated for the woman receiving this therapy.

Many classes of drugs can be used as chemotherapy. The alkylating agents cross-link DNA. These drugs, including busulfan, chlorambucil, cyclophosphamide, and nitrogen mustard, are all considered teratogens in the first trimester. The antimetabolites are also teratogenic, possibly due to their effects on folic acid metabolism. This class includes aminopterin and methotrexate. Other antimetabolites that do not affect folic acid metabolism, such as the pyrimidine antagonist 5-fluorouracil, 6-mercaptopurine, and cytarabine, have much less frequently been associated with birth defects.

The taxanes, including paclitaxel, have not been used in pregnancy enough to comment on safety. Cisplatin has been used in pregnancy, but most experience is in the second and third trimesters. Growth restriction is common.

The therapy of a pregnant woman with cancer must be individualized and must be based on collaboration among the primary care provider, perinatologist, oncologist, and neonatologist.

ANTICOAGULATION

Thromboembolism is a leading cause of morbidity and mortality in pregnancy and postpartum. In is the second most common cause of pregnancy-related maternal mortality in the United States. Anticoagulation is used for thromboembolism, valvular heart disease, inherited thrombophilias, and acquired thrombophilias such as antiphospholipid antibody syndrome. The agents available (Table 7.8) are the coumarin derivatives, unfractionated heparin, and low-molecular-weight heparin (LMWH).

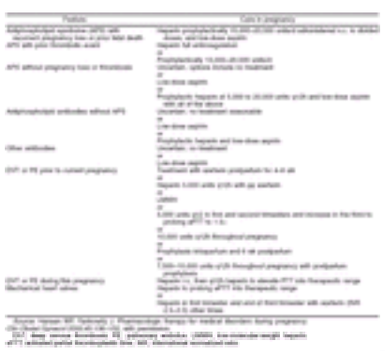

TABLE 7.8. *Anticoagulation in pregnancy*

Thromboembolism occurs in 0.5 to 3.0 of every 1,000 pregnancies. Treatment of acute deep vein thrombosis includes bed rest, elevation of the extremity to promote venous return, and heparin. Heparin is used with a target activated partial thromboplastin time (aPTT) of 1.5 to 2.5 times control. For pregnant patients, a switch to subcutaneous heparin takes place after 3 to 5 days, as opposed to the initiation of warfarin in the nonpregnant state.

Anticoagulation in a patient with artificial heart valves can be a difficult dilemma. For those with particularly thrombogenic valves it may be necessary to consider oral anticoagulation. For the inherited and acquired thrombophilias, use of unfractionated or LMWH probably is acceptable.

Use of the oral anticoagulant warfarin sodium (coumadin) is problematic, because there is a known teratogenic effect. This agent easily crosses the placenta. Warfarin depresses the vitamin K-dependent clotting factors (II, VII, IX, and X). Its effectiveness is measured by the prothrombin time (PT), expressed as an international normalized ratio (INR). The first case of teratogenicity of warfarin was reported in 1966, and this infant had nasal hypoplasia, bilateral optic atrophy, blindness, and mental retardation. In a review of all published cases up to 1980, one sixth had abnormalities, and another one sixth ended in stillbirth or spontaneous abortion. Two thirds of exposed pregnancies had a normal outcome. Some reports cite a teratogenic effect in up to two thirds of fetuses exposed between 6 and 12 weeks gestation. Other reports state that the embryopathy affects as few as 5% to 10% of fetuses exposed in the first trimester. The problem is in differing dosages and nature of neonatal evaluation.

It appears that neither unfractionated heparin nor LMWH crosses the placenta to any appreciable degree and is, therefore, not teratogenic. Patients can develop heparin-induced thrombocytopenia at about 2 weeks after initiation of therapy. Osteopenia is a problem with prolonged use. Both of the latter complications are more common with unfractionated heparin.

All three classes of anticoagulants are compatible with breast-feeding.

RADIOLOGIC EXAMINATIONS

Many women require diagnostic imaging studies during pregnancy. The two main concerns are exposure to ionizing radiation and effects of contrast agents. The vast majority of data derives from relatively few pregnant women exposed to high doses of radiation from the atomic bombs dropped over Hiroshima and Nagasaki. From these few individuals it has been extrapolated that there is a threshold dose of at least 5 rads required to cause concerning effect on the developing fetus. The particular effect depends on gestational age at exposure and radiation dose (Table 7.9). Lethality may be possible during preimplantation with doses as low as 5 rads, but by 9 days postconception at least 25 to 50 rads is needed. Malformations occur only between about 9 and 60 days postconception, and the threshold is at least 10

rads. Mental retardation is possible between 61 and 104 days postconception, with a threshold of 12 rads.

Defect and gestational age	Occurrence	Threshold	Risk per rad
Lethality			
0–8 days (PC) maximum	+++	5–10 rads	1%
9–60 days	+	25–50 rads	ND
61–104 days	+	50 rads	ND
105–175 days	—	—	—
>175 days	—	—	—
Malformation			
0–8 days	—	—	—
9–60 days	+++	10–20 rads	0.50%
61–104 days	—	—	—
105–175 days	—	—	—
>175 days	—	—	—
Mental Retardation			
0–8 days	—	—	—
9–60 days	—	—	—
61–104 days	+++	12 rads	0.40%
105–175 days	+	65 rads	0.10%
>175 days	—	—	—
Microcephaly			
0–8 days	—	—	—
9–60 days	++	10–20 rads	1%
61–104 days	++	10–20 rads	1%
105–175 days	—	—	—
>175 days	—	—	—
Growth Retardation			
0–8 days	—	—	—
9–60 days	+++	5–25 rads	ND
61–104 days	++	5–25 rads	ND
105–175 days	—	—	—
>175 days	—	—	—

PC, postconception; ND, no data; —, no observed effect; +, demonstrated effect; ++, readily apparent effect; +++, occurs in high incidence.

TABLE 7.9. *Risks of irradiation per gestational age*

Due to increasing concern about the escalating number of rads of exposure inherent in newer computed tomography (CT) technology, the University of Iowa Department of Radiology has developed a protocol to avoid unnecessary exposures and adequately counsel the pregnant patient. Counseling includes a discussion of a 1.5-fold to 2-fold increased risk in childhood leukemias for a 1-rad to 2-rad exposure in the midtrimester and into the third trimester. It is important to be aware of typical radiation exposures of commonly used examinations (Table 7.10) but also to enlist the expertise of a radiation physicist to assist in calculation of doses in specific cases.

Chest x-ray	2–8 millirads
Dental x-rays	<1 millirad
Mammography	7–10 millirads
Abdominal x-ray	200–700 millirads
Lumbar spine x-ray	300–600 millirads
Hip x-ray	200–500 millirads
Upper GI series	100–550 millirads
Barium enema	800–1,300 millirads
Intravenous pyelogram	600–1,000 millirads
Cholecystography	100 millirads
CT head	50 millirads
CT chest	1,000 millirads
CT abdomen	3,000–4,000 millirads
CT pelvimetry	250 millirads
Cardiac catheterization	<500 millirads

GI, gastrointestinal; CT, computed tomography.

TABLE 7.10. *Typical radiation exposure to the fetus for selected diagnostic studies (1 rad = 1,000 millirads)*

Nuclear medicine studies involve exposure to ionizing radiation from a variety of isotopes. In most cases the fetal dose will be less than 1 rad except for sodium iodide, Ga67, iodinated red blood cells, or Ti201. Iodine-131 can cause fetal thyroid damage, goiter, and local effects when concentrated by the fetal thyroid after 70 days post-LMP. Use of iodine-131 to treat hyperthyroidism or ablate the thyroid can result in substantial fetal dosage.

The most widely used radioisotope in pregnancy is technetium-99. It can cross the placenta, but the amount of radiation from any routine study is small.

Magnetic resonance imaging (MRI) involves exposure to magnetic fields rather than ionizing radiation. There are few studies evaluating the effects of MRI on fetuses. There are also virtually no data on gadolinium, a nonionic contrast agent typically used for MRI evaluations. For this reason, MRI is reserved for situations when it clearly is clinically warranted.

COMPLEMENTARY AND ALTERNATIVE THERAPY

Complementary and alternative therapy includes acupuncture, acupressure, massage, aromatherapy, and herbal preparations (phytomedicine). A wide variety of herbs are used but they have received limited scientific evaluation. Thus, safety and efficacy cannot be addressed clearly. Certain ingredients should be avoided altogether and include anthraquinone and berberine, which may stimulate uterine contractions. Many other herbs are thought to have similar properties and should be avoided. Patients should be queried about use of complementary medicines. An effort should be made to determine the constituents of a preparation and then evaluate the safety of each component.

SUMMARY POINTS

- Disease treatment in the pregnant patient should be similar to that given to other patients.
- Rather than using the FDA Drug Classification System, references and information in databases should be sought for particular medications in specific clinical situations.
- Most drugs are safe to use during pregnancy, including most antibiotics and medications to treat common conditions, such as upper respiratory tract and gastrointestinal complaints.
- A few medications are known teratogens, and the list includes coumadin, lithium, the anticonvulsive medications, several antineoplastic drugs, and vitamin A and its derivatives.
- Most drugs are safe during lactation because the amounts that appear in breast milk are subtherapeutic, approximately 1% to 2% of the maternal dose. One notable exception is lithium.

Introduction
General Principles
Documentation and the Basic Ultrasonographic Examination
Techniques of Fetal Testing

The use of ultrasonography in obstetrics and gynecology has made sweeping changes in the management of pregnant patients. The purpose of this chapter is to review existing recommendations regarding the use of ultrasonography in pregnancy. The background setting of a patient's progress in pregnancy—from her initial visit confirming an intrauterine pregnancy through the anatomic survey to her third-trimester testing—was chosen. Many excellent textbooks dedicated to obstetric ultrasonography already exist. This chapter is intended to provide information about current ultrasonographic practice, guidance for performing the examination, and assistance in recognizing common anomalies. Future ideas and new technology will be reviewed at the end of the chapter.

Most ultrasound providers recognize two categories of examination: a basic ultrasonographic examination that includes a routine anatomic survey, estimate of gestational age, evaluation of placenta and amniotic fluid, and evaluation of maternal anatomy; and a more comprehensive examination that may be targeted based on the abnormal findings in a basic examination. In the past, the terms “level I” and “level II” examination were used erroneously to describe these two categories. Such classification schemes must be avoided to prevent misguided patient and physician expectations for the purposes of the examination. Every ultrasonographic examination should be as complete as possible within the limits of the provider and equipment. An ultrasonogram performed simply for the purpose of sex determination that fails to identify an anencephalic fetus has certainly done only harm. A limited ultrasonographic examination for a specific purpose, such as evaluation of fetal presentation, is appropriate in cases in which the pregnancy has been examined previously or in a clinical emergency.

GENERAL PRINCIPLES

Ultrasound images are generated using the same principle as sonar. High-frequency sound waves (3.5-7.5 MHz) pass from the surface of the ultrasound transducer through the tissues of the imaging target. Echoes of the transmitted sound waves return to the transducer. Because the average speed of ultrasound in human tissue is known (1,540 m/s), the distance of the reflector from the transmitter can be calculated using the time required for the echo to return. The resulting depth and signal strength data are plotted on a display screen. The position on the screen corresponds to the depth in the tissue. The brightness of the picture element corresponds to the strength of the return signal. Ultrasound systems display a black background and use increasingly bright shades of gray and white to represent stronger echoes.

The acoustic impedance for a tissue determines the degree to which that tissue reflects or transmits ultrasound energy. Because the acoustic impedance of tissue varies by density and consistency, interfaces between dissimilar tissues and within heterogeneous tissues act as reflectors that echo part of the transmitted signal back to the transducer. The degree of dissimilarity between one tissue type and the next determines the strength of the return echo received. Simple fluids such as water or amniotic fluid generate very few echoes, because they are homogeneous. Bone generates very strong echoes because the adjacent soft tissues have very dissimilar acoustic properties, producing a marked acoustic impedance mismatch. The strength of the return echo also depends on the angle between the face of the reflector and the ultrasound beam. As the reflector becomes closer to perpendicular with the transmitting source, a greater proportion of the echo is received. This property is well illustrated by the midline structures of the fetal brain, which are imaged best when perpendicular to the incident beam. The strength of the transmitted signal, which is controlled by the ultrasound operator, also contributes to the strength of the return echo.

Transducers spend only a small fraction of the time generating the ultrasound signal compared with the time spent detecting return echoes. The duty factor, expressed as the time spent transmitting divided by the time spent listening, is on the order of 0.01 for modern equipment. When a patient has an ultrasonographic examination lasting 20 minutes, the maternal and fetal total exposure to ultrasound energy is only 12 seconds. This exposure increases when Doppler sonography is employed due to the longer energy pulses.

The American College of Obstetricians and Gynecologists (ACOG) and American Institute of Ultrasound in Medicine (AIUM) recommend that ultrasound systems used for obstetrics display the thermal index (TI) and mechanical index (MI) of acoustic output on the screen. The TI is an estimate of the increase in temperature in tissue due to conversion of mechanical energy from the ultrasound beam to heat. Values of the TI less than 1.0 are not of concern for generating significant temperature changes. Temperature increases are most likely to occur during Doppler ultrasonography because of the larger duty factors. The MI estimates the compressive and decompressive forces caused by the ultrasound beam. If these mechanical forces are excessive, microscopic bubbles might form in the tissue being imaged. This bubble formation is called cavitation. As long as the MI values are less than 1.0, cavitation is not a concern.

The Food and Drug Administration has set the upper limit of acoustic intensity at 94 mW/cm ^{2} (spatial peak temporal average) for obstetric ultrasonography. For other applications, ultrasound systems are limited to a maximum output of 720 mW/cm ^{2}. Furthermore, the systems must display the TI and MI if either or both of these indices can exceed 1.0. Because many systems can be used for both obstetric and nonobstetric ultrasonography, the provider should be aware of the acoustic output and TI and MI of the system in use. Overuse of power Doppler and color Doppler imaging is especially noteworthy as settings in which the recommended maximums could be exceeded. The ALARA principle (*a*s *l*ow *a*s *r*easonably *a*chievable) has been suggested to govern the amount of fetal exposure to ultrasound energy while obtaining useful image data. The ultrasound provider should also remember that although there are no *known* bioeffects of diagnostic ultrasonography, future discoveries of adverse effects are certainly possible. As such, obstetric ultrasonography should be used only when indicated (Table 8.1).

TABLE 8.1. *Indications for ultrasonography in pregnancy*

Ultrasonographic images are most correctly described using terms that acknowledge sound as the source of the image. Highly sound-reflective structures that produce large reflections and correspondingly bright screen images are called hyperechoic or hyperechogenic structures. Regions that produce very few echoes are termed hypoechoic or hypoechogenic. Regions that are echo free are termed anechoic. The reader is encouraged to avoid terms such as translucent or sonolucent, which are derived from the Latin root *lucere*, meaning “to shine.”

INDICATIONS

The currently accepted ACOG recommendations for ultrasonographic examination in pregnancy are based on the opinion of a National Institutes of Health consensus

panel and are summarized in Table 8.1.

Several studies have addressed the question of whether routine ultrasonographic screening for all pregnancies should be performed. Recommendations from ACOG, based on an analysis of existing literature, suggest that women with low-risk pregnancies should not receive screening ultrasonography unless medically indicated. Thus far the evidence indicates that there is no reduction in perinatal morbidity or mortality from routine ultrasonographic screening in the low-risk population. The rate of unnecessary interventions in pregnancies screened with routine ultrasonography is also unchanged. There are not yet enough data to conclude whether fetuses with life-threatening anomalies have an improved outcome because of routine ultrasound use.

Although these studies demonstrate that routine ultrasonography in the low-risk pregnancy is not effective in improving perinatal mortality or morbidity, there are articles and editorials challenging those conclusions. Many of these studies offered routine screening to all patients except those who would stand to benefit most. Furthermore, a population agreeing to participate in a randomized study of routine screening does not necessarily constitute an accurate cross-section of the intended study population. The ability to perform a physical examination on the second patient—the fetus—is important. When performed with adequate equipment by properly trained personnel, prenatal ultrasonographic examinations can and do offer important information to the provider and patient.

Good evidence exists to demonstrate that fetal anatomic surveys are over 99% specific in detecting anomalies; that is, when ultrasonographic examination findings are normal, the fetus will indeed be normal over 99% of the time. The sensitivity of the anatomic survey, or the probability that an ultrasonogram will demonstrate an anomaly if one is present, varies widely depending on the ultrasound provider, the quality and age of the ultrasound system, the anomaly in question, and the frequency of the anomaly in the practitioner's own population. For this reason, it is recommended that ultrasound specialists perform examinations for genetic screening or evaluation of abnormal scan results.

FIRST TRIMESTER

With the advent of extremely sensitive home pregnancy tests which can detect human chorionic gonadotropin (hCG) levels down to 20 to 30 mIU/mL, the early diagnosis of pregnancy is now within reach of the typical consumer. Initial visits to the obstetrician can occur earlier instead of later, sometimes even before the first missed menstrual period.

Ultrasonographic examinations in the first trimester should be performed with transvaginal imaging and augmented with transabdominal imaging, if necessary. Although first-trimester detection of an intrauterine gestation is possible, it still is limited by the size of the gestation. Corresponding levels of serum ß-hCG help to determine a threshold level at which sonographic evidence of an intrauterine pregnancy should be detected. Various sources place this level between 1,500 and 2,000 mIU/mL for transvaginal sonography and 3,000 and 5,000 mIU/mL for the transabdominal approach. Protocols have been developed for the management of patients with a positive pregnancy test but no ultrasonographic evidence of intrauterine gestation. This scenario may be of concern for ectopic pregnancy, especially when there is pain or vaginal bleeding. In the clinically stable patient, a repeat ultrasonogram in 3 to 7 days may yield more useful information and help avoid errors in management.

Two methods are commonly used for determining the gestational age in the first trimester. These are the mean sac diameter (MSD) and the more accurate crown-rump length (CRL). The MSD is determined by two methods. The method selected depends on the reference table used to determine the gestational age. The first method involves imaging the sac and measuring the longest axis (length) and the largest axis perpendicular to the long axis (width). These two orthogonal measurements are averaged and the value used to estimate a gestational age. The second technique requires the addition of the depth of the sac from an image that is transverse and perpendicular to the length. The three values are averaged and an appropriate table used (Fig. 8.1). The CRL is measured from an image of the fetus that includes the maximum distance from the cephalic pole to the caudal pole. Although the CRL is regarded as highly accurate in determining the gestational age, the biparietal diameter (BPD) in the late first trimester and before 20 weeks of gestation offers comparable accuracy. The MSD is more useful if no embryo is present in a gestational sac. The identification of a yolk sac or an embryo determines that a gestational sac is present. Using transvaginal ultrasonography, an embryo should be seen by 5 to 6 weeks of gestation as measured from the first day of the last menstrual period. By the time the CRL equals 5 millimeters, cardiac activity should be seen. If the CRL is less than 5 millimeters, the examination should be repeated. Table 8.2 lists the signs of an abnormal gestation. If the patient is at 6 weeks of gestation with a positive pregnancy test and there is no gestational sac visualized in the uterus, an ectopic pregnancy is highly suspect.

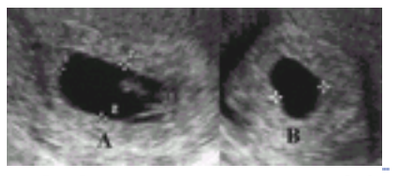

FIG. 8.1. Measurement of the mean sac diameter (MSD). The distances measured by the calipers in the longitudinal axis (**A**, number one) and the depth (**A**, number two) and the transverse diameter measured in **(B)** are added together and divided by three to produce the MSD. Some authors use only the sum of the longitudinal and depth measurements divided by two.

Greater than 16 mm MSD without an embryo
Greater than 13 mm MSD without a yolk sac
No fetal heart activity in an embryo with a CRL greater than 5 mm
Yolk sac without an embryo by 6 wks gestation
No gestational sac by 6 wks
Markedly distorted gestational sac
Visualization of the amnion without an embryo

MSD, mean sac diameter; CRL, crown-rump length.

TABLE 8.2. *Signs of an abnormal gestation*

The obvious diagnosis of an ectopic pregnancy, in which a small gestational sac with cardiac activity present is seen outside the uterus, can be made even when serum ß-hCG levels are not at the threshold for determination of intrauterine pregnancy. The more difficult ectopic pregnancy cases usually involve abnormal adnexal findings such as ovarian or paratubal cysts, free peritoneal or pelvic fluid, but no definite pregnancy sac. The pseudogestational sac may be seen when the endometrium responds to chemical changes of pregnancy and may resemble a fluid-filled structure within the endometrial cavity. Some authors describe a *ring of fire* that may be seen around ectopic pregnancies developing in the adnexa when evaluated with color Doppler interrogation or power Doppler imaging (Fig. 8.2). The ring represents increased blood flow about the developing embryo, but it is possible for a corpus luteal cyst or even normal ovarian tissue to demonstrate such a ring. It is recommended that further diagnostic information be gathered, using sequential determination of serum ß-hCG levels and clinical findings, as long as the clinical situation is stable.

FIG. 8.2. Ring of fire. A corpus luteum **(A)** can be confused with an ectopic pregnancy **(B).** The *arrow* indicates blood flow in the embryo **(B).** (From Diana M. Strickland, RDMS, RDCS; with permission.) See color figure 8.2.

When the serum ß-hCG levels are abnormally high (greater than 100,000 mIU/mL) for the estimated gestational age by last menstrual period dating or by the uterine size, the diagnosis of molar gestation should be entertained. The classic “snowstorm” description of ultrasonographic imaging in molar gestation has been discarded to reflect the improved resolution of ultrasound transducers. A complete molar pregnancy, in which no fetal tissue is identified, may demonstrate clusters of vesicles on ultrasonographic examination. Identification of a partial molar pregnancy is more difficult, but it may be suggested by the presence of a fetus with a cystic or multicystic placenta (Fig. 8.3). The fetus might demonstrate numerous anomalies, including findings consistent with triploidy.

FIG. 8.3. Partial mole. The placenta appears cystic and enlarged for gestation. No fetal heartbeat was noted and, although fetal tissue was found at pathology, no chromosome studies were obtained.

During imaging of the early fetus several important features should be visualized. The number of fetuses in the uterus should be reported. A multiple gestation should not be diagnosed until the yolk sacs or embryos can be counted. This will avoid counting the empty gestational sac of an anembryonic pregnancy or blighted ovum as a viable pregnancy. Early gestation may be the best possible time to determine the amnionicity and chorionicity of multiple gestations, information of crucial importance in the later management of these pregnancies. A thick rim of tissue surrounding each fetus is more suggestive of dichorionic, diamniotic gestations. If the intervening tissue is thin or absent, monochorionic, diamniotic, or even monoamniotic gestations are more probable. Conjoined twins may also be detected in the first trimester (Fig. 8.4). Determination of zygosity is possible only if a monoamniotic with monochorionic or diamniotic with monochorionic configuration is found, in which case the twins are monozygotic. Placentation in multiple gestations is often an important clue in determining zygosity and the risk of twin-to-twin transfusion syndrome. The single placenta associated with monochorionic monoamniotic twinning can be identified during the first and second trimesters. A fused placenta will appear as a single placenta but with the additional finding of dichorionic diamniotic membranes (Fig. 8.5). Determination of fetal sex also may be helpful in determining zygosity.

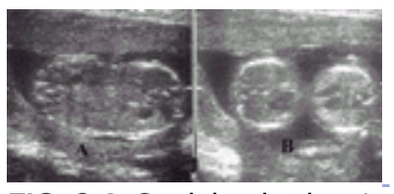

FIG. 8.4. Conjoined twins. In **(A)** the twins are joined at the abdomen (abdominophagus) and separated at the chest **(B).**

FIG. 8.5. Fused placenta with diamniotic, dichorionic membranes. The fused chorions *(open arrow)* are noted between the amnions *(closed arrow)* of each twin. The twins could be either mono- or dizygotic.

The fusion of the expanding amnion with the chorion, obliterating the intervening space, occurs around 12 weeks. Prior to this union, the unfused amnion may be seen as a wispy echogenic membrane surrounding the developing fetus and should not be confused with a gestational sac (Fig. 8.6). It is theorized that rupture of the unfused amnion followed by settling of the fragmented ends onto the surface of the developing embryo is the source of amniotic band syndrome. These disruptions of normally developing fetal anatomy may lead to amputations of random fetal parts or even to fetal death.

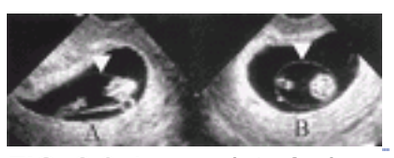

FIG. 8.6. Incomplete fusion of the amnion in the first trimester **(A).** The amnion in the singleton gestation resembles the membrane in a multiple gestation. However, in a different plane **(B)** the amnion surrounds the embryo in a more characteristic manner.

Later in the first trimester it may be possible to identify the normal rotation of the fetal gut, which occurs in the proximal part of the umbilical cord (Fig. 8.7). Such normal development may be confused with an omphalocele, an abnormality of the abdominal wall at the umbilical ring. Completion of gut rotation occurs by week 14, with subsequent resolution of the normal developmental hernia.

FIG. 8.7. Normal rotation of the fetal gut. The *double arrow* indicates the portion of the umbilical cord transiently occupied by the fetal gut during migration and rotation.

One of the earliest markers for aneuploidy in the developing fetus is an abnormally thick but hypoechoic ridge of skin over the nuchal portion of the skull. This may be detected in the first trimester and is suggestive of, but not diagnostic of, Down syndrome (trisomy 21). Some authors believe that this thickened region represents a resolving cystic hygroma that is characteristic of many fetuses with Down syndrome. Further discussion of nuchal hypoechogenicity can be found in the “Second Trimester” section.

The placenta is due more than the typical cursory glance during the first trimester. Early detection of placenta previa is possible but should be interpreted with caution. As the lower uterine segment develops in pregnancy, placentas that were previously low lying or covering the internal cervical os may no longer occupy that precarious location. The placenta may seem to migrate away from the os. The change actually occurs due to preferential placental development in areas of improved blood flow

and regression in poorly supplied regions. Blood flow in the lower uterine segment is less marked than in the fundus, encouraging placental development away from the lower uterine segment. Other abnormalities such as succenturiate lobes and circumvallate or circummarginate placentas may also be seen in the first trimester (Fig. 8.8). In cases of suspected placenta previa, transvaginal imaging can be performed to confirm the placental location relative to the cervix. Doppler flow studies may also reveal a vasa previa, in which the fetal vessels lie across the internal cervical os. This phenomenon may occur secondary to a succenturiate lobe or velamentous umbilical cord insertion.

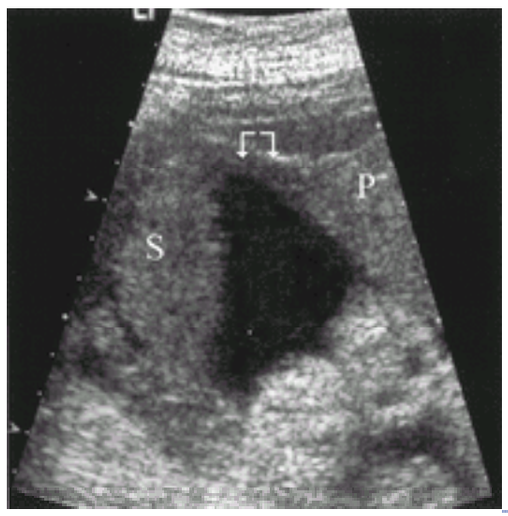

FIG. 8.8. Succenturiate lobe. The succenturiate lobe *(S)* is connected to the placenta *(P)* by the bridge of tissue and vessels.

Careful imaging of maternal anatomy should not be neglected in the excitement of finding a new pregnancy. Abnormal uterine masses such as leiomyomata (Fig. 8.9) or maternal embryologic abnormalities such as a bicornuate or septate uterus (Fig. 8.10) may be identified most easily when the pregnancy is not large enough to occlude good visualization. More unusual developments such as anterior and posterior sacculation of the uterus may be visualized, but these findings are extremely rare. Abnormalities of the adnexal structures in pregnancy may include any of the typically encountered abnormalities in the nonpregnant state. The most commonly encountered ovarian neoplasm in pregnancy is the mature teratoma or dermoid. Hemorrhagic cysts of the corpus luteum have the sonographic appearance of complex adnexal masses, but they usually will resolve over time (Fig. 8.11).

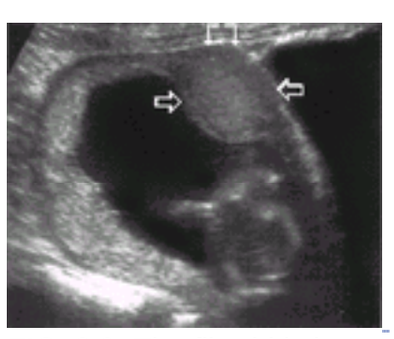

FIG. 8.9. The fibroid is located anteriorly in the uterine wall and distorts the outer contour of the uterus, which helps to differentiate this from a uterine contraction.

FIG. 8.10. Transverse section of a bicornuate uterus in the first trimester. The gestational sac is in the right horn and the left horn shows decidual changes.

FIG. 8.11. Hemorrhagic corpus luteum cyst. In February **(Feb)** the cyst is complex, but by April **(Apr)** it has resolved and a normal ovary is present.

SECOND TRIMESTER

A complete fetal anatomic survey can be performed most comprehensively in the late second trimester. This head-to-toe examination of the fetus identifies normal fetal anatomy, many but not all structural abnormalities, and markers for aneuploidy. As previously mentioned, there is not a consensus on the best use of ultrasonography in screening for abnormal pregnancies in low-risk populations. Additional information should be used to identify patients who will benefit from ultrasonographic examination. This information includes a family history of abnormal pregnancies or genetic anomalies, teratogenic exposures, abnormal laboratory findings including the maternal serum a-fetoprotein-human chorionic gonadotropin-estriol triple test, and abnormal clinical findings in the developing pregnancy.

In some cases, the second trimester marks the first prenatal visit for patients. Such patients often will depend on ultrasonography for an accurate estimation of the gestational age. This estimation is based on ultrasonographic measurements of the BPD, head circumference (HC), abdominal circumference (AC), and femur length (FL). These values are averaged to generate a composite score that is compared with standards. Some equipment calculates the average automatically. Additional measurements that may improve the accuracy of age determination include other long bone lengths, foot length, cerebellar width, and intraocular distance.

The physician must ascertain that only normal measurements are averaged. For example, adding the abnormal measurement of a shortened femur in skeletal dysplasia to the head and abdominal measurements will produce an incorrect gestational age. Two approaches can be used to calculate the gestational age if the anatomy is abnormal. One is to omit the data from the abnormal part. For example, obtaining the estimated fetal weight of an anencephalic fetus using the ultrasound system may require the BPD or HC. Because cranial measurements will be abnormal in this case, an equation that uses only the AC and FL can be used. The other option is to substitute a normal measurement from a table containing such data for the same point in the gestation as the patient. In the case of the anencephalic fetus, the appropriate head measurements for gestational age can be found in a reference table and substituted for the abnormal measurements.

The anatomic survey seeks to identify major structures in the developing fetus. During this survey, many abnormal ultrasonographic findings may be discovered. Such findings will lead to referral or subsequent diagnosis of abnormal conditions. Table 8.3 contains only a few of the more commonly encountered findings and anomalies that warrant further investigation.

TABLE 8.3. *Abnormal ultrasonographic findings by location and potentially associated diagnoses*

DOCUMENTATION AND THE BASIC ULTRASONOGRAPHIC EXAMINATION

Standards for performing an ultrasonographic examination can be found on the Web sites of the national organizations involved in ultrasound practice: the American College of Obstetricians and Gynecologists (ACOG.org), the American Institute of Ultrasound in Medicine (AIUM.org), and the American College of Radiology (ACR.org). Because these standards are being updated continually, they are not repeated here. These standards are developed with the intention of improving patient care and assisting the physicians and sonographers performing the examinations. The flow of the basic examination is important because, with a disciplined approach, the examiner will have the opportunity to recognize a majority of congenital defects while obtaining information about the normal pregnancy. The examiner should develop a technique for performing the examination that is logical and consistent with published standards. The technique that follows is not the only method but is one that has proved helpful to the initiate and the experienced.

Standard orientation should be used. On a transverse scan, the patient's right is on the left of the image. On a longitudinal scan, the patient's head is placed on the left of the image. If standard orientation is not used, the images should be labeled to provide orientation to the interpreter. Any measurement should be accompanied by an image. Documentation can be by any combination of thermal photographs, videotape, digital images, or radiographic film. Thorough documentation of the ultrasonographic examination is imperative for providing a historical reference for future examinations, images for referrals, and a permanent record for the patient's file.

After fetal heart activity is confirmed, begin imaging in the long axis of the uterus and move to the maternal adnexae to look for ovarian and adnexal masses. The large venous complexes in the adnexae during pregnancy should not be confused with pathology. Return to the midline of the uterus, and locate and document the lowest edge of the placenta. Although this image will not help with the lateral location of the placenta, it will document anterior or posterior orientation and the extent to which the edge approaches the cervical os. A transvaginal or translabial ultrasonographic examination may be necessary to locate the lower edge of the very low-lying placenta (Fig. 8.12). Document the area of the cervix unless the bladder is overly filled. Document the placental umbilical cord insertion site in order to diagnose possible marginal or velamentous cord insertions and to assess for vasa previa. The number of vessels in the umbilical cord should be documented in a cross-section of the cord, at the fetal cord insertion, or by visualization of the umbilical arteries around the bladder (Fig. 8.13). By this point in the examination, there should be a general impression of amniotic fluid volume. An amniotic fluid index (AFI) is not required in most standards; a subjective determination is acceptable. If more examinations are anticipated during the pregnancy or there is a question about the trend in fluid volume, the AFI provides consistency among examiners.

FIG. 8.12. Low-lying, posterior placenta. In **(A)** the placenta *(P)* could be mistaken for a posterior placenta previa. Transvaginal ultrasound **(B)** demonstrates the lower border of the placenta *(P)* separate from the internal os *(OS)* by the distance indicated between the plus signs *(+)*.

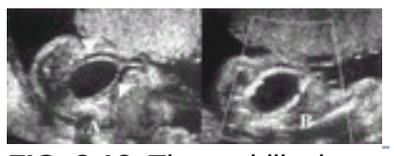

FIG. 8.13. The umbilical arteries around the fetal bladder frequently can be seen without the use of color Doppler as in **(B).**

Document the lie and presentation of the fetus with a longitudinal scan of the fetal axis. Subsequent imaging of the fetus transverse to the longitudinal fetal axis is usually most helpful. Begin with the fetal head. This provides an opportunity to diagnose cranial defects, which are both common and serious, and to locate the anatomy for the head measurements (BPD and HC) used in determining gestational age (Fig. 8.14). A normal cavum septum pellucidum eliminates the diagnoses of agenesis of the corpus callosum, hydranencephaly, hydrocephaly, holoprosencephaly, and anencephaly (Fig. 8.15). The plane used for measurements should be documented. The choroid plexuses are near the anatomic plane for the BPD. Choroid plexus cysts will appear as smooth-walled anechoic spaces within the echogenic choroid plexus (Fig. 8.16). The risk of a chromosomal anomaly with the isolated finding of choroid plexus cysts during a routine ultrasonographic examination is less than the risk associated with amniocentesis, regardless of the number or persistence of the cysts.

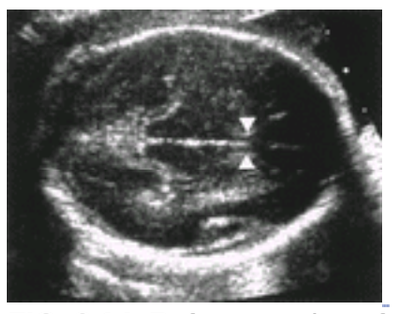

FIG. 8.14. Reference plane for the biparietal diameter and head circumference. The cavum septum pellucidum is a major landmark for this reference plane and for anomaly screening.

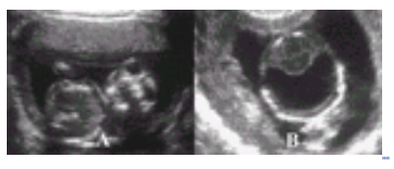

FIG. 8.15. The cavum septum pellucidum is absent in anencephaly **(A)** because the cranium and majority of the brain are absent. In holoprosencephaly **(B)** it is absent because the normal brain midline is not developed.

FIG. 8.16. Unilateral choroid plexus cyst. In the absence of other ultrasonographic findings or risk factors, the chances for trisomy 18 are less than the risk from an amniocentesis. This is also the case even if there are multiple or bilateral cysts **(inset).**

Posterior and inferior to the BPD plane is the cerebellum. Documentation of a normal configuration will provide assurance that there is a minimal chance of an open neural tube defect (Fig. 8.17). Slightly more inferior, the nape of the neck is visualized. Abnormalities in this area include cystic hygromas or posterior encephaloceles (Fig. 8.18). Identification of nuchal translucency, more properly termed nuchal hypoechogenicity, is accomplished in the same plane. Although the finding of nuchal hypoechogenicity in the first trimester appears to be a promising tool to screen for aneuploidy, it should be regarded as investigational. The most recent ACOG recommendation is that nuchal skin measurements should not be used clinically until better standardization is developed and more convincing data support such a practice. The fetal neck is smaller than the fetal head, so any enlargement should be evident. Fetal goiters or teratomas may be seen anteriorly (Fig. 8.19).

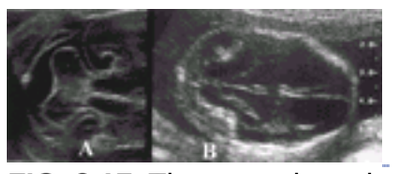

FIG. 8.17. The normal cerebellum **(A)** has a characteristic “doughnut” shape compared with the elongated cerebellum **(B)** described as the “banana sign” associated with an open neural tube defect.

FIG. 8.18. A cystic hygroma **(A)** is more fluid filled than a cephalocele **(B)**, which contains brain tissue and generally contains a septum. Usually the bony defect in the skull can be also be detected in the latter case.

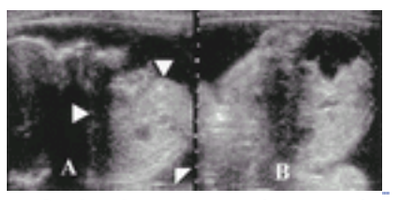

FIG. 8.19. An anterior cervical teratoma is seen in longitudinal section **(A)** and transverse **(B).** Although the diagnosis was made prenatally, intubation at delivery was unsuccessful. Tracheal compression is a significant risk with cervical tumors in the fetus and generally is the cause of death.

The upper part of the fetal chest is symmetric and consists mostly of lung tissue and the fetal thymus, which is difficult to image. The normal orientation of the fetal heart lies along a 45-degree left axis relative to the anterior-posterior thoracic diameter. The apex of the heart overlying the fetal stomach is an important relationship. Malrotations and situs inversus can be missed if careful correlation with the fetal lie is not included (Fig. 8.20). A lack of homogeneous lung tissue with or without displacement of the heart suggests cystic adenomatoid malformations, diaphragmatic hernias, teratomas, or other lesions. The fetal heart can still maintain a normal 45-degree axis but be displaced laterally by these and other anomalies (Fig. 8.21). Documentation of a normal four-chamber view eliminates the majority of fetal heart defects (Fig. 8.22). A short-axis view is not currently a requirement of a basic examination but increases the sensitivity for detecting cardiac defects.

FIG. 8.20. Situs inversus. Using standard orientation, in a transverse image **(A)**, the maternal right *(R)* and left *(L)* appear on the left and right of the image, and in the longitudinal image **(B)**, the maternal feet are to the right of the image. This indicates a vertex presentation with the fetal back to the left side of the mother, which means the apex of the fetal heart points to the right side of the fetus in **(A).**

FIG. 8.21. The heart is displaced from a more central position by the cystic adenomatoid malformation in the right side of the chest, but the normal 45-degree axis of the heart is preserved. The line from the fetal spine to the sternum normally should pass through the atria.

FIG. 8.22. A normal four-chamber view **(A)** compared with the same view in Ebstein anomaly **(B)** and in transposition of the great vessels **(C).** *RV*, right ventricle; *LV*, left ventricle; *RA*, right atrium; *LA*, left atrium; *AO*, aorta; *PA*, pulmonary artery. (From Dr. Alfred Abuhamad; with permission.)

With the transducer held in the same orientation for the four-chamber heart view, move inferiorly in the fetus to locate and document the plane for the AC measurement. The fetal gall bladder, which may be seen during this transition, is one of the three anechoic areas normally seen in the fetal abdomen. The other two are the stomach and urinary bladder. The observation of additional areas requires explanation. The fetal liver occupies most of the abdominal cavity in the plane used for the circumference measurement, which is why that measurement is sensitive for fetal weight and disturbances in growth. Below the AC plane, the abdomen consists mostly of fetal bowel and the kidneys posteriorly. An image showing both kidneys is useful for eliminating unilateral agenesis, horseshoe kidney, and multicystic or polycystic kidneys (Fig. 8.23). The fetal umbilical cord insertion site should be documented. If a gastroschisis or omphalocele is present, further investigation is needed (Fig. 8.24).

FIG. 8.23. The cysts *(c)* of the multicystic kidney **(A)** involve the left kidney. A normal contralateral kidney with normal amniotic fluid volume portends a good prognosis. In **(B)** the polycystic horseshoe-shaped kidney is accompanied by oligohydramnios, a poor prognosis.

FIG. 8.24. Although the umbilical cord insertion site is normal, a gastroschisis will appear as a mass to the right of the insertion site. **B:** The umbilical cord inserts into the sac of an omphalocele which, in this case, contains fetal liver *(L).* Isolated gastroschisis is not associated with an increased risk of chromosomal anomalies, contrary to an omphalocele which has significant associated risk. A smaller omphalocele has further increased risks.

Moving caudally in the fetus, document the fetal urinary bladder. Following that image, rotate the transducer to image the femur. Although documentation of the FL suggests that a portion of the lower extremity has formed, an additional image of the fetal feet is helpful. Be aware of the orientation of the foot with respect to the tibia in order to diagnose clubfoot (Fig. 8.25). Images of the fetal hands, although difficult and not required in standards, are useful in finding soft markers of aneuploidy such as shortened phalanges, characteristic posturing of the fetal hands, or polydactyly.

FIG. 8.25. The clue to the diagnosis of clubfoot is that the sole of the foot and the toes are in the same plane as the longitudinal axis of the leg.

THIRD TRIMESTER

There are a few anatomic structures that may be seen in the second trimester that can be visualized more easily in the third trimester. The fetal adrenal glands can be located on the superior poles of the kidneys. It is usually possible to distinguish the adrenal cortex and adrenal medulla. The lens of the eye and fetal scalp hair are more easily distinguished in the early third trimester.

Helpful adjuncts to estimation of gestational age also appear in the third trimester. Ossification of the distal femoral epiphysis occurs predictably around 32 weeks. The proximal tibial epiphysis ossifies around 35 weeks. These two ossification centers of the long bones are seen as prominent echoes distinct from the ends of the long bones. Because fetal growth rate varies widely in the third trimester, estimation of fetal weight alone may not accurately predict the gestational age. Finding the additional ossification centers of the long bones may provide more guidance for the patient who has not entered prenatal care until late in the pregnancy.

A worrisome source of third-trimester bleeding is placental abruption, which is mainly a diagnosis made on clinical grounds. In some cases ultrasonography provides information about gestational age and fetal life, allowing for more informed management decisions. In extreme cases, ultrasonography may reveal a portion of an abruption (Fig. 8.26) or a free-floating placenta and intrauterine fetal death.

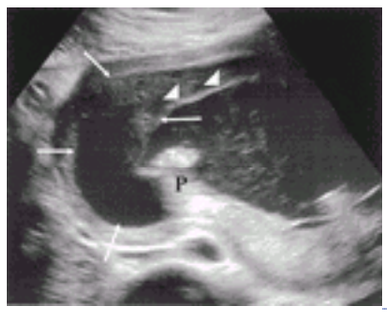

FIG. 8.26. Placental abruption. The edge of the placenta *(P)* has been elevated by the bleeding. A portion of the amnion and chorion attached to the edge appears to be floating in the uterine cavity.

Transvaginal scanning with appropriate caution in cases of undiagnosed vaginal bleeding in pregnancy can be very useful. The transducer should be inserted slowly while the sonographer watches the path of the transducer on the monitor. The ability to guide the tip of the transducer relative to maternal anatomy avoids the pitfalls of blind digital or speculum examination. Placental tissue overlying the internal os is seen clearly (Fig. 8.27), so the uncertainty of terms such as *partial placenta previa* or *low-lying placenta previa* can be avoided. The percentage of placenta overlying the internal cervical os can be reported to provide more information. The largest reportable percentage is 50%, indicating a central placenta previa (Fig. 8.28).

FIG. 8.27. Transvaginal ultrasonogram of a placenta previa. The placenta *(P)* covers the internal os. The tip of the transvaginal probe is in the anterior fornix. See color figure 8.27.

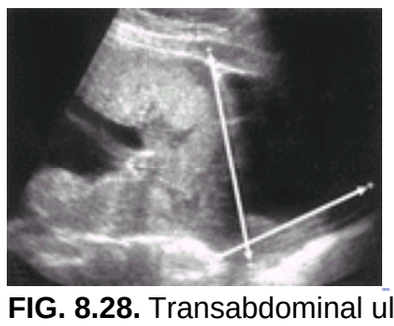

FIG. 8.28. Transabdominal ultrasonogram of a central placenta previa. The intersection of arrows indicates the approximate location of the cervix, which cannot always be visualized using transabdominal sonography. The arrows are drawn along the bladder-uterine interface and the axis of the vagina.

TECHNIQUES OF FETAL TESTING

The amount of amniotic fluid surrounding the fetus has been shown to be a very sensitive indicator of fetal status. Poor placental blood flow in cases of maternal hypertension or diabetes results in a diminished substrate for fetal kidney filtration and a subsequent decrease in the amount of fetal urine. A low AFI is one of the early indicators of such compromise, although a wide variation in the normal range is possible. Estimation of the fluid index requires measurement of the deepest vertical pocket of amniotic fluid not occupied by fetal parts or umbilical cord. This measurement is performed in each of four quadrants of the uterus. Measurements should be performed with the patient supine and the transducer held perpendicular to the floor. The sum of the four measurements expressed in centimeters equals the AFI. Two approaches have been suggested to define oligohydramnios and polyhydramnios using the AFI. One method is to use fixed values of less than or equal to 5 centimeters for oligohydramnios and greater than or equal to 18 centimeters for polyhydramnios. The second approach is to use gestational-specific percentiles below or equal to the fifth percentile for oligohydramnios and above or equal to the 95th percentile for polyhydramnios. Some authors have also proposed defining adequate amniotic fluid volume as the presence of a pocket of fluid measuring at least 2 centimeters horizontally and vertically. The method selected should depend on the experience and data from each sonographer's institution and further correlation with outcomes.

Manning and Platt described the biophysical profile (BPP) as a method for noninvasive monitoring of fetal status. There are five parts to the BPP. Four of these parameters are ultrasonographic variables that are evaluated during a 30-minute observation period: fetal breathing, fetal movement, fetal tone, and amniotic fluid volume. Fetal breathing can be observed by watching the fetal diaphragm or chest wall for characteristic breathing motion. The fetus must breathe continuously for 30 seconds during the 30-minute observation period to receive a normal score. Fetal movement of the limbs or body must occur at least 3 times to be considered adequate. Normal fetal tone is demonstrated by one active extension and flexion of the limbs or trunk. Opening and closing of the fetal hand also qualifies for a normal tone score. Slow extension of the extremity or trunk with incomplete return to flexion is not considered normal. The fourth part of the BPP is measurement of the amniotic fluid volume. Originally the normal fluid volume was described as the presence of at least one pocket of amniotic fluid measuring 1 centimeter in vertical dimension. Manning and colleagues later modified this definition to 2 centimeters measured vertically. Many centers use a normal AFI as a substitute measurement. Each ultrasonographic variable is scored zero (abnormal) or two points (normal). The fifth component of the BPP is a nonstress test, which receives a score of two points when reactive and zero when nonreactive. The best possible BPP score is ten. A detailed discussion of the use of the BPP in antepartum care can be found in Chapter 9.

Doppler velocimetry of both maternal and fetal vessels is based on the principle that sound waves returning from a moving reflector will be affected by the direction and speed of that reflector relative to the transmitting or receiving source. A reflector traveling toward the receiver will cause the return signal to be higher in frequency. The opposite is true for a reflector moving away from the receiver. Return echoes from the receding reflector will be lower in frequency than the transmitted pulse. The degree of change in the returning signal can be used to calculate the velocity (speed and direction) of the reflector. By applying this property to the red blood cell mass moving within maternal or fetal vasculature, characteristic profiles were obtained for mother and fetus. Doppler interrogation of the maternal uterine artery may reveal a characteristic notch during diastole, which is a sensitive predictor for preeclampsia during the pregnancy. The umbilical artery Doppler waveforms can be used to evaluate the resistance of the placental circuit. The systolic-to-diastolic (S/D) ratio is defined as the ratio of peak velocity in systole to the velocity nadir in diastole. This value is typically between 1.5 and 2.5 in the third trimester. As placental flow resistance increases with vascular compromise, the S/D ratio also increases. Increased resistance to the point of stopping or reversing diastolic blood flow is worrisome for fetal outcome and should prompt further evaluation (Fig. 8.29).

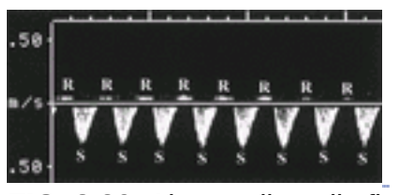

FIG. 8.29. Absent diastolic flow with or without reverse flow *(R)* is an indicator of poor fetal health. *S*, systole. (From Diana M. Strickland, RDMS, RDCS; with permission.)

INTERVENTIONAL ULTRASONOGRAPHY

Ultrasonography is now a standard adjunct for amniocentesis, chorionic villus sampling, percutaneous umbilical blood sampling (PUBS), and other invasive procedures. Amniocentesis for genetic studies generally is performed after 13 weeks gestation. The tip of the amniocentesis needle is visualized during insertion to reduce the number of attempts. Post-procedure determination of fetal heart rate usually is performed to assure that the procedure was well tolerated. Chorionic villus sampling can be performed blindly, but many providers find that the procedure is easier and less risky when transabdominal imaging provides visualization of the uterus and guidance of the catheter. PUBS depends heavily on ultrasonographic imaging to locate the placental umbilical cord insertion for needle placement, for monitoring the fetus during sampling, and for post-procedure monitoring to watch for hemorrhage.

Ultrasonographic guidance may be employed during interventional procedures for fetal benefit. Intrauterine fetal blood transfusion can be performed in severe cases of isoimmunization when the fetus is too premature to deliver. Replacement of fetal thyroid hormone in cases of maternal thyroid dysfunction can also be performed. The fetus can then be treated and followed with ultrasonography for resolution of the goiter, indicated by return of the thyroid gland to normal size. Selected obstructions of the fetal urinary tract can be bypassed with percutaneous catheters that are removed after birth. This procedure may also be performed in cases in which fluid-filled areas are found to be compressing thoracic structures (Fig. 8.30). In cases of twin-to-twin transfusion syndrome, therapeutic drainage of the polyhydramnic twin may permit the pregnancy to progress to a reasonable chance of viability.

FIG. 8.30. Insertion of shunt in unilateral hydrothorax. The anechoic, fluid-filled area is drained by the needle during insertion of the shunt. The baby was delivered at term with no pulmonary complications.

FUTURE DIRECTIONS

New developments in the field of diagnostic ultrasonographic imaging include power Doppler imaging, harmonic imaging, three-dimensional (3D) ultrasonography, real-time 3D ultrasonography (often called four-dimensional [4D] imaging), compound imaging, B-flow imaging, and panoramic ultrasonographic imaging.

Power Doppler imaging uses the same principle as Doppler velocimetry. However, instead of targeting a single vessel, power Doppler imaging is used over a region of tissue. When the Doppler shift is detected in the return echoes, that region of tissue is assigned flow data that appear on the screen as colors different than those of the surrounding image. Direction of flow is not indicated. The resulting image contains a standard ultrasonographic image of the target tissue, with a color overlay representing vascular flow. This type of imaging may become useful in placental flow studies, analysis of the umbilical cord, or detection of ectopic pregnancy. Use of power Doppler should be monitored carefully, because the acoustic output increases dramatically with its use.

Harmonic imaging utilizes the harmonics of the transmitted pulse to receive double the transmitted frequency. This improves the image by removing clutter and artifact and improving resolution. This feature is very useful for the patient whose body habitus makes imaging difficult.

Three-dimensional ultrasonography relies on a special transducer that can sample tissue in multiple sections simultaneously and on computer processors that can reconstruct the data as a virtual block of tissue. This block can then be viewed at any angle and in any section. Proponents of 3D ultrasonography advocate its use in first-trimester anatomic surveys, monitoring of cervical cerclage, and evaluation of fetal surface defects such as cleft lip or myelocele. This technology requires good fetal position and a moderate amount of amniotic fluid in front of the targeted tissue in order to create adequate images. Special transducers, for both transvaginal and transabdominal imaging, are required to insonate the tissue of interest. The extra graphics processors and memory required to generate 3D images are the rate-limiting steps to producing real-time 3D ultrasonography. Also known as 4D ultrasonography, real-time 3D ultrasonography is currently in development. This technology requires the same transducers as 3D ultrasonography but uses faster processors to generate 3D images in actual real time. The same limitations apply to fetal position and amniotic fluid. It might be possible eventually to assess the functional status of fetal organs with 4D ultrasonography. The results from current research will provide the evidence for using real-time ultrasonography in different applications.

Compound imaging utilizes electronic beam focusing to emit ultrasound energy at angles to the axis of the transducer. A single target will be insonated from numerous different angles by the array of emitters across the transducer face. Shallow reflectors that would otherwise block tissue penetration are bypassed by the angled signals from and to the transducer. Reflectors from deeper in the tissue are imaged more precisely and a more detailed grayscale image is produced.

The increased resolution of modern transducers and data processing capabilities of systems have led to the development of B-flow imaging. Rather than using the Doppler effect to calculate velocities of blood flow, the B-mode function actually collects the tiny echoes emitted from blood cells. The resulting image is a real-time anatomic image combined with grayscale flow imaging. Color is not required for the display. An advantage of B-flow is the decreased exposure of the patient to ultrasound energy compared with Doppler interrogation.

Panoramic imaging relies on the ultrasound system to link a series of images into a large single image, much as a vacationer would align snapshots into a panoramic landscape photo. Although this mode is not real time, it has the advantage of displaying images much larger than the transducer's field of view.

CONCLUSION

In the changing spectrum of obstetric practice, ultrasonography has established a niche that is unlikely to be challenged significantly. It is a safe imaging modality when used properly. Numerous applications exist, from anatomic surveys to guidance during interventional procedures. The skills of the provider and the quality of the equipment have a direct impact on the sensitivity of the examination in detecting anomalies. Although the usefulness of screening every pregnant woman with an ultrasonographic examination is still in question, there is no doubt that under the guidelines of accepted medical indications, ultrasonography improves prenatal care.

SUMMARY POINTS

- Every ultrasonographic examination should be as complete as possible within the scope of the provider and the equipment.
- There is no evidence to suggest that medical ultrasonography carries a risk to the mother or fetus; nevertheless, such risks might be identified in the future. An ultrasonographic examination should be performed only when medically indicated.
- The sensitivity of ultrasonography in detecting fetal anomalies is variable and relies on the experience of the provider and the quality of equipment. Specialists with additional training in ultrasonography, such as a maternal-fetal medicine fellowship, should perform ultrasonographic examinations for abnormal findings or for genetic indications.

In the beginning of the 19th century, reports on the presence of fetal heart tones were published, and nearly 150 years later, continuous fetal heart rate (FHR) monitoring became a reality. By 1998, electronic fetal monitoring was used in 84% of all U.S. births, regardless of whether the primary caregiver was a physician or a midwife. With the advent of these technologies, fetal monitoring is implemented in nearly all pregnancies, either in the antepartum or intrapartum period. The challenge of fetal surveillance is to identify those fetuses whose physiological defense mechanisms are compromised, in order to be able to act before decompensation has occurred. The goal is to prevent fetal and neonatal morbidity, and especially mortality.

WHY PERFORM FETAL MONITORING?

Since its inception, the primary objective of FHR monitoring has been to identify the fetus in distress so that measures might be taken in time to avert permanent fetal damage or death. However, a clear consensus regarding the definition of “fetal distress” has not been established. It has been described as “a condition in which fetal physiology is so altered as to make death or permanent injury a probability within a relatively short period of time,” and is usually considered to denote disruption of normal fetal oxygenation, ranging from mild hypoxia to profound fetal asphyxia. The term *hypoxia* refers to the reduction of tissue oxygen supply below physiologic levels. *Asphyxia*, derived from the Greek word meaning “a stopping of the pulse,” implies a combination of hypoxia and metabolic acidosis. Historically, the clinical diagnosis of birth asphyxia has been based on findings such as meconium-stained amniotic fluid, abnormal FHR patterns, low Apgar scores, abnormal blood gases, and neonatal neurologic abnormalities. When present together, these findings are highly suggestive of a recent asphyxial insult. Isolated abnormalities, however, correlate poorly with birth-related asphyxia and subsequent neurologic impairment. In 2002, the American College of Obstetricians and Gynecologists Task Force on Neonatal Encephalopathy and Cerebral Palsy stated the criteria to define an acute intrapartum event sufficient to cause cerebral palsy.

Essential criteria (must meet all four):

1. Evidence of a metabolic acidosis in fetal umbilical cord arterial blood obtained at delivery (pH <7 and base deficit =12 mmol/L).
2. Early onset of severe or moderate neonatal encephalopathy in infants born at 34 or more weeks of gestation.
3. Cerebral palsy of the spastic quadriplegic or dyskinetic type.
4. Exclusion of other identifiable etiologies such as trauma, coagulation disorders, infectious conditions, or genetic disorders.

Criteria that collectively suggest an intrapartum timing (within close proximity to labor and delivery, eg., 0–48 hours) but are nonspecific to asphyxial insults:

1. A sentinel (signal) hypoxic event occurring immediately before or during labor.
2. A sudden and sustained fetal bradychardia or the absence of fetal heart rate variability in the presence of persistent, late, or variable decelerations, usually after a hypoxic sentinel event when the pattern was previously normal.
3. Apgar scores of 0–3 beyond 5 minutes.
4. Onset of multisystem involvement within 72 hours of birth.
5. Early imaging study showing evidence of acute nonfocal cerebral abnormality.

At the cellular level, asphyxia triggers a cascade of events, including membrane depolarization, disruption of energy metabolism, altered neurotransmission, ion shifts, protease activation, free radical production, and phospholipid degradation. Profound and prolonged asphyxia may result in cell death and, eventually, death of the organism. Sublethal asphyxia may lead to multi-organ system dysfunction. Severe asphyxial brain injury may lead to long-term neurodevelopmental impairment.

Cerebral palsy (CP) is a major disorder of neurodevelopment, defined as “a chronic disability, characterized by aberrant control of movement and posture, appearing early in life and not the result of recognized progressive disease.” It may be accompanied by mental retardation (41%), seizures (23%), or cortical visual impairment. The insult responsible for the development of CP may occur at any time during the prenatal, perinatal, or postnatal periods. Unlike other major neurodevelopmental disorders, the relationship between CP and abnormal or difficult birth has long been recognized, publicly dating back to a treatise presented by William John Little in 1862. In 1943, Windle demonstrated clinical and histopathologic evidence of neural damage in experimentally asphyxiated fetal guinea pigs. He later reported the effects of prolonged anoxia on fetal rhesus monkeys. Total anoxia for less than 8 minutes did not produce consistent injury, whereas anoxia for more than 10 minutes invariably resulted in neuropathology. There were no survivors beyond 20 to 25 minutes of anoxia. The pattern of injury produced by prolonged anoxia, however, did not correlate with the cerebral injury, mental retardation, and spasticity seen in CP. Later work demonstrated that prolonged partial asphyxia in monkeys produced acidosis, late FHR decelerations, and neuropathologic defects consistent with the findings in the common forms of CP. In addition to lesions in the thalamus and basal ganglia, prolonged partial asphyxia caused generalized cerebral necrosis or focal necrosis in the parasagittal regions and the border zones between the parietal and occipital lobes.

Although early studies created and fostered the assumption that birth-related asphyxia was the primary cause of CP, recent evidence challenges this assumption. In 1986, Nelson and Ellenberg reported a multivariate analysis of risk in 189 cases of CP. After accounting for major congenital malformations, low birth weight, microcephaly, and alternative explanations for the disorder, they were able to attribute only 9% of CP cases to birth asphyxia. Others have reached similar conclusions. Although birth asphyxia nearly tripled the odds of developing CP, only 8.2% of CP cases were potentially attributable to birth asphyxia.

As early as the 19th century, researchers using auscultation recognized that certain FHR patterns were associated with adverse perinatal outcome. The introduction of

direct electronic fetal monitoring and fetal scalp blood sampling in the 1960s provided tools for evaluating the fetus. FHR decelerations have been found to be correlated with fetal acidosis. Fetuses with no decelerations, early decelerations, or mild variable decelerations had average scalp pH values greater than or equal to 7.29, whereas those with severe variable or late decelerations had pH values less than or equal to 7.15. In addition, FHR variability was found to be correlated with scalp pH values as fetuses with normal FHR variability had higher scalp pH values than those with decreased variability. The absence of FHR accelerations was correlated with poor perinatal outcome and the presence of FHR accelerations has been shown to predict normal scalp pH values. With the development of indirect monitoring techniques, the experience derived from direct intrapartum monitoring became applicable to the antepartum period, leading to the development of antepartum testing.

Antepartum fetal monitoring has the goal of identifying the fetus at risk, allowing sufficient time to intervene before permanent injury or death occur. Intrapartum fetal monitoring should be able to identify three groups of fetuses:

- the fetus that is not affected by labor
- the fetus that is negatively affected by labor but has enough reserve to compensate fully and is in no immediate danger
- the fetus that is negatively affected and lacks the reserve to compensate, thus uses its key resources to survive and is in danger for morbidity/mortality.

It is the third group that would most benefit from intervention.

WHO SHOULD BE MONITORED?

Antepartum fetal monitoring is typically offered to patients at increased risk of fetal or neonatal morbidity/mortality. These include maternal medical complications (e.g., diabetes mellitus, chronic hypertension, systemic lupus erythematosis), fetal conditions (Rh isoimmunization, fetal growth restriction), and pregnancy complications (multiple gestation, oligohydramnios). Overall, the studies supporting the methods of testing, the timing, and initiation are extremely varied; thus absolute guidelines based on scientific evidence cannot be established. However, recommended gestational ages for initiation of testing, timing, and methods for specific maternal conditions, and the supportive evidence can be found in Table 9.1.

TABLE 9.1. *General guidelines for initiation of antenatal testing*

Intrapartum fetal monitoring has remained controversial since its inception. The FHR many be evaluated by auscultation or by electronic monitoring. Auscultation is typically performed with a DeLee stethoscope or Doppler ultrasound. Electronic monitoring can be either performed externally or internally, external monitors use a Doppler device with computerized logic to interpret and count the signals. Internal monitoring uses a fetal electrode that records the fetal electrocardiogram (ECG). Well-controlled studies have shown the equivalence of intermittent auscultation to continuous fetal heart monitoring when auscultation was performed at specific intervals with a 1:1 nurse-to-patient ratio. The intensity of monitoring is based on risk factors, with more intensive surveillance required for high-risk pregnancies.

WHAT CAN WE MONITOR?

Fetal Heart Rate

The FHR can be monitored and recorded indirectly through the use of an ultrasound transducer or directly via a subcutaneous ECG electrode placed on the fetus (Fig. 9.1). The indirect method can be used throughout pregnancy and has no contraindications. Using the indirect method, ultrasound waves originating from the transducer penetrate the tissues and are reflected by tissue interfaces. Waves reflected from the moving structures of the fetal heart return to the transducer and are translated into electrical signals. In the direct method, the subcutaneously placed ECG electrode detects electrical impulses originating in the fetal heart. Amplified signals are processed by a cardiotachometer, comparing each incoming QRS complex to the one immediately preceding it. The interval between the two complexes is used to calculate a heart rate. The process is repeated with each cardiac cycle yielding a graphic beat-to beat display of the FHR. The direct method requires rupture of the fetal membranes for placement of the ECG electrode. In addition, in light of the potential risk of infection, the electrode for direct assessment should only be used when the benefits outweigh this risk.

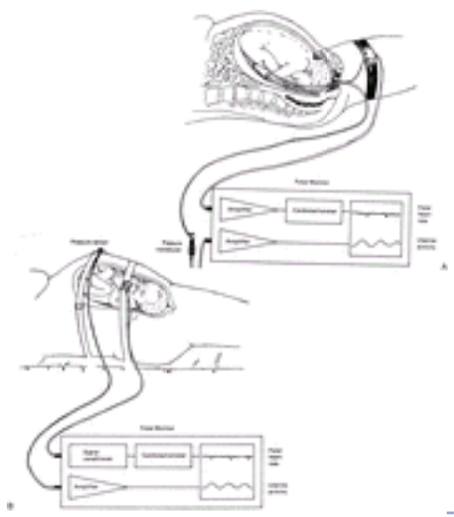

FIG. 9.1. Direct and indirect fetal monitoring. **A:** Direct method. Recordings are made from a fetal electrocardiograph electrode applied directly to the fetus. A transcervical intrauterine pressure catheter is used to monitor the strength of uterine contractions. **B:** Indirect method. The fetal heart rate is derived from a Doppler ultrasound transducer applied to the maternal abdominal wall. A pressure sensor (tocodynamometer) detects uterine contractions. (Courtesy of Richard H. Paul.)

Uterine Activity

Similar to FHR, the detection and measurement of uterine activity can be performed indirectly or directly (see Fig. 9.1). Indirect assessment of uterine activity is performed with a pressure ransducer (tocodynamometer) applied tightly to the maternal abdomen over the uterine fundus. Uterine contractions exert pressure on the abdominal wall that is transmitted to the tocodynamometer. Changes in pressure are converted into signals and plotted on the uterine activity graph. The indirect method is noninvasive and can be performed at any time during pregnancy. The limitations of the indirect method are that the readout can only be used to determine contraction frequency, not strength of the contraction (a tightly fit belt will record larger contractions than a loosely fitting or misplaced belt) and the ability to detect contractions in extremely obese women may be difficult. Direct assessment of uterine activity employs a thin, flexible intrauterine pressure catheter (IUPC) placed transcervically into the amniotic cavity. Intrauterine pressure is transmitted from the amniotic fluid through the fluid-filled IUPC to a pressure transducer. The transducer converts pressure measurements into electrical signals, and continuous pressure readings are displayed on the uterine activity graph. The direct assessment is invasive and requires ruptured membranes. Aside from some research indications, the IUPC should only be used in patients when the benefits outweigh the risk of infection. The direct method allows the readout of both the frequency and the strength of the uterine contractions. This can be especially useful in the evaluation and

assessment of patients with prolonged labor.

Fetal State (Tone/Breathing/Movements)

Using real-time ultrasound, the state of the fetus can be evaluated. Typically included in this evaluation are assessments of fetal tone, movements, and breathing. Fetal voiding and swallowing can also be evaluated. Specific assessments of fetal tone, breathing, and movements are discussed later in the chapter “Biophysical Profile.”

Amniotic Fluid Volume

The volume of amniotic fluid is a measure of fetal well-being. By the second trimester the predominant source of amniotic fluid is fetal urine. The level of amniotic fluid is thought to represent “long-term” fetal well-being. A compromised fetus will preferentially shunt blood to the major organs (central nervous system, adrenals) and away from others, such as the kidney. Decreased fetal renal perfusion results in a decrease in fetal renal function and subsequent oligohydramnios. The amniotic fluid can be assessed ultrasonongraphically. There are a number of methods to quantitate the volume, including the amniotic fluid index, single deepest pocket, two-dimensional pocket, and a subjective assessment.

HOW DO WE MONITOR?

Equipment

The fetal monitor tracing is a continuous paper strip composed of two Cartesian graphs. The FHR tracing is displayed on the upper graph, with time on the x-axis and heart rate on the y-axis (range 30 to 240 beats per minute). Uterine activity is displayed on the lower graph, with time on the x-axis and pressure on the y-axis (range 0 to 100 mm Hg). Heart rate and uterine activity are plotted separately on the heat-sensitive paper by two thermal pens. On both grids, fine vertical lines represent 10-second intervals, and heavy lines denote 1-minute intervals. In the United States, the standard paper speed is 3 cm per minute.

INTERPRETATION OF THE FETAL MONITOR

Analysis of the fetal monitor strip requires a systematic approach. First, the FHR is analyzed with respect to (a) the baseline, (b) variability, and (c) periodic patterns, including FHR accelerations and decelerations (Table 9.2). Uterine activity is evaluated with attention to the frequency, duration, and strength of contractions, as well as the baseline uterine tone between contractions.

FETAL HEART RATE INTERPRETATION

Baseline Fetal Heart Rate

The normal FHR baseline ranges from 120 to 160 beats per minute. Early in pregnancy, it is closer to 160 beats per minute, declining as gestational age advances. Likewise, the FHR may decrease gradually toward 120 beats per minute during the course of labor. An FHR baseline below 120 beats per minute is termed *bradycardia*, and a rate in excess of 160 beats per minute is termed *tachycardia.* Abnormalities in the FHR baseline may have very different causes and consequences. It is important therefore to characterize the underlying etiology as accurately as possible and to institute appropriate therapy at the earliest possible time.

Bradycardia Bradycardia is defined as an abnormally low baseline FHR (< 120 beats per minute) and must be differentiated from the episodic FHR changes characteristic of decelerations. Although FHR decelerations are very common, true fetal bradycardia is not. A bradycardic FHR baseline between 100 and 120 beats per minute observed in association with otherwise reassuring FHR patterns probably represents a normal variant. Rarely, fetal bradycardia may be seen in association with maternal ß-blocker therapy, hypothermia, hypoglycemia, hypothyroidism, or fetal cardiac conduction defects (congenital atrioventricular block). Documentation of fetal heart block should prompt a search for structural fetal cardiac abnormalities, which may be present in 20% of cases. Other causes of heart block include viral infections (e.g., cytomegalovirus) and damage to the cardiac conduction system by transplacental passage of maternal anti-Ro (anti–SS-A) antibodies. Most congenital causes of fetal bradycardia do not present as abrupt changes in the FHR and rarely require emergency intervention. Any abrupt decline in the FHR below 120 beats per minute more likely represents a deceleration than a change in the baseline, and should be considered pathologic until proven otherwise.
Tachycardia Fetal tachycardia has many possible etiologies. Most often, it is the result of decreased vagal or increased sympathetic outflow, associated with fever, infection, fetal anemia, or fetal hypoxia. Other causes include maternal hyperthyroidism, fetal tachyarrhythmias (e.g., paroxysmal supraventricular tachycardia, atrial fibrillation, atrial flutter, and ventricular tachyarrhythmias), and medications including sympathomimetics (e.g., ritodrine, terbutaline) and parasympatholytics (e.g., atropine, phenothiazines).
Sinusoidal Pattern The sinusoidal FHR pattern is an uncommon FHR baseline abnormality. It has the appearance of a smooth sine wave with an amplitude of 5 to 15 beats per minute and a frequency of 2 to 5 cycles per minute. There is little beat-to-beat variability, and accelerations are absent. Although the pathophysiologic mechanism is unclear, this pattern classically is associated with hypoxia and severe fetal anemia. Additionally, it has been reported in association with fetomaternal hemorrhage, chorioamnionitis, fetal sepsis, and administration of narcotic analgesics. A persistent sinusoidal pattern that is not attributable to medications is a concerning finding and demands immediate evaluation.

Fetal Heart Rate Variability

Variability in the FHR results from constant interplay between the sympathetic and parasympathetic arms of the fetal autonomic nervous system. Modulation of vagal tone occurs in response to changes in blood pressure detected by baroreceptors in the fetal aortic arch. Oxygen and carbon dioxide fluctuations, detected by chemoreceptors in the carotid bodies, similarly influence vagal outflow. In the absence of stress, sympathetic outflow is thought to be relatively tonic. Continual adjustments in vagal tone are manifested in the FHR tracing as “short-term” (beat-to-beat) variability superimposed on broader, cyclical fluctuations of 3 to 5 cycles per minute, referred to as “long-term” variability. In clinical use, the term *FHR variability* refers to the composite of short-term and long-term variability and is quantitated by measuring the difference between the peaks and troughs of the long-term fluctuations (Fig. 9.2). FHR variability is considered normal or average when both short-term and long-term variability are present, and the difference between the peaks and troughs of the long-term fluctuations is 6 to 25 beats per minute. Average variability reflects a nonacidotic vagal connection between the fetal central nervous system (CNS) and the cardiac conduction system. Increased variability (more than 25 beats per minute), or *saltatory* FHR pattern, is uncommon and most often represents an exuberant autonomic response of a normal fetus. On occasion, it may reflect increased catecholamine release in the early stages of fetal hypoxia. Careful evaluation of the associated FHR findings should help to clarify such cases. Decreased (3 to 5 beats per minute) or absent (0 to 2 beats per minute) FHR variability reflects diminished fetal CNS activity, usually attributable to fetal sleep cycles or to medications administered to the mother (e.g., analgesics, magnesium sulfate, benzodiazepines, phenothiazines, atropine). Persistently decreased variability, however, may signal fetal acidosis. This is particularly true in the presence of other FHR findings suggestive of hypoxia, including tachycardia, loss of reactivity, or repetitive decelerations.

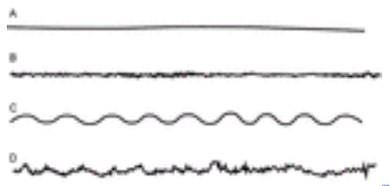

FIG. 9.2. Fetal heart rate variability. **A:** Short-term variability absent, long-term variability absent—abnormal. **B:** Short-term variability present, long-term variability absent—abnormal. **C:** Short-term variability absent, long-term variability present—abnormal. **D:** Short-term variability present, long-term variability present—normal.

Periodic Patterns

The FHR baseline is frequently interrupted by accelerations or decelerations in rate. These periodic patterns have important clinical implications regarding the well-being of the fetus.

Accelerations Accelerations in the FHR occur with 90% of fetal movements as early as the second trimester, probably as a result of increased catecholamine release and decreased vagal stimulation of the heart (Fig. 9.3). By 32 weeks gestation, nearly all normal fetuses will have 15 to 40 spontaneous accelerations per hour, reflecting normal oxygenation of the CNS–cardiac axis. The frequency and amplitude of accelerations may be diminished by fetal sleep states, medications (narcotics, magnesium sulfate, atropine), prematurity, or fetal acidosis. Often, fetal scalp stimulation or vibroacoustic stimulation will provoke fetal movement and FHR accelerations. If these measures fail to induce FHR accelerations, hypoxia should be suspected, particularly if other FHR characteristics are not reassuring.

FIG. 9.3. Fetal heart rate accelerations.

Decelerations Decelerations in the FHR are most commonly encountered during the intrapartum period. They are divided into three categories: early, variable, and late decelerations (Fig. 9.4). Classification is based on the characteristic appearance of the deceleration and its temporal relationship to the onset of a uterine contraction.

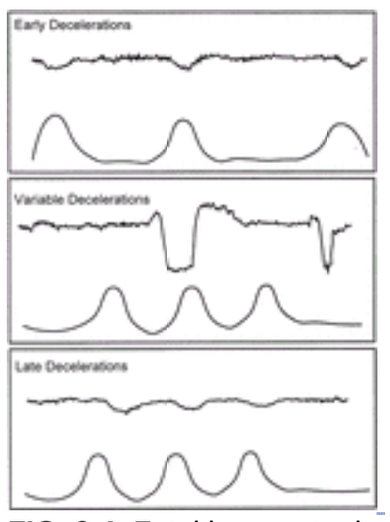

FIG. 9.4. Fetal heart rate decelerations.

Early Decelerations Early decelerations are typically uniform, shallow dips in the FHR (rarely below 100 beats per minute) that mirror uterine contractions, beginning at the onset of the contraction and ending when the contraction ends. They are thought to result from fetal head compression, transient elevation of intracranial pressure, and reflex augmentation of vagal tone. Early decelerations classically appear during labor when the cervix is dilated 4 to 6 cm. Perinatal outcome is not adversely affected by these decelerations, and they are considered clinically benign.

Variable Decelerations and Prolonged Decelerations Variable decelerations result from umbilical cord compression. They are abrupt and angular in appearance and have a variable temporal relationship to uterine contractions. As the umbilical cord is compressed, the thin-walled, compliant umbilical vein is the first vessel occluded, resulting in decreased fetal venous return, relative hypovolemia, and a reflex increase in the FHR. This observation often is termed a “shoulder.” Further compression of the umbilical cord leads to occlusion of the umbilical arteries, removing the low-resistance placenta from the circuit and dramatically increasing fetal peripheral resistance. This leads to elevation of the fetal blood pressure and a baroreceptor-mediated slowing of the FHR in an attempt to return the blood pressure to normal. Maximum vagal tone may result in a junctional or idioventricular escape rhythm that appears as a relatively stable rate of 60 to 70 beats per minute at the nadir of the deceleration. As cord compression is relieved, this sequence of events occurs in reverse, at times resulting in transient tachycardia or “overshoot” at the end of the deceleration. Variable decelerations are classified as:

- Mild—duration less than 30 seconds, depth of deceleration less than 70 beats per minute
- Moderate—duration 30 to 60 seconds, depth less than 70 beats per minute
- Severe—duration greater than 60 seconds, depth less than 70 beats per minute.

Isolated, infrequent variable decelerations have little clinical significance. Repetitive severe variables, however, may not allow sufficient fetal recovery between decelerations, resulting in persistent hypoxemia, hypercapnia, and respiratory acidosis. Prolonged tissue hypoperfusion may lead to metabolic acidosis and, ultimately, fetal death. In animal models, Clapp reported that frequent episodes of hypoxemic stress, produced by intermittent umbilical cord occlusion over a period of hours, produced fetal injury even in the absence of acidosis. When repetitive, severe variable decelerations are present, prolapse of the umbilical cord must be excluded. Other causes include nuchal cord, true knot in the cord, uterine rupture, placental abruption, uterine hypertonus, and tachysystole. Occasionally, variable decelerations fail to return promptly to the baseline and may more accurately be termed *prolonged* decelerations. Prolonged decelerations usually result from umbilical cord compression (cord prolapse, nuchal cord) or other acute interruption of uteroplacental transfer of oxygen (tetanic contraction, uterine rupture, maternal hypotension, maternal apnea, placental abruption).

Late Decelerations Late decelerations reflect inadequate uteroplacental transfer of oxygen during contractions. Typically, they are smooth, uniform decelerations that begin after the onset of a contraction and end after the contraction stops. During uterine contractions, decreased maternal perfusion of the uteroplacental unit causes a decline in fetal PO_2. Fetal PO_2 levels below a critical threshold of 15 to 18 mm Hg trigger a complex chemoreceptor- and baroreceptor-mediated reflex. Initially, centralization of blood volume (favoring perfusion of the brain, heart, and adrenals) occurs via vasoconstriction in the vascular beds of the limbs and gut. The resulting increase in peripheral resistance provokes a reflex deceleration in the FHR. Isolated late decelerations within an otherwise normal tracing have little clinical significance. However, repetitive hypoxemia and centralization of blood volume, as evidenced by repetitive late decelerations, may force hypoperfused tissues to convert from aerobic to anaerobic metabolism. Organic acid by-products of anaerobic metabolism (pyruvate, lactate) diffuse slowly across the placenta and may accumulate in the fetus, leading to metabolic acidosis, asphyxia, and possibly death. Late decelerations may be caused by any factor that (a) reduces the normal placental transfer of oxygen or (b) increases the fetal oxygen demand beyond the available supply. Such factors include uterine hypertonus or tachysystole (oxytocin, prostaglandins, uterine rupture, placental abruption), maternal hypertension (chronic hypertension, preeclampsia, collagen vascular disease, renal disease, diabetes), suboptimal maternal cardiac output (cardiac disease, hypovolemia, supine hypotension, sympathetic blockade from regional anesthesia, sepsis), maternal hypoxia (apnea, cardiac disease, pulmonary disease), reduced oxygen-carrying capacity of maternal blood (anemia, hemoglobinopathy), and fever (increased fetal metabolism and increased oxygen consumption).

Uterine Activity Uterine activity is evaluated with attention to the frequency, duration, and strength of contractions, as well as the baseline uterine tone between contractions. The frequency is assessed by counting the number of contractions as recorded over a period of time. The normal frequency of uterine contractions during labor is every 2 to 3 minutes; however, cervical change may result from contractions occurring less frequently. In most cases, five to seven uterine contractions within a 15-minute period reflect adequate uterine activity. Increased contraction frequency is termed uterine tachysystole and is defined by six or more uterine contractions within a 10-minute window for two consecutive windows. Tachysystole may be seen in cases of placental abruption or hyperstimulation of the uterus by oxytocin or prostaglandin cervical-ripening agents. The duration is assessed by calculating the length of the contraction, the fine vertical lines represent 10-second intervals, and heavy lines denote 1-minute intervals (run at 3 cm per minute). Normal uterine contractions last approximately 40 to 60 seconds. Prolonged contractions may result from “coupling” of contractions, uterine hyperstimulation, or acute complications such as placental abruption or uterine rupture. The strength of the contractions can only be assessed with the direct IUPC. The normal baseline uterine pressure between contractions is approximately 10 mm Hg. Abnormally high baseline pressures in excess of 20 mm Hg may result from hyperstimulation or occasionally from overdistention of the uterus by excessive amnioinfusion, polyhydramnios, or fetal macrosomia. During contractions, normal uterine pressure ranges from 30 to 80 mm Hg, although pressures in excess of 80 mm Hg may be observed during the second stage of labor. A calculation of the strength of the contraction is based on the sum of contraction pressures (peak minus baseline) and is expressed in Montevideo units. For example, four contractions in a 10-minute window, each 50 mm Hg above the baseline, would yield 200 Montevideo units. Montevideo units in

excess of 180 to 200 usually are considered to reflect adequate uterine activity to effect cervical change in labor.

Antepartum Testing/Fetal Monitoring Early in its development, electronic FHR monitoring required direct access to the fetus and was limited to the intrapartum period. Later, Doppler ultrasound technology made it possible to monitor the FHR before labor. The experience gained from intrapartum monitoring was applied to the antepartum period and led to the development of antepartum testing. The goals of antepartum testing are (a) to identify fetuses in jeopardy so that permanent injury or death might be prevented and (b) to identify healthy fetuses so that unnecessary intervention might be avoided. The key measure of the effectiveness of an antepartum test is the false-negative rate, defined as the incidence of fetal death within 1 week of a normal antepartum test. Reported false-negative rates range from 0.4 to 1.9 per 1000 with current testing methods. Another important measure is the false-positive rate. A false-positive test may be defined as an abnormal test that prompts delivery but is not associated with evidence of acute fetal compromise (e.g., meconium-stained amniotic fluid, intrapartum fetal distress, low Apgar scores) or chronic fetal compromise (e.g., fetal growth restriction). False-positive rates range from 30% to 90% with current testing methods. Antepartum testing is used primarily in patients who are considered to be at increased risk for fetal hypoxia or asphyxia secondary to suboptimal uteroplacental transfer of oxygen. It is expected that the use of antepartum testing in these high-risk patients will reduce their risk of fetal/neonatal morbidity/mortality to the level of the low-risk patient. The optimal gestational age at which to begin antepartum testing is not known and varies according to the underlying condition. However, for most medical indications, testing is initiated by 32 to 34 weeks. In view of the high false-positive rates of most testing protocols, earlier initiation of testing should be expected to increase the incidence of unnecessary intervention and iatrogenic prematurity, with its attendant complications.

Fetal Movement Counts Maternal perception of normal fetal movement has long been recognized as a reliable indicator of fetal well-being. Conversely, prolonged absence of fetal movement may signal fetal death. Cessation of fetal movement in response to hypoxia has been demonstrated in animal studies; however, controlled data in human fetuses are lacking. Nevertheless, any acute decrement in the number or strength of fetal movements should raise the suspicion of fetal compromise and should prompt further evaluation. Many clinicians recommend routine fetal movement counting, particularly in patients who are considered high-risk. A common approach is to recommend daily counting of fetal movements for 1 hour. Ten fetal movements in a 1-hour period are considered reassuring. If fewer than 10 movements are appreciated, counting is continued for another hour. Fewer than 10 movements in a 2-hour period should alert the patient to contact her physician for further evaluation. Another protocol calls for movement counting two to three times daily for 30 minutes. With this approach, further evaluation is recommended if there are fewer than four strong movements in a 30-minute period. Although controlled trials in low-risk patients have not demonstrated a significant benefit of formalized movement counting over routine questioning during prenatal visits, evidence from one study using nonconcurrent controls suggests a lower rate of fetal death and a higher incidence of intervention for fetal distress in patients using a formalized protocol of fetal movement counting. Fetal movement counting is an inexpensive method of involving the patient in her own care and may be a valuable adjunct to routine prenatal care, regardless of risk category. Some fetal monitors have the capability to display a Doppler-detected fetal movement profile. This technology may aid the clinician in determining the true baseline FHR and has been shown to reduce the incidence of nonreactive nonstress tests by half.

Nonstress Test FHR accelerations occurring in association with fetal movements form the basis of the nonstress test (NST). Although many criteria have been reported, a normal or “reactive” NST usually is defined by two accelerations in a 10- to 20-minute period, each lasting at least 15 seconds and peaking at least 15 beats per minute above the baseline. In most institutions, the test is repeated once or twice weekly. Boehm and colleagues (1986) reported that the latter approach yielded a three-fold reduction in the incidence of fetal death, although the difference was not statistically significant. Freeman and co-workers (1982) reported a false-negative rate of 1.9 per 1000 among 1542 women tested weekly with the NST. Manning and associates (1983) reported an average false-negative rate of 6.4 per 1000 among nine large clinical trials using the NST as the primary method of surveillance. Assessment of FHR characteristics other than reactivity (baseline rate, variability, decelerations) may improve the sensitivity of the test. The findings from an NST must be interpreted in the context of the pregnancy. Preterm infants commonly do not meet the 15 beats per 15 seconds criterion for reactivity. Once the fetus is 34 weeks, the tracing should be reactive. However, once a fetus demonstrates FHR reactivity, even if earlier than 34 weeks gestation, it should continue to have reactive tests. Reported false-positive rates of the NST vary widely, with an average rate of approximately 50%. When performed twice weekly and interpreted in the context of associated FHR patterns, the NST alone appears to be an acceptable, though not optimal, method of antepartum testing. Advantages include ease of use and interpretation, low cost, and minimal time requirement. The chief disadvantages include a high false-positive rate and a higher false-negative rate than achieved with other methods. Commonly the NST is used as a screening test, and if abnormal, a backup test such as the contraction stress test or biophysical profile is used.

Contraction Stress Test and Oxytocin Challenge Test The first antepartum testing technique, the contraction stress test (CST) or oxytocin challenge test (OCT), arose from intrapartum observations linking late FHR decelerations with poor perinatal outcome. The test sought to identify uteroplacental insufficiency by demonstrating late decelerations in fetuses exposed to the stress of spontaneous (CST) or induced (OCT) uterine contractions. Late decelerations occurring during uterine contractions were associated with increased rates of fetal death, growth retardation, and neonatal depression. The CST is performed weekly and is considered negative if there are at least three uterine contractions in a 10-minute period with no late decelerations on the tracing. Failure to produce three contractions within a 10-minute window or inability to trace the FHR results in an unsatisfactory test. Prolonged decelerations, variable decelerations, or late decelerations occurring with fewer than half of the contractions constitute a suspicious or equivocal test. Unsatisfactory, suspicious, or equivocal tests require repeat testing the following day. The CST or OCT is considered positive when at least half of the contractions during a 10-minute window are associated with late decelerations. Freeman and colleagues (1982) tested more than 4600 women with the CST and reported a false-negative rate of 0.4 per 1000. When the last test before delivery was a reactive, negative CST, the perinatal mortality rate was 2.3 per 1000, compared to a mortality rate of 176.5 per 1000 when the last test was a nonreactive, positive CST. Reported false-positive rates for the CST range from 8% to 57%, with an average of approximately 30%. Principal advantages of this form of testing include excellent sensitivity and a weekly testing interval. Limitations include a high rate of equivocal results requiring repeat testing, increased expense and inconvenience (particularly if oxytocin is required), and increased time requirement compared to the NST. Additionally, use of the CST is contraindicated in several clinical settings, including preterm labor, placenta previa, vasa previa, cervical incompetence, multiple gestation, and previous classic cesarean section.

Biophysical Profile The biophysical profile (BPP) assesses five biophysical variables: FHR reactivity, fetal movement, tone, and breathing reflect acute CNS function, while amniotic fluid volume serves as a marker of the longer-term adequacy of placental function. Two points are assigned for each normal variable and zero for each abnormal variable for a maximum score of 10. A BPP score of 8 to 10, with normal amniotic fluid volume, is considered normal. A score of 6 is considered suspicious, and testing usually is repeated the following day. Scores less than 6 are associated with increased perinatal morbidity and mortality; they usually warrant hospitalization for further evaluation or delivery. Among 12,620 women tested weekly using the BPP, Manning and co-workers reported a false-negative rate of 0.6 per 1000. The false-positive rate of the BPP varies with the score of the last test prior to delivery. Manning and co-workers reported a false-positive rate of zero among 11 patients in whom the last BPP score before delivery was zero, compared to a false-positive rate greater than 40% among 182 patients with a last BPP score of 6. The BPP is a reliable predictor of fetal well-being. The false-negative rate is superior to that of the NST alone and compares favorably with the false-negative rate of the CST. Advantages of BPP include excellent sensitivity, a weekly testing interval, and a low false-negative rate. The primary limitation is the requirement for personnel trained in sonographic visualization of the fetus. Additionally, although the duration of ultrasound observation is less than 10 minutes in the majority of cases, the complete BPP is more time-consuming than other noninvasive tests.

Modified Biophysical Profile The modified biophysical profile (MBPP) combines the strengths of the NST (ease of use, low cost) and the complete BPP (improved sensitivity, low false-negative rate), while minimizing the requirement for additional training in sonographic visualization of the fetus. The test is performed once to twice weekly and uses the NST as a short-term marker of fetal status and the amniotic fluid index (AFI) as a marker of longer-term placental function. Interpretation of the NST incorporates assessment of reactivity, baseline rate, variability, and FHR decelerations. Late, prolonged, or significant variable decelerations, particularly in the setting of borderline amniotic fluid volume (AFI 5 to 10 cm), are considered abnormal. Regardless of reactivity, oligohydramnios (AFI < 5 cm) constitutes an abnormal test. Nageotte and co-workers (1994) evaluated 2774 high-risk pregnancies with twice weekly MBPPs and reported one unexplained fetal death within 1 week of a normal test result, for a false-negative rate of 0.36 per 1000. Miller and colleagues (1996) reported 54,617 MBPPs in 15,482 high-risk pregnancies. Antepartum testing in high-risk pregnancies yielded a fetal death rate that was nearly sevenfold lower than that in the untested, low-risk population. The overall false-negative rate of the MBPP was 0.8 per 1000, and the false-positive rate was 60%. Abnormal test results prompted intervention in 15.5% of the tested population; however, iatrogenic prematurity occurred in only 1.5% of women tested before 37 weeks. The false-negative rate of the MBPP is similar to the CST and the complete BPP. Additionally, it is easier to perform and less time-consuming than the CST or the complete BPP. The sensitivity of the MBPP is superior to that of the NST alone. Limitations include the need for backup testing in 10% to 50% of patients, a high false-positive rate, and a twice weekly testing interval.

Doppler Velocimetry Doppler velocimetry of fetal, umbilical, and uterine vessels has been the focus of intensive study in recent years. This technology uses systolic-to-diastolic flow ratios and resistance indices to estimate blood flow in various arteries. Studies have shown statistically significant improvement in perinatal outcome with the use of Doppler ultrasonography in pregnancies complicated by fetal growth restriction. Although severe restriction of umbilical artery blood flow, as evidenced by absent or reversed flow during diastole, has been correlated with fetal growth restriction, acidosis, and adverse perinatal outcome, the predictive values of less extreme deviations from normal remain undefined. In conditions other than fetal growth restriction, Doppler velocimetry does not appear to be a useful screening test for the detection of fetal compromise and is not recommended for use as a screening test in the general obstetric population. Doppler velocimetry is used in some settings as an adjunct to standard methods of fetal assessment but should not be considered a replacement for traditional fetal monitoring.

OTHER METHODS AND INTRAPARTUM EVALUATIONS

Fetal Scalp Blood Sampling

Fetal scalp blood sampling allows for the determination of the fetal acid–base status during labor. The technique requires dilation of the cervix, rupture of the membranes, and access to the fetal presenting part. A lighted plastic endoscopic cone is inserted into the vagina and through the cervical os so that it rests against the fetal presenting part. Care should be taken to ensure that it is not placed over a fontanelle. The area to be sampled is dried with a sponge and coated with a thin layer of silicone to facilitate the formation of a blood globule. The scalp is then punctured with a microscalpel, and blood is collected by capillary action in a heparinized capillary tube. After the sample is mixed, it is transported on ice to the laboratory for blood gas analysis. During labor, a normal scalp blood pH is 7.25 to 7.35. A fetal scalp pH of greater than or equal to 7.25 provides evidence of a nonacidotic fetus. A scalp pH of 7.20 to 7.25 is considered suspicious, and sampling should be repeated within 30 to 60 minutes. Historically, pH values less than 7.20 have been considered acidotic; however, minor deviations below normal correlate poorly with perinatal outcome. Because abnormal perinatal outcome has not been consistently observed with values greater than 7.0, there is debate regarding the specific pH value that should be considered acidotic. In addition, fetal scalp sampling reflects the status of the peripheral blood, where acidosis is inherent, owing to the accumulation of CO_2. Since respiratory acidemia is generated in the blood and metabolic acidemia is generated in the tissues, a scalp sample may not reflect the state

of the fetus. In light of the technical difficulty of the procedure and the uncertainty regarding interpretation of results, many centers have reduced their reliance on fetal scalp blood sampling.

Percutaneous Umbilical Blood Sampling

Electronic FHR monitoring, ultrasound, and fetal scalp blood sampling can provide useful information regarding the acid–base status of the fetus. Occasionally, however, direct access to circulating fetal blood is necessary. A classic example is the fetus with severe anemia secondary to Rh-isoimmunization. In this condition, maternal antibodies directed against fetal red blood cell antigens cross the placenta and bind to fetal red blood cells, resulting in hemolysis. At term, suspected fetal anemia can be managed by delivery and treatment of the neonate. Earlier in pregnancy, however, it may be preferable to delay delivery by assessing the fetal hematocrit and, if necessary, performing intrauterine blood transfusion. Percutaneous umbilical blood sampling (PUBS) is a procedure that affords direct access to fetal venous blood. Using sterile technique and direct ultrasound guidance, a fine needle is passed transabdominally into the umbilical vein. Medications or blood may be infused through the needle once fetal blood samples have been obtained. Other indications for PUBS include suspected antibody-mediated fetal thrombocytopenia and fetal cardiac arrhythmias requiring assessment of fetal drug levels or direct fetal administration of antiarrhythmic agents.

Fetal blood sampling can be used along with cardiotocography (CTG) to assess fetal acid–base status during labor. However it requires additional expertise, is time-consuming, has some significant risks, and has only intermittent information. For these reasons, it is not widely used.

Fetal Scalp Stimulation and Fetal Vibroacoustic Stimulation

FHR accelerations of 15 beats per minute for 15 seconds in response to fetal scalp stimulation have been shown to predict a scalp pH greater than or equal to 7.19. Among fetuses without an acceleratory response to scalp stimulation, 39% were considered acidotic (pH < 7.19). A similar relationship has been reported between fetal scalp pH and the FHR response to vibroacoustic stimulation with an artificial larynx applied to the maternal abdomen over the fetal head for 1 to 3 seconds. Among 30 fetuses with FHR accelerations in response to this stimulus, all had scalp pH values greater than or equal to 7.25. Half of the fetuses that did not respond to acoustic stimulation had pH values less than 7.25. FHR accelerations in response to external stimuli are thought to have the same predictive value as spontaneous accelerations. Fetal stimulation is used in antepartum testing to shorten the time of the NST and in the intrapartum period to confirm fetal well-being when spontaneous accelerations are absent. There is no evidence in humans of adverse long-term effects of vibroacoustic stimulation.

Fetal Pulse Oximetry (Fetal Oxygenation)

The aim of fetal pulse oximetry is to provide a continuous assessment of fetal oxygen saturation. The fetal pulse oximeter provides a noninvasive continuous measurement of fetal arterial oxyhemoglobin saturation once membranes have been ruptured. A sensor, similar to an IUPC is placed transvaginally between the uterine wall and fetal face and measures oxyhemoglobin saturation. The system includes an optoelectronic sensor and a microprocessor-based monitor. It has two low-voltage, light-emitting diodes as light sources and one photodetector. One of the light-emitting diodes emits red light (735 nm) and the other emits infrared light (890 nm). When light from each light-emitting diode passes through fetal tissues at the sensor application site, a fraction is absorbed. The photodetector measures the reflected (nonabsorbed) light using a process similar to measurement of transmitted light in conventional pulse oximetry. The amount of light absorbed is related to the amount of oxy- and deoxyhemoglobin. Their ratio determines fetal oxygen saturation during each arterial pulse. The potential is that this technology will provide a practical and easy method for better evaluation of fetal well-being during labor.

In 1994, fetal oximetry was marketed in countries outside of the U.S., including Europe and Canada. In January 2000, the Obstetrics and Gynecology Devices Panel of the Medical Devices Advisory Committee of the Food and Drug Administration (FDA) recommended approval of a fetal oximeter for use in obstetrics (OxiFirst: N-400 Fetal Oxygen Monitoring System, Nellcor).

A U.S. multicenter, randomized, controlled trial of fetal oximetry enrolled 1010 women with abnormal FHR patterns. The objective of the trial was to determine whether fetal pulse oximetry with fetal monitoring would reduce the rate of cesarean delivery performed for non-reassuring fetal status. The rate of cesarean delivery for fetal distress was significantly lower in the fetal oximetry group (4.5%) compared to 10.2% in the conventional fetal monitoring group. Unexpectedly, however, the cesarean rate for dystocia was significantly higher in the oximetry group (18.5%) versus 8.6% in the control group), thus the overall cesarean rates were not different (29% oximetry plus FHM vs. 26% FHM).

Clearly, continuous measurement of fetal oxygen saturation could be an important addition to the interpretation of heart rate patterns. The device is attractive in that it offers a direct measure of fetal oxygenation during labor. However, like its predecessor, electronic FHR monitoring, oximetry has the potential for widespread application without conclusive evidence that it is efficacious. The use of this technology is the focus of several ongoing clinical studies and trials.

Fetal Cardiotocography Plus Pulse Rate-Interval Analysis Normally there is a negative relationship between the pulse rate (PR) interval and the FHR: as the FHR slows, the PR interval lengthens, and vice versa. In acidemic infants, this relationship is reversed. A retrospective study of 265 women suggested that the addition of time-interval analysis of the fetal ECG would decrease the rate of unnecessary fetal blood sampling or assisted delivery for presumed fetal distress. However, in a prospective randomized trial of the use of fetal ECG time-interval variables in addition to cardiotocography in fetal surveillance during labor there was no difference in operative intervention or neonatal outcome. The use of fetal cardiotocography plus PR-interval analysis is presently considered investigational.
ST Waveform Analysis Since different fetuses may be able to tolerate varied oxygenation levels based on their situation prior to the hypoxic event, reliance on the level of oxygenation may not be the most applicable measure. In the search for other parameters, an evaluation of the changes in specific end organs, such as the fetal heart, have been pursued. One development is the ST waveform analysis to aid in the interpretation of ominous FHR patterns. ST analysis of the ECG during exercise is a method for assessing myocardial function in the adult. As a corollary, ST waveform analysis of the fetus during labor is analogous to a fetal “stress test” and should provide information on the ability of the fetal heart to respond. An ST segment rise indicates a fetus responding to hypoxia. A negative ST indicates a fetus that is unable to respond or has not had time to react. The fetal ECG is readily obtainable during labor from the same scalp electrode used to obtain the FHR. The evidence from experimental work indicates that ST waveform elevation reflects compensated myocardial stress and a switch to anaerobic myocardial metabolism. A study of 4966 women with CTG versus CTG plus ST analysis revealed that intrapartum monitoring with cardiotocography combined with automatic ST waveform analysis increased the ability of the obstetrician to identify fetal hypoxia. Currently, the use of ST segment elevation in clinical interpretation of fetal heart tracings is considered investigational and studies are ongoing to assess its effectiveness.

SUMMARY POINTS

- Fetal evaluation and interpretation of the findings has made some significant advances. However, there are many limitations with the available technology.
- Electronic FHR monitoring is a very sensitive tool for the detection of fetal compromise; truly compromised fetuses rarely fail to exhibit abnormal FHR patterns. The converse, however, is not true. Abnormal FHR patterns frequently are observed in the absence of fetal compromise. The limited positive predictive value is the principal shortcoming of FHR monitoring.
- Accuracy may be improved by combining FHR analysis with assessment of biophysical variables such as amniotic fluid volume, fetal movement, breathing, tone, and blood flow characteristics.
- Other variables under investigation include continuous intrapartum fetal pulse oximetry, fetal ECG interpretation, and ST waveform analysis.
- To date, the most effective combination of variables has not been defined, and no one approach to fetal surveillance has demonstrated clear superiority over the others. Yet, despite the limitations, antepartum testing in “high-risk” pregnancies has been reported to yield a fetal death rate nearly seven times lower than that in untested, “low-risk” pregnancies. If this observation is substantiated, future investigation will be needed to address the role of antepartum fetal surveillance in uncomplicated, low-risk pregnancies.

SUGGESTED READINGS

Over the past two decades we have seen a marked increase in survival of very low birth weight infants. This increase in survival has been attributed to increased use of corticosteroids, regionalization of perinatal care, improved methods of mechanical ventilation, availability of exogenous surfactant, and improved nutritional therapy. However, the reduction in mortality has not been accompanied by a reduction in neonatal morbidity or long-term handicaps. It is estimated that 50% of all major neurologic handicaps in children result from premature births.

Despite widespread awareness of the problem and use of therapies believed to be beneficial to prevent preterm births, the rate of preterm delivery is increasing in the United States. The majority of spontaneous premature births occur to women who develop preterm labor or preterm premature rupture of the membranes (PPROM). Cervical incompetence may also result in preterm delivery. Historically, researchers and epidemiologists have approached these conditions as being distinct processes that were mutually exclusive of one another. Recent evidence would suggest that many women have overlapping conditions, which predispose them to deliver preterm. This concept is depicted in Figure 10.1. For example, a women who has preterm delivery secondary to PPROM at 27 weeks gestation, may have had weeks of “silent” or painless contractions or cervical dilation prior to developing ruptured membranes and delivery. Using this broader conceptual framework, this chapter will review the epidemiology, etiology, prevention, and treatment of women with preterm labor.

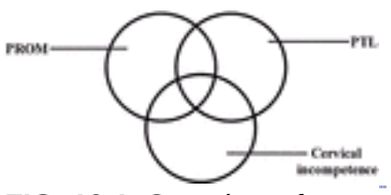

FIG. 10.1. Overview of spontaneous preterm birth.

MECHANISMS OF LABOR ONSET

Labor occurs when mechanisms are present that convert the uterus from a state of containment to an environment that attempts to expel the fetus. In humans, the average gestational period is 280 days ± 14 days. Therefore, term labor is defined as *labor that occurs between 37 and 42 weeks gestation*. Preterm labor is defined as *labor that occurs between 20 and 37 weeks gestation*. In theory, pathologic activation of the normal parturition process results in preterm labor and delivery.

In both term and preterm labor, following an unknown stimulus, the mechanisms that produce labor override those that maintain the pregnancy. Activation of the parturition process results in membrane activation, cervical ripening, and an increase in myometrial responsiveness to endogenous and exogenous signals. Subsequently, labor progresses along a common pathway that results in uterine contractions that are sufficient to cause progressive cervical dilation to allow for expulsion of the fetus. A number of inciting events have been implicated in premature births. These events include decidual hemorrhage (abruption), mechanical factors (overdistension of the uterus, cervical incompetence), hormonal changes (fetal or maternal stress) or subclinical/clinical infection. Infection is associated with as many as one third of preterm deliveries, particularly those occurring at the earliest gestational ages. The role of infection in preterm labor will be reviewed separately in this chapter.

Animal models have helped in understanding labor. Important findings in animal labor models include an increase in oxytocin receptors present in the myometrium, gap junctions developing between myometrial cells, an increased response to agents capable of producing contractions in the uterus, and physical and biochemical changes of the cervix resulting in a softened consistency. Uterine smooth muscle contractility is produced by the actin–myosin interaction, following myosin light chain phosphorylation, which is controlled by myosin light chain kinase. Myosin light chain kinase is activated by calcium as a calmodulin–calcium complex. Cyclic adenosine monophosphate (cAMP) also regulates kinase by inhibiting phosphorylation. Many factors are involved in this control. Some of the proposed theories of labor will be discussed in the following sections.

Hormonal

Alteration in systemic or local levels of steroid hormones is an initiating factor of labor in some animals. The understanding of their possible role in human labor has been continuously evolving. The withdrawal of the uterine inhibitor hormone progesterone has been shown to play a major role in many animals (e.g., sheep, rats, rabbits). In sheep, this withdrawal seems to be caused by an increased responsiveness of fetal adrenal cells to adrenocorticotropic hormone (ACTH) that results in increased production of cortisol. Through several steps, cortisol redirects placental steroid biosynthesis and decreases progesterone secretion. The decreased circulating progesterone in the sheep permits increased myometrial gap junction formation, an increase in prostaglandin formation, and increased response of the uterus to agents capable of producing contractions. In this sheep model, fetal ACTH secretion has control of the onset of labor.

Major differences exist, however, between sheep hormonal status and that of primates, including humans. In humans, there is no great increase in cortisol from the fetal adrenal gland before labor, nor has a dramatic decrease in progesterone been consistently demonstrated. Progesterone, however, is important in human pregnancy, and numerous studies have examined the role of the progesterone-to-estrogen ratio before the onset of labor. In 1974, investigators demonstrated a significant fall in serum progesterone levels and a rise in estrogen levels in many women before labor. This finding has not been reproduced consistently. Estriol may be a signal from the fetus indicating that it is mature and ready for delivery. Production of estriol increases during the last month of pregnancy. In the large amounts produced, estriol is as active as estradiol in stimulating uterine growth. There are reports of an elevation in the estradiol/progesterone ratio at the end of pregnancy.

Administration of progesterone has not been demonstrated to delay term or preterm labor in primates. The antiprogesterones—RU-486 or mifepristone and ZK-98299 or onapristone—in humans and other primates can enhance the responsiveness of the uterus and induce cervical change within 12 to 48 hours, again suggesting a role for progesterone in preventing labor onset.

Oxytocin

It is well known that oxytocin produces uterine activity when administered to pregnant women. The role of endogenous oxytocin as an initiator of term or preterm labor is less well defined. Some reasons to suspect that oxytocin is a universal initiator of labor are its ability to induce labor when given exogenously, and the increase in blood levels that accompanies labor in most species. Because of the pulsatile manner of oxytocin release and the difficulty in measuring the hormone, its precise role in humans has been difficult to ascertain. Compared with oxytocin levels in nonlaboring patients, levels appear to be significantly increased during the first stage of labor and increase to a greater amount during the second stage of labor. Oxytocin levels are higher in umbilical artery blood than in umbilical vein or maternal blood. This finding suggests that the fetus is a source of oxytocin production and release during labor. It is clear that the uterus becomes more sensitive to oxytocin in the days preceding labor. The number of myometrial cell membrane oxytocin receptors greatly increases as pregnancy advances, with a further increase during labor itself. In humans as well as in other species, the concentration of oxytocin receptors is a major reason for increased contractility of the uterus. The increase in oxytocin receptors is the result of increased estrogen levels.

Prostaglandins

Another important part of the parturition model is the synthesis and release of prostaglandins E_2 and F_2. This is supported by an increase in prostaglandins or metabolites in the amniotic fluid, endometrium, decidua, myometrium and blood at the time of labor, the administration of prostaglandins inducing labor, and inhibitors to prostaglandin synthesis delaying labor. It is likely that the prostaglandins have a role in parturition originating from the decidua and myometrium. Oxytocin has the ability to stimulate prostaglandin release through the decidual receptors. In addition, infection of the membranes can release prostaglandins and may be an initiating factor in many cases of preterm labor.

Bacterial by-products may be directly responsible for the stimulation of prostaglandin release in the following ways: Bacterial phospholipase releases the precursor arachidonic acid from the amnion, leading to increased prostaglandin synthesis. Gram-negative organisms may also be able to produce prostaglandins through endotoxin stimulation of the decidua or membranes. Gram-positive organisms may also have prostaglandin-stimulating abilities through peptidoglycans. Phospholipase A_2 is contained within the lysosome of the fetal membranes. As phospholipase A_2 is released from the lysosome, prostaglandin may be synthesized, resulting in uterine contractions.

Cytokines

Cytokines are substances secreted by the immune system in response to infection. There is recent interest in the role of cytokines and growth factors, (e.g., epidermal growth factor, insulin-like growth factors 1 and 2) as potential initiators of labor. The cytokines interleukin 1 (IL-1), IL-6, and tumor necrosis factor (TNF) stimulate the amnion and decidua to produce prostaglandins and increase at time of labor, while transforming growth factor-ß (TGF-ß) inhibits prostaglandin production by other cytokines and may have antiprogestin properties. Finally, several different cytokines have been found in the amniotic fluid of patients with preterm labor.

Other Factors

Endothelins are potent vasoconstrictors in the sarafotoxin-like family. Some isoforms of endothelins are potent uterotonics. Although endothelin does not appear to increase at time of labor, uterine sensitivity and endothelin-receptor numbers do increase in the pregnant uterus. There is some decrease of endothelin-1 in the amniotic fluid of patients in labor, but this may be a consequence rather than an initiator of labor. Nitric oxide, produced from L-arginine by the enzyme nitric oxide synthase (NOS), mediates relaxation of vascular smooth muscle. It has been shown in various animal tissues, including human, that the NOS enzyme is decreased in myometrial tissue at term. Thus, nitric oxide may have a role in maintaining a quiescent uterus.

It can be hypothesized that parturition is a development of an estrogen environment. This estrogen environment promotes changes in the maternal pituitary with increased oxytocin synthesis and release. Estrogen may also be acting directly on the placenta and cervix. As the antiestrogen progesterone level decreases, estrogen can act to increase oxytocin receptors, prostaglandin production, and gap junction number and size. As the cervix ripens, the underlying membranes and decidua become exposed to the vaginal bacteria, triggering an inflammatory response with release of cytokines and prostaglandins. At this point, the paracrine events take dominance over the endocrine effects. Some conditions, such as infection, can overwhelm the endocrine phase of parturition.

INFECTION AS A CAUSE OF PRETERM BIRTH

Preterm birth has been linked with symptomatic nongenital infections, such as acute pyelonephritis and pneumonia. In the last 15 years, new information has suggested that subclinical infection may be an important cause of premature labor, especially labors resulting in very early delivery.

The hypothesis linking subclinical infection and premature birth may be summarized as follows: microbes or their products such as endotoxin enter the uterine cavity during pregnancy, most commonly ascending from the lower genital tract. Blood-borne infection from a nongenital focus occurs less commonly. Microbes or their products then interact, most likely with the decidua or possibly with the membranes, producing prostaglandins or directly leading to uterine muscle contraction. This interaction is most likely mediated through a cytokine cascade. As a result, there is cervical dilation, entry of more microbes into the uterus, and continuation of “the viscous cycle” resulting in premature birth.

The first piece of evidence linking subclinical infection to preterm birth is that the prevalence of histologic chorioamnionitis is increased among preterm births. In membranes from preterm deliveries, there is a consistent and very strong association between positive membrane cultures and the likelihood of membrane infiltration. For example, when the birth weight is greater than 3,000 g, the percentage of placentae showing histologic chorioamnionitis is less than 20%; when the birth weight is below 1,500 g, the percentage was fully 60% to 70%. Most cases of histologic chorioamnionitis are caused by infection.

Second, clinically recognized infection is increased in mothers and neonates after preterm birth. This association is also consistent. Sepsis and meningitis are increased three- to ten-fold in preterm infants. Less widely recognized is the increase in maternal infection after preterm birth. These observations suggest that subclinical infection underlies preterm birth and that the infection became clinically evident during or shortly after birth. Alternatively, the preterm infant may be more susceptible to infection that develops after delivery.

Third, there are associations of preterm birth with various maternal lower genital infections or microbes (Table 10.1). Although *Ureaplasma urealyticum* in the lower genital tract has been associated with low–birth-weight (LBW) infants in earlier studies, a large National Institutes of Health (NIH) study reported no associations of *U. urealyticum* in the vagina with any adverse pregnancy outcome (preterm birth, PPROM, LBW, or BW <1,500 g). Interestingly, then, *U. urealyticum* in the lower genital tract is *not* associated with LBW/preterm pregnancies, even though this organism is one of the most common isolated in the amniotic fluid of women in preterm labor. Lower genital infection with *Chlamydia trachomatis* has also not been consistently associated with adverse pregnancy outcome. However, women with active chlamydial infection and with a positive serum antichlamydial immunoglobulin M (IgM) have shown an increase in rates of preterm delivery. Although a consistent association has not been observed between maternal group B streptococci (GBS) colonization and premature birth in several small studies, a large investigation of approximately 13,000 women showed that pregnant women with heavy GBS colonization had a small but significant increase in risk for LBW (odds ratio [OR] = 1.2; 95% confidence interval [CI] = 1.01–1.5). There were no significant increases in other adverse outcomes, including preterm birth, among heavily colonized women. Women with light colonization were not at an increased risk for any adverse outcomes. Results are also contradictory regarding an association between *Trichomonas vaginalis* and premature birth. Although small, earlier studies had conflicting results, the large Vaginal Infections and Prematurity Study found the presence of *T. vaginalis* in the vagina at midpregnancy was significantly associated with preterm LBW (7.1% of women with vs. 4.5% without *T. vaginalis*: OR = 1.6; 95% CI = 1.3–1.9). Considerable data have linked lower genital tract anaerobes with preterm labor. Further, bacterial vaginosis, in which there is a predominance of anaerobes, has been consistently associated with approximately a two- to three-fold increase in spontaneous preterm delivery. Among other infections, untreated pyelonephritis has been associated with a risk of preterm delivery of approximately 30%, and asymptomatic bacteriuria is associated with a 60% higher rate of LBW (95% CI =

1.4–1.9) and a 90% higher rate of preterm delivery (95% CI = 1.3–2.9).

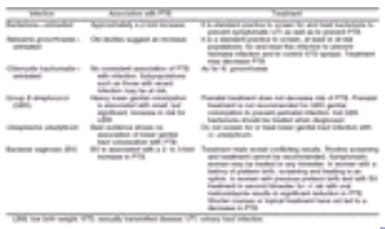

TABLE 10.1. *Prenatal infections as a cause of preterm birth (PTB): association and treatment recommendations*

Fourth, positive cultures of the amniotic fluid/membranes/decidua are found in some patients in premature labor. The range of positive amniotic fluid cultures obtained by amniocentesis from asymptomatic women in premature labor is 3% to 24%. When more sensitive testing for detection of bacteria (polymerase chain reaction) is carried out in amniotic fluid from women in preterm labor, bacteria are detected in 30% to 50%. The most widely discussed route of upper genital tract infection in preterm labor is an ascending path through the vagina and cervix. Similarities in organisms isolated from the amniotic fluid and the lower genital tract support this pathogenic route. It is also possible to speculate that bacteria may enter the uterine cavity hematogenously through spread via the placenta, by contamination at the time of instrumentation such as during amniocentesis or chorion villus sampling, or even by spread from the abdominal cavity via the fallopian tubes. Other sources of organisms for hematogenous spread include bacteremia from periodontal disease or procedures. Among women in spontaneous preterm labor with intact membranes, genital mycoplasmas and anaerobic organisms as well as *Gardnerella vaginalis* (the so-called bacterial vaginosis organisms) are in fact those organisms most commonly found in the amniotic fluid. Sexually transmitted organisms such as *Neisseria gonorrhoeae* and *C. trachomatis* are rarely found in the amniotic fluid, and GBS and *Escherichia coli* are found just occasionally. Patients in preterm labor with the highest likelihood of having a positive culture of the amniotic fluid are those in preterm labor at early gestational ages. It may be speculated that intrauterine infection occurs early in pregnancy (or even has preceded the pregnancy) and may remain without clinical detection for months.

Fifth, biochemical “markers” of infection are often present among women in premature labor. In infection-induced premature labor, the primary site of infection is probably not the amniotic fluid, but the decidua or membranes. More sensitive markers of infection potentially include amniotic fluid glucose concentrations, serum white blood cell counts, C-reactive protein, and amniotic or serum cytokines. Unfortunately, relatively few are clinically useful. Among patients in preterm labor, a low amniotic fluid glucose (<14 mg/dL) correlates well with the likelihood of a positive culture. Among the cytokines, an elevated amniotic fluid IL-6 level is probably the most sensitive marker for infection, but is not yet widely available for clinical use.

Sixth, bacteria or their products induce preterm birth in animal models. The evidence presented here that indicates that infection is a cause of preterm birth in humans is circumstantial. Animal models have provided direct evidence that infection triggers preterm birth in the rabbit, monkey, and mouse.

Seventh, in some clinical circumstances, use of antibiotics has led to a lower rate of preterm birth and to delayed delivery. Antibiotic treatment trials may be classified as one of three designs:

- those conducted prenatally in patients at high risk for preterm delivery
- those conducted among women in preterm labor with intact membranes, as adjuncts to tocolytic therapy
- those conducted among women with PPROM.

Chapter 11 discusses antibiotics in PPROM. Table 10.2 summarizes current practices for use of antibiotics to prevent preterm birth. The discordant results in antibiotic trials raise the question as to why antibiotics have not consistently prevented preterm birth or neonatal morbidity associated with preterm birth. One explanation is that infection is simply not a significant cause of preterm labor, but this seems unlikely in view of all the other evidence. Another explanation is that studies have had too low a power. However, large meta-analyses and the ORACLE trial appear to rule out this possibility. Further, because preterm labor has multiple causes, a true effect of antibiotics may be diluted by those cases of preterm labor not caused by infection. It may also be that only a subset of pregnant women (e.g., perhaps genetically predisposed women) with high cytokine response are at risk for preterm labor after subclinical infection. Another reasonable explanation is that the antibiotics studied in most of the trials were simply the wrong ones (e.g., not including antibiotics with better anaerobic activity) or the antibiotics were given too late or the antibiotic dose or timing were incorrect. It has also been speculated that bacterial lysis as a result of antibiotic therapy may lead to increased exposure to lipopolysaccharide and thus enhance preterm labor. Finally, because infection is more likely to cause very early preterm birth (<32 weeks), trials focusing on women at later gestational ages may not show an effect. For example, the ORACLE I trial enrolled women up to 37 weeks gestation, and only 10% delivered at less than 32 weeks.

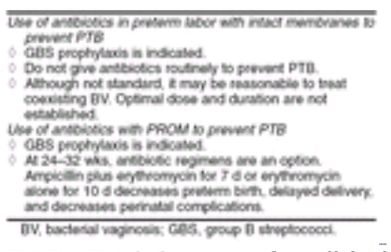

TABLE 10.2. *Use of antibiotics to prevent preterm birth (PTB) in women with preterm labor and premature rupture of the membranes (PROM)*

EPIDEMIOLOGY OF PRETERM LABOR

Currently, 11.8% of women deliver preterm. The vast majority of preterm deliveries are a result of preterm labor (50%), premature rupture of the membranes (33%), or cervical incompetence. The contributions of preterm labor and premature rupture of the membranes to preterm deliveries vary depending upon a number of factors including socioeconomic status (Fig. 10.2). In a large study from North Carolina, Meis and colleagues found that the most common reason for delivery less than 2,500 g in women who were receiving public assistance was PPROM (34%). In contrast, in women who had private insurance, the most common reason for early delivery was preterm labor (52%). Indicated preterm deliveries accounted for 14% and 18% of preterm deliveries, respectively.

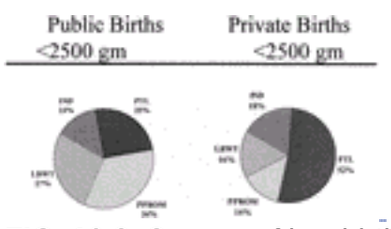

FIG. 10.2. Causes of low birth weight births in public and private patients. (Meis P, Ernest J, Moore M. Causes of low birth weight births in public and private patients. *Am J Obstet Gynecol* 1987;156:1165–1168, with permission). IND, indicated by maternal–fetal condition; PTL, preterm labor; PPROM, preterm premature rupture of membrane; LBWT, low birth weight.

Several major and minor risk factors are associated with development of preterm labor and premature rupture of the membranes (Table 10.3, Table 10.4). One of the most obvious and important risk factors for prematurity is a prior history of preterm delivery. To better quantify this relationship, Mercer and associates performed a subgroup analysis of data collected during a large population-based observational study evaluating risk factors for preterm delivery. In this study, gravid women with any prior spontaneous preterm birth had a 2.5-fold increased risk of spontaneous preterm delivery in the current pregnancy. This risk increased to 10.6-fold if the spontaneous preterm birth occurred prior to 28 weeks gestation. Interestingly, women with a history of loss between 13 and 22 weeks gestation had rates of prematurity that were similar to women who did not have this history (10.1% vs. 8.8%, *P* = .69).

	Relative risk
Prior preterm birth	6–8×
Multiple gestations	6–8×
African-American race	3.3×
Low socioeconomic status	1.9–2.6×

TABLE 10.3. *Major preterm labor risk factors*

Modifiable risks	Nonmodifiable risks
Poor maternal weight gain	Extremes of age (<17 or >40)
Physically demanding work	Prior multiple abortions
Smoking	History of DES exposure
Anemia	History of uterine abnormality
Bacteriuria	Short stature
Bacterial vaginosis	Low prepregnancy weight
Maternal systemic infections: pyelonephritis	

DES, diethylstilberol.

TABLE 10.4. *Minor preterm labor risk factors*

Another major risk factor for preterm labor and birth is multiple gestation. The rate of multiple gestations has increased dramatically over the past 15 years. The increase in twins and higher order multiples is largely a reflection of increased use of ovulation induction and assisted reproductive technologies. Fifty percent of twins deliver prematurely with a mean gestational age at delivery of approximately 35 weeks. As expected, the percent of preterm deliveries increases in proportion to the number of fetuses. Triplets and quadruplets deliver on average at 32 weeks and 30 weeks, respectively. Until researchers develop techniques to perform artificial reproductive technologies that minimize the risk of having high order multiples, then these women will continue to be at significant risk for delivering prematurely and suffering the consequences of preterm birth.

African Americans are 1.6 to 2.5 times more likely to deliver prematurely than Caucasian women of similar age and socioeconomic status. Although African Americans have higher rates of prematurity, the rates of neonatal morbidity are lower in African-American neonates when compared to Caucasians born at similar gestational ages. This suggests that the gestational period may be shorter in African-American women. Low socioeconomic status is also strongly associated with prematurity. It is not clear whether this is related to environment, genetic predisposition, infection or access to medical care.

Table 10.4 also lists a number of “minor” risk factors for preterm labor and delivery. Several of these will be discussed in more detail later in this chapter. In general, the minor risk factors can be broken into two categories: those that are potentially modifiable and those that are not. Many of the minor risk factors are common in pregnancy. Individually their contribution to prematurity is small; however, the risk is compounded by addition of other risk factors. The impact of work on preterm birth remains controversial. Prolonged, physically demanding work does appear to independently increase the risk of prematurity and is potentially modifiable.

PREDICTION OF WOMEN AT RISK FOR PRETERM LABOR

Over the past two decades many researchers have focused on identification of women who are at risk for preterm delivery. Theoretically, identification of asymptomatic women at risk for preterm delivery would allow obstetricians to effectively intervene to prevent preterm delivery or to decrease neonatal morbidity and mortality in preterm neonates. In an American College of Obstetricians and Gynecologists' (ACOG) Practice Bulletin titled *Assessment of Risk Factors for Preterm Birth*, the authors wrote “the ability to predict whether a women is at risk of preterm delivery has value only if an intervention is available that is likely to improve the outcome.” It is believed that identification of women at risk for preterm birth will be beneficial if it allows women to:

- receive a complete course of antenatal corticosteroids prior to delivery
- if necessary, receive tocolytic agents to maximize the probability that antenatal corticosteroids will be given
- be transported to a level III perinatal center.

Another potential benefit of screening is to identify women at low risk for preterm delivery and thereby avoiding administration of potentially dangerous medications or therapies to these women.

Table 10.5 is a review of “ideal” criteria for a screening test. An ideal screening test should have high sensitivity and positive predictive value as well as high specificity and high negative predictive value. Most screening tests do not meet these requirements and trade off sensitivity for specificity. Depending on the clinical scenario where screening tests are used and the consequences of treatment or no treatment, one must decide which test characteristic to stress. For example, one could argue that given the high morbidity associated with preterm birth, the ideal screening test should have a high sensitivity to allow treatment of the majority of women “at risk” and accept a lower specificity rate. On the other hand, one could argue, as ACOG did, that avoidance of treatment with potentially hazardous drugs is beneficial in women with symptoms who are at “low risk” for delivery, thus stressing the importance of the test's specificity and negative predictive value. The following will review available screening tests.

Ascertainment of early, asymptomatic disease
Early treatment alters health outcomes
Disease is important, prevalent
Screening acceptable to population
Diagnosis/treatment readily available
Screening test: simple, reliable, valid
Cost proportional to benefit

TABLE 10.5. *Criteria for screening tests*

Risk Scoring Systems

Risk scoring systems were promoted heavily in the 1980s to identify women at risk for preterm delivery. The risk scoring systems weigh major and minor risk factors for preterm birth as well as current pregnancy complications (see Table 10.3, Table 10.4). The scoring systems work best in multiparous patients and worst in privately insured nulliparas with singleton gestations. Overall, the sensitivity of the screening tool ranges from 3% to 30% and the positive predictive values from 0% to 20% depending on the population studied. While easy to use to identify women who may have modifiable risk factors for preterm delivery, the scoring systems do not reliably identify women at risk. They should not be used alone to institute interventions that may or may not be warranted.

Contraction Monitoring

Contraction monitoring has also been advocated to identify women at risk for preterm birth. Main and associates, in an inner-city clinic in Philadelphia, had low-risk women wear tocometers while waiting in the clinic to be seen between 28 and 32 weeks gestation. Women with 6 or more uterine contractions per hour were more likely to deliver prematurely than women who did not. Using this cutoff, the sensitivity was 75% and the specificity was 79%. As technology became more advanced, this concept was developed further and home uterine activity monitoring (HUAM) became possible. HUAM, as initially promoted, was a combination of telemetric recording of uterine activity and daily contact with perinatal nurses trained to identify signs and symptoms of early preterm labor. The following assumptions were used to establish a role for HUAM:

Women with preterm uterine activity are more likely to deliver prematurely than women who deliver at term.

Women at risk for preterm labor may be unaware of their contractions, thus they present too far along in established labor for treatment to be effective.

Effective treatment for preterm labor is available.

At least 13 randomized clinical trials have evaluated the role of HUAM. These trials differ dramatically depending on the inclusion and exclusion criteria, the use of adjunctive tocolytic agents, and the primary end points. Despite being “randomized clinical trials”, many of the reports were so severely flawed that they were not

included into several meta-analyses on the subject. After review of all of the evidence, both ACOG (HUAM: not recommended') and the U.S. Preventive Services (HUAM: devise not effective) discouraged the use of this expensive and unproven therapy. Additional research may be warranted in specific at-risk subgroups.

Salivary Estriol

Salivary estriol has also been promoted as a tool to identify women at risk for preterm birth. The basis for this theory is that estriol, a fetal product, is increased following activation of the fetal hypothalamic–pituitary–adrenal axis prior to spontaneous preterm birth. The estriol can be measured in maternal salivary secretions. Salivary estriol levels have a diurnal variation that peaks at night. Therefore, samples need to be collected in the morning to improve specificity. Using longitudinal sampling with morning collections, the sensitivity of SalEst is 71% and the specificity 77%. The false-positive rate is unacceptably high at 23%. Currently, there are no commercially available salivary estriol kits. Salivary estriol should be considered only as a research tool with limited, if any, clinical indications for use.

Screening for Bacterial Vaginosis

Bacterial vaginosis is a common alteration of normal vaginal flora affecting 10% to 25% of normal women. The majority of infections are asymptomatic. The presence of bacterial vaginosis has been clearly associated with preterm births in both prospective cohort studies and case-control studies. As a result, investigators and clinicians have attempted to eradicate bacterial vaginosis in an effort to reduce the incidence of preterm delivery. Brocklehurst and colleagues evaluated this treatment strategy using meta-analysis. They included five randomized clinical trials. As expected, treatment was highly effective in eradicating bacterial vaginosis (OR = 0.22; 95% CI = 0.17–0.27). The included trials used oral metronidazole, vaginal metronidazole, or vaginal clindamycin. Overall, treatment did not reduce preterm delivery prior to 37 weeks gestation (OR = 0.78; 95% CI = 0.60–1.02), preterm delivery prior to 34 weeks gestation (OR = 0.83; 95% CI = 0.32–2.08), or preterm delivery prior to 32 weeks gestation (OR = 1.51; 95% CI = 0.60–1.61). In a subgroup analysis, no effect was noted with vaginal administration of metronidazole or clindamycin. However, patients with a history of preterm delivery and bacterial vaginosis in the current pregnancy who received active treatment had a significant reduction in preterm delivery rates (OR = 0.37; 95% CI = 0.23–0.60). This meta-analysis has not been updated since the publication of the largest randomized controlled trial to date conducted by the Maternal–Fetal Medicine (MFM)-units network. In this double-blinded, randomized clinical trial, women with bacterial vaginosis were randomized to receive metronidazole 2 g orally for two consecutive days or placebo. Women were re-screened and re-treated, if indicated at 24 to 29 weeks gestation, according to the original treatment assignment. Figure 10.3 summarizes the principal findings of the trial. Overall, there was no reduction in preterm deliveries. This result was confirmed in women who had prior preterm delivery. This study has been widely criticized for using a short course treatment regimen and leaves the question of whether or not it is appropriate to “seek and treat” in high-risk women. In a statement by ACOG, the organization does not endorse routine, universal screening for bacterial vaginosis, but recommends further research on the subject in women with prior preterm delivery.

Fetal Fibronectin

Fetal fibronectin has been widely promoted as a tool to identify women at risk for preterm delivery. Fetal fibronectin, a basement membrane protein, is a normal constituent of the extracellular matrix of the maternal–fetal interface. It is present in normal human pregnancies prior to 20 weeks gestation and near term. Its presence between 20 and 34 weeks gestation has been strongly associated with preterm birth, but more importantly, its absence has been associated with low risk of preterm delivery.

Leitich and co-workers performed a comprehensive meta-analysis on the efficacy of fetal fibronectin in identifying women at risk for preterm delivery. They included 27 articles using fetal fibronectin in a variety of settings. Similar to other investigators, they noted that the test's usefulness was a result of its high specificity, and was limited by the low sensitivity in identifying women who would go on to deliver prior to 34 weeks gestation. The sensitivity of the test decreased further in identifying women who would deliver prior to 37 weeks but increased when it was used serially.

In order to maximize fetal fibronectin, its use should be restricted to women with intact membranes, cervical dilation less than 3 cm, and gestational age between 24 and 34 completed weeks gestation, and results should be available within 24 hours. False-positive fetal fibronectins may be obtained in women with recent intercourse or vaginal examinations, or in the presence of bacterial vaginosis and vaginal bleeding.

In general, the sensitivity of fetal fibronectin increases in symptomatic women, women with a cervical length less than 2.5 mm, women with a history of prior preterm delivery, and women with bacterial vaginosis. The negative predictive value in women with preterm contractions ranges from 69% to 92% before 37 weeks gestation. Importantly, a negative fetal fibronectin has a 95% likelihood that delivery will not occur within 14 days of sampling.

Will fetal fibronectin change management and improve outcomes? Fetal fibronectin results have been shown to alter clinical management in certain settings and may be cost-effective. Physicians may use the test to determine who will receive tocolytic therapy and antenatal corticosteroids as well as who is appropriate for a maternal transport. Clearly, this test has potential, yet further work is required to determine what interventions are appropriate and whether the test improves outcomes. An ACOG summary states, “fetal fibronectin may be useful in determining women at high risk for preterm labor. However, their clinical usefulness may rest primarily with their negative predictive value given the lack of proven treatment options to prevent preterm birth.”

Cervical Evaluation

It has long been noted that premature dilation or effacement of the maternal cervix is associated with preterm birth. There has been a great deal of research interest in precisely measuring the uterine cervix with ultrasound to identify women at risk for preterm birth. Several techniques for measuring the cervix have been advocated. In general, it is believed that vaginal measurements are superior to abdominal measurements. Furthermore, several measurements should be obtained and averaged given the variability in cervical lengths for a given individual at a single monitoring session. In order to improve inter-interpreter variability, individuals who are performing the ultrasound should undergo formal training and participate in continuing quality assurance.

Several large prospective cohort studies have been performed which have been useful in establishing cervical nomograms for low-risk and high-risk women. In general, as the cervix becomes progressively shorter or dilates, the risk of preterm delivery increases. Cervical length is also correlated with gestational age (i.e., as gestation advances the cervix matures and shortens). Different cutoff values have been tested. The sensitivity and positive predictive value depend on the prevalence of preterm birth in the population and the gestational age at testing and delivery. A cervical length of =30 mm or a dilation of the internal cervical os will identify 80% to 100% of women or 70% to 100% of women who will subsequently have a preterm delivery.

The proponents of cervical ultrasound evaluation stress the benefit in obtaining more precise measurements with vaginal ultrasound than digital evaluation and the improved ability to detect subtle changes. Furthermore, vaginal ultrasound allows one to avoid vaginal examinations. To date, only two published randomized clinical trials have evaluated the use of cervical cerclage in women with premature shortening of the cervix with no evidence of preterm labor. In the first, the cervical incompetence prevention randomized cerclage trial (CIPRACT), women with the following histories were approached:

- a history consistent with cervical incompetence
- PPROM prior to 32 weeks gestation
- history of cold-knife conization
- diethylstilbestrol exposure
- uterine anomaly

Consenting women who met the inclusion criteria and who had a cervical length less than 2.5 cm prior to 27 weeks were randomized to receive a McDonald cerclage and bed rest or bed rest alone. Placement of a cervical cerclage resulted in a significant decrease in preterm delivery prior to 34 weeks gestation (0 of 19 in cerclage

group vs. 7 of 16 in the expectant management group, *P* = .002). The decrease in preterm delivery prior to 34 weeks gestation was also associated with a decrease in composite neonatal outcome (1 of 19 vs. 8 of 16, *P* = .005). In contrast, Rust et al. randomized women with a shortened cervix detected on routine ultrasound evaluation between 16 and 24 weeks gestation were randomized to receive a cerclage (n = 31) or expectant management (n = 30). The groups were well balanced at randomization for potential confounders. Overall, there was no difference in gestational age at delivery (33.5 ± 6.3 weeks cerclage group vs. 34.7 ± 4.7 weeks in expectant management group, *P* = .4) or the perinatal death rate (12.9% cerclage group vs. 10.0% in expectant management group, *P* = .9).

At this time there does not appear to be sufficient evidence to recommend routine ultrasound screening of the uterine cervix since no treatment has been definitively established that will improve neonatal outcome.

Summary of Screening Tests Used to Identify Women at Risk for Preterm Labor

Several screening tests are available to identify women at risk for preterm delivery. All fail to meet the goals of an “ideal screening test”, since no therapy has been proven to be effective in preventing preterm labor and delivery. As a result, these tests should be considered experimental and used as part of randomized clinical trials with sufficient power to evaluate treatments for prevention of preterm birth.

PRETERM LABOR DEFINITION

Preterm labor is defined as *labor occurring prior to 37 weeks gestation.* Clinically it is difficult to distinguish women with true preterm labor from women who are experiencing preterm uterine contractions. In order to improve the accuracy of the diagnosis, Creasy has proposed using the following criteria: uterine contractions (>4 contractions per 20 minutes) *and* cervical dilation (=2 cm in a nullipara and =3 cm in a multipara) *and* cervical effacement (>80%) or uterine contractions and cervical change. Cervical change is the most well-accepted clinical criteria, yet it is the criteria most vulnerable to bias. For example, what constitutes minimal cervical change and over what time period does cervical change need to occur to be acute and warrant intervention? While this definition is more stringent than that proposed by ACOG and others, over 50% of women who fulfill Creasy's criteria will deliver at term with or without treatment. An alternate approach is to await cervical change during a prescribed period of observation. Utter and colleagues defined “minimal” cervical change as dilation of the cervix by at least 1 cm and effacement of at least 1 cm in women less than 3 cm dilated on admission. Is it appropriate to wait for cervical change and will waiting until labor becomes more established affect treatment success? In a retrospective case-control study, Utter et al. compared the outcomes of pregnancies in women who were treated with ritodrine upon admission who had uterine contractions and “minimal” cervical change to women who were observed and treated only when cervical change as defined above was determined. There were no differences in any maternal or neonatal outcomes including the number of days to delivery and “success” rates with tocolysis. Similarly, Guinn and associates randomized women with uterine contractions who were =2 cm to one of three therapies: observation alone, subcutaneous terbutaline, or intravenous hydration. Overall, there were no differences in any outcome measures between groups. Approximately 15% of women assigned to each of the groups went on to make cervical change during observation and were treated with parenteral tocolysis. In all cases, parenteral tocolysis was successful in delaying delivery for a minimum of 48 hours to allow treatment with antenatal corticosteroids. This approach avoided administration of tocolytic agents to 85% of women with no increase in morbidity or preterm delivery rates. An alternative strategy to awaiting cervical change is to use the rapid fetal fibronectin test and treat only women with a positive test. However, this strategy remains under investigation.

TREATMENT OF PRETERM LABOR

Once the diagnosis of preterm labor is made what treatments are available and do they work? Several agents have been used as tocolytic agents to suppress uterine activity in hopes that prolongation of pregnancy would improve neonatal outcomes (Table 10.6). The vast majority of placebo-controlled clinical trials were published during the 1970s and 1980s. Most of the placebo-controlled trials were small and the concurrent use of antenatal corticosteroids was low. Overall, women who received any tocolytic agent had a mean time to delivery of approximately 48 hours. Therefore, it is not surprising that tocolytic therapy has not been associated with improvements in neonatal outcomes. Despite this finding, tocolytic agents are widely prescribed throughout the world. The justification for the continued use of unproven drugs is the supposition that had the drugs been administered along with antenatal corticosteroids that the 48 hours gained in utero would be beneficial to the neonate and result in improved outcomes. This theory remains untested. However, given the current “standard of care” in the United States, it is unlikely that placebo-controlled trials will be performed to confirm the need to administer tocolytic agents in addition to antenatal corticosteroids. The individual agents that are commonly used throughout the world will be reviewed subsequently. The absolute and relative contraindications to administering tocolytic therapy are listed in Table 10.7 and Table 10.8.

- Hormone treatment
- Alcohol treatment
- Beta-mimetics
- $MgSO_4$
- Antiprostaglandins
- Anti-oxytocics
- Ca^{++} channel blockers

TABLE 10.6. *Overview of the tocolytic agents*

- Severe preeclampsia
- Severe abruptio
- Severe bleeding any cause
- Frank chorioamnionitis
- Fetal death
- Fetal anomaly incompatible with life
- Severe fetal growth restriction
- Mature lung studies
- Maternal cardiac arrythmias

TABLE 10.7. *Absolute contraindications to tocolytic therapy*

- Mild chronic hypertension
- Mild abruptio
- Stable previa
- Maternal cardiac disease
- Hyperthyroidism
- Uncontrolled diabetes mellitus
- Fetal distress
- Fetal anomaly
- Mild intrauterine growth restriction
- Cervix >4 cm

Beta-Adrenergic Agonists

The ß-mimetics are the most widely prescribed and best-studied tocolytic agents. The two most commonly used ß-mimetic agents in the United States are ritodrine and terbutaline. There are a number of treatment protocols for both ritodrine and terbutaline. In the acute setting, the medications can be administered intravenously (ritodrine and terbutaline) or subcutaneously (terbutaline). The dose is increased until uterine quiescence is achieved or maternal side effects develop that prevent the provider from increasing the dose further. Development of tachyphylaxis occurs rapidly. As a result it is common to need to increase the dose of the medication to maintain an acontractile state once steady-state levels are achieved.

The maternal side-effect profile with the ß-agonists is of particular concern. None of the ß-agonists used for tocolysis are completely ß-2 selective. Therefore, mothers can experience side effects from both ß-2 and ß-1-sensitive tissues. The negative ß-2 effects include: maternal hypotension, decreased urinary output, increased glucose secretion, hypokalemia, and pulmonary edema. The negative ß-1 effects include: tachycardia, palpitations, constipation, decreased gastric emptying, hypokalemia (decrease 0.6 to 1.5 mEq below pretreatment levels), agitation, and jitteriness. The most severe maternal adverse effects include cardiac arrhythmias, myocardial infarction, pulmonary edema, postpartum cardiomyopathy, and death. These risks can be minimized by judicious use of fluids, close monitoring of intake and output, and avoidance of other tocolytic agents.

Beta-mimetics rapidly cross the placenta. The fetal response is similar to the adult. Cardiovascular effects include tachycardia, increased cardiac output and redistribution of blood flow, increased thickness of the intraventricular septum, neonatal supraventricular tachycardia, myocardial ischemia, myocardial necrosis, hydrops, and hypoglycemia. Long-term follow-up studies demonstrated no overall difference in children exposed to ß-mimetics versus control groups that received placebo. However, evidence suggests that the ß-mimetics may increase the incidence of intraventricular hemorrhage in preterm neonates. This finding has been noted

in a couple of case-control studies performed in large neonatal databases. This finding was not previously noted in the randomized placebo-controlled trials of the ß-mimetics. Further studies are necessary to evaluate this potential adverse effect of ß-mimetics.

Are the ß-mimetics efficacious? The largest placebo-controlled trial of the ß-mimetics was performed in Canada and published in 1992. In this trial, 708 women with preterm labor, with or without ruptured membranes, were randomized to receive ritodrine or placebo infusions. Treatment with ritodrine did not reduce perinatal mortality or morbidity, prolong pregnancy, decrease the percent of preterm deliveries, or increase the percentage of women who completed a course of antenatal corticosteroids. The findings of this individual trial are consistent with a previously published meta-analysis of the ß-mimetics when used as tocolytic agents. The Canadian study has been widely criticized for including women with PPROM. Tocolytics and antenatal corticosteroids do not appear to be as efficacious in the setting of PPROM, thus potentially diluting any positive effect of the ritodrine.

At this time advocates for the use of the ß-mimetic believe that the benefit-to-risk ratio is favorable and that prolonging pregnancy may increase the proportion of women who complete a course of antenatal corticosteroids prior to delivery. As newer agents with less potential for maternal and fetal adverse effects become available, the use of the ß-mimetics will continue to decrease in the acute setting.

Magnesium Sulfate

Magnesium sulfate is probably the most widely prescribed tocolytic agent used in the United States. Although the exact mechanism of action is unknown, it likely decreases the free calcium ion concentration in the intracellular compartment of the uterine myometrial myosin light chains, which blocks kinase phosphorylation and therefore decreases the electrical potential of the cell. For acute tocolysis, magnesium sulfate is administered intravenously. A number of protocols for loading the patient and maintenance dosing exist. In general, the magnesium “bolus” is administered in doses that range from 4 to 8 g over a period of 20 minutes to 1 hour. Next, a maintenance infusion (2 to 4 g per hour) is started and adjusted until uterine contraction frequency decreases to less than 4 contractions per hour and no further cervical change is occurring. The infusion is stopped after the patient remains acontractile for 12 to 24 hours. In certain clinical situations (advanced dilation at early gestational ages, women who continue to contract despite high doses of magnesium sulfate, etc.) it may be warranted to continue the infusion for 48 hours to allow for administration of a full course of antenatal corticosteroids.

Magnesium sulfate is primarily cleared by the kidneys and is rapidly excreted in the pregnant woman with normal renal function. It is generally accepted that blood levels of 6 to 8 mg per dL of magnesium sulfate are optimal for tocolysis. However, there is a great deal of variation in the biological response to this agent including the level that is required to achieve uterine quiescence and the level associated with toxicity. For example, in one study investigators used a case-control study design and compared women who did and did not respond to magnesium sulfate tocolysis. Overall, there were no significant differences in serum levels of magnesium sulfate in the women who did and did not respond to tocolysis. This finding is similar to that of a randomized controlled trial comparing a high-dose magnesium protocol (8-g load, then 2–4 g per hour) to a low-dose magnesium protocol (4-g load, then 2–4 g per hour). The high-dose protocol did achieve tocolysis more rapidly than the low-dose protocol. However, there was a corresponding increase in maternal side effects with the high-dose protocol. Overall, there was no difference between the protocols with respect to prolongation of pregnancy or a reduction in neonatal morbidity. Finally, many physicians believe it is necessary to wean patients from magnesium sulfate tocolysis. This practice was evaluated in a randomized trial comparing a weaning protocol to immediate withdrawal of magnesium sulfate. Not surprisingly, weaning prolonged labor and delivery stays by approximately 8 hours. Overall, there was no difference in time gained in utero or differences in neonatal outcomes between the two groups. Women who were weaned had significantly higher rates of recurrent labor in the current admission and in the future.

Maternal side effects are common with magnesium sulfate and are presented in Table 10.9. As blood levels of magnesium increase, so does the potential for severe toxicity. Maternal deaths have occurred with magnesium sulfate as a result of respiratory depression and cardiac arrest. In general, these events should be preventable by following the patient's clinical status carefully. This monitoring should include hourly assessments of intake and output, level of deep tendon reflexes, and oxygen saturation using a pulse oximeter. Careful labeling of all medications as well as strict adherence to concentration should reduce the likelihood of an inadvertent bolus of large amounts of magnesium sulfate. In cases of extreme magnesium toxicity, administration of calcium gluconate may be useful to try and reverse the effects of magnesium sulfate.

◊ Common
Flushing
Sense of warmth
Headache
Nystagmus
Nausea
Dizziness
Lethargy
◊ Serious
Pulmonary edema
Neuromuscular blockage
Osteopenia

TABLE 10.9. *Maternal side effects related to* $MgSO_4$

Finally, long-term magnesium exposure has been associated with significant bone loss and fractures. Therefore, women receiving long-term magnesium therapy should receive supplemental calcium.

Magnesium sulfate also has significant fetal and neonatal effects. Magnesium sulfate crosses the placenta and accumulates in the fetus. As a result, it can affect fetal biophysical parameters (primarily fetal breathing activity) and decrease fetal heart rate variability. Neonates born with cord levels of magnesium sulfate greater than 4 mg per 100 mL may show signs of depression including decreased muscle tone, drowsiness, poor respiratory effort, and low Apgar scores. A case of neonatal osteoporosis with associated fractures has been reported in a woman undergoing long-term tocolysis with magnesium sulfate.

Controversy exists over the long-term effects of magnesium sulfate. A number of cohort and case-control studies have suggested that magnesium sulfate exposure at birth may reduce rates of cerebral palsy in preterm infants. The data are compelling enough that several investigators are now testing this hypothesis in randomized trials. The MagNet trial was the first trial published that formally evaluated this hypothesis. The MagNet trial randomized women with preterm labor and intact membranes to receive magnesium sulfate or other tocolytics if =4 cm dilated on admission or magnesium sulfate or placebo if more than 4 cm dilated. The trial was stopped at the first planned interim analysis because there were 7 pediatric deaths (n = 46) in the magnesium arm compared to no pediatric deaths (n = 47) in the tocolytic/placebo arm (OR = 15.2; 95% CI = 4.8–25.6). The groups were well balanced at randomization for potential confounders. Thus, there was no obvious explanation for the excess deaths in the magnesium arms of the trial other than magnesium sulfate exposure. The dramatic findings from this small trial have not been previously noted in large neonatal databases or in placebo-controlled trials. Ultimately, we will need to await the results of ongoing trials to either confirm or refute the findings of the MagNet trial.

Is magnesium sulfate efficacious? Only three small placebo-controlled trials have evaluated the efficacy of magnesium sulfate as a tocolytic agent. In the placebo-controlled trials, magnesium sulfate did not significantly prolong pregnancy or decrease neonatal morbidity. However, the majority of trials with magnesium sulfate compare it to the ß-mimetic agents. In these larger trials magnesium sulfate does appear to be equally “efficacious” to the ß-mimetics in prolonging pregnancy with a superior maternal side-effect profile. As a result, magnesium sulfate is generally used throughout the United States as a first-line tocolytic agent.

Calcium Channel Blockers

The calcium channel blockers are promising tocolytic agents. Calcium channel blockers or calcium antagonists are nonspecific smooth muscle relaxants. They prevent the influx of extracellular calcium ions into the myometrial cell. The effects are not specific to the uterus.

Numerous protocols for nifedipine exist. In general, 10 mg nifedipine is administered orally. If contractions persist the dose can be repeated every 20 minutes for a total of 30 mg in 1 hour. Maternal hypotension is relatively common. If hypotension develops, additional doses of nifedipine must be held. Once contractions decrease, the patient may receive 10 mg every 6 hours of nifedipine orally or receive 30 to 60 mg of the sustained-release nifedipine per day. Nicardipine, a potent uterine relaxant, may be administered as a 40-mg loading dose followed in 2 hours by a 20-mg dose to a maximum dose of 80 mg if uterine contractions do not abate. This can be followed by sustained-release nicardipine 45 mg every 12 hours.

The calcium channel blockers produce vasodilation and decrease peripheral vascular resistance. Maternal hypotension defined as either a 25% decrease in mean arterial pressure or symptomatic hypotension is relatively common. Many patients experience transient facial flushing or develop nausea and headache. Maternal side effects appear to be less common than in women treated with the ß-sympathomimetics but severe complications have been reported. For example, there has been a case of maternal myocardial infarction associated with high-dose nifedipine therapy following ritodrine treatment in women in preterm labor. We have had a similar case using a low dose of nifedipine following magnesium sulfate tocolysis. Nifedipine potentiates the toxicity of magnesium sulfate by causing neuromuscular blockade. There have been reports of profound hypotension, neuromuscular blockade, and maternal death resulting from the combination of magnesium sulfate therapy and calcium channel blockers. This complication may not be as frequent as initially believed. However, there are no protocols that establish the safety of using these

medications together. Therefore, they should not be used concurrently.

In general, the calcium channel blockers appear to be well tolerated by the fetus and neonate. There has been one case of neonatal heart block associated with their use. Concerns remain that the calcium channel blockers may have adverse effects on the fetal and placental circulation resulting in growth restriction, acidosis, and stillbirths. These concerns do not appear to be supported by the literature.

Prostaglandin Synthetase Inhibitors

Prostaglandins are integrally involved in cervical ripening and labor. Therefore, it would make sense that inhibiting prostaglandin synthesis should prevent preterm labor and delivery. Nonsteroidal antiinflammatory drugs (NSAIDs) inhibit cyclooxygenase, thus preventing the conversion of arachidonic acid to prostaglandin. The effects are not limited to the uterus. Indomethacin is the most widely studied prostaglandin synthetase inhibitor used for treatment of women in preterm labor.

Our protocol for indomethacin tocolysis involves the administration of a 100-mg loading dose given as a suppository per rectum. If regular uterine contractions persist 1 to 2 hours after the initial 100-mg suppository, an additional 50 to 100 mg may be given. Oral therapy is then instituted at 50 mg every 6 hours for 48 hours while betamethasone is dispensed. The absorption of indomethacin is excellent from both the rectal and oral routes. Therefore, if rectal suppositories are not available, the oral formulation can be effectively substituted. Fetal echocardiography is not considered necessary when administering indomethacin as outlined above. Fetal contraindications to the use of indomethacin include growth restriction, renal anomalies, chorioamnionitis, oligohydramnios, ductal dependent cardiac lesions, and twin–twin transfusion syndrome.

Indomethacin is very well tolerated in the gravida in comparison to other tocolytic agents. Serious maternal side-effects are rare when the agent is used in a brief course of tocolysis. As with any NSAID, mild gastrointestinal upset may occur. More serious potential complications include gastrointestinal bleeding, alterations in coagulation, thrombocytopenia, and asthma in aspirin-sensitive patients.

Prolonged treatment can lead to renal injury, especially when nephrotoxic drugs such as aminoglycosides are employed. Drugs of this class are antipyretic agents and may obscure a clinically significant fever. Maternal contraindications to indomethacin include renal or hepatic disease, active peptic ulcer disease, poorly controlled hypertension, asthma, and coagulation disorders.

In contrast to the generally favorable maternal side-effect profile, the potential for fetal and neonatal complications of indomethacin tocolysis is worrisome. In actuality, serious complications are rare when limiting treatment to short courses and adhering to established protocols.

The principal side effects of indomethacin tocolysis have been constriction of the ductus arteriosus, oligohydramnios, and neonatal pulmonary hypertension. The ductal constriction occurs because formation of prostacyclin and prostaglandin E_2, which maintain ductal vasodilation, is inhibited by indomethacin. Moise and colleagues reported Doppler evidence of ductal constriction in 7 of 14 fetuses exposed to indomethacin between 27 and 31 weeks of gestation. Tricuspid regurgitation occurred in three fetuses. All ductal abnormalities resolved within 24 hours of discontinuation of indomethacin and none of the neonates had pulmonary hypertension. The Moise group later reported on the effect of advancing gestational age on ductal constriction in association with indomethacin and stated that “a dramatic increase in constriction was noted at 32 weeks gestation when the rate of compromise approached 50%.” However, ductal constriction was noted as early as 24 weeks, and occurred in 11 of the 23 fetuses prior to 30 weeks. This was a retrospective analysis of echocardiograms performed on 44 patients with premature labor or hydramnios treated with indomethacin. Although never clearly stated, these patients appeared to be on courses of therapy for greater than 48 hours. Indomethacin was the “third-line agent” in premature labor unresponsive to terbutaline or magnesium sulfate.

Oligohydramnios associated with indomethacin tocolysis is common, dose-related, and reversible. The oligohydramnios is a consequence of reduced fetal urine production due in turn to reduction by indomethacin of the normal prostaglandin inhibition of antidiuretic hormone and by direct effects on the renal blood flow. Indomethacin can be an effective therapy for hydramnios, especially when complicated by preterm labor.

Primary pulmonary hypertension in the neonate is a serious condition that has also been reported with prolonged (more than 48 hours) indomethacin therapy. This complication has not been reported when therapy was restricted to 24 to 48 hours, however, the incidence may be as high as 5% to 10% with long-term therapy.

Necrotizing enterocolitis and intraventricular hemorrhage have been observed in the LBW neonate exposed to indomethacin in utero when it was used outside of standardized protocols that did not limit the duration of treatment, or was the second or third agent added to recalcitrant preterm labor. Since such patients have an increased risk of subclinical intraamniotic infection, and since intraamniotic infection is associated with a greater risk of such complications, it is not clear that indomethacin incurs independent risk for these morbidities. Subsequently, two larger studies have not confirmed this finding or demonstrated any association between indomethacin exposure and any adverse neonatal outcome. Follow-up studies of children treated in utero with indomethacin have not found significant long-term effects although they did not specifically target the LBW neonate.

Indomethacin has been reported to be effective in two small randomized, placebo-controlled trials. The first found indomethacin was superior to placebo in delaying delivery for 48 hours (80% vs. 33%). The second demonstrated a sustained delay in delivery for patients treated with indomethacin (95% at 48 hours and 83% at 7 days) compared with placebo (23% at 48 hours and 16% at 7 days). Additional prospective, randomized trials have found indomethacin to be comparable to ritodrine and magnesium sulfate and superior to nylidrin for tocolysis. There are additional reports that describe indomethacin tocolysis favorably, but many used other tocolytic agents simultaneously or sequentially.

Indomethacin appears to be an effective tocolytic agent that is well tolerated by the mother, and appears to be tolerated by the fetus when used appropriately. Exposure should be limited to 48 consecutive hours to allow for administration of antenatal corticosteroids and should be restricted to gestational ages less than 32 weeks.

Other Tocolytic Agents

Several other tocolytic agents have been proposed for use. These include the oxytocin analogs, nitroglycerin, cyclooxygenase 2 (COX-2) inhibitors, ketorolac, progestins, and nitric-oxide inhibitors. The oxytocin analogs have been the most widely tested. These agents appear promising in delaying delivery and have acceptable maternal side-effect profiles. However, use of these agents did not appear to improve neonatal outcome. Therefore, the Food and Drug Administration (FDA) did not approve Antosiban for use in women with preterm labor. As a result of the failure to bring an “effective” drug to market, it is doubtful that any of the pharmaceutical companies will invest the capital necessary to develop new tocolytic agents in the near future.

MAINTENANCE TOCOLYIS FOLLOWING ARREST OF PRETERM LABOR

If preterm labor is arrested, the patient remains at high risk for a recurrent episode of preterm labor and preterm birth. Maintenance tocolytic therapy may decrease chances for delivery in some cases. Several agents including the ß-mimetics (ritodrine and terbutaline), magnesium sulfate, prostaglandin synthetase inhibitors, and the calcium channel blockers have been tested in randomized trials.

Efficacy of Oral Tocolysis with Beta-Mimetics

We have been able to identify eight randomized placebo-controlled trials of oral ß-mimetic maintenance therapy to prevent recurrent preterm labor and preterm delivery. A total of 915 patients were randomized in these eight trials. In six of the eight trials there was no decrease in the preterm delivery rate or a prolongation of pregnancy with maintenance tocolytic therapy when compared to controls receiving no treatment. Seven of the eight trials reported on the number of women treated for recurrent preterm labor. Overall, for women receiving a ß-mimetic, the rate of recurrent preterm labor was 32.5% (range, 2%–59%) and for patients receiving placebo or no therapy 28.3% (range, 12.9%–63%). Despite obvious differences in the trials, Sanchez-Ramos and colleagues combined these data using meta-analysis (Table 10.10). When they restricted the analysis to trials comparing ß-mimetics to placebo or no therapy, there was no benefit of treatment for prevention of preterm birth (OR = 1.08; 95% CI = 0.82–1.43) or risk of recurrent preterm labor (OR = 0.90; 95% CI = 0.63–1.28). One could argue that it is not appropriate to combine trials when there is no consistency between the trials in inclusion criteria and definitions of preterm labor and recurrent preterm labor. Regardless, whether the trials are evaluated individually, cumulatively as a review, or using meta-analysis, there does not appear to be any benefit of oral ß-mimetic tocolysis.

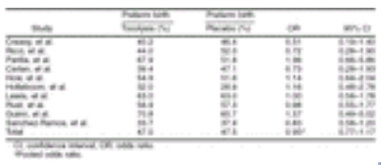

TABLE 10.10. *Impact of maintenance tocolysis on preterm delivery*

Several potential explanations can be offered as to why oral ß-mimetic therapy appears to be ineffective. Oral administration of terbutaline results in inconstant drug levels, characterized by peaks and troughs. The need to take the drug every 2 to 4 hours throughout the day, including awakening at regular intervals throughout the night, may decrease compliance. Finally, long-term exposure to ß-mimetic agents results in desensitization of the ß-adrenergic receptors in the myometrium. Development of tolerance is related to both the duration of therapy and the total dose of the ß-mimetics. As a result the drugs may lose effectiveness over time.

Efficacy of Continuous Subcutaneous Administration of Terbutaline

Terbutaline may be administered by a continuous portable subcutaneous pump for maintenance therapy. Its theoretical advantages over oral maintenance therapy are continuous low maintenance drug levels and the ability to bolus the drug if uterine contractions develop, thus preventing or decreasing the development of tolerance of the ß-receptors to the ß-agonist terbutaline.

A number of descriptive studies of terbutaline pump therapy for prevention of preterm birth have been published in peer review journals. It was not until 1997 that the first randomized, placebo-controlled trial of the terbutaline pump was published. In this study women with preterm labor were assigned to receive terbutaline pump therapy (n = 15), placebo pump therapy (n = 12), or oral terbutaline (n = 15). If women developed recurrent preterm labor, the blind was broken and women receiving placebo were crossed-over to terbutaline. Although conclusions were limited by the small number of patients in each group and the crossover design, there were no differences in the mean delay to delivery or in neonatal morbidity.

In 1998, Guinn and associates reported their randomized double-blind trial of terbutaline pump therapy. Preterm labor was defined prospectively as the presence of uterine contractions and =1 cm cervical dilation, =80% effacement or cervical change. Women received magnesium sulfate with or without indomethacin therapy for acute preterm labor. Women with singleton gestations and intact membranes between 22 and 33 $^{6}/_{7}$ weeks gestation were eligible. Consenting women were randomized to receive terbutaline pump (n = 24) or placebo pump therapy (n = 28). Pump therapy was initiated by the research nurse using a standard protocol. In addition to their programmed infusion, patients were allowed to administer up to two additional boluses (either 0.25 mg terbutaline or 0.25 cc saline depending on the treatment group) for uterine contractions. At randomization, the groups were well balanced with respect to parity, prior preterm delivery, gestational age, and cervical examination. Overall there was a 1-day difference in mean time to delivery between the groups (terbutaline 29 days and placebo 28 days, $P = .78$). There were no differences in the rates of preterm delivery at less than 34 and less than 37 weeks gestation, recurrent preterm labor (terbutaline 38% and placebo 37%, $P = .89$), or rates of neonatal morbidity.

Despite very limited information regarding terbutaline pump therapy, its use has been widely promoted by several home health care corporations that target the majority of their services to the obstetric patient. Terbutaline pump therapy whether used alone or in conjunction with HUAM programs is extremely expensive, averaging over $200 per day, when compared to oral therapy or no therapy. As its use has increased, so have reports of complications related to therapy. As a result, the FDA issued an alert regarding the potential dangers associated with terbutaline pump therapy and the lack of data supporting the efficacy of this treatment.

Risks Associated with Oral or Subcutaneous Beta-Mimetic Therapy

Frequent unwanted effects of ß-mimetic therapy include palpitations, tremor, nausea, vomiting, headache, thirst, nervousness, and restlessness. Complications of the oral ß-mimetics and the subcutaneous administration of terbutaline include sudden death, pulmonary edema, cardiac arrhythmias, hepatitis, glucose intolerance, and gestational diabetes. There has also been one case of neonatal myocardial necrosis in a woman receiving high doses of subcutaneous terbutaline.

Summary of Beta-Mimetics for Maintenance Therapy

There is no compelling evidence from the randomized controlled trials to support the use of ß-mimetics for maintenance therapy. Given the potential risks associated with the ß-mimetics, there is no justification for its continued use as a chronically administered therapy.

Other Maintenance Tocolytic Agents

Compared to the ß-mimetics, there have been relatively few trials exploring options for maintenance therapy. Magnesium sulfate has been administered on a chronic basis intravenously and orally. Long-term magnesium exposure can result in significant osteopenia, especially when used in conjunction with multiple doses of corticosteroids and bed rest. There have been reports of both mothers and neonates developing significant osteopenia following prolonged magnesium exposure. In the randomized trials that compare oral magnesium to placebo, no apparent benefits were noted in time to delivery or neonatal outcomes.

Long-term tocolysis with the prostaglandin synthetase inhibitors is contraindicated. The fetal risk is far in excess of any potential benefits. It is possible that more selective COX-2 inhibitors will be useful for maintenance therapy. The calcium channel blockers appear to be gaining popularity to reduce recurrent preterm labor. Two trials have compared nifedipine to ß-sympathomimetics agents. These investigations were equivalent or superior to the ß-mimetics for prolonging pregnancy, with lessened maternal side effects. Carr and colleagues published the only randomized trial of nifedipine compared to no therapy. They randomized 74 women to receive oral nifedipine (20 mg every 4 to 6 hours) or no treatment. The groups were well balanced at randomization for potential confounders. There were no differences in the time gained from initiation of therapy until delivery in the two groups (37 days nifedipine and 32 days no therapy) or gestational age at delivery (35.4 weeks nifedipine and 35.3 weeks no therapy). Oral nifedipine following successful tocolysis with magnesium sulfate did not improve pregnancy outcome. While this study did not report any significant complications of therapy, there has been a report of a myocardial infarction following treatment with nifedipine for maintenance tocolysis.

Conclusions Regarding Maintenance Tocolysis

At this time there is no evidence that any of the available maintenance tocolytic agents are effective in prolonging gestation, reducing preterm births, or improving neonatal outcome. Each of the therapies has been associated with significant complications. Therefore, we cannot recommend that any of these agents be used outside of properly designed randomized trials.

ANCILLARY THERAPY FOR WOMEN IN PRETERM LABOR

Several investigators have studied the impact of adjunctive antibiotic therapy in women with preterm labor and intact membranes. These studies have included women across the spectrum of gestational ages and cervical dilations and have used a variety of antibiotic regimens. This subject was reviewed by King and Flenady in the Cochrane Database. Beneficial effects of antibiotics included a significant prolongation of pregnancy (5.4 days), reduction in maternal infectious morbidity, and a trend toward reduction in neonatal sepsis. However, this was coupled with an increase in perinatal mortality (OR = 3.36; 95% CI = 1.21–9.32). The largest study published to date was ORACLE II. This study included women in preterm labor between 20 and 37 weeks gestation. In this trial, 6,295 women were enrolled, and data from 6,241 women was available for analysis. Overall, use of antibiotics was not associated with a reduction in neonatal morbidity or mortality or prolongation of pregnancy. The only exception was decreased use of postpartum antibiotic prescription in women who had received antibiotics. Based on the results of this trial and the Cochrane Database review, at this time, adjunctive antibiotic therapy for women in preterm labor is not indicated. GBS prophylaxis should be administered following the 2002 Centers for Disease Control and Prevention (CDC)/ACOG guidelines.

Hydration therapy, either oral or intravenously, is widely used as adjunctive therapy for women with preterm contractions and preterm labor. This practice was popularized during the 1980s when the ß-mimetics were being widely prescribed. Prior to administration of the ß-mimetics, women were hydrated to prevent hypotension. In many cases, as women were receiving their hydration therapy, their contractions reduced in frequency, thus obviating the need for parenteral tocolysis. Guinn and associates published a randomized trial comparing two commonly used therapies for preterm contractions to observation only. Women were included who had cervical dilation less than 2 cm, effacement less than 80%, gestational age 24 to 33 completed weeks gestation, and regular uterine contractions. Women were randomly assigned to receive intravenous hydration, one dose of subcutaneous terbutaline (0.25 mg), or observation only. There were no differences between the groups with time gained in utero, the proportion of women who delivered preterm, or the proportion of women who developed cervical change and received parenteral treatment with tocolytic agents. Intravenous hydration was associated with the highest hospital costs and charges and has the highest potential for adverse effects. Intravenous hydration should be reserved only for women who are obviously dehydrated.

Bed rest has also been widely prescribed for women in preterm labor. There is little if any data that suggests that bed rest is efficacious in women with threatened preterm labor or arrested preterm labor. There are significant costs associated with bed rest including hospital days, lost wages, and lost domestic productivity. It should not be routinely prescribed to women at risk for preterm labor or delivery.

Two therapies are extremely beneficial to women with preterm labor. The first is antenatal corticosteroids. There have been 15 randomized, placebo-controlled trials that tested the efficacy of antenatal corticosteroids in women at risk for preterm birth. Exposure to a complete course of antenatal corticosteroids (betamethasone 12 mg i.m. q24h ×2 doses or dexamethasone 6 mg i.m. q12h ×4 doses) significantly improves neonatal outcomes including a reduction in respiratory distress syndrome, intraventricular hemorrhage, and death. The data are so compelling that the ACOG and the NIH recommend that all women at risk for preterm birth prior to 34 weeks gestation receive antenatal corticosteroids. Repeat courses of antenatal corticosteroids are not recommended as they may reduce respiratory morbidity while increasing the potential for intraventricular hemorrhage and chorioamnionitis. Long-term follow-up studies are underway which will help to define the long-term risks and benefits of repeat courses of antenatal corticosteroids.

The other therapy that appears to be highly efficacious in improving neonatal outcomes is the administration of GBS prophylaxis to women at risk for preterm birth. The attack rates for preterm neonates colonized with GBS are significantly higher than in term infants. As a result, prophylaxis has been demonstrated to be highly beneficial in preventing invasive GBS and its sequelae in preterm neonates.

CONCLUSIONS

Prevention of preterm birth remains an elusive goal. Despite widespread recognition and interest in the problem, the rate of preterm delivery is increasing in the United States. Clearly continued research efforts are necessary to better elucidate the biology of parturition and abnormal parturition to allow us to develop more effective therapies. In the mean time, it is premature to incorporate screening tests to identify women at risk for preterm labor outside of randomized treatment trials since no treatment has been proven to prevent preterm delivery. In women with an acute episode of preterm labor, tocolysis can be administered with antenatal corticosteroids. All of the tocolytic agents are potentially dangerous and should be used with caution in a supervised setting. Currently, there is no data to support the use of maintenance tocolysis in women whose preterm labor is successfully arrested. All women in spontaneous preterm labor should receive a single course of antenatal corticosteroids and GBS prophylaxis following the 2002 CDC/ACOG guidelines.

SUMMARY POINTS

- The rate of preterm birth is increasing in the United States.
- Subclinical infection is an important cause of preterm labor and delivery.
- Risk factor screening misses the majority of women who deliver preterm.
- Fibronectin and vaginal ultrasound of the cervix are promising technologies to identify women at low and high risk for preterm delivery.
- Universal screening for bacterial vaginosis is not warranted.
- Management of women with asymptomatic shortening of the uterine cervix is controversial.
- The diagnosis of preterm labor should be made using objective and reproducible criteria to avoid over and under treatment of women at risk for delivery.
- Tocolytic therapy has not been associated with improvements in neonatal outcome.
- All tocolytic agents have the potential to adversely affect the mother and the neonate and should only be administered in a supervised setting.
- Currently, there is no data to support the use of maintenance tocolytic therapy.
- Tocolytic therapy should *not* be administered without concurrent administration of antenatal corticosteroids.
- Weekly courses of antenatal corticosteroids should not be routinely prescribed.

SUMMARY POINTS

SUGGESTED READINGS

Premature rupture of the fetal membranes (PROM) is one of the most common problems in obstetrics, complicating approximately 5% to 10% of term pregnancies and up to 30% of preterm deliveries. Although the etiology of premature rupture of the membranes is often not clinically evident, a degree of consensus has arisen regarding management options. Indeed, the problem is intricate. Considerations in selecting management in a particular patient are gestational age and patient demographics. The clinician is confronted by a complex set of options including use of corticosteroids, tocolytics, more potent antibiotics, and innovative approaches using various tests (such as amniocentesis, ultrasound, and biophysical testing). Of major importance is the marked improvement in survival of low–birth-weight infants.

DEFINITIONS

PROM is usually defined as rupture *at any time before the onset of contractions*. Unfortunately, “premature” also carries the connotation of preterm pregnancy. To avoid confusion, we use the word *preterm* to refer to gestational age of less than 37 weeks. Thus, preterm PROM (PPROM) refers to PROM prior to 37 weeks gestation. The *latent period* is defined as the time from membrane rupture to onset of contractions. It is to be distinguished from a similar term, *latent phase*, designating the early phase of labor before the active phase. Various terms have been used to describe presumed *maternal or perinatal infections* related to PROM. During labor, designations have included “fever in labor,” “intrapartum fever,” “chorioamnionitis,” “amnionitis,” and “intrauterine infection.” The degree of temperature used to define “fever” has varied. After delivery, maternal infection is referred to as “endometritis” or “postpartum infection.” These diagnoses are usually based upon fever, uterine tenderness, and exclusion of other sources of fever. In neonates, the most common term used to report infection was *neonatal sepsis*, but this may mean strictly a positive blood culture or simply clinical signs or symptoms of sepsis.

INCIDENCE

The incidence of PROM ranges about 5% to 10% of all deliveries, and preterm PROM occurs in approximately 1% of all pregnancies. Approximately 70% of cases of PROM occur in pregnancies at term, but in referral centers, more than 50% of cases may occur in preterm pregnancies. PROM is the clinically recognized precipitating cause of about one third of all preterm births. Despite some progress in prolonging the latent period after preterm PROM and prevention of recurrence (in women with bacterial vaginosis), PPROM remains a leading contributor to the overall problem of premature birth.

ETIOLOGY

In the vast majority of cases, the etiology is not clinically evident. Earlier studies had identified selected clinical conditions such as cervical incompetence and polyhydramnios as being risk factors evident in some cases of PROM.

A scholarly review of the etiology of PPROM identified numerous potential causes in any given case. These included: a generalized decrease in tensile strength of membranes, local defects in the membranes, decreased amniotic fluid collagen and a change in collagen structure, uterine irritability, apoptosis, collagen degradation, and membrane stretch. The Maternal-Fetal Medicine (MFM) Network found that risk factors for PPROM were previous PPROM, positive fetal fibronectin at 23 weeks, and short cervix (<25 mm) at 23 weeks.

Substantial evidence is available to show that subclinical infection may be a cause of PROM, not merely its result. Support for a role of infection is provided by studies showing an association between clinically diagnosed bacterial vaginosis (or isolation of anaerobes in the vagina) and preterm birth/preterm premature rupture of the membranes. Some genital bacteria elaborate enzymes such as proteases, phospholipases, and collagenases that may act to weaken the membranes. Positive cultures of the amniotic fluid in cases of PPROM are obtained in approximately 30%.

In a large case-control study, three factors were associated with preterm PROM in a multifactorial analysis. These were previous preterm delivery (odds ratio [OR] = 2.5; 95% confidence interval [CI] = 1.4-2.5), cigarette smoking (stopped during pregnancy, OR = 1.6; 95% CI = 0.8–3.3; continued during pregnancy, OR = 2.1; 95% CI = 1.4–3.1), and bleeding (first trimester, OR = 2.4; 95% CI = 1.5–3.9; third trimester, OR = 6.5; 95% CI = 1.9–23; more than one trimester, OR = 7.4; 95% CI = 2.2–26). This study enrolled controls at the same gestational age as cases (thus correcting for the decreasing frequency of coitus closer to term) and found no association between coitus and PROM. However, other large studies have not confirmed smoking or vaginal bleeding as risk factors. Recent coitus is probably not a cause of PROM.

Investigations into the placental histology have provided correlates with clinical outcomes in cases of preterm premature rupture of the membranes. Overall, acute inflammation was seen in 43%, vascular lesions were seen in 20%, inflammation plus vascular lesions in 20%, normal findings in 14%, and “other” findings in 3% (Fig. 11.1). When acute inflammation was seen in the placenta (either by itself or mixed with vascular lesions), birth less than 26 weeks was more common, and delivery for suspected or proved clinical infection was also more common.

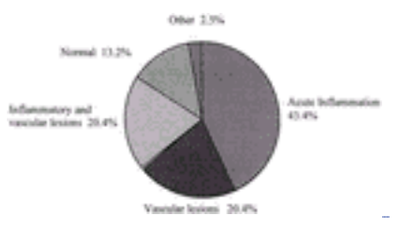

FIG. 11.1. Placental histology in 235 cases of premature PROM. (From Sweet RL, Gibbs RS. *Infectious diseases of the female genital tract*, fourth ed. Philadelphia: Lippincott Williams & Wilkins, 2002; with permission.)

COMPLICATIONS AND CONSEQUENCES OF PROM

Onset of Labor

At term, the onset of labor occurs within 24 hours after membrane rupture in 80% to 90% of patients. Among patients with PROM prior to term, latent periods occur longer. Latent periods of more than 24 hours occur in 57% to 83%, of more than 72 hours in 15% to 26%, and of 7 days or more in 19% to 41%. There is an inverse relationship between gestational age and the proportion of patients with latent periods longer than 3 days. For pregnancies between 25 and 32 weeks, 33% had latent periods longer than 3 days, whereas for pregnancies of 33 to 34 and 35 to 36 weeks, the corresponding values were 16% and 4.5%, respectively.

Effect of Tocolytic Drugs

The value of tocolytics in PPROM remains controversial. None of eight prospective trials showed a decrease in neonatal morbidity, whether tocolysis was used prophylactically (for all patients in admission regardless of uterine activity) or therapeutically (for patients who developed uterine contractions). Only three of the eight showed a prolongation of the latency period; an additional study showed a prolongation for gestation less than 28 weeks. In three studies steroids were used; in another three studies antibiotics were used.

A comparison of short-term versus long-term tocolysis in preterm PROM at 26 to 35 weeks showed adverse effect of “long-term tocolysis.” Patients with preterm PROM at 26 to 35 weeks were randomized to receive either an intravenous ß-mimetic drug for less than 48 hours versus until delivery. All patients received corticosteroids, and group B streptococci (GBS) and gonococci were treated. There was no significant difference in the latent period or in neonatal infection, but there was a significant increase in both chorioamnionitis and endometritis with long-term tocolysis. Accordingly, use of tocolytics in patients with preterm PROM remains controversial, but the bulk of the evidence shows no benefit. However, if tocolytics are used, such as during transfer to a tertiary care center or obtaining benefits of corticosteroids, the course of tocolytics should be limited to less than 48 hours.

Respiratory Distress Syndrome, Infections, and Other Complications

The risks of PROM have generally been viewed as those of infection versus those of prematurity. The most common clinically evident complication among pregnancies with PROM before 37 weeks is respiratory distress syndrome (RDS), which, in general, is found in 10% to 40% of neonates. Bona fide neonatal sepsis is documented in less than 10%, and amnionitis (based always on clinical criteria) occurs in approximately 3% to 31%. Subclinical infection, based upon positive amniotic fluid culture or histologic inflammation of the cord or membranes, is seen much more often, in up to 80% at very early gestational ages with PPROM. Endometritis develops in 0% to 29%. Abruption after PROM is reported in 4.0% to 6.3% of cases, higher than the usually quoted rate of 0.5% to 1.0%. Pulmonary hypoplasia is a serious fetal complication occurring in preterm PROM. Pulmonary hypoplasia is more common when there is very early preterm PROM, especially when this occurs in the presence of prolonged PROM and with severe oligohydramnios. There is nearly a 100% probability of lethal pulmonary hypoplasia when PROM occurs before 23 weeks and when there is severe oligohydramnios. With later gestational age at the onset of preterm PROM, the likelihood of pulmonary hypoplasia decreases. Notably with preterm PROM more than 28 to 29 weeks, even with oligohydramnios, pulmonary hypoplasia is rare. When preterm PROM occurs less than 25 weeks with severe oligohydramnios lasting more than 14 days, the likelihood of lethal pulmonary hypoplasia is estimated to be 80%. At the other extreme, when preterm PROM occurs at more than 25 weeks and when there is either no severe oligohydramnios or severe oligohydramnios for less than 5 days, then the predicted probability of lethal pulmonary hypoplasia is only 2%. These data provide important information for counseling patients with mid-trimester PROM.

RECURRENCE

The reported recurrence rate for PPROM is 32% for patients who had PPROM in an index pregnancy. Based on these data, the risk of recurrence is considerable, prompting patient education and close follow-up in subsequent pregnancies.

EVALUATION

Diagnosis

The initial evaluation may reveal amniotic fluid egressing from the vagina. The differential diagnosis of rupture of membranes includes loss of mucus plug, vaginal discharge associated with infection, and urinary incontinence. If the patient is not going to be delivered immediately, then a digital examination should be deferred as examination may introduce bacteria into the uterus and shorten the latent phase. A sterile speculum exam may demonstrate pooling of fluid in the posterior vaginal vault. Direct observation of fluid leaking from the cervical os is proof of ruptured membranes. The normal pH of the vagina is between 4.0 and 4.7 in pregnancy, whereas the pH of the amniotic fluid is 7.1 to 7.3. Nitrazine paper changes to a dark blue from yellow with a pH above 6.5. Nitrazine paper to diagnose amniotic fluid in the vagina has an overall accuracy of approximately 93%, but false-positive results can result from blood, semen, alkaline urine, bacterial vaginosis, and trichomoniasis.

The diagnosis of PROM may also be confirmed by observing arborization or “fern” of dried amniotic fluid on a slide. This method has an overall accuracy of diagnosis of PROM of approximately 96%. False positives occur with contamination by semen or cervical mucus. False negatives can result from a dry swab, contamination with blood at a 1:1 dilution, or not allowing sufficient time for the fluid to dry on the slide. Amniotic fluid arborization is unaffected by meconium at any concentration and is unaffected by pH alteration.

Ultrasound examination has been used widely, since oligohydramnios suggests PROM, but there have been no evaluations of its sensitivity and specificity. A multicenter clinical trial compared fetal fibronectin detection with standard tests for detection of rupture of membranes at term. Fetal fibronectin showed an excellent sensitivity (98.2%) but a low specificity, leading to speculation that fetal fibronectin in cervicovaginal secretions may be a marker for impending labor, even without frank rupture of the membranes.

When the diagnosis of ruptured membranes is unclear by these tests, a transabdominal dye injection is sometimes performed. A dye such as indigo carmine blue is injected into the amniotic fluid, and a sponge is placed into the vagina and later inspected for the dye. Methylene blue should not be used because of reported methemoglobinemia in the fetus. This test is invasive, and the accuracy of diagnosis is not established. After dye injection, an observation period of 30 minutes is sufficient to detect passage of dye from the vagina.

Fetal Maturity

Determination of the fetal age and maturity status is useful in developing a treatment plan. The patient's history and early milestones of the pregnancy should be used. Ultrasound examination of the fetus can be limited because of the decreased fluid surrounding the fetus, and some measurements, especially of the abdomen and head, may be altered with oligohydramnios after PROM. As part of the overall decision process as to delivery, assessment of fetal lung status may be incorporated, for example, if gestational age is 32 to 34 weeks or if there is uncertainty regarding growth restriction versus prematurity. Amniotic fluid may be collected by amniocentesis or by collection from the vaginal pool. Vaginal pool collection is less accurate for lecithin/sphingomyelin ratio (L/S R) determination. Whereas phosphatidylglycerol (PG) production by vaginal bacteria has been described, there has been an excellent correlation between PG detection in amniotic fluid obtained vaginally and transabdominally.

Cervical Status

In addition to documentation of ruptured membranes, the sterile speculum exam can evaluate the degree of cervical dilation and can exclude the possibility of a fetal extremity or umbilical cord prolapsing through the cervix. Endovaginal ultrasound may be used in patients with preterm PROM without increasing the risk of infection or shortening the latent period.

Infection

When the diagnosis of PROM is made, a rectovaginal culture should be taken for GBS and appropriate antibiotics for prevention of GBS infection should be given

pending culture results.

All patients with preterm PROM should be evaluated for possible evidence of chorioamnionitis. Physical exam includes maternal or fetal tachycardia, uterine tenderness, and detection of a purulent, foul-smelling discharge. Temperature elevation is often a late sign of chorioamnionitis, especially in preterm PROM. In Table 11.1, we show the positive and negative predictive values of several tests for intrauterine infection in PPROM. Amniocentesis may be performed to evaluate for an intrauterine infection, for example, if there are equivocal clinical signs of infection. Because of the high likelihood of subclinical infection and the association of intrauterine infection with cerebral palsy, there is a growing enthusiasm for early detection of subclinical infection. Accordingly, amniocentesis may become more widely used. Analyses of amniotic fluid for possible infection include Gram stain, glucose concentration, and culture. Gram stain does not identify colonization with genital mycoplasmas. A low amniotic fluid glucose predicts a positive amniotic fluid culture. When the glucose is greater than 20 mg per dL, the likelihood of a positive culture is less than 5%; when glucose is less than 5 mg per dL, the likelihood of a positive culture approaches 90%. Although not widely available, an elevated interleukin 6 (IL-6) in amniotic fluid may be the most sensitive predictor of intrauterine infection. A biophysical profile of 6 or less has been shown in several studies to correlate with intrauterine infection. Most newborns who are delivered after clinical chorioamnionitis do not show clinical infection.

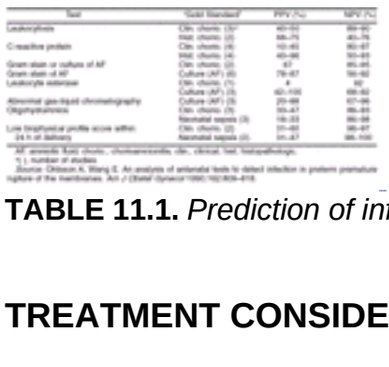

TABLE 11.1. *Prediction of infection in PROM*

TREATMENT CONSIDERATIONS

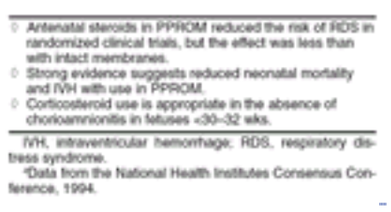
The overall approach to management of PROM takes into consideration neonatal survival at the gestational age when rupture occurs. Management may be divided into four different phases of pregnancy. During the second trimester, neonatal survival is nil, leading numerous investigators to adopt a policy of expectant management or induction. Early in the third trimester, neonatal survival rises markedly, but there is still considerable morbidity associated with delivery at this gestational age. In the mid-third trimester, neonatal survival is high, but there is still considerable morbidity, whereas in the late third trimester (at or near term) neonatal mortality and morbidity are low. Neonatal outcome is one of the driving features in determining clinical management.

Diagnosis of Infection After PROM

Both invasive and noninvasive tests have been assessed. As shown in Table 11.1, none of these tests is ideal, particularly because of their low positive predictive values.

Use of Steroids

Clinicians remain unable to agree on the risks and benefits of steroids in preterm PROM. The first meta-analysis in 1989 concluded that the use of steroids “increases the incidence of endometritis and may increase neonatal infections.” The 1994 National Institutes of Health (NIH) Consensus Conference concluded that the risk of maternal and infant infection may be increased with corticosteroid use after PROM but that the magnitude of this risk was small. The NIH recommendations are summarized in Table 11.2. The benefits of steroids with PPROM before 28 weeks, however, have not been firmly established.



- Antenatal steroids in PPROM reduced the risk of RDS in randomized clinical trials, but the effect was less than with intact membranes.
- Strong evidence suggests reduced neonatal mortality and IVH with use in PPROM.
- Corticosteroid use is appropriate in the absence of chorioamnionitis in fetuses <30–32 wks.

IVH, intraventricular hemorrhage; RDS, respiratory distress syndrome.
[a]Data from the National Health Institutes Consensus Conference, 1994.

TABLE 11.2. *Corticosteroid use in PPROM* [a]

Effect of Latent Period and Vaginal Examination upon Incidence of Amnionitis

In earlier studies, the incidence of amnionitis rose with increasing length of the latent period, but other investigators have found no increase in the incidence of amnionitis among preterm pregnancies with increasing latent periods. In a comparison of outcomes, women with digital examination after PROM had a significantly shorter latent period (2.1 ± 4.0 vs. 11.3 ± 13.4 days; $P < .001$), more maternal infection (44% vs. 33%; $P = .09$), and more positive amniotic fluid cultures (11/25 [44%] vs. 10/63 [16%]; $P < .05$). Thus, routine vaginal examination should be avoided until labor develops in patients with preterm PROM.

Use of Prophylactic Antibiotics

In patients with PROM prior to term, there are two rationales for prophylactic antibiotics. The first is a clear one; namely, for prevention of perinatal GBS infection.

A second rationale for antibiotic prophylaxis has been based upon the hypothesis that infection is either the triggering cause of preterm PROM or that infection ensuing after preterm PROM triggers the labor. Accordingly, this rationale for prophylactic antibiotics has been to delay delivery after preterm PROM rather than to prevent clinically evident infection. We believe that good evidence has been provided to favor use of broad-spectrum antibiotics in selected cases of preterm PROM. This support was provided in a meta-analysis and in prospective randomized trials. In the meta-analysis, 24 trials were identified and 13 were included, containing 1,594 women. However, only 6 of the trials were placebo-controlled, and the trials were heterogeneous with regard to antibiotics used. In addition, there was no standard use of steroids, tocolytics, or prophylaxis for GBS. Nevertheless, benefits were demonstrated in favor of women receiving antibiotics. These benefits included a significant delay in delivery within 7 days, a reduction in chorioamnionitis, and a reduction in neonatal sepsis. There were also reductions (that did not achieve statistical significance) in postpartum infection, neonatal death, neonatal pneumonia, and neonatal bacteremia.

In the large MFM trial, patients were enrolled if they had preterm PROM for less than 72 hours at 24 to 32 weeks gestation. Patients were excluded if there was chorioamnionitis, labor, or fetal distress. Patients were then randomized to a course of ampicillin plus erythromycin (each for 2 days i.v. followed by up to 7 days orally) vs. placebo. Patients with GBS were given treatment during the latent period and no tocolytics were used. However, at the time the study was designed, it was decided not to use corticosteroids in any patients. The primary end point was a prospectively defined composite of neonatal death, neonatal RDS, grade III or IV intraventricular hemorrhage, grade II or III necrotizing enterocolitis, or neonatal sepsis. Patients randomized to antibiotic therapy had a significantly greater likelihood of remaining undelivered when assessed at 2 days, 7 days, 14 days, and 21 days (Fig. 11.2). In addition, the primary composite outcome was significantly reduced in the total population and in the GBS-negative cohort. Individual adverse outcomes significantly reduced in the antibiotic group included RDS, chorioamnionitis, neonatal sepsis, and neonatal pneumonia. Table 11.3 summarizes the benefits of antibiotics in patients with preterm PROM and stratifies the results by total population versus the GBS-negative cohort.

TABLE 11.3. *Maternal–Fetal Medicine network trial of antibiotics after PPROM: summary of benefits*

Subsequent to this trial, others have appeared assessing antibiotics in conjunction with antenatal corticosteroid therapy for patients with preterm premature rupture of the membranes. One study assessed 112 women with PROM from 25 to 35 weeks and randomized them to ampicillin sulbactam/amoxicillin clavulanate versus ampicillin/amoxicillin versus placebo. Tocolytics were used in this trial and betamethasone was used weekly up to 32 weeks. Patients receiving the antibiotics had less serious neonatal complications including neonatal death, RDS, and neonatal sepsis ($P < .05$) and they also had significantly higher mean birth weight ($P = .03$). Lewis and colleagues reported a randomized clinical trial of corticosteroids in patients with preterm PROM after treating these patients for a minimum of 12 hours with ampicillin/sulbactam. Antibiotics were continued for 7 days and steroids were repeated weekly. No tocolytics were used. The authors defined the primary outcome as the incidence of RDS, whereas secondary outcome measures included latency and neonatal or maternal infections. In this study of 77 patients, no statistically significant difference in latency was noted comparing the steroid versus no steroid group, and both neonatal and maternal infections were similar. However, there was a significant reduction in the incidence of RDS, 18.4% in the steroid group compared with 43.6% in the no steroid group. The authors concluded that treating preterm PROM with a broad-spectrum antibiotic before corticosteroids decreased RDS without apparent adverse effect. In 1998, a meta-analysis of five trials on antibiotic and glucocorticoid treatment reportedly did not show a significant effect on outcomes including maternal infection, neonatal sepsis, RDS, intraventricular hemorrhage, necrotizing enterocolitis, and neonatal morbidity. In contrast, the authors note “antibiotic therapy without concomitant use of glucocorticoids significantly reduced the odds of maternal infection, neonatal sepsis, and intraventricular hemorrhage substantially.” However, this meta-analysis did not include some of the more recent studies noted immediately above.

In a very large (nearly 5,000 patients) international trial (ORACLE I), patients with PPROM were randomized to one of four courses: oral erythromycin, oral amoxicillin-clavulanic acid, both antibiotics, or oral placebo. Each regimen was taken four times a day for 10 days or until delivery. The primary outcome measure used was a composite of neonatal death, chronic lung disease, or major cerebral abnormality on ultrasound. Erythromycin was associated with several benefits to the neonate (fewer cases with the composite outcome, prolongation of pregnancy, and fewer positive blood cultures). Amoxicillin-clavulanic acid—with or without erythromycin—was associated with prolongation of pregnancy, but it was also associated with a significant increase in neonatal necrotizing enterocolitis. The applicability of this study to contemporary U.S. practice is limited, however, because the authors made no provision for GBS prophylaxis. Other features of the study to emphasize are that antibiotics were used orally, enrollment was permitted up to 37 weeks (only 50% of cases were less than 32 weeks), and there was no standard approach for use of steroids or tocolytics. (Steroids were used in 75% of cases and tocolytics in <15%.)

Widespread use of antibiotics in this situation has raised concern about selection pressure toward resistant organisms, but in the MFM trial, there was no significant increase in maternal yeast infection or neonatal Candida sepsis, nor were there any cases of pseudomembranous colitis, maternal sepsis, or maternal death.

Determination of Fetal Lung Maturity

Because RDS is the single greatest threat to infants with PROM, some investigators have determined the status of fetal pulmonary maturity and proceeded with delivery when there was lung maturity. One study used amniocentesis and obtained fluid in about half of the cases. Others have attempted to collect amniotic fluid from the vagina and have had success rates of 80% to 94%. Presence of either PG or an L/S R of more than two in amniotic fluid collected vaginally has been reported to be a good predictor of pulmonary maturity.

In a larger series of patients with PROM before 36 weeks, investigators determined whether PG was present in the vaginal pool and delivered patients when there was presence of PG, spontaneous labor, or evidence of sepsis. PG in amniotic fluid from the vagina reliably predicted fetal lung maturity. However, absence of PG did not necessarily mean that RDS would develop. Of the 131 patients who did not show PG in the vaginal pool in any sample, 82 (62%) were delivered of infants who had no RDS. Thus, even with PROM, delivery of a premature infant simply because its lungs showed biochemical maturity may be questioned in view of other potential hazards of prematurity and the difficulty of the induction. Of note, some genital tract bacteria have been found to yield a false-positive test for PG.

MANAGEMENT

PROM at or Near Term (Table 11.4)

- Induction usually preferred, with oxytocin or prostaglandin preparations (especially with unripe cervix), either upon admission or after a finite period of observation (up to 12 or even 24 h).
- Prophylaxis for group B streptococci with a positive screening culture at 35–37 wks, or with rupture of membranes >18 h in patients with unknown culture status.

TABLE 11.4. *Summary of management: PROM at or near term (= 35 wks)*

In the last few years, new studies have influenced changes in management of PROM at term. Previously, induction of labor (with oxytocin) within 12 to 24 hours after PROM at term was a practice followed by most U.S. obstetricians. Studies in the United States and in Scandinavia supported the safety of this approach and reported shorter maternal hospital stays with less clinically evident neonatal infection. Although expectant management with inpatient observation had been shown to be safe in most patient populations, this approach has become less popular because of the inconvenience and expense of the hospitalizations. Several studies have reported the safety and benefits of prostaglandins and have supported the increased popularity of induction with these preparations. In comparison to patients managed expectantly, those given intravaginal prostaglandin E_2 (PGE_2) shortly after admission had significantly less likelihood of a need for oxytocin and a significantly shorter time to delivery. There was no significant difference in cesarean section rate or in maternal or neonatal infection rates. In the largest trial of management of PROM at term, patients were studied in a four-arm trial with approximately 1,250 patients in each arm. These arms were as follows: Expectant management plus oxytocin for induction as needed; induction with i.v. oxytocin shortly after admission; induction with PGE_2 gel in a dose of only 1 to 2 mg shortly after admission; and expectant management followed by PGE_2 induction as needed. One methodological concern regarding this study is the low dose of PGE_2 gel used vaginally. With most patients receiving less than 2 mg, the dose was smaller than used in most U.S. trials. As shown in Figure 11.3, patients randomized to expectant management initially had significantly longer times to delivery than patients randomized to either of the induction arms ($P < .001$). In addition, the rate of clinically diagnosed chorioamnionitis was less in the patients randomized to induction initially (with significance achieved at $P < .01$ comparing arms *1 vs. 2*). The distribution of postpartum infection was similar to that of chorioamnionitis. In addition, there was no significant difference in rates of neonatal infection or cesarean section. Of note, patient satisfaction was significantly higher in the induction arms.

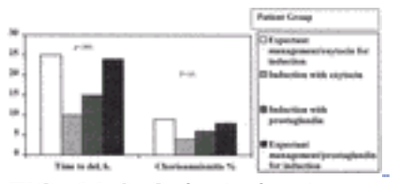

FIG. 11.3. Selected outcomes in an international term PROM trial. (From Sweet RL, Gibbs RS. *Infectious diseases of the female genital tract*, fourth ed. Philadelphia: Lippincott Williams & Wilkins, 2002; with permission.)

A large meta-analysis involving 23 studies and including nearly 7,500 patients concluded that conservative management may result in more maternal infections than immediate induction with either oxytocin or prostaglandins. This meta-analysis also showed that the rate of chorioamnionitis was higher in patients induced with prostaglandin versus those induced with oxytocin. However, this meta-analysis was heavily influenced by the large international trial, and as noted previously, this trial used a very low dose of prostaglandin.

Within the last few years, intravaginal misoprostol (a PGE_1 analog) has assumed marked popularity for induction because of its efficacy and low cost. Intravaginal misoprostol (50 µg every 4 hours for a maximum of 12 tablets) was compared with oxytocin in women with single pregnancies and an unfavorable cervix (<2 cm dilated and <80% effaced). The results of this trial are presented in Table 11.5. Overall, patients randomized to misoprostol had a shorter induction time, by approximately 2 hours, but they had significantly more uterine tachysystole. Of note, over 85% of patients required only one dose of misoprostol. Compared to other trials evaluating misoprostol in patients at term with intact membranes, the dose used in this trial is relatively high.

	Misoprostol (n = 70)	P	Oxytocin (n = 71)
Induction time (min)	416.0	0.04	539
One dose, %	85.7		
Uterine tachysystole*, %	28.6	<.04	14.0

*≥6 contractions/10 min. × 20 min. No difference in mode of delivery or any other complications.

TABLE 11.5. *Misoprostol vs. oxytocin in PROM*

A 1998 American College of Obstetricians and Gynecologists' (ACOG) Practice Bulletin concluded that with term PROM, labor may be induced at the time of admission or that patients may be observed for up to 24 to 72 hours after PROM. In sum, while a range of practices is available and supported in the literature, the decision regarding delivery after PROM at term must take into account fetal presentation, fetal status, cervical ripeness, presence of infection, and patient desires. For patients with a breech (or other malpresentation) infant or an infant with evidence of intolerance of labor, prompt cesarean delivery is most appropriate. If there is clinically evident infection and no contradiction to vaginal delivery, then immediate induction and antibiotic therapy are indicated. If the cervix is ripe, then a short period of observation is reasonable, but induction with oxytocin resolves the situation. When the cervix is unripe, induction with either prostaglandins or oxytocin shortens the time to delivery, decreases risk of infection, and does not appear to increase cesarean section rate. The epidemiologic data linking chorioamnionitis with cerebral palsy provide additional impetus to move toward delivery after PROM at term.

PROM at 32 to 34 Weeks (Table 11.6)

◊ Expectancy vs. induction, especially if there is evidence of fetal lung maturity based upon analysis of amniotic fluid collected by amniocentesis or from vaginal pool.
◊ Prophylaxis for group B streptococci.
◊ Although broad-spectrum antibiotics have been used in some studies to prolong pregnancy in the gestational age bracket, there are concerns about selection pressure for resistant organisms and about masking fetal infection. Therefore, the author limits such broad-spectrum antibiotic use to earlier gestational ages.
◊ Do not use tocolytics.
◊ Do not give corticosteroids.

TABLE 11.6. *Summary of management: PROM at 32–34 wks*

Management in this gestational age category remains controversial. When there is evidence of fetal lung maturity, two trials have reported benefits to induction versus continued expectancy. In one trial, induction had several benefits, including a shorter time to delivery (14 vs. 36 hours; P < .001), shorter maternal hospital stay (2.3 vs. 3.5 days; P < .001), and less chorioamnionitis (11 vs. 28%; P = .06). Neonatal hospital stay was also shorter (6.3 vs. 7.3 days), but this difference was not significant. Although the authors found less clinically diagnosed neonatal sepsis in the induction group (28 vs. 60%; P < .003), there was no difference in confirmed sepsis (7 cases in induction group vs. 4 in expectant). There were no significant differences in the rates for cesarean delivery, postpartum infection, or neonatal survival. The other trial also found advantages to induction versus expectancy. Despite the reasons advanced by these authors, there is not yet compelling evidence to induce all pregnancies with PROM at 32 to 34 weeks simply because there is evidence of lung maturity. There is no improvement in perinatal mortality (PNM), and in other populations, induction in the presence of an unripe cervix at 32 to 34 weeks might result in higher infection rates or cesarean delivery rates. However, the evolving concern of intrauterine infection causing cerebral palsy adds strength to arguments for induction in the presence of lung maturity.

For pregnancies with PROM at 32 to 34 weeks, we have generally used expectant management. We do not routinely perform amniocentesis, but use this selectively when we suspect infection or growth restriction. We assess fetal status during expectant management with usual testing, mainly daily nonstress tests with biophysical profiles as needed for backup. In selected pregnancies at 32 to 34 weeks, we induce labor in the presence of lung maturity. Such situations include development of a favorable cervix (noted on a speculum examination) or poor patient compliance. We, of course, proceed with delivery when there are maternal or fetal indications including evidence of infection. For pregnancies with PROM at 32 to 34 weeks, we give intrapartum prophylaxis per the Centers for Disease Control and Prevention (CDC)/ACOG guidelines. We also obtain an appropriate rectovaginal culture for GBS at the time of admission, unless delivery is imminent. We then begin empirical intravenous prophylaxis until the culture result is available and is negative. If at 33 to 34 weeks the culture is positive, we will continue intravenous penicillin for 48 hours, then stop and re-culture.

PROM at 25 to 31 Weeks (Table 11.7)

◊ Expectancy.
◊ Prophylaxis for group B streptococci.
◊ Antibiotics for 7 d. No standard regimen has been established. (ampicillin + erythromycin or erythromycin), or alternative regimens.
◊ Corticosteroids.
◊ Use of tocolytics remains controversial. If used, they should be limited to 48 h.

TABLE 11.7. *Summary of management: PROM at 25–32 wks*

Management in the gestational age category also remains especially controversial. For management of PROM after viability but before 32 weeks, our practice is to generally follow expectant management and proceed with delivery where there is spontaneous onset of labor or clinical evidence of infection. We follow national guidelines for intrapartum prophylaxis for prevention of GBS neonatal sepsis. For patients in whom delivery is not imminent, we also obtain an appropriate culture for GBS from the rectovaginal area. We do administer corticosteroids in a standard regimen. We also apply broad-spectrum antibiotic therapy, usually following the ampicillin/amoxicillin plus erythromycin regimen of the MFM trial. This regimen is limited to 7 days. When the patient goes into labor, we begin GBS prophylaxis unless the GBS culture was negative on admission, as recommended by the CDC. Use of tocolytics during this gestational age in patients with preterm premature rupture of the membranes remains controversial.

PROM at Less Than 25 Weeks (Table 11.8)

◊ Induction vs. expectancy, depending upon gestational age and patient desires. ◊ No data on steroids, tocolytics, or antibiotics (prophylaxis for group B streptococci or prolonging pregnancy). ◊ It is unlikely that tocolytics achieve any significant prolongation of pregnancy and may mask early evidence of infection. Therefore, they are not recommended. ◊ It is unlikely that corticosteroids provide any fetal benefit at this gestational age, and corticosteroids may also increase the risk of intrauterine infection. Therefore, corticosteroids should be reserved for gestational ages where benefit is more likely. ◊ A course of antibiotics for 7 d may prolong pregnancy and decrease complications as in pregnancies with PPROM at 25–32 wks. ◊ After a period of inpatient hospitalization, home management may be used for uncomplicated, selected patients.

TABLE 11.8. *Summary of management: PROM <25 wks*

For PROM before viability (approximately 24 weeks), several descriptive reports have demonstrated a highly variable latent period, high maternal infection rates (but with little serious morbidity), and an appreciable survival rate, especially when delivery occurs after week 24 (Table 11.9). Outcome data with expectant management of PROM in the second trimester showed perinatal survival and "intact" neurologic survival stratified by the gestational age at the time of PROM (Fig. 11.4). In sum, when gestational age occurred from weeks 14 to 19, overall survival was only 40% whereas when PROM occurred at 20 to 25 weeks, overall survival was nearly 90%. The alternative to expectant management is induction. In the patient with PROM this early in pregnancy, we individualize the decision, involving the family fully. In the proper setting, we offer expectant management.

Outcome measure	Result
Gestational age at rupture of membranes (median [range])	23.5 wks (17–26)
Latent period (median [range])	7.6 d (1–161)
Amnionitis (mean [range])	39% (22–63)
Survival (mean [range])	38% (25–46)
Normal development at 1 y (mean [range])	59% (20–68)

TABLE 11.9. *Summary of management: PROM at =24 wks*

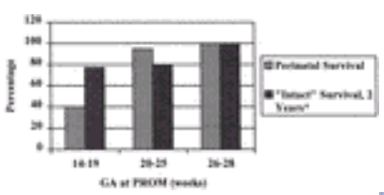

FIG. 11.4. Outcome with expected management of second trimester PROM. (From Sweet RL, Gibbs RS. *Infectious diseases of the female genital tract*, fourth ed. Philadelphia: Lippincott Williams & Wilkins, 2002; with permission.)

Chorioamnionitis Complicating PROM at Any Gestational Age (Table 11.10)

◊ Begin intravenous, broad-spectrum antibiotics, based upon the array of aerobic and anaerobic organisms isolated in amniotic fluid of cases of clinical chorioamnionitis. ◊ There is no place for expectant management in clinically overt chorioamnionitis. ◊ The route of delivery should be determined by standard obstetric considerations. Immediate cesarean delivery increases maternal morbidity and does not improve neonatal outcome. However, the cesarean delivery rate is high in pregnancies complicated by clinical chorioamnionitis because of poor progress in labor, nonreassuring fetal heart rate patterns, and malpresentation.

TABLE 11.10. *Management of clinically evident chorioamnionitis*

When clinically evident chorioamnionitis is diagnosed at any gestational age, broad-spectrum antibiotics, appropriate for the array of suspected aerobes and anaerobes, should be initiated intravenously. There is no place for expectancy when intrauterine infection becomes clinically overt and preparation should be made for delivery.

SUMMARY POINTS

Management of PROM

- At or near term (35 weeks) induction is usually preferred; GBS prophylaxis is given with a positive screening culture at 35 to 37 weeks or with rupture of membranes greater than 18 hours plus an unknown culture status.
- At 32 to 34 weeks, manage by either expectancy or by induction (especially with evidence of lung maturity). Give GBS prophylaxis. Do not use tocolytics or corticosteroids.
- At 25 to 32 weeks, manage by expectancy. Give GBS prophylaxis and give corticosteroids. We give antibiotics for 7 days to prolong pregnancy. No standard regimen is established. We use ampicillin plus erythromycin most often. Use of tocolytics is controversial.
- At less than 25 weeks, manage by induction or expectancy, depending upon gestational age and patient desires. We do not use tocolytics or corticosteroids in this situation. A course of antibiotics for 7 days may prolong pregnancy as at 25 to 32 weeks.

SUMMARY POINTS

SUGGESTED READINGS

Approximately 10% of the almost 4 million infants born each year in the United States are classified as low birth weight (LBW). Terminology used to describe the small fetus/newborn can be confusing. The term LBW is used clinically by pediatricians postnatally and is defined strictly as a birth weight less than 2500g with no regard for gestational age. The term “small for gestational age” (SGA) was originally defined by pediatricians as a newborn with a birth weight less than expected given gestational age and which can occur in a term or a preterm neonate. However, use of the term SGA subsequently expanded from the postnatal period to the antenatal period and is currently used interchangeably with intrauterine growth restriction (IUGR). For the purposes of this chapter, the use of the term SGA will be reserved for the newborn and IUGR, as implied by the name, will be restricted to the fetus. IUGR is more specifically defined later in the chapter. The fetus or newborn classified as IUGR or SGA, respectively, encompasses a group of fetuses-newborns that are small for a variety of reasons with varying prognoses, including congenital infections, congenital malformations, aneuploidy, uteroplacental insufficiency, and constitutionally small. It is important to recognize that not all fetuses or newborns that are classified as IUGR or SGA are small due to pathologic reasons (i.e., constitutionally small), but simply represent the smaller fetuses/newborns at the lower end of the bell-shaped distribution of the normal poulation. The prognosis for a given IUGR fetus is dependent on the etiology. Placental insufficiency accounts for the majority of IUGR fetuses. The scope of the problem with IUGR is quite broad, not just because it increases morbidity and mortality of the fetus, but also because it does so for the newborn and adult the fetus is destined to become. IUGR places the fetus at risk for hypoxemia, acidemia, antepartum death, and intrapartum distress. It places the neonate at risk for a number of metabolic disturbances, polycythemia, pulmonary transition difficulties, intraventricular hemorrhage, impaired cognitive function, and cerebral palsy. Several epidemiologic studies and animal studies in the early 1990s began to report on long-term sequelae of IUGR including adult hypertension, heart disease, stroke, and diabetes. The theory of fetal programming as the origin of adult disease was introduced by Barker and colleagues and is commonly referred to as the “Barker hypothesis.” The challenge in management of the IUGR fetus is to identify the condition and manage it such that adverse sequelae are minimized. The use of real-time ultrasound and Doppler velocimetry play pivotal roles in the diagnosis and management of IUGR. This chapter reviews normal placental–fetal growth, etiologies of the IUGR fetus, and practical uses of ultrasound and Doppler velocimetry in the diagnosis and management of the IUGR fetus.

DETERMINANTS OF NORMAL AND ABERRANT PLACENTAL GROWTH

Normal Placental Development

In most mammalian species, the placental and fetal mass increase exponentially for at least a portion of pregnancy. Normal growth of the fetus is in turn dependent on normal placentation and growth of the placenta. The placenta is a dynamic and multifaceted organ that serves as an interface between mother and fetus with the critical role of meeting the metabolic and circulatory demands of the growing fetus. The roles of the placenta include:

Nutritional: Provides oxygen, glucose, amino acid, and volume (fluid) transfer.
Immunologic: Protects the fetus from pathogens and the maternal immune system.
Endocrinologic: Produces numerous hormones, growth factors, cytokines, and other vasoactive mediators.
Metabolic: Serves as the respiratory and the kidney organ for the fetus and is responsible for elimination of carbon dioxide, metabolic acids, and other waste products from the fetus to maintain acid–base balance.

Placentation must be normal in order for these functions to be met.

Research has begun to provide an understanding of the complexity of the implantation and placentation processes, which requires production and coordination of numerous angiogenic growth factors (fibroblast growth factor, hepatocyte growth factor, placental growth factor, vascular endothelial growth factor), cell-adhesion molecules, cytokines, nitric oxide, extracellular matrix metalloproteinases, hormones, and transcription factors (hypoxia inducible factor). This process of coordination begins very early in pregnancy and can dictate whether the pregnancy grows in a normal or abnormal direction. During the luteal phase of the menstrual cycle, the endometrium becomes decidualized in preparation for acceptance of the products of conception. Shortly after entering the uterine cavity on day 4 postconception, the morula becomes a blastocyst with an inner cell mass at one pole that is called the *embryoblast* and an outer cell mass that is called the *trophoblast.* On day 7 postconception, the trophoblast differentiates into the cytotrophoblast, which envelops the blastocyst circumferentially. Simultaneously, the newly developed cytotrophoblast cells further differentiate into a sheet of syncytiotrophoblast cells. The syncytiotrophoblast produces proteins and steroid hormones. The cytotrophoblast, made up of nucleated cells, continues to produce the anucleate syncytiotrophoblast throughout gestation primarily by mitotic activity and loss of cytotrophoblastic cell walls. By day 13, the cytotrophoblast layer has differentiated into invasive and noninvasive cytotrophoblast. The invasive cytotrophoblast forms invasive cell columns that invade the uterine epithelium to anchor the fetus and establish blood flow to the placenta and fetus. During this process, the invasive cytotrophoblast cells (extravillous trophoblast):

- *migrate* through the syncytiotrophoblast and into the decidualized endometrium and myometrium
- *invade* the vessel walls of the maternal-based spiral arteries in these areas
- *transform* the spiral arteries from a high-resistance to a low-resistance vessel.

As the invasive cell columns of the cytotrophoblast penetrate the syncytiotrophoblast, spaces called *lacunae* are created, which subsequently fuse to form the intervillous space with intervening syncytiotrophoblast columns called *trabeculae.* The process of intervillous space formation and spiral artery transformation directs an increasing maternal cardiac output into the intervillous space. Loss of spiral artery vessel media is the mechanism by which the spiral arteries drop their resistance to blood flow. The syncytiotrophoblast-based trabeculae branch laterally to initiate placental villi formation on approximately day 13. The extent of vascularization of the villus architecture defines the villus as stem or primary villus, secondary villus. or tertiary villus. The stem villus is without vessels and only has trophoblast cells. The secondary villus is formed by central invasion of the primary villous core by the allantoic mesenchyme of the embryoblast. The tertiary villus forms during vasculogenesis, which is the development of de novo blood vessels from mesenchymal cells differentiating into hemangioblasts. Hemangioblasts are precursors of endothelial cells. This process begins in the 5th week of gestation.

Each cotyledon, labeled by some as a fetal unit, is characterized by a villous tree that contains three basic types of villi:

1. stem villi

2. intermediate villi
3. terminal villi.

These three villous types represent progressively smaller generations of villous branching with the terminal villi serving as the end point. The stem villi extend from the chorionic plate to the basal plate. The stem villi contain a single truncus that progressively branches into the rami chorii, which in turn branches into the ramuli chorii. It is from the ramuli chorii that the intermediate villi appear of which there are two types: The immature and mature intermediate villi. The terminal villi are the primary gas exchanging villi, which have actually been identified at all levels of branching. They account for 55% of the total number of cross-sectional villi in the peripheral villous tree. Smooth muscle staining shows that vessels coursing through the villi contain smooth muscle media down to the level of the immature villi. This distinguishes the stem and immature villi from the gas-exchanging mature and terminal villi. It has been noted that the intermediate villi, because of the smaller arterioles, venules, pre- and postcapillaries contained within, may serve a hemodynamic regulatory function (i.e., control of blood pressure and flow). The concept of blood flow control at this level is further supported by previously described sphincterlike precapillary structures.

In contrast to vasculogenesis, angiogenesis represents the formation of new blood vessels from endothelial cells and is classified into branching and nonbranching angiogenesis. *Branching* angiogenesis occurs primarily in the first and second trimesters and leads to the formation of the immature villous tree. Branching angiogenesis continues until the end of the second trimester when there is a transition to *nonbranching* angiogenesis. During this process there is a dramatic increase in mature intermediate and terminal villi. The nonbranching angiogenesis forms terminal capillary loops with minimal branching and provides the network of capillaries for the intermediate and terminal villi. A dramatic decrease in vascular resistance and an increase in blood flow through the placenta are coincident with this process. The progressive decline in vascular resistance is depicted by increased end-diastolic velocities in Doppler flow velocity waveforms of the umbilical artery (Fig. 12.1).

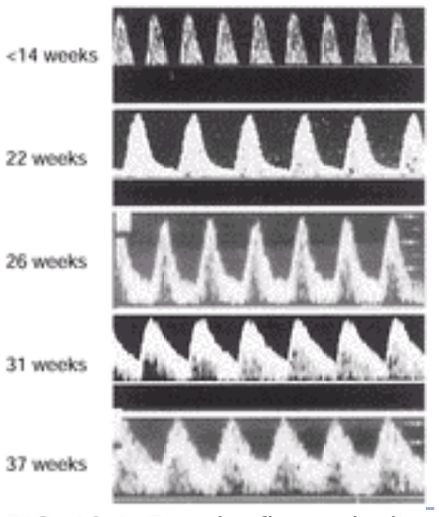

FIG. 12.1. Doppler flow velocity waveform profiles in the umbilical artery across normal gestation. Note the progressive increase in end-diastolic flow.

Abnormal Placental Development

In pregnancies complicated by preeclampsia and IUGR, trophoblast invasion is limited to the decidualized endometrium, which results in failure of the spiral arteries to become low resistance vessels. The inability of spiral arteries to transition from high to low blood flow resistance can be detected by Doppler velocimetry of the uterine artery which supplies blood to the spiral arteries. The blood flow velocity waveforms in the uterine artery obtained with pulsed-wave Doppler velocimetry are reflective of the waveforms downstream at the spiral arteries. These abnormalities are identified on a Doppler flow velocity waveform (FVW) profile by a high resistance pattern (low velocity of flow at end-diastole relative to that at systole) and by a protodiastolic (early diastolic) notch. Failure of this process to occur on the maternal side of the circulation may lead to adverse effects on both the mother and the fetus. Maternal vascular endothelial dysfunction may lead to production of a variety of vasoactive mediators, which could subsequently lead to the development of preeclampsia. Poor growth of the placental–fetal unit may also result from poor invasion and remodeling of the spiral arteries by the cytotrophoblast.

A variety of villous and vascular abnormalities have been described in the placenta of the IUGR fetus. Placentas from IUGR pregnancies have fewer gas-exchanging villi. The gas-exchanging villi are also slender, elongated, poorly branched, and poorly capillarized. Vascular abnormalities include reduced branching of stem arteries and disorganized vascular patterns including less coiling as depicted by placental vascular cast studies. There are also fewer terminal villi with smaller lumens. The reduced branching seen in the villous vasculature creates abnormal blood flow and an increase in vascular resistance to flow that can be likened to that of an electric circuit—the fewer downstream tributaries that exist from the main supply line, the higher the resistance.

DETERMINANTS OF NORMAL AND ABERRANT FETAL GROWTH

Normal Fetal Growth

In order for a fetus to grow normally, the placental developmental activities described earlier must proceed undisturbed. At 37 weeks gestation, the placenta has reached maximal surface area (11 m^2) and weighs approximately 500 g. Coincident with this is maximal amniotic fluid volume and maximal human placental lactogen levels, suggesting peak placental function. Fetal growth velocity also curtails at this juncture in pregnancy. Interestingly, although the fetus grows less quickly, calorie acquisition by the fetus continues to be quite high. At this time in pregnancy, the fetus is rapidly accumulating fat which provides thermal stability for the immediate postnatal period. Fat has a high caloric content (9 calories/g) compared to carbohydrates and proteins (4 calories/g). The high metabolic demands of the fetus result in a fetal temperature that is 0.5°C above that of the mother. This difference in temperature is seen in the maternal immediate postpartum shivering, which reflects a compensatory response to the loss of fetal-derived heat.

For the fetus to achieve maximal growth potential, the uterine–placental–fetal circulation must be normal in order for the fetus to receive a variety of necessary substrates. A key feature of the uterine vascular bed in pregnancy is the lack of responsiveness to changes in blood gas tensions (PO_2, PCO_2). Thus, oxygen therapy for either maternal disease or for fetal benefit will not cause vasoconstriction. In contrast, the lack of responsiveness and lack of autoregulation in the uterine vascular bed renders these vessels incapable of compensating for maternal hypotension. Animal studies have shown that the volume blood flows (mL/min) in the uterine and umbilical circulations are unaffected by maternal hyperoxygenation. This is important clinically since the improvement in fetal PO_2 by maternal oxygen therapy does not appear to have an adverse affect on fetal blood flow.

Glucose, oxygen, and amino acids are the major substrates needed for normal fetal growth. Glucose freely crosses the placenta by facilitated diffusion into the fetus. The maternal–fetal glucose concentration gradient that exists widens with advancing gestational age in order to accommodate the increasing metabolic demands of the fetus. Under normal circumstances, glucose is metabolized by the fetus to produce energy in the form of adenosine triphosphate (ATP) in the presence of oxygen. Oxygen passes across the placenta to the fetus by simple diffusion and is regulated by concentration gradients and uterine blood flow as described by the Fick principle. Transplacental transport of all essential and nonessential amino acids occurs by active transport. Animal and human studies have confirmed that amino acid carrier systems are present on both the maternal and fetal sides of the placenta. The placenta is quite active in amino acid metabolism contributing significantly to net umbilical–fetus uptake of certain amino acids.

Abnormal Fetal Growth

Failure of the placenta to deliver these primary substrates to the fetus will result in diminished protein production by the fetus, reduced glucose metabolism, and reduced glycogen deposition in the liver. If oxygen supply is markedly reduced either from an acute or chronic insult, the fetus will convert from an aerobic to an anaerobic metabolic state in order to meet energy (ATP) requirements. Anaerobic metabolism is far less efficient at producing ATP from a given unit of glucose compared to aerobic metabolism. Furthermore, anaerobic activity will produce “fixed” acids (lactate, urate, etc.), which diffuse slowly across the placenta thus accumulating in the fetal system. If the anaerobic process is not reversed, the accumulation of acids will consume available buffers, and the fetal blood pH will fall, leading to an acidemic and acidotic fetus.

The IUGR fetus attempts to compensate for reduced substrate delivery by different mechanisms. From a metabolic standpoint, the fetus changes the maternal–fetal glucose gradient. The normally wide glucose gradient that exists between the mother and fetus, which is needed for movement of glucose to the fetus, widens further. This compensatory mechanism enhances glucose movement across the placenta to the fetus. The smaller abdominal circumference noted in the IUGR fetus is a result

of less hepatic glycogen formation in order to maximize glucose availability. In a similar fashion to the liver, fat stores, which are normally an important depot site for fat-soluble vitamins and fatty acids, are reduced. This change in body composition is reflected in the ponderal index, which neonatologists use as an index of "scrawniness." The fetus also adjusts to reduced nutrient delivery by redistributing systemic blood flow to vital organs. The fetus will reduce flow to nonvital organs by reducing vascular resistance and increasing blood flow to the brain which normally has a relatively high vascular resistance pattern compared to other organ systems. This can be demonstrated with pulsed-wave Doppler velocimetry of the middle cerebral artery (MCA) in which the flow velocity profile shows an increase in end-diastolic velocity. Other organs being "spared" through vascular redistribution include the heart and adrenal glands. Redistribution of blood flow to vital organs in experimental animal models of hypoxemia or infusion of angiotensin II into the sheep fetus mimic the hemodynamic alterations observed in the human IUGR fetus.

DEFINITION OF IUGR

A number of definitions of IUGR have been proposed based on percentile, standard deviation, or growth rate. The most commonly used clinical definition of IUGR is an estimated fetal weight (EFW) less than the tenth percentile as determined by ultrasound. This mirrors the definition of SGA, which was originally described by Battaglia and Lubchenco in 1967 as a birth weight less than the 10th percentile for gestational age. They noted that SGA infants were at increased risk for neonatal death. The problem with the tenth percentile as a cutoff for the diagnosis of IUGR is that a number of fetuses with an EFW below that value will be normally small, otherwise referred to as "constitutionally" small and not at risk. Studies have demonstrated that if determinants of birth weight, such as maternal ethnicity, parity, maternal weight and height are considered, up to 50% of fetuses less than the tenth percentile will be constitutionally small. This has been the basis for using other definitions including less than the third or fifth percentile or less than 2 SDs from the mean. Some authors have suggested using an abdominal circumference (AC) of less than 2 SDs for gestational age. The AC measurement represents a single objective ultrasound measurement rather than combining several fetal biometric ultrasound parameters into a formula where each parameter is weighted differently.

While it seems that an EFW less than the tenth percentile is not a sufficiently strict definition of IUGR, there is also a significant problem associated with the use of more strict criteria. If a definition of less than the third percentile is used, there is a reasonable chance that one could miss some fetuses that do not meet their growth potential and could be at risk for adverse events. We believe that the fetus genetically programmed to be born at the 90th percentile that is born at the 20th percentile may be in more trouble than the baby born to a jockey and a gymnast who is at the 8th percentile. The bottom line is that no receiver operator curves have been established to assess sensitivity and specificity in order to establish a "cutoff" for the diagnosis of IUGR. This has been quite difficult to do, in part because of a wide biologic variation between patients and because of a wide variation of parameters used to diagnose IUGR (EFW, AC < 2SD, etc.). Customized growth curves, such as those envisioned and created by Gardosi that include variables that impact fetal size, may be the answer to establishing a better cutoff value for IUGR. Until such standards become published and available, the use of tools such as pulsed-Doppler velocimetry to investigate the status of the fetal circulation will help identify an IUGR pregnancy that is secondary to uteroplacental insufficiency and potentially at risk of perinatal morbidity and mortality. Doppler velocimetry is discussed in detail later in the chapter.

ETIOLOGY OF IUGR

The type and timing of insult during fetal development will dictate the subsequent development and morphology of the fetus. Fetal growth in the first trimester is characterized primarily by an increase in cell number or hyperplasia. In the second trimester, growth is a combination of hyperplasia and hypertrophy of preexisting cells. The third trimester is characterized primarily by hypertrophy. If an insult occurs in the first half of pregnancy where hyperplasia predominates, all fetal cell numbers can be reduced and lead to a small fetus that is *symmetrically* proportioned. That is, somatic and cerebral growth will both be similarly reduced. The underlying etiology of symmetric IUGR varies widely and includes: Karyotypic abnormalities, congenital anomalies, or congenital infections. Maternal medical illness, obstetric conditions, or primary placental pathology place the fetus at risk for uteroplacental insufficiency that may lead to a small fetus, which is asymmetrically proportioned. If these types of insults occur sufficiently early enough in pregnancy, there can be an impact on hyperplasia of cells and a symmetric growth pattern. More commonly, there is an impact upon hypertrophy that occurs late in pregnancy and primarily affects fat and hepatic glycogen deposition. The reduction in hepatic glycogen stores reduces liver size and results in an increase in the head-to-liver ratio, which defines asymmetric growth. Asymmetric growth is also characterized by a redistribution of fetal cardiac output to vital organs including the brain, heart, and adrenal glands. The redistribution of blood flow to the head allows the fetal head and brain to be preserved and maintain a normal growth velocity compared to parameters of somatic growth (abdomen and extremities). This is the basis for the common phrase, "brain-sparing". Thus, the relative proportions of fetal dimensions can provide some insight to the etiology of IUGR based on the symmetric or asymmetric nature of the ultrasound parameters.

DIAGNOSIS OF IUGR

Dating the Pregnancy

Studies in the past decade have clarified the associations of IUGR and long-term health hazards by confirming good gestational age dating. The use of actual gestational dating rather than birth weight alone is critical since it more clearly establishes that the link of cardiovascular disease and diabetes with IUGR status at birth is not due to prematurity, but to true intrauterine growth restriction. Establishing the most accurate gestational age is probably the single most important service we provide the pregnant patient since every test or intervention performed during pregnancy is dictated by the gestational age of the patient.

The diagnosis of IUGR begins with accurate dating of the pregnancy, which in turn begins with the establishment of the estimated date of confinement (EDC) based on information gathered on the last menstrual period (LMP). Normal human gestation lasts 280 days from the LMP, and it is this time frame that "pregnancy wheels," commonly used to determine estimated gestational age and date of confinement, are based upon. The 280-day gestation is, in turn, based upon a normal menstrual cycle length of 28 days. However, a portion of patients will have menstrual cycle lengths that vary from 21 to 35 days, which will shorten or lengthen the gestational dating, respectively. Therefore, the EDC should be adjusted accordingly. Other important questions regarding the LMP include regularity, certainty (calendar recorded, etc.), date of conception, and oral contraceptive use at the time of the LMP. It has been previously reported that the LMP is unreliable up to one-third of the time, and it is in these circumstances that ultrasound becomes a valuable resource.

After establishment of gestational age by LMP and/or ultrasound, clinical acumen can lead to a presumptive diagnosis of IUGR. The most commonly used clinical tool for assessing growth of the pregnancy is serial measurement of uterine fundal height during regular clinic visits. Measurement of uterine fundal height (cm) from the symphysis across the uterus to the top of the fundus provides an index of growth for which a nomogram has been reported (Fig. 12.2). In general, the uterine fundus will be within 2 cm of the gestational age in weeks. This simple screening technique has been reported to be 75% accurate in diagnosing IUGR. However, the measurement may be erroneous because of several variables that impact uterine size, including interobserver variation, obesity, uterine fibroids, multiple gestation, polyhydramnios, and so forth.

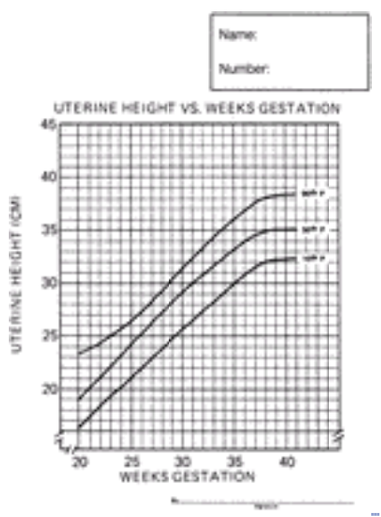

FIG. 12.2. Uterine fundal height chart for the diagnosis of fetal growth restriction.

Ultrasound

While LMP dating and clinical acumen are important in screening for IUGR, ultrasound remains the cornerstone for the diagnosis and management of this condition. The diagnosis of IUGR is made by combining ultrasound biometric measurements of the fetus into a formula that calculates the estimated fetal weight (EFW). The most

commonly measured fetal biometric parameters include the biparietal diameter (BPD), the head circumference (HC), the abdominal circumference (AC), and the femur length (FL). As described earlier, IUGR is diagnosed when the EFW falls below the tenth percentile for gestational age. If available, it is important to use local standards for the diagnosis since it has been previously shown that tenth percentile for EFW can vary depending on the population studied. Goldenberg and colleagues have shown that growth charts can differ dramatically among different patient populations. For example, a fetal weight nomogram constructed by ultrasound in Colorado suggests that consistently, across gestational ages, fetuses in Denver are lighter than fetuses at sea level. The Shepard and Hadlock formulas are the most commonly used formulas for calculating EFW. Table 12.1 shows the estimated fetal weight using Hadlock's formula plotted across gestation. In general, the more parameters included, the more accurate the EFW (Hadlock: 4 parameters; Shepard: 3 parameters). However, as you increase the number of parameters in the formula above, EFW begins to lose accuracy because of the standard error of the method associated with the measuring of each parameter. Using the Shepard formula, a practitioner will obtain an EFW that will fall within 5% of the true weight 50% of the time and within 10% of the weight 80% of the time.

Menstrual week	Percentiles (g)				
	3rd	10th	50th	90th	97th

TABLE 12.1. *In utero fetal weight standards at ultrasound*

A commonly encountered clinical scenario is the patient who is sent for evaluation of suspected IUGR in whom the clinical dating criteria are poor and gestational age unknown. For example, a fetus measuring 3 to 4 weeks less than expected may be the result of any of the following three possibilities:

1. The patient is 3 to 4 weeks off on clinical dating.
2. The fetus is truly 3 to 4 weeks less than clinical dating, but is genetically predisposed to be small.
3. The fetus is small, growth-restricted, and at risk.

Several ultrasound strategies are available to address this problem and to categorize the fetus into one of the categories. The ultrasound biometric parameters can be used to calculate ratios and provide some insight into the severity of the IUGR. In the 1970s, Campbell and Thoms first described the HC/AC ratio. In approximately 60% of cases with IUGR, the HC/AC ratio is in the 90th percentile for gestational age, which suggests a “brain-sparing” process. The FL/AC ratio provides information on the amount of muscle and fat mass present on the fetus providing a picture of the “scrawniness” of the fetus. This is analogous to the ponderal index used by neonatologists. Unlike the HC/AC ratio, the FL/AC ratio is gestational-age independent and may be useful when the gestational age is unknown. Other aspects of the fetus that appear to be relatively independent of the IUGR process and that remain consistent throughout gestation include the transcerebellar diameter (TCD), foot length, and epiphyseal centers. These are other strategic tools to help approximate the gestational age when dating criteria are poor.

The TCD measured in centimeters mirrors the gestational age until about 22 weeks and then accelerates. Cerebellar measurements are shown in Table 12.2. While original studies by Reece and co-workers showed that the TCD is “spared” in IUGR, one study suggests that only 40% of IUGR fetuses demonstrated the sparing effect. However, the etiologies for IUGR in this study were not clearly identified. If the gestational age by TCD is greater than that suggested by other biometric parameters and is consistent with the unsure LMP dating criteria, it may be that the fetus is indeed further along and possibly growth restricted. In a similar fashion, Hadlock and colleagues showed that the foot length is gestational-age independent and may be useful in IUGR. Although not useful for estimating gestational age in the second and early third trimester, the appearance of epiphyseal centers of the long bones on ultrasound provides reassurance that the fetus is in the second half of the third trimester of gestation. In a nondiabetic population, the presence of a distal femoral epiphysis of greater than 3 mm and the presence of any proximal tibial epiphysis indicated a mature lung profile in almost all cases. The proximal tibial epiphysis is not typically present prior to 36 weeks gestation. Additionally, the proximal humeral epiphysis rarely appears prior to 38 weeks gestation. Unpublished information suggests that appearance of the epiphyseal centers in IUGR fetuses may be delayed. This should be taken in the context that it is the presence of the tibial and humeral epiphyseal centers that are useful markers of pulmonic maturity, while the absence of these centers may suggest a more immature fetus.

TABLE 12.2. *A nomogram of the transverse cerebellar diameter (mm)*

Serial ultrasound measurements of fetal biometry and estimated fetal weight are also useful in assessing the growth-restricted fetus. The fetus that demonstrates appropriate growth, that is, continued growth along nomograms, probably represents a fetus genetically predisposed to being small and one that is likely not at immediate risk. A couple of problems of relying on growth potential alone is that it does not tell you where in gestation the fetus is or how the fetus is doing at the first evaluation. As with all these biometric tools, it is best to look at the big picture and formulate an opinion based on all information that one can obtain with the ultrasound. Another tool that can be used to categorize a small fetus is pulsed-wave Doppler velocimetry. This ultrasound modality, which has revolutionized the management of the IUGR fetus, can also be used to help delineate whether a fetus is “normal” small or “abnormal” small based on the umbilical FVW.

DOPPLER VELOCIMETRY IN THE ASSESSMENT OF IUGR

Doppler Ultrasound

The concept of Doppler, which is used in ultrasound, is named after Johann Christian Doppler. The Doppler concept refers to energy that is reflected from a moving boundary, and how the frequency of the reflected energy varies in relation to the moving boundary. In ultrasound terms, Doppler depends on the ability of an ultrasound beam to be changed in frequency when encountering a moving object (red blood cells). After cosmetic manipulation, a waveform is generated that has a clear systolic and diastolic component. Although resistance to blood flow in a given interrogated vessel in the fetus cannot be directly measured, it is possible from the waveform to obtain an index of resistance. Figure 12.3 shows a FVW in the umbilical artery with clear systolic and diastolic cardiac components. Using the peak systolic and peak diastolic values, it is possible to generate Doppler indices of resistances. These include the systolic-to-diastolic (S/D) ratio, pulsatility index, and resistance index. Because these three indices are functions of the same variables, they are correlated highly with one another. The characteristics of these indices are also shown in

Figure 12.3. The original continuous-wave Doppler technology has been replaced by pulsed-wave Doppler technology. Doppler velocimetry is useful in cases where the fetus is asymmetrically grown due to a uteroplacental etiology.

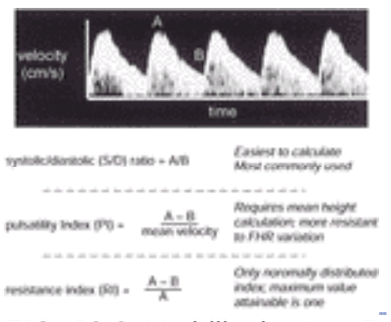

FIG. 12.3. Umbilical artery Doppler flow velocity waveform demonstrating peak systolic (**A**) and peak end-diastolic (**B**) velocities. Doppler indices are defined below.

Over the past decade, numerous centers across the United States and in Europe have shed light on circulatory physiology in the normal and growth-restricted fetus. This has been approached by assessing FVWs in a number of different vessels in the fetus. While these reports provide useful information on any given vessel, reports on one or two vessels alone are not practical from the clinical standpoint since these were primarily cross-sectional studies and did not provide any information on the temporal nature of Doppler changes. After the turn of the 21st century, three reports appeared in the literature that combined longitudinal information on several different vessels with biophysical data obtained from the IUGR fetus. These studies showed that there are sequential changes in Doppler FVW-resistance measurements in different vessels of the severely growth-restricted fetus that is progressively deteriorating.

Normal Fetal Circulation

The umbilical vein leaves the placenta and enters the umbilicus with oxygen and nutrient-rich blood and volume, which are necessary for normal development of the fetus. The venous vasculature of the liver consists of the umbilical and portal veins, hepatic veins, and the ductus venosus. The umbilical vein turns acutely cephalad as it passes through the umbilicus and in the inferior portion of the falciform ligament. The hepatic portion of the umbilical vein then travels horizontally and posteriorly, and bends to the right where it joins the transverse part of the left portal vein. These then join the right portal vein, which branches anteriorly and posteriorly. As the hepatic portion of the umbilical vein bends to the right, the ductus venosus emanates, heading in a posterior and cephalad direction and joins the inferior vena cava (IVC) just below the diaphragm. The three hepatic veins (right, middle, and left) fuse and join at the juncture of the ductus venosus and IVC confluence. The ductus can be visualized easily on both axial and midline sagittal views of the fetus with the use of color velocimetry. Its detection can be enhanced by adjusting the velocity scale and looking for aliasing of the color that indicates the area of highest flow velocity. The ductus venosus plays a critical role in shunting the most oxygenated and nutrient-rich blood from the hepatic portion of the umbilical vein to the right atrium. More than half of the umbilical vein blood enters the ductus venosus. Portal blood primarily travels to the right lobe of the liver and, as a result, 98% of the blood passing through the ductus venosus comes from the umbilical vein. Some of the blood supply to the left lobe of the liver comes from branches of the umbilical vein, which increases blood oxygen levels in the left hepatic vein compared to the right. Preferential streaming is a phenomenon that occurs within precordial venous structures and the heart to ensure delivery of the most nutrient-rich blood to the left side of the heart. Briefly, nutrient-rich blood within the ductus and left hepatic vein course preferentially through the posterior and left portions of the column of blood in the thoracic IVC. Blood that is deoxygenated and contains waste products from the abdominal IVC and the right hepatic vein streams, preferentially, along the anterior and right portions of the column of blood in the thoracic IVC. Blood from the superior vena cava joins the blood traveling anteriorly and rightward, enters the right atrium across the tricuspid valve, and exits via the pulmonary artery. Only 10% of the blood from the pulmonary artery enters the pulmonary circulation with the majority crossing the ductus arteriosus into the aorta and the systemic circulation. The posterior and leftward nutrient-rich blood passes across the right atrium through the foramen ovale into the left atrium and out the left ventricle. This ensures that the heart and brain see the most oxygenated blood.

The precordial veins (ductus venosus, hepatic veins, IVC, umbilical and portal veins) have characteristic FVWs as shown by pulsed-wave Doppler velocimetry. The umbilical and portal veins have FVWs that are steady and without pulsations, while the other precordial “systemic” veins have FVWs that reflect the central venous pressures. The following information on the precordial venous FVWs is in reference to the hepatic vein, ductus venosus, and IVC, which have three characteristic phases during a single cardiac cycle. Ventricular systole induces the greatest pressure gradient between the right atrium and the precordial veins during the cardiac cycle. Thus, the blood traveling within these vessels to the heart will have the highest velocity during systole. This is referred to as the “S” component of the FVW. During early diastolic filling, the second highest velocity of blood through these venous conduits will occur and is referred to as either “D” or “e”. The lowest velocity of blood traveling through these vessels is in late diastole when the atria are contracting; this phase of the FVW is referred to as the “a”-wave. The a-wave in the ductus venosus remains in a positive direction (i.e., blood continues to move toward the heart even during the phase of lowest pressure gradient during atrial contraction). In contrast, the a-wave in the IVC and hepatic veins is in a negative direction indicating that blood is moving away from the heart. The difference in the a-waves between these vessels is important clinically because one can easily confuse reverse flow in the ductus venosus due to the close proximity of these vessels. However, the use of color Doppler and the identification of aliasing should easily distinguish the vessels.

The vast majority of fetal Doppler studies have adopted qualitative indices to describe FVW indices both for arterial flow and venous flow (i.e., S/a ratio of the venous flow of the ductus venosus). For some selected areas of investigation, quantitative parameters are calculated (i.e., peak velocity of the outflow tract of the great vessels). The arterial pipelines to almost all organs have been investigated, including the kidneys, the adrenal glands, the spleen, the lower limbs, the lungs, and the coronary arteries. While these reports provide a piece of the big picture, they do not add to information on fetal status and management gained from cardiac and precordial Doppler studies. As such they are not discussed, but are referenced at the end of the chapter (see “ Suggested Readings”).

Circulation of the IUGR Fetus

A convenient way to clinically approach the variety of fetal vessels that lend themselves to Doppler investigation is to conceptualize the progressive nature of the IUGR disease process and categorize them into three compartments related to the fetal heart:

1. Postcardiac (arterial) Dopplers
2. Cardiac Dopplers
3. Precardiac (precordial or venous) Dopplers.

The three general categories and vessels for each category are shown in Table 12.3. This organization follows the physiologic adaptations by the fetal circulation to progressive abnormalities in the placental vascular tree. Changes in the circulatory architecture of the IUGR placenta create a high-resistance vascular bed, which can be detected by Doppler velocimetry of the umbilical artery and the MCA. These represent the earliest Doppler changes in the IUGR fetus. As the IUGR fetus deteriorates, one can detect changes in peak velocities of the cardiac outflow tracts and abnormal valvular flow. Precordial or venous Dopplers also change in the IUGR fetus that is decompensating and these vessels include the ductus venosus, hepatic veins, IVC, and intrahepatic and intraamniotic umbilical veins.

1. **Postcardiac (arterial)**
Umbilical artery
Middle cerebral artery
2. **Cardiac**
Outflow tract peak velocities
Mitral and tricuspid valve E/A ratios
Tricuspid regurgitation
3. **Precardiac (precordial or venous)**
Ductus venosus
Hepatic veins
Inferior vena cava
Hepatic and amniotic cavity umbilical vein

TABLE 12.3. *Categorization of fetal vessels for Doppler study*

Umbilical Artery Doppler

The first fetal vessel to be assessed by Doppler velocimetry FVW analysis was the umbilical artery in the mid-1970s. During the late 1970s and early 1980s, Gill and colleagues and Trudinger and co-workers described the umbilical artery FVW in normal and IUGR pregnancies. In 43 infants with birth weight less than the 10th percentile, Trudinger and colleagues found that the umbilical artery S/D ratio was elevated above the 95th percentile in 85% of cases. This was determined to be related to a decrease in diastolic velocity, which was in turn due to an increase in resistance to blood flow within the placenta. This was supported by work from Giles

and colleagues who correlated the pathologic FVW in IUGR pregnancies with placental lesions. The key concept was that a poorly developed placental vascular bed and progressively abnormal vascularization in the face of increased fetal metabolic demands lead to an increase in placental vascular resistance. This is further supported by research work on hemodynamic bases of waveform changes as affected by increased impedance, changes in the viscosity of the blood, loss of vessel wall compliance, and decreasing inotropic function of the myocardium, all of which contribute to the increased resistance seen in abnormal arterial flow. The umbilical artery was chosen because it was the vessel that extended from the fetus to the placenta and because it reflects resistance patterns downstream within the placenta. This, in turn, could be identified clinically simply by switching a Doppler beam on the umbilical arteries and looking for an increased S/D ratio (low diastolic velocity) of the arterial waveform. During the 1990s, multiple studies on umbilical artery Doppler velocimetry in the IUGR fetus were followed by three major meta-analyses that showed a reduction in perinatal mortality by approximately one-third when umbilical artery Doppler velocimetry was used as an adjunct to other means of antenatal biophysical testing. In 1993, a European multicentered, prospective, observational trial reported by Karlsdorp and colleagues provided strong evidence suggesting that growth restricted fetuses with abnormal umbilical pulsatility index, with absent diastolic flow and with reverse diastolic flow, had progressively more severe perinatal outcomes.

Middle Cerebral Artery (MCA)

As mentioned earlier in this chapter, prolonged fetal hypoxia as a result of uteroplacental insufficiency will result in a redistribution of blood flow within the fetus in an attempt to deliver more oxygen by increasing volume blood flow to vital organs. This has been shown to be the case in some classic animal studies where prolonged hypoxia leads to blood flow redistribution that is favorable to the heart, brain, and adrenal glands. This redistribution has also been shown by pulsed-wave Doppler velocimetry to occur in human IUGR fetuses. The fetal brain normally has a high-resistance blood flow pattern, which is depicted by low flow velocity at end-diastole, relative to other organs and large vessels. During hypoxia, cerebral vascular autoregulation adjusts blood flow within the brain by decreasing the resistance to flow. The decrease in resistance can be easily detected by pulsed-wave Doppler, which provides an FVW profile that depicts an increase in end-diastolic flow velocity. This will in turn result in a calculated Doppler index of resistance that is low compared to the normally high resistance seen in the cerebral circulation. The most common cerebral artery used for Doppler assessment of the fetal brain-sparing effect is the MCA. The anatomic site and direction of the MCA is perpendicular to the cerebral midline (Fig. 12.4). This allows for the Doppler beam to be easily positioned along the midportion of the vessel with a minimal angle of insonation, thereby optimizing FVW acquisition. Incidentally, another advantage of the MCA position is that acquisition of a direct measurement of the absolute velocity in cases of fetal anemia (i.e., Rh isoimmunization and parvovirus) is easily obtained at this location.

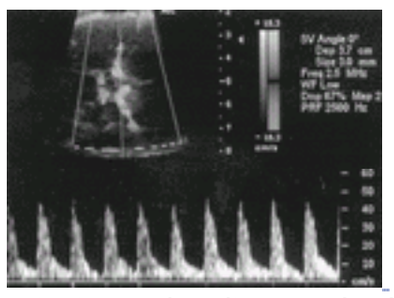

FIG. 12.4. The ultrasound color Doppler image shows the circle of Willis and the middle cerebral artery branches. Also shown is the near 0-degree angle of insonation and the middle cerebral artery flow velocity waveform. See color figure 12.4.

Both direct and indirect evidence acknowledge that hypoxia is a plausible mechanism for the decrease in MCA pulsatility index (PI) in IUGR. Direct evidence supporting this mechanism was reported by Capponi and associates in a group of IUGR fetuses with an abnormal umbilical PI. They showed that the best predictor of hypoxia at cordocentesis was the MCA PI. Baschat and co-workers provided good indirect evidence in support of hypoxia as a mechanism for the decreased MCA PI. In this study of IUGR fetuses with an abnormal umbilical artery PI, those with a decreased MCA PI had significantly higher nucleated red blood cell counts compared with those who had no Doppler evidence of MCA dilation.

The reduction in abdominal circumference typically precedes Doppler abnormalities in the umbilical artery and the MCA. Doppler studies have shown that the decrease in resistance by the fetal brain and the increase in resistance in the umbilical artery are the earliest arterial changes in Doppler flow velocities in the IUGR fetus. In our experience, they begin more than 3 weeks prior to non-reassuring fetal heart rate recordings. The primary message conveyed by Doppler investigation of the MCA vessel in IUGR fetuses is that the fetus is adapting appropriately to intrauterine hypoxia by “brain-sparing.” Loss of the “brain-sparing” adaptation is thought to be due to loss of cerebral autoregulation, and is considered to be a very late or terminal sign in the decompensating fetus. Before a *loss* of the “brain-sparing” is acted upon, one must be sure to avoid excessive transducer pressure because this will artificially lower the end-diastolic velocity. Furthermore, one will not see a loss of “brain-sparing” in the face of otherwise normal Doppler waveforms elsewhere, especially on the venous (precordial) side.

Precordial and Cardiac Flows

Cardiac Doppler studies in the IUGR fetus primarily include assessment of peak velocities of the outflow tracts, left and right ventricular cardiac output, and flow ratios across the valves. Variables that influence these measurements include preload, afterload, and intrinsic contractility of the left and right ventricles, as well as the valve dimensions. Significant contributions have been published on the changes in the atrioventricular filling waveform, and on the flow velocities of the outflow tract of the great vessels. Cross-sectional and longitudinal studies of IUGR fetuses with increased umbilical artery vascular resistance and decreased MCA vascular resistance show a progressive decrease in outflow tract velocity and cardiac output with advancing gestation. Valvular abnormalities tend to occur late in the course of an IUGR fetus that is rapidly decompensating. In one study of 31 IUGR fetuses and 289 normally grown fetuses, tricuspid valve regurgitation (TR) was a frequent, but in most cases, transient finding. Only 2 of the 31 IUGR fetuses showed TR. In one fetus it was only part-systolic, while the other fetus it was severely compromised with abnormal flows in both the arterial and venous system. That TR is a late sign in the course of IUGR has been confirmed elsewhere.

As mentioned earlier, Doppler velocimetry has been used to assess blood flow through the venous circulation of the IUGR fetus including the umbilical vein, ductus venosus, hepatic veins, and IVC. The IVC and the ductus venosus essentially represent the preload profile of the cardiovascular system. Interesting information conveyed by research on these vessels is the significant correlation between abnormal changes in the vessels and acid-base changes of the fetus. Others have correlated these Doppler indices with fetal heart monitoring patterns. Abnormalities in the ductus venosus are characterized by a decrease in velocity of the a-wave, and if the fetus continues to deteriorate, the ductus venosus may show absent or reversed flow velocity of the a-wave. The ductus venosus waveform in a severely growth restricted fetus from 20 to 22 weeks gestation of a mother with severe renal disease and hypertension is shown in Figure 12.5. The a-wave at 20 weeks showed reasonable flow velocity, but progressively deteriorated to intermittent absent and reverse flow velocity.

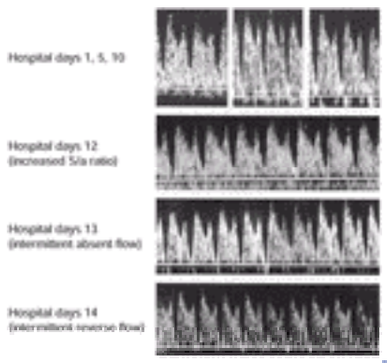

FIG. 12.5. Ductus venosus flow velocity waveform with abnormal a-waves in a severely growth restricted fetus admitted at 20 weeks gestation. Note the progressive decrease in velocity of flow in the a-wave.

The umbilical vein normally has a steady FVW. The presence of pulsations or nicking in the umbilical vein FVW is a very late sign of the decompensating fetus and likely due to ventricular failure. These pulsations have been shown through animal studies to be initiated from atrial pressure changes and transmitted in a retrograde fashion. In early pregnancy, umbilical venous pulsations can be a normal finding. While assessing the umbilical vein with pulsed-wave Doppler, it is important to be cognizant that fetal breathing can mimic the nicking or pulsations of cardiac origin and these obviously have largely differing implications. Pulsations due to fetal breathing and due to cardiac failure can easily be distinguished by looking for fetal breathing motions or determining the rate of the pulsations seen on the FVW. A

normal umbilical waveform, pulsations due to breathing, and pulsations due to cardiac failure are shown in Figure 12.6.

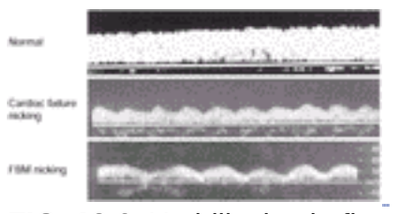

FIG. 12.6. Umbilical vein flow velocity waveform profiles demonstrating pulsations due to fetal breathing motions and cardiac failure compared to normal.

Temporal Doppler Changes in the IUGR Fetus

While umbilical artery Doppler is useful as an adjunct in antenatal testing, it alone is not capable of distinguishing a decompensating fetus to the extent that morbidity can be reduced. Waiting until there is reverse flow nearly always results in an acidotic fetus with adverse long-term sequelae. It is here where venous Doppler studies will likely play a role in identifying earlier signs of deterioration in the IUGR. Since the late 1990s, more than 100 papers have been published both on the pathophysiology and clinical correlation of Doppler studies with traditional monitoring and with neonatal outcome. Advances in digital ultrasound technology have had a tremendous impact on the basic knowledge of fetal circulatory adaptation to placental supply deprivation. Clinically, this technology has allowed us to collect information and take a snapshot of fetal adaptation to placental dysfunction, which in turn can be interpreted as appropriate or inappropriate (i.e., decompensating) based upon the pattern of Doppler findings. The considerable knowledge gained through Doppler studies on isolated vessels or organs subsequently lead to two basic study questions regarding the “big picture”:

Is there a consistent temporally related sequence of Doppler changes within the circulation of the IUGR fetus?

If there is a progressive sequence of changes, is there a parallel increase in fetal morbidity and mortality?

These questions are just now being addressed.

In 2001 and 2002, three studies introduced the idea that a deteriorating fetus follows a sequence of Doppler abnormalities prior to having a markedly abnormal biophysical test (nonstress test [NST], biophysical profile [BPP]) that would normally dictate delivery. It is important to understand that these studies were conducted on very preterm and severely growth-restricted fetuses. Baschat and colleagues reported that sequential deterioration of arterial and venous flows precedes BPP score abnormalities, and that perhaps adding Doppler to the BPP may enhance the performance of the BPP. Hecher and others reported that short-term variability and ductus venosus abnormalities are the important indicators for optimal timing of delivery. More recently, Ferrazzi and colleagues reported on fetal–neonatal injury and the sequential changes in Doppler velocimetry. Briefly, increased pulsatility in the umbilical artery, decreased pulsatility in the MCA (i.e., brain-sparing), and absent flow in the umbilical artery are considered “early” changes and alone were not associated with fetal injury. The next vessel to become abnormal was the ductus venosus, which was subsequently followed by other venous and cardiac Doppler abnormalities. These were considered “late” changes, frequently preceded by NST abnormalities, and were associated with a significant increase in fetal and neonatal morbidity and mortality. These “early” and “late” Doppler changes are shown in Figure 12.7. Thus, these studies suggest that waiting until the NST or the BPP become abnormal before delivery might be too late to prevent serious sequelae to the newborn and the child or adult that newborn is destined to become. They also suggest that the vessel that best determines the optimal timing for delivery is the ductus venosus.

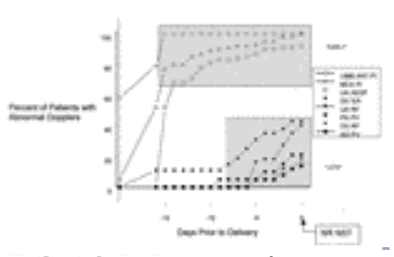

FIG. 12.7. Temporal sequence of Doppler velocimetry changes in intrauterine growth restricted fetuses. (Modified from Ferrazzi E, Bozzo M, Rigano S, et al. The temporal sequence of changes in fetal velocimetry indices for growth-restricted fetuses. *Ultrasound Obstet Gynecol* 2002;19:140–146.)

MANAGEMENT OF THE IUGR FETUS

Historically, the management of the IUGR fetus was based on the fetus reaching fetal lung maturity, flattening of the growth curve, or awaiting a fetal heart rate change. In the mid-1990s, several meta-analyses demonstrated that perinatal mortality could be reduced by including umbilical artery Doppler velocimetry as part of the fetal biophysical assessment. While this was clearly a major advancement in management of the IUGR fetus, it still fell short of the goal of not only reducing perinatal mortality, but also reducing perinatal morbidity. In 1993, investigators in Milan, Italy reported a useful classification for IUGR severity. Table 12.4 shows the classification scheme that is based on fetal heart rate monitoring and umbilical artery Doppler velocimetry and the risk of fetal hypoxemia and acidemia. The study showed that waiting for the fetal heart rate to become non-reassuring would result in a hypoxic–acidemic fetus more than 60% of the time. Studies on Doppler changes in the IUGR fetus suggest that the fetus experiencing progressive compromise tends to follow a sequence of Doppler changes that may allow for better timing of delivery. These Doppler studies will likely be most useful in the management of the very preterm and severely IUGR fetus. Figure 12.8 is an algorithm for management guidelines of the IUGR fetus, which includes workup considerations for symmetric and asymmetric growth, daily routines, fetal monitoring, and gestational age based timing of delivery. Since amniotic fluid volume is a function of urine output and renal perfusion, the presence of oligohydramnios in an IUGR fetus should serve as a red flag. Oligohydramnios is not included in the algorithm. However, if it is present, delivery should be considered. If the fetus is extremely premature, hospitalization should be considered for in-house fetal monitoring.

Group	FHR tracing	UmA Doppler	Hypoxemia/acidemia
I	Normal	Normal	0%
II	Normal	Abnormal	5%
III	Abnormal	Abnormal	60%

FHR, fetal heart rate; IUGR, intrauterine growth rate.

TABLE 12.4. *Fetal heart tracings, umbilical artery doppler, and the IUGR fetus*

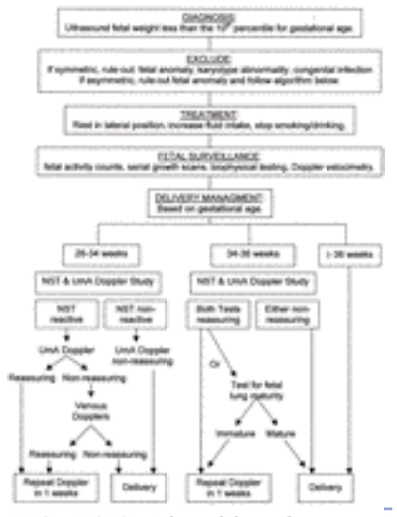

FIG. 12.8. Algorithm for management guideline of the intrauterine growth restricted fetus.

QUANTIFICATION OF FLOW

Until recent advancements in high-resolution digital imaging with simultaneous imaging and Doppler methodologies, the reproducibility and clinical feasibility of flow quantification have been limited. Studies show that umbilical venous flow can be measured accurately (inter- and intra-observer variability <7%) and in a timely fashion (<5 min). These flow measurements have been validated by invasive physiologic preparations in fetal lambs. Ultrasound images and formula for calculation of umbilical venous flow is shown in Figure 12.9. In a longitudinal study, not only was volume flow found to be reduced in the IUGR fetus compared to controls, but the variable responsible for this reduction was a low velocity of blood flow and not the umbilical vein diameter. Interestingly, the low umbilical flow in IUGR fetuses was identified very early in the course of IUGR before Doppler changes in other vessels became apparent. Quantitative flow measurements can even be obtained in very small vessels such as the ductus venous. Quantitative flow measurements are a potentially new-tool approach for the assessment of the growth-restricted fetus since quantification of placental flow to the fetus and its redistribution to the liver and heart is now possible.

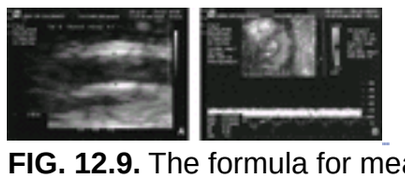

FIG. 12.9. The formula for measurement of umbilical venous flow is shown. **A:** On ultrasound, how to obtain umbilical vein diameter (note that the calipers are placed just inside the specular reflections). **B:** On ultrasound, how color is used to ensure an angle of insonation at nearly 0 degrees and how Doppler velocimetry is used to obtain a steady umbilical vein waveform velocity. See color figure 12.9.

Doppler Prediction of IUGR and Preeclampsia

The maternal side of the uteroplacental circulation has also been investigated by Doppler ultrasound and FVW analysis in hopes of identifying those pregnancies at increased risk for developing preeclampsia, abruption, and IUGR. Since the original reports on uterine artery Doppler waveform analyses, several important methodological issues have been established that include proper technology (color Doppler-guided, pulsed-wave Doppler sampling, and site of sampling), and normal reference values (S/D ratio >2.6, or resistance index >0.58). The pathophysiologic basis for abnormal uterine artery resistance is that resistance of the smaller spiral artery branches that lie downstream fail to become low-resistance vessels as a result of poor trophoblastic invasion early in pregnancy.

This test has gained a popular role in screening for preeclampsia and IUGR at 20 to 24 weeks of gestation. Scoring systems based on FVW abnormalities (increased resistance and notching) have been developed. For the most part, the highest risk for encountering an adverse pregnancy outcome goes up by having both early diastolic notching and high resistance, and if these occur bilaterally. The problem with the uterine artery Doppler test is that reported positive values vary considerably and there is a reasonably high false-positive rate. The false-positive rate can be reduced by repeating the test at 24 weeks gestation.

SUMMARY POINTS

- Proper establishment of the uterine–placental–fetal circulation early in gestation is critical to appropriate placental and fetal growth.
- Abnormal uterine artery Doppler waveforms reflect abnormal placentation and may be predictive of adverse pregnancy outcome.
- Establishment of accurate dating in pregnancy is necessary for assessment of appropriate growth and management of the pregnancy.
- Ultrasound dating of the pregnancy is most accurate in the first trimester.
- The transcerebellar diameter remains relatively unaffected in asymmetrically growth restricted fetuses.
- A distal femoral epiphysis of more than 3 mm is consistent with a pregnancy greater than 36 weeks gestation.
- In IUGR, it is important to remember to consider the possibility of a constitutionally small baby.
- In IUGR, use of umbilical artery Doppler velocimetry reduces perinatal mortality when used as an adjunct to other tests of fetal well-being.
- Doppler velocimetry studies of the venous circulation may be the best way to optimally assess the timing of delivery in the very preterm and growth-restricted fetus.

SUMMARY POINTS

REFERENCES

A prolonged pregnancy, also commonly called postterm pregnancy, is one that has lasted longer than 42 weeks or 294 days beyond the first day of the last menstrual period ([1]). Postdatism implies pregnancy lasting beyond the estimated due date at 40 weeks. The term “postmature” is reserved for the pathologic syndrome in which the fetus experiences placental insufficiency and resultant intrauterine growth restriction. Prolonged pregnancies have been recognized since antiquity. Hadrian, emperor of Rome from 117 to 138 A.D., decreed that a child born 11 months after the death of a husband was illegitimate. French law recognizes as legitimate a child born 300 days after the husband's death ([2]). Postdatism as a risk factor for adverse fetal outcome has been recognized since the early part of the 20th century. Whether prolongation of a low-risk pregnancy results in increased perinatal morbidity and mortality is a matter of debate.

Postdatism occurs in 3% to 12% of all pregnancies ([1]). The definition of prolonged pregnancy is, however, somewhat arbitrary and was formulated before ultrasound dating of gestation became routine. Divon and colleagues ([3]) have suggested that the definition should be changed so that pregnancies =41 weeks are considered post-term. This recommendation is based on a study of over 180,000 pregnancies at 40 weeks or more in which a significant increase in perinatal mortality was seen after 41 weeks. This same finding was noted by Browne ([4]), who described perinatal mortality after 41 weeks as 10.5 per 1,000 pregnancies, doubling that at 43 weeks, and tripling that amount at 44 weeks.

Prolonged pregnancies are at risk for macrosomia resulting in shoulder dystocia and fetal injury, oligohydramnios, meconium aspiration, intrapartum fetal distress, and stillbirth. Maternal risks include trauma, hemorrhage, and labor abnormalities (Table 13.1). Interventions for preventing or improving outcomes in low-risk, prolonged pregnancies have proven to be of minimal benefit.

Fetal/neonatal	Maternal
Shoulder dystocia	Trauma
Fetal injury	Hemorrhage
Oligohydramnios	Labor abnormalities
Meconium aspiration	
Intrapartum fetal heart rate abnormalities	
Stillbirth	

TABLE 13.1. *Complications of prolonged pregnancy*

ETIOLOGY

The most common cause of a prolonged pregnancy is inaccurate dating. Early ultrasound dating of pregnancies has been shown to reduce the number of women who are induced for apparently prolonged pregnancies ([5]).

The physiology underlying the spontaneous onset of labor remains enigmatic. Several animal models have been studied, and a great deal of information on the process has been gathered. Parturition in the human female, however, is very different from other species. In humans, the role of the fetal hypothalamic–pituitary–adrenal (HPA) axis appears to be permissive rather than essential as in other species ([6]). Consistent with this, the average gestational age at delivery was 39.6 weeks for a group of anencephalic pregnancies, the same as for normal gestations. This number is questionable because there was a high incidence of extremely preterm (25–30 weeks) and extremely postterm (48–52 weeks) gestations in this series. This seems to demonstrate a loss of precision in timing the onset of labor in anencephalic fetuses.

The synthesis of estrogen and progesterone is controlled differently in humans than nonhumans. In humans the fetal adrenal is deficient in 3ß-hydroxysteroid dehydrogenase that converts pregnenolone to progesterone and dehydroepiandrosterone to androstenedione. The placenta is deficient in 17a-hydroxylase and C17-20 lyase but has high sulfatase and aromatase activity. The fetal adrenal secretes dehydroepiandrosterone sulfate (DHEA-S) which the placenta converts to estrogen. Placental sulfatase deficiency is an X-linked disorder that affects male fetuses. The sulfatase-deficient placenta is unable to use DHEA-S and other fetal adrenal precursors to synthesize estrogens ([7]). These pregnancies are associated with poor response to cervical ripening and induction as well as postdatism.

Postulated maternal risk factors for prolonged pregnancy include primiparity, previous prolonged pregnancy, and young maternal age.

AMNIOTIC FLUID

Reduced amniotic fluid (i.e., oligohydramnios) is a frequent finding in prolonged pregnancies. It presents a problem because it can be a marker for fetal compromise and because it puts the fetus at risk for cord accidents. Oligohydramnios has been attributed to placental insufficiency causing the fetus to redistribute blood flow to protect the brain. This, in turn, is considered to cause renal hypoperfusion with reduced glomerular filtration and urine production leading to decreased amniotic fluid. However, a study of 57 women at gestations greater than 41 weeks in which the resistance index of the fetal middle cerebral, renal, and umbilical arteries was evaluated, found no evidence that oligohydramnios was associated with redistribution of blood flow ([8]).

It is commonly accepted that amniotic fluid volume decreases as gestational age advances beyond term. In at least one study, this was not found to be the case. Among 511 women at 41 weeks or more, only 11.5% had oligohydramnios defined as a four-quadrant amniotic fluid index (AFI) of 5 or less. The average AFI at 41 weeks was 12.4 cm ± 4.2 cm ([9]).

The best method to accurately estimate the amount of amniotic fluid is also a matter of debate. Commonly used ultrasound techniques include the four-quadrant AFI and the largest vertical pocket. In a study of 190 women at 40 weeks or more in which four ultrasound methodologies were studied for amniotic fluid volume estimation (the four-quadrant AFI, the largest vertical pocket, the largest transverse pocket, and the sums of all pockets), the only technique which demonstrated diagnostic value was use of the largest vertical pocket. A cutoff of 2.7 cm correlated well with favorable outcomes ([10]). The traditional cutoff of 2 cm in largest vertical diameter was also found to be an indicator of favorable outcome, but the authors thought that sensitivity could be increased by raising the cutoff to 2.7 cm.

ANTENATAL TESTING

Any pregnancy at risk for uteroplacental insufficiency is a candidate for antenatal fetal monitoring. It is most likely that the morbidity and mortality associated with prolonged gestation is due to placental insufficiency in which fetal requirements for oxygen and nutrients can no longer be met. The goal of antenatal testing is to identify those fetuses that should be delivered. It is useful to remember that no form of antenatal testing will predict random unfortunate events such as sudden significant umbilical cord compression.

Some form of antenatal testing is usually initiated between 41 and 42 weeks in otherwise healthy pregnancies. The frequency and the type of antenatal testing is based mostly on physician preference and experience since no testing modality has been shown to improve outcomes in uncomplicated post-term pregnancies whether

initiated before or after 42 weeks ([1]).

Grubb and colleagues ([11]) reviewed 8,038 postterm gestations that were followed with twice-weekly nonstress tests (NSTs) and determination of the AFI. Prior to 42 weeks patients received one assessment. There were 9 antepartum deaths giving a stillbirth rate of 1.12 per 1,000. Two of those deaths occurred before 42 weeks. Using twice-weekly biophysical profiles (BPPs), an older study reported a stillbirth rate of 0.44 per 1,000.

Ratios of the middle cerebral artery (MCA) blood flow to the umbilical artery (UA) blood flow have been studied as indicators of fetal compromise. Two common ratios are the UA/MCA pulsatility index ratio and the MCA/UA systolic/diastolic (S/D) ratio. Normally, the UA should have low impedance flow with a relatively low S/D ratio and low pulsatility index. The MCA should have high impedance flow with a high S/D ratio and a high pulsatility index. With brain-sparing redistribution of blood flow, we would expect impedance in the UA to increase resulting in decreased or absent end-diastolic flow. Impedance in the MCA should decrease, with lowering of the S/D ratio and the pulsatility index and an increase in the peak velocity of the blood flow. With redistribution of blood flow, the MCA/UA S/D ratio should be low as the values approach each other. A study of women at 41 weeks or more, by Devine and colleagues ([12]) found that an MCA/UA S/D ratio less than 1.05 had an 80% sensitivity and 95% specificity with 80% positive predictive value of an adverse perinatal outcome.

The contraction stress test (CST) was the first test used for antepartum fetal monitoring. The underlying premise is that the fetus with uteroplacental insufficiency would experience late decelerations with contractions in response to hypoxia generated by decreased blood flow to the intervillous space. The NST is the first-line screening test at many medical centers. It is quickly and easily performed in an outpatient setting. The NST is based on the knowledge that fetal hypoxia interrupts the pathway between the fetal heart and an intact central nervous system (CNS). The fetus with an intact CNS will have heart rate accelerations with movement or stimulation. The CST has a high false-positive rate and the NST has a false-negative rate of 2.7 per 1,000 in a high-risk population ([13]). The BPP score predicts the presence or absence of asphyxia. The loss of the components of the BPP reflects sequential adaptive deletions to reduce fetal oxygen requirements. A normal BPP has a false-negative rate of 0.7 to 0.8 per 1,000.

The CST, NST, and BPP were compared in 583 women who had completed 42 weeks gestation ([14]). There were three protocols:

1. Weekly NST with CST for nonreactive NST.
2. Twice weekly NST with BPP for nonreactive NST with induction for a 4/10 BPP.
3. Twice weekly NST with BPP for nonreactive NST and a weekly determination of the amniotic fluid volume.

Patients were induced for low fluid or decelerations on the NST. In protocol 1, patients were reevaluated in 24 hours for a suspicious CST and induced for a positive CST. Protocol 3 had the highest intervention rate and the least perinatal morbidity. Protocol 1 had no interventions and the highest perinatal morbidity rate. Cesarean delivery was more common in protocols 2 and 3. Of note, the best outcomes were achieved with a low threshold for intervention.

THE FETUS

In 1954 Clifford ([15]) described the fetal postmaturity syndrome in which the postmature infant was characterized by peeling, parchmentlike skin, wasted appearance and meconium staining of skin, membranes, and the cord. The syndrome progressed in three stages from placental insufficiency with minimal associated morbidity and mortality to chronic insufficiency with an associated anoxic event.

The postmaturity syndrome described by Clifford is seen in only a small percentage of prolonged pregnancies. By far the most common complication is macrosomia resulting in dystocia with associated brachial plexus injuries and fractures.

Seven thousand infants were studied to determine the rate of growth after 39 weeks ([16]). Mean birth weight increased from 39 to 42 completed weeks. A similar increase was seen in head circumference and crown-to-heel length. In a study of 519 pregnancies beyond 41 weeks, 23% weighed more than 4,000 g and 4% were larger than 4,500 g ([17]).

To assess the risk to the fetus in a prolonged uncomplicated gestation, 1,408 infants delivered at 41 weeks and 340 delivered at 42 weeks were compared to 5,915 delivered at 39 or 40 weeks ([18]). Fetal distress and meconium release were twice as common at or after 42 weeks than at term. There was an eight-fold increase in meconium aspiration, which occurred 1 per 455 at term, 1 per 175 at 41 weeks, and 1 per 57 at 42 weeks. There was no increase in the incidence of birth asphyxia measured by the need for mechanical ventilation at birth.

MANAGEMENT

The management of uncomplicated prolonged pregnancies is controversial. An adverse event in a pregnancy that has carried beyond 40 weeks seems especially difficult because it might have been avoided by simply delivering the patient. Although rare, the risk of stillbirth increases as gestational age increases. Nonetheless, available data indicate that induction and expectant management have similar outcomes, and either is suitable for managing the uncomplicated prolonged gestation.

The National Institutes of Health (NIH) ([19]) sponsored a clinical trial to compare induction at 41 weeks (n = 265) to expectant management (n = 175) consisting of twice weekly NST and AFI. There were no differences in outcome between the two groups. The trial concluded that either approach was acceptable.

Active management of the prolonged pregnancy, defined as induction at 42 weeks was studied in 707 patients ([20]). Sixty-two percent of the patients labored spontaneously and 38% were induced. Perinatal mortality was 12 per 1,000. All deaths were in the spontaneously laboring group. Cesarean sections and indications for cesarean sections were similar in both groups. Meconium was present in 23% of inductions and 34% of the spontaneously laboring group. The authors concluded that routine induction at 42 weeks was justified to prevent perinatal deaths in this population.

The Parkland Group studied 56,317 pregnancies at 40, 41, and 42 weeks ([21]). Labor was induced at 42 weeks. Neonatal outcomes were similar in all groups. Sepsis and neonatal intensive care unit admission were more common in the 42-week group. Labor complications increased between 40 and 42 weeks, including length of labor and operative delivery. Their data suggest that routine induction at 41 weeks would increase labor complications with little or no neonatal benefit.

The Canadian Multicenter Post-term Pregnancy Trial was conducted at 22 hospitals, over a 5-year period ([22]). Singleton pregnancies at 41 weeks or more were assigned to induction or monitoring. In the monitored group, women were asked to perform kick counts each day. In addition, the fetuses received NSTs three times a week and AFI determinations two or three times weekly. Patients in the monitored group were delivered at 44 weeks or for maternal–fetal indication(s). Perinatal morbidity and mortality were the same for both groups.

PREVENTION

Separation of the membranes from the lower uterine segment (membrane sweeping) is a safe and inexpensive method of inducing labor, although its effectiveness is most likely operator-dependent. Membrane sweeping works by causing prostaglandin release from the chorionic membranes. One hundred eighty women at 38 weeks were randomized to either weekly membrane sweeping or a gentle cervical exam to determine Bishop score. The treatment group had a significant reduction in prolonged gestation, 3.3% compared to 15.6% in the control group ([23]). In another investigation, women with a Bishop score =4 and negative fetal fibronectin at 39 weeks received either membrane sweeping every 3 days or gentle cervical exams. The mean gestational age for onset of labor in the treatment group was 39.9 ± 0.3 compared to 41.5 ± 0.6 in the control group. Eighteen of 32 women in the control group were induced at 42 weeks versus none in the treatment group ([24]). In summary, membrane sweeping prior to 40 weeks appears to be an effective method for reducing postdate inductions.

INDUCTION OF LABOR

In the presence of a favorable cervix, induction after 41 weeks is reasonable.

Because induction of an unfavorable cervix may be unsuccessful and lead to cesarean delivery, the course of action in an otherwise uncomplicated prolonged gestation with an unfavorable cervix is less clear. Patients at 41 weeks of an uncomplicated gestation with Bishop scores of 4 or less were randomized to daily cervical exams, daily membrane sweeping, or daily prostaglandin gel for 1 week ([25]). Sixty-nine percent of the control group required induction at 42 weeks compared to only 20% (prostaglandin gel) and 17% (membrane sweeping) in the treatment groups. Wing and colleagues gave women who were at 41 weeks or more with unfavorable cervixes either 200 mg of mifepristone or placebo 24 hours before induction. They found only a modest effect on cervical ripening ([26]). Sequential application of

prostaglandin E_2 (PGE_2) gel for cervical ripening was tested in 50 women at or beyond 41 weeks. All had Bishop scores less than 9 and received 2 mg of PGE_2 gel twice a week as outpatients. PGE_2 gel failed to improve cervical ripening over placebo ([27]). Alexander and colleagues ([28]) scheduled 1,325 women at 41 weeks for induction at $41^6/_7$ weeks. Six hundred eighty-seven women entered spontaneous labor before their scheduled inductions and served as controls. Labor was longer in the women who were induced and there was an increase in cesarean sections for failure to progress in the induced group but not for fetal distress. Associated risk factors for cesarean delivery in this study were undilated cervix, analgesia, and nulliparity.

SUMMARY POINTS

- Solid evidence from several randomized controlled trials indicates that uncomplicated prolonged gestations can be managed expectantly or by induction of labor and that outcomes are similar for either method.
- Accurate dating of the pregnancy is important and an early dating ultrasound can prevent unnecessary interventions.
- Perinatal morbidity and mortality increase significantly beyond 41 weeks gestation.
- Membrane sweeping can help to reduce the number of pregnancies that continue beyond 40 weeks.
- Antenatal testing is initiated to identify the fetus in need of delivery. No testing modality has been shown to improve outcomes in prolonged gestations.
- The uncomplicated post-term pregnancy with an unfavorable cervix can be watched expectantly with twice weekly fetal assessments or labor induction can be undertaken. Induction at 41 weeks reduces the risk of stillbirth.
- It remains unclear which method of induction is most effective for prolonged pregnancy.

POSTPARTUM MANAGEMENT
SUMMARY POINTS

SUGGESTED READINGS

Multiple gestations have become one of the most common high-risk conditions encountered by the practicing obstetrician/gynecologist. In 1998, there were 118,295 multiples born in the United States, the highest number ever recorded. Since 1980, the number of twins delivered in the United States has risen 62% and twins now represent approximately one out of every 40 deliveries. Triplets and higher order births, formerly statistical improbabilities according to the Hellin hypothesis, have increased 470% over the same time period and triplets now occur with a frequency approaching one in every 500 deliveries.

Although multiples account for only a small percentage of all live births, they are responsible for a disproportionate share of all the perinatal morbidity and mortality suffered in the United States. Multiples result in 13% of all preterm births less than 37 weeks; 15% of all preterm births less than 32 weeks; 21% of all low–birth-weight (LBW) (<2,500 g); and 25% of all very low–birth-weight (VLBW) (<1,500 g) infants. As a consequence of these high rates of both prematurity and LBW, twins are at an approximate five-fold greater risk of dying before their first birthday compared to singletons, while triplets are at an almost 14-fold greater risk. Multiples account for 16% of all neonatal deaths in the United States.

Among survivors, there is an increased risk of long-term mental and physical handicaps. Twin pregnancies result in a child with cerebral palsy 12 times more often than do singleton births. One-fifth of all triplet pregnancies and one-half of all quadruplet pregnancies result in at least one child with a major long-term disability. While many cases of cerebral palsy are related to extreme prematurity, not all are the result of premature birth. Even when matched for gestational age, multiples have a nearly three-fold greater risk of developing cerebral palsy than do singletons.

Multiples also experience a significantly increased risk of growth restriction, which can compound the problems associated with prematurity. Growth-retarded, premature infants, regardless of plurality, experience greater morbidity and mortality than do appropriately grown infants of the same gestational age. Twins and triplets with intrauterine growth restriction have been shown to experience an excess of neurodevelopmental abnormalities compared to appropriately grown, gestational age-matched multiples. Multiples are at risk for numerous other complications that contribute to adverse outcomes. These complications include higher rates of congenital anomaly, twin-to-twin transfusion, monoamnionicity, cord prolapse, placental abruption, placenta previa, intrapartum asphyxia, and birth trauma.

Not unexpectedly, multiples are also associated with significantly higher health care costs. Neonatal intensive care unit (NICU) admission is required by one-fourth of twins, three-fourths of triplets, and virtually all quadruplets with average NICU stays of 18 days, 30 days, and 58 days, respectively. Women pregnant with multiples are almost six times more likely to be hospitalized with antepartum complications—most frequently preterm labor, preterm premature rupture of the membranes (PPROM), and preeclampsia. In addition to higher rates of antepartum admission, hospital costs for the birth admission average 40% higher than for gestational age-matched singletons due to longer lengths of stay and increased intrapartum complications with multiples.

ETIOLOGY AND EPIDEMIOLOGY

Monozygotic twins are those gestations where both fetuses arise from single fertilized ova and are genetically identical. Monozygotic twinning is considered to be a random event, independent of modifying influences such as age, race, parity, or heredity. The incidence of monozygotic twinning is 3 to 4 per 1,000 live births in virtually all populations. One of the few known influences on the rate of monozygotic twinning is the use of assisted reproductive technologies such as in vitro fertilization. The increased frequency of monozygotic twinning with infertility treatment has been attributed to a defective zona pellucida, which allows premature and partial hatching of the blastomeres.

The incidence of dizygotic twinning, on the other hand, is extremely variable and accounts for most of the increase in multiple births seen over the past few decades. Dizygotic, or fraternal twins, result from multiple ovulation with fertilization by separate sperm. Multiple factors are known to affect the incidence of dizygotic twinning including personal or family history. If a woman has already had one set of dizygotic twins, her chance of having a second set is increased two-fold and a first-degree relative with twins will increase a woman's risk as well. The father's side of the family contributes little or no hereditary risk.

It is estimated that approximately one-fourth of the increase in the number of multiple births is due to delayed childbearing and the fact that dizygotic twinning occurs more frequently among older women. The trend toward delayed childbirth has been a dramatic sociologic phenomenon of the past quarter century. Since 1975, the proportion of first births among women 30 years and older has increased from 5.3% to 22.8% and the proportion of all births to women =30 years of age rose from 16.5% to 35.5%. In women younger than 20 years, the multiple birth rate is only 1.5% compared to 4.1% among women between the ages of 30 to 39 years and up to 17.8% for women 45 years or older.

The majority of the increase in dizygotic twinning has been a result of ovulation induction therapy and newly developed assisted reproductive technologies (ART). An annual summary of ART programs in the United States reported on 14,702 deliveries of 21,196 neonates. Of these ART cycles resulting in clinical pregnancies, 39% of in vitro fertilization, 34% of gamete intrafallopian transfers, and 36% of zygote intrafallopian transfers resulted in multiples. Approximately 40% of all triplets and more than 90% of all quadruplet pregnancies in the United States are secondary to either ovulation induction or ART. Women contemplating assisted reproduction should receive preconceptional advisories regarding the risk of multiple birth and the risks associated with those births. Among pregnancies resulting from ART, approximately 25% to 30% will be twins, 5% will be triplets, and 0.5% to 1% will be higher order multiples. Efforts are being made to reduce the number of oocytes, zygotes, or embryos that are being transferred back in order to minimize the risk of multiple pregnancy. However, three or more oocytes, zygotes, or embryos are still being

transferred in many cases, especially among older women where the rate of successful implantation is reduced.

Maternal race also affects the frequency of dizygotic twinning. Dizygotic twinning occurs approximately 7 to 10 times per 1,000 live births among Caucasians, 10 to 40 times per 1,000 live births for persons of African descent, and only 3 times per 1,000 live births among Asians. Interestingly, white women are more than twice as likely as black women and three times as likely as Hispanic women to have a triplet or higher order multiple, which almost certainly reflects a greater use of ART in the white population. Increased maternal parity, higher body mass index (BMI), and recent discontinuation of hormonal birth control agents have also been associated with higher rates of dizygotic twinning.

PLACENTATION

The placentation of dizygotic twins will always be diamniotic, dichorionic. Two complete placental units are produced, each composed of an amnion and a chorion. As a result, the membrane separating dizygotic twins will consist of four layers; an amnion and a chorion from each fetus. The placentas themselves may be separate or fused in dizygotic twins but the central membrane will always consist of four layers. In monozygotic twins, the placentation depends on the time at which twin division occurs. If division of the zygote occurs in the first three days, two complete placental units will be formed and the central membrane will contain two amnion and two chorion layers, just as with dizygotic twins. The syncytiotrophoblast cells, which will give rise to the chorion, begin to differentiate about day 3 from the periphery of the blastocyst. If division occurs between days 3 and 8, the placental unit will consist of a single chorion which has already differentiated and two amnions which have not yet begun to form. As a result, the central membrane will be thin and wispy because it consists of only two opposed amniotic membranes without the intervening chorionic layers. This placentation is referred to as diamniotic, monochorionic. The amnion begins to differentiate by about day 8 and if embryonic division occurs between days 8 and 13, the twins will share a single amnion and chorion; a monoamnionicity, monochorionic placentation. This situation, with no central membrane separating the fetuses, allows for potentially lethal entanglement of the umbilical cords. Different types of placental development in dizygotic and monozygotic twins are illustrated in Figure 14.1. Division, which occurs after day 13, results in a physical attachment producing conjoined twins.

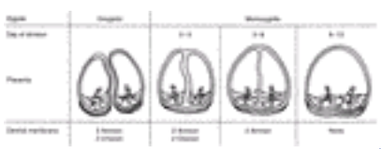

FIG. 14.1. Types of placentation in monozygotic and dizygotic twinning.

Examination of the placenta(s) and a detailed description of its central membrane are critical for determining zygosity of the infants. The microscopic appearance of the central membrane consisting of either two or four layers is seen in Figure 14.2. Diamniotic, dichorionic twins are dizygotic if the twins are of opposite sex. If the central membrane contains only amnionic layers and a monochorionic placenta, the infants are monozygotic. If the central membrane has two amnion and two chorion layers (i.e., diamniotic, dichorionic) and the infants are the same sex, the twins may be either dizygotic or monozygotic. Despite this limitation, the obstetrician can still accurately determine zygosity in the delivery room in over 50% of cases by simply observing the fetal sex and grossly inspecting the placenta. In those cases that remain uncertain, a more specific diagnosis can be made by blood or HLA antigen typing or more sophisticated DNA analyses.

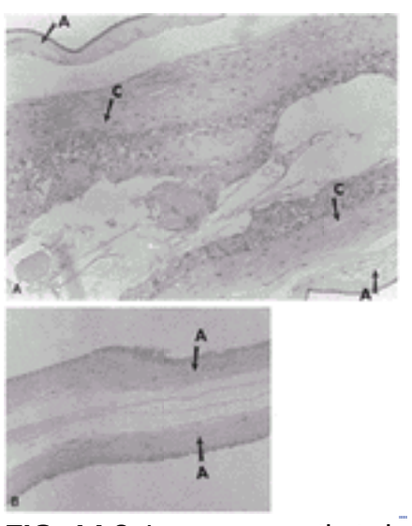

FIG. 14.2. In monozygotic twinning, the central membrane contains **(A)** four layers or **(B)** two layers (*A*, amnion; *C*, chorion).

MATERNAL COMPLICATIONS

Women pregnant with multiples are more likely to be hospitalized antenatally for both an increased frequency and severity of pregnancy-related complications. Some of these increased risks are associated with maternal characteristics that predate the pregnancy such as older maternal age, nulliparity, increased pregravid BMI, and conception by ART. However, the majority of these complications are directly related to higher plurality and the more extreme maternal adaptation required.

Cardiovascular Risks

One of the major physiologic changes occurring with a multiple pregnancy is significant expansion of the plasma volume and cardiac output above that seen in singleton pregnancies. This increased plasma volume has obvious adaptational value as the maternal host tries to meet the demands of a multiple conception. Increased cardiac demand is reasonably well tolerated in the absence of underlying cardiac disease such as undiagnosed mitral valve stenosis. However, the common use of tocolytic therapy, the not uncommon iatrogenic fluid overload, and the occasional infection will all generate significant additional cardiovascular stress. Although infrequent, tocolytic therapy (especially ß-adrenergic agonists) has been associated with pulmonary edema, myocardial ischemia, and potentially lethal maternal tachyarrhythmias in multiples. An increased risk of postpartum cardiomyopathy has also been reported, especially among older gravidas with higher order multiples. A case-controlled study of pregnant women found that multiple pregnancy was an independent and significant risk factor (odds ratio [OR] = 2.3; confidence interval [CI] 95% = 1.2–4.5) for admission to an intensive care unit.

Hematologic Abnormalities

Increased red blood cell volume expansion is unable to keep pace with plasma volume expansion in either singleton or multiple gestations. This results in a physiologic hemodilution. The average hemoglobin concentration for women pregnant with twins is 10 g per dL at 20 weeks gestation. Hemoglobin and hematocrit values decline beginning in the first trimester, reaching a nadir in the second trimester before gradually rising again in the third trimester. Hemoglobin levels below 11 g per dL in either the first or third trimester accompanied by a serum ferritin less than 12 µg per dL represents iron deficiency anemia, which complicates some 21% to 36% of multiple gestations. This rate is two- to three-fold higher than in singletons. Multiples generate a great demand for elemental iron, which might not be available in the average diet. This need should be addressed through the consumption of heme-rich animal protein and supplementation with 60 mg per day of elemental iron and 1 mg per day of folic acid when the woman has low or absent stores of these nutrients.

Metabolic Disorders

Women pregnant with multiples have lower fasting and postprandial glucose levels, exaggerated insulin responses to eating, and higher levels of ß-hydroxybutyrate than women pregnant with singletons. These differences suggest more rapid depletion of glycogen stores and resultant metabolism of fat between meals and during an overnight fast.

Gestational diabetes represents a disorder of relative insulin deficiency exposed as a consequence of the antiinsulin effects of several placental hormones, most notably human placental lactogen. Multiple gestations are at increased risk for gestational diabetes due to the elevated levels of these placental hormones associated with the increased placental mass. Gestational diabetes appears to be increased two- to three-fold among multiples (7% among twins, 9% among triplets, and 11%

among quadruplets) compared to the 3% to 4% incidence among singletons. Given the high rate of premature labor among multiples, it should be remembered that both ß-adrenergic agents and corticosteroids can induce both insulin resistance and hyperglycemia.

Premature Birth

The risk of preterm birth increases with the number of fetuses in utero and is the single greatest threat to the health of the newborns. Premature labor and PPROM are responsible for more than 70% of these premature deliveries. The incidence of preterm birth less than 37 weeks gestation in the United States is between 30% to 55% for twins, between 66% to 80% for triplets, and is virtually 100% for quadruplets. The mean gestational age at delivery is inversely proportional to fetal number: 39 weeks for singletons, 35 to 36 weeks for twins, and 32 to 33 weeks for triplets. Of all infants born in Australia and New Zealand prior to 32 weeks gestation in 1995, more than one-fourth were the products of a multiple gestation.

Pregnancy-Induced Hypertension/Preeclampsia

Pregnancy-induced hypertension or preeclampsia is frequently encountered in multiple gestations. Reported frequencies increase from approximately 7% in singletons to 14% for twins, 21% for triplets, and 40% for quadruplets. A population-based study of singleton and twin births in the state of Washington found twins to have a four-fold higher risk of preeclampsia and a 14-fold higher risk if the woman is primigravid. Pregnancy-induced hypertension or preeclampsia frequently occurs earlier, is more severe, and is more often atypical in multifetal gestations. Hypertension is not always the presenting sign, nor is proteinuria universally present, especially in higher order multiples. Only 3 of 16 triplets and quadruplets reported in one study met the traditional criteria for preeclampsia. The most common presentation among these higher order multiples was maternal symptoms typical of severe preeclampsia associated with laboratory abnormalities consistent with the HELLP (hemolysis, elevated liver enzymes, low platelet count) syndrome.

Placental Abruption

Antepartum maternal hemorrhage is also increased in multiple gestations. Twin pregnancies have an approximately three-fold increased frequency of abruption, even when controlling for maternal hypertension. Abruption occurs most frequently in the third trimester, and is also a significant risk immediately after vaginal delivery of the first infant. Conformational changes in the uterine shape that occur between deliveries can predispose to sheering off of the attached placenta.

Hydramnios

Hydramnios occurs in 2% to 5% of twin gestations, and twins account for approximately 8% to 10% of all cases of hydramnios. Polyhydramnios may develop as a consequence of twin-to-twin transfusion syndrome with the co-twin experiencing both growth restriction and oligohydramnios. The development of idiopathic acute hydramnios with respiratory embarrassment has also been reported in multiples.

Urinary Tract Infection

Women with multiples have a 1.4-fold increased risk of developing urinary tract infection during pregnancy. These infections usually involve only the lower urinary tract because the incidence of pyelonephritis is not significantly increased. This complication is thought to be a consequence of increased urinary stasis due to the gravid uterus.

Postpartum Hemorrhage

Overdistention of the uterus in a multifetal gestation predisposes to postpartum hemorrhage caused by uterine atony. In addition, women carrying multiples are at increased risk for retention of placental tissue, surgical or mechanical trauma to the genital tract, pharmacologic effects of medications such as magnesium sulfate which is frequently used to manage both preeclampsia and preterm labor, as well as other maternal characteristics such as advanced age, obesity, or higher parity. In a British population-based study of postpartum hemorrhage, multiple pregnancy was associated with a significantly increased risk ratio (RR = 4.46; 99% CI = 3.01–6.61). In the British study, the risk of postpartum hemorrhage among singletons was 1.2% compared to 6% for twins, 12% for triplets, and 21% for quadruplets. Compared to the twins, the risk of postpartum hemorrhage was two-fold higher for triplets and four-fold higher for quadruplets.

While the above scenarios represent several of the more significant maternal complications associated with multiples (Fig. 14.3), others are encountered with increasing frequency. These include cholestatic jaundice, pruritic urticarial plaques and papules of pregnancy (PUPP), hyperemesis, and deep venous thrombosis. Women with multiple gestations also experience an increased number of somatic complaints such as shortness of breath, loss of balance, varicose veins, significant dependant edema, constipation, and hemorrhoids. Thankfully, multiples are less often asked to carry their pregnancy postdates.

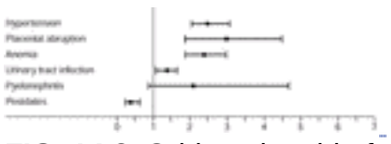

FIG. 14.3. Odds ratio table for maternal antepartum complications among 1,253 twin and 5,119 singleton pregnancies between 1982 and 1987. (Adapted from Spellacy WN, et al. A case-controlled study of 1,253 twin pregnancies from a 1982–1987 perinatal database. *Obstet Gynecol* 1990;75:168–171.)

COMPLICATIONS UNIQUE TO MULTIPLES

Vanishing Twin Syndrome

The loss of one or more fetuses can complicate a multiple gestation at any point during pregnancy but is most common in the first trimester. Between 20% to 50% of multiple gestations identified by ultrasound in early pregnancy are lost either as a spontaneous abortion of all fetuses or by the spontaneous loss and reabsorption of at least one of the multiples. This latter occurrence is referred to as the “vanishing twin phenomenon” and its exact frequency is difficult to ascertain for obvious reasons.

The published experience of the Norfolk in vitro fertilization program allows an estimation of the frequency of this occurrence. Spontaneous loss of all fetuses with previously documented cardiac activity occurred in 17 of 165 twin (10.3%), 2 of 26 triplet (7.7%), and 1 of 5 quadruplet (20%) pregnancies. In addition, 33 twins spontaneously reduced to a singleton and nine triplets spontaneously reduced to twins. Considering both the spontaneous abortion rate and the “vanishing twin phenomenon”, the overall first trimester pregnancy loss rate was 50 of 165 twins (30.3%), 11 of 26 triplets (42.3%), and 1 of 5 quadruplets (20%). Although these data are limited by the fact that all pregnancies were the result of in vitro fertilization, similar loss rates have been reported in spontaneously conceived multiples.

When a “vanishing twin phenomenon” does occur, it is usually silently reabsorbed. However, in some cases, the reabsorption may be associated with a modest amount of vaginal bleeding. Some have estimated that up to 5% of all patients with first trimester bleeding may be experiencing a vanishing twin. Maternal reassurance should be offered as the prognosis for the surviving twin is excellent when silent reabsorption occurs in the first trimester. Following delivery, the placenta will frequently show a whitish plaque on the membranes representing the remnant of the other gestational sac.

While the “vanishing twin phenomenon” occurs with a greater frequency than previously appreciated, it is important not to overdiagnose this event. The diagnosis of a vanishing twin should be preceded by identification of specific embryonic parts in each sac as opposed to an anembryonic cavity. Numerous sonographic findings can mimic a second anembryonic cavity including subchorionic blood clots, chorioamnionic separations, a decidual pseudosac in the contralateral horn of a bicornuate or didelphic uterus, a cystic uterine fibroid, or even excessive transducer pressure on a thin woman. The emotional impact of a vanishing twin should not be underestimated. Parents will perceive the situation as the loss of a child and perinatal grief counseling may even be appropriate in some situations.

Fetal Death in Utero (Acute Intertwin Transfusion Syndrome)

After the first trimester, single fetal demise occurs in 2% to 5% of twin gestations and 10% to 15% of triplet gestations. The risk of a single fetal death in utero is increased three- to four-fold by monochorionicity. When death of one fetus occurs in a dichorionic gestation, the risk to the surviving co-twin is minimal although higher rates of preterm labor or PPROM have been reported. Virtually all the adverse sequelae for the surviving co-twin occur in monochorionic gestations. Antenatal demise

of a monochorionic co-twin is associated with an approximate 25% mortality rate and a similar high rate of morbidity for the second fetus.

Injury to the surviving co-twin was previously thought to be a result of intervascular coagulation and embolism of tissue thromboplastins through ubiquitous placental anastomoses from the fetal demise. The passage of these tissue thromboplastins result in embolic ischemic organ injury or development of disseminated intervascular coagulopathy in the survivor. A more recent theory suggests that following fetal demise, there is an acute transfusion into the dead fetus through the shared placenta. This hemorrhage into the dead fetus may cause severe fetal hypotension, hypoxic end-organ injury, and potentially lethal fetal exsanguination. This is often referred to as acute intertwin transfusion syndrome. In prospective studies, 5% to 25% of surviving monochorionic twins have ischemic end-organ injury, most notably neurologic. Neurologic abnormalities reported among surviving twins include necrosis and cavitation of the cerebral white matter, cerebellar necrosis, multicystic encephalomalacia, hydranencephaly, hydrocephalus, porencephaly, microcephaly, and hemorrhagic infarction. In addition to neurologic injuries, other abnormalities seen among surviving co-twins include ischemic bowel lesions, intestinal atresia, renal cortical necrosis, and cystic renal dysplasia.

Most reported cases of demise or neurologic injury occurring in a monochorionic co-twin following death of its sibling have occurred in the third trimester. However, neurologic deficit has been reported in a surviving monochorionic twin following loss of its co-twin as early as 18 weeks gestation.

Following a fetal demise in utero, continuing pregnancy management will depend upon gestational age, chorionicity, and maternal and fetal status. If the pregnancy is known to be dichorionic, then no intervention is required unless a term gestation has already been achieved or there is a specific maternal or fetal indication for delivery. A single fetal demise in a monochorionic gestation is an indication for immediate delivery if fetal maturity can be inferred based on gestational age or documented by amniocentesis. Decisions regarding delivery at earlier gestations should be based on an assessment of the neonatal complications likely to result from delivery as opposed to the potential risk of remaining in utero. Since it is possible, if not probable, that hypoxic/ischemic end-organ injury occurs almost immediately after demise of the monochorionic co-twin, it is unclear if these injuries can be prevented by prompt delivery. With expectant management, increased fetal surveillance of the surviving twin should be performed and any evidence of fetal compromise would also necessitate immediate delivery.

Monoamniotic Twins

Monoamniotic twins are rare, complicating fewer than 1% of monozygotic gestations. Their importance is that they carry a fetal mortality rate that approaches 40%, primarily as a consequence of cord entanglement and subsequent occlusion. Cord entanglement is present in virtually every case of monoamniotic twins. Monoamniotic twins are also at greater risk for other complications such as congenital anomaly and twin-to-twin transfusion syndrome.

Some reviews have suggested that spontaneous intrauterine fetal demise due to cord entanglement is unlikely after 32 weeks gestation as intrauterine crowding limits the ability of the fetuses to make major moves in relationship to each other. However, a review of over 200 non-conjoined, monoamniotic twins demonstrated that fetal deaths occur throughout pregnancy, with a large percentage occurring after 32 weeks. In this large review, those monoamniotic twins that were prenatally diagnosed and subjected to intensive antepartum surveillance enjoyed a much higher perinatal survival rate than has been historically reported. Prenatal diagnosis allows for institution of an aggressive management protocol designed to identify fetal compromise, enhance fetal lung maturity, and electively deliver once neonatal survival can be anticipated (Table 14.1).

Confirm monoamnionicity (exclude stuck twin syndrome)
Ultrasonographic evaluation at 18–20 wks to exclude congenital anomalies and conjoining
Parental education regarding unique risks
Serial ultrasonographic assessment of fetal growth (twin–twin transfusion syndrome common)
Daily fetal kick counts beginning at 26 wks
Nonstress testing 3×/wk beginning at 26 wks
Antenatal glucocorticoid administration
Amniocentesis for fetal lung maturity at 32 wks
Elective delivery at 34–35 wks if fetal lung maturity not previously confirmed
Cesarean delivery usually recommended

TABLE 14.1. *Management recommendations for monoamniotic/monochorionic twin gestations*

Cesarean delivery is usually recommended due to concerns over intrapartum fetal distress related to tightening of the umbilical cord entanglement. If vaginal delivery is planned, continuous fetal monitoring is essential along with capability for immediate cesarean birth.

Discordant Twin Growth

In addition to the concordant intrauterine growth restriction (IUGR), ultrasound is useful for the detection of significantly discordant fetal growth, which is unique to multiple gestations. In terms of actual birth weight, a large review found that twin birth weight differed by 500 to 999 g in 18% of sets and the difference was greater than 1,000 g in 3%. Some 15% to 30% of twins exhibit birth weight differences of 20%. Discordance between the largest and smallest triplet is 20% in more than 40% of triplet gestations with 7% being as much as 40%.

Evidence suggests that the smaller infant may be at risk for both increased perinatal morbidity and mortality when birth-weight discordance is excessive. Another concern is that significant diversions in twin growth may predispose the smaller twin to disadvantages in long-term physical and intellectual development.

Much of the discordance in birth weight will be due to constitutional factors such as the genetic dissimilarity of dizygotic twins. The more severe the discordancy, the more likely the possibility that pathologic conditions exist such as twin-to-twin transfusion syndrome, an anomalous fetus with a normal co-twin, congenital infection, or growth restriction affecting a single fetus due to local placental implantation factors. Percent discordance is calculated by dividing the actual or estimated weight difference by the actual or estimated weight of the larger twin.

It is also important to appreciate that birth-weight discordance and intrauterine growth restriction are interrelated. When birth-weight discordance of 20% is present, one of the fetuses will be IUGR in more than 50% of the cases. When discordant fetuses are both appropriately grown for gestational age, differences in perinatal outcome have not been identified. Both prematurity and intrauterine growth restriction are much greater threats to the fetus than is the degree of discordancy.

Evaluation of discordant growth should be undertaken simultaneously with consideration of gestational age, individual fetal growth, and fetal well-being. In the absence of fetal anomalies or intrauterine growth restriction, and in the presence of reassuring fetal testing, birth-weight discordance among preterm twins should be managed expectantly in anticipation of achieving more advanced gestation or enhanced fetal maturity. Some caution is appropriate given that the ultrasound diagnosis of both intrauterine growth restriction and in utero growth discordance is limited. The sensitivity of ultrasonography for substantial intertwin discordance is, at best, only 60%. Alternatively, ultrasound evidence suggesting 20% to 25% growth discordance or intrauterine growth restriction of either twin at 35 weeks gestation would be appropriate indications for delivery.

Twin-to-Twin Transfusion Syndrome: Chronic Intertwin Transfusion

Twin-to-twin transfusion is a serious complication affecting multiple pregnancies and is sometimes referred to as chronic intertwin transfusion syndrome. Chronic intertwin transfusion syndrome is a complication of monozygotic/monochorionic twins in which intraplacental arterial venous shunts are uncompensated and preferential blood flow exists. Vascular communications are present in virtually all monochorionic placentas and approximately one third will demonstrate at least some clinical evidence of the syndrome. Severely affected pregnancies are much less common, occurring in fewer than 5% of monochorionic gestations. Contrary to what might be expected, severe twin-to-twin transfusion syndrome is associated with fewer, or even a single arterial venous malformation within the placenta rather than multiple vascular anastomoses. Multiple anastomoses function to restore a balance of bi-directional flow within the monochorionic placenta while a limited number predispose to preferential flow. Severe chronic intertwin transfusion syndrome identified in the second trimester is associated with loss rates approaching 100% if untreated. Chronic intertwin transfusion syndrome accounts for 15% to 17% of all perinatal mortality in twin gestations.

In chronic intertwin transfusion, the arterial donor twin may be growth retarded, anemic, hypotensive, and oligohydramniotic. If there is little or no amniotic fluid surrounding the smaller fetus, the amniotic membrane may lay in close apposition to the smaller fetus restricting it to the uterine wall. This is referred to as the “stuck twin”. The “stuck twin” can sometimes be misidentified as monoamniotic. The arterial donor twin may also experience ischemic organ damage involving the brain, kidneys, or bowel. The venous recipient twin can be hypervolemic, hyperviscous, hypertensive, and polyhydramniotic due to increased renal blood flow. Either twin may be hydropic due to volume overload in the recipient or high output failure in the donor. Polyhydramnios, which is common in the venous recipient, also contributes to a high incidence of premature labor or PPROM.

The diagnosis of chronic intertwin transfusion syndrome has become controversial. Older diagnostic criteria, focused primarily on neonatal measures (i.e., cord blood

hemoglobin differences of 5 g per dL or birth-weight differences of 20%). These parameters have generally been discarded since they did not efficiently identify those gestations thought to be affected by this disorder. Chronic intertwin transfusion syndrome is now diagnosed using ultrasonographic criteria including:

- marked size disparity in fetuses of the same sex
- disparity in size between the two amniotic sacs
- disparity in size of the umbilical cords
- a single placenta
- evidence of hydrops in either fetus
- findings of congestive heart failure in the recipient.

Doppler ultrasound has also been proposed as a tool that may help improve diagnostic accuracy and assess fetal well-being. The normal placenta in chronic intertwin transfusion syndrome results in normal, non-discordant systolic/diastolic (S/D) ratios. Abnormal SD ratios are more likely to reflect placental abnormalities associated with fetal growth restriction. The absence of underlying placental vascular lesions in chronic intertwin transfusion syndrome results in concordant uterine artery waveforms helping differentiate chronic intertwin transfusion syndrome from fetal growth restriction.

Management of chronic intertwin transfusion syndrome will be individualized depending on the stage of pregnancy at which it is encountered. The option of delivery will depend on fetal maturity and the potential morbidity to be encountered. At earlier gestational ages, serial decompression amniocentesis and tocolytic therapy have been successful in prolonging pregnancy. With the development of fetoscopy, direct laser occlusion of the placental vascular anomaly has become an option. For those patients not delivered, fetal health should be frequently evaluated with biophysical profile scoring or fetal heart rate monitoring. Of all available management options, large volume-reduction amniocentesis is an efficacious and minimally invasive therapy that is probably the treatment of choice after attainment of viability. For the previable patient, the prognosis is extremely poor and consideration might be given to intrauterine laser ablation of placental surface vascular anastomoses, fetoscopic cord clamping, or termination.

FETAL AND NEWBORN COMPLICATIONS

Prematurity

The contribution of multiple gestations to national rates of both perinatal morbidity and mortality has been delineated earlier in this chapter. Multiples contribute disproportionately to virtually every measure of perinatal health as well as longer-term measures of infant mortality and long-term mental and physical handicap. Infants of multiple gestations account for approximately 20% of all NICU admissions. An admission to an NICU can be expected in approximately 25% of all twins, 75% of all triplets, and in more than 90% of quadruplets. Respiratory distress syndrome, one particularly costly measure of neonatal morbidity, occurs in approximately 14% of twins, more than 40% of triplets, and more than 60% of quadruplets. The average length of NICU stay is 18 days for twins, approximately 1 month for triplets, and almost 2 months for quadruplets. Birth weight and gestational age account for the vast majority of increased use of NICU services among multiple gestations.

While the consequences of prematurity are easily calculable in terms of fetal and neonatal adversity, it must not be forgotten that prematurity also contributes significantly to the long-term health and well-being of these infants. Compared to singletons, the risk of dying before the first birthday is 5 times greater for twins and 14 times greater for triplets. Among survivors, the relative risk of severe handicap, controlling for both birth weight and gestational age is 1.7 (95% CI = 1.6–2.0) for twins and 2.9 (95% CI = 1.5–5.5) for triplets compared to singleton gestations.

Intrauterine Growth Restriction

Although intrauterine growth restriction is not unique to multiple gestations, it is certainly more common. During the third trimester, the average growth of multiples begins to diverge from average singleton rates. Healthy twin gestations demonstrate growth velocities similar to that of singletons until approximately 30 to 32 weeks gestation while triplet and quadruplet growth velocity begins to slow at 27 to 28 and 25 to 26 weeks, respectively. The mean estimated fetal weight for twins falls below the singleton 50th percentile at about 32 weeks but typically remains between the 10th and 50th percentile until approximately 36 weeks. Beyond 36 weeks, twins frequently fall below the 10th percentile compared to singleton norms. Between 36 to 38 weeks gestation, approximately one-third of all twins will demonstrate intrauterine growth restriction. In comparison, approximately 12% of triplets will have a birth weight less than the 10th percentile based on singleton standards by 32 to 34 weeks, and the rate of IUGR increases to more than 60% by 35 to 36 weeks. Evaluation of the individual parameters of fetal biometry suggests that the reduced growth velocity seen in multiples is most consistent with an asymmetric intrauterine growth restriction. Relative placental insufficiency magnified by the inherent competition for nutrients presented by the multiple fetuses is the most likely cause of this constrained pattern of growth. Other potential contributors to the intrauterine growth restriction identified in multiples include a higher incidence of abnormal placental implantation, umbilical cord abnormalities including a two-vessel cord, velamentous or marginal insertions, chromosomal or structural abnormalities, and intertwin transfusion syndrome.

Intrauterine growth restriction in multiples is best predicted using an estimated fetal weight calculated from multiple biometric parameters including the abdominal circumference. The detection of IUGR is also aided by early diagnosis and accurate dating of the pregnancy. Beyond 20 weeks gestation, fetal growth in multiple gestations should be periodically evaluated by detailed ultrasonographic studies. In general, these scans can be performed on a monthly basis although little data exist that define the optimal interval. That interval can likely be extended if results of the previous scan were reassuring, especially in a dichorionic gestation. Shorter intervals of every 2 to 3 weeks may be required once IUGR has been identified or is suspected. The diagnosis of IUGR in one or both twins should lead to the institution of antenatal fetal surveillance, nonstress testing, assessment of amniotic fluid volume, umbilical artery Doppler velocimetry, and consideration given to the safety of early delivery just as it would be in a singleton gestation. If amniocentesis is used to assess fetal lung maturity, results obtained from the amniotic fluid of either twin will usually reflect the lung maturity status of both making only a single puncture necessary. If intrauterine growth restriction is suspected in only one of the twins, it is likely that the smaller twin will have accelerated lung maturity and therefore the amniotic fluid of the larger twin should be sampled.

Congenital Anomalies

Congenital malformations occur approximately twice as often in multiples as compared to singletons. The majority of malformations occur in monozygotic twins. However, twins are concordant for fetal anomaly in only a minority of cases. Even higher rates of congenital malformation have been reported in triplet gestations.

Identification of congenital malformations represents a major use of ultrasonography in multiples. Transabdominal evaluation of fetal anatomy is best performed between 18 to 22 weeks. However, transvaginal sonography may allow an opportunity to detect certain malformations even earlier. In a single center series of 245 consecutive twin gestations (490 infants), the use of antepartum ultrasound for the detection of congenital anomalies (4.4% anomaly rate) was excellent with a sensitivity of 88% (21 of 24 anomalous fetuses detected), a specificity of 100%, a positive predictive value of 100%, and a negative predictive value of 99%. An accurate diagnosis of congenital anomaly is an obvious prerequisite for antepartum or intrapartum interventions. These interventions may include increased fetal surveillance, a change in the timing, location or mode of delivery, consultation with various neonatal and pediatric subspecialists, and in some cases, interventions such as fetal therapy, selective reduction, or pregnancy termination.

ANTEPARTUM CARE

Beneficial Interventions

Maternal Nutrition Alterations in fetal growth described in multiple gestations have been attributed, in part, to the intensified fetal competition for maternal nutrients. This inherent competition results in a drain on maternal resources and an accelerated depletion of maternal reserves. Placental transfer of an adequate nutrient supply is diminished after a combined fetal weight of 3,000 g is exceeded. Unfortunately, most of the investigations that have evaluated the impact of nutrition on perinatal outcome have involved singleton gestations, overlooking the prenatal care of multiples. This is unfortunate because there is accumulating evidence that nutrition is an important and modifiable variable which can improve intrauterine fetal growth and potentially lengthen gestation. The constrained pattern of fetal growth experienced by multiples makes environmental factors, such as nutrition, a greater influence on ultimate fetal growth than in singleton gestations. This allows a proportionately greater opportunity to positively influence birth weight and pregnancy outcome in multiple gestations by modifying maternal nutrition and monitoring the rate of maternal weight gain. Studies have identified maternal weight gains of 24 lbs by 24 weeks and overall weight gains of 40 to 45 lbs as being associated with optimal pregnancy outcomes defined as an average twin birth weight of 2,500 g. A 35- to 45-lb weight gain has been recommended in normal weight women with twins. Investigators have noted the importance of adequate early weight gain (<24 weeks gestation). A ripple effect of maternal weight gain on fetal growth has been demonstrated with gains before 20 weeks and between 20 to 28 weeks influencing subsequent twin growth from 20 to 28 weeks and 28 weeks to delivery, respectively. Poor weight gain prior to 24 weeks (<0.85 lbs per week), regardless of the rate of gain after 24 weeks, has been associated with both reduced intrauterine growth and higher perinatal morbidity. Studies among large cohorts of multiples have demonstrated that maternal weight gain prior to 20 weeks and between 20 to 28 weeks had a greater effect on birth weight in both twin and triplet pregnancies than did weight gain in the third trimester. These findings were particularly notable among underweight women. Patterns of higher maternal weight gain throughout pregnancy results in a favorable combined twin birth-weight difference of more than 1 lb at term compared to low patterns of maternal weight gain. Almost certainly, weight gain recommendations for twins need to be modified based on the maternal body mass index just as they are for

singletons. Analyzing patterns of both intrauterine fetal growth and twin birth weights, Luke and colleagues have proposed BMI-specific weight gain guidelines for twin pregnancies. These guidelines were modeled using multiple regression analysis for the gestational periods of 0 to 20 weeks (early), 20 to 28 weeks (middle), and 28 weeks to delivery (late). As might be expected, excellent twin growth was achieved with lesser maternal weight gains among overweight and obese women compared to underweight or normal weight women. Optimal rates of fetal growth and optimal birth weights were associated with BMI-specific rates of maternal weight gain (lb per wk) as described in Table 14.2.

TABLE 14.2. *Body mass index: specific weight gain recommendations for women pregnant with twins*

In an analysis of over 1,000 triplet pregnancies, Elster and colleagues identified male gender, older maternal age, increased parity, maternal height, pregravid weight, and maternal weight gain as factors associated with improved intrauterine fetal growth. They noted that a longer length of gestation was associated with higher maternal age, parity, and weight gain. Maternal weight gain was also associated with higher birth weight, improved birth weight for gestational age, and a longer length of gestation in a study of 144 triplets reported by Luke. Regression analyses again indicated that periods of maternal weight gain with the greatest impact on triplet birth weight were from conception to 20 weeks and between 20 and 28 weeks gestation. Maternal nutrient requirements are all increased in multiples. Due to the greater expansion of blood volume, increases in maternal tissues (body fat, muscle, breast, uterine) and fetal mass, caloric requirements are estimated to increase by about 40% in twins and by 80% in triplets. Although there are no national guidelines, an estimate of individual nutrient needs in multiples is provided in Table 14.3 based on the recommended daily allowances for nonpregnant and singleton pregnancies published by the National Research Council, Food and Nutrition Board, and extrapolations for twin and triplet pregnancies published by Luke.

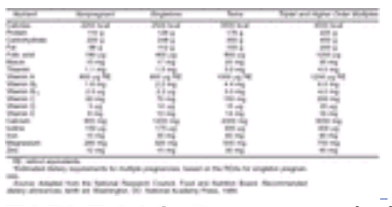

TABLE 14.3. *Recommended dietary allowances (RDAs) for nonpregnant women and women pregnant with singletons and estimated dietary requirements for women with twins, triplets, and higher order multiples* [a]

Maternal anemia, both the iron and folate deficiency types, are common in multiples. Many have recommended supplementation of the standard prenatal vitamin with iron (60 mg per day) and folic acid (1 mg per day) when a multiple pregnancy is diagnosed. The frequency of maternal anemia is related to the overall nutritional status of the woman, which reemphasizes the need for adequate nutrition with a focus on heme-rich protein intake and an emphasis on folate-containing green leafy vegetables. Other nutrients often lacking in women's diets include calcium, magnesium, and zinc, and their specific supplementation has been recommended by some to both prevent their depletion and to reduce pregnancy complications. There is good evidence that intensive patient education, aggressive nutritional counseling, and an emphasis on early and appropriate maternal weight gain can all contribute to improved intrauterine growth and perinatal outcomes in multiple gestations.

Ultrasound Ultrasound plays numerous critical roles in the antepartum care of multiples. These include their diagnosis, determination of amnionicity and chorionicity, identification of fetal or placental anomalies, evaluation of fetal growth and amniotic fluid volume, evaluation of fetal biophysical parameters, and determination of presentation. Accurate determination of chorionicity and amnionicity is important in antepartum management. Monochorionic pregnancies are at substantially higher risk for intrauterine growth restriction, growth discordance, congenital anomalies, and intrauterine fetal death. Although rare, monoamniotic placentation represents an extreme risk with high rates of twin-to-twin transfusion, cord entanglement, and fetal demise. Dichorionic twins are at lower risk as this placentation does not carry the potential for vascular communication and is associated with a lower risk of congenital anomaly. The value of antepartum ultrasound for the identification of fetal congenital malformations has already been described. If two separate placentas are identified or if the fetuses are of different sex, the placentation is dichorionic. A thin, wispy membrane along with a single placenta and same sex fetuses suggest monochorionicity. There are several membrane characteristics that can help differentiate a monochorionic placenta from a fused dichorionic placenta. A “thick” dividing membrane composed of four layers suggests dichorionicity. Another helpful characteristic is the “twin peak” or “lambda sign”. The “twin peak” represents a wedge-shaped projection of placental tissue extending above the fused chorionic surface and separating the diamniotic/dichorionic intertwin membrane. Using these criteria, chorionicity can be predicted accurately in more than 80% to 90% of twin gestations. Determination of chorionicity is most accurate in the first trimester; as pregnancy progresses, the dividing membrane progressively thins and the likelihood of placental fusion increases. Few studies have specifically addressed either the value of serial ultrasound assessment of fetal growth or the appropriate interval for screening. It can be easily inferred, however, that ultrasound has an important role. Intrauterine growth restriction is three times more common among twins compared to singletons and ultrasound is the only modality capable of assessing individual fetal growth. In twin gestations, asymmetric growth restriction becomes increasingly more common as gestational age advances. The presumption is that ultrasound will allow identification of multiples with growth restriction resulting in antenatal surveillance or delivery which may improve perinatal outcome. Evidence of improved outcomes in multiples through the use of ultrasound is limited. In the routine antenatal diagnostic imaging with ultrasound (RADIUS) trial, twins were diagnosed both more consistently and at earlier gestational ages than in the control group receiving selective ultrasound. More than a one third of the triplets in the control group were not diagnosed until after 26 weeks gestation and approximately 10% were not diagnosed until the onset of labor. The RADIUS trial demonstrated a 50% reduction in the incidence of composite adverse perinatal outcomes among the multiple gestations in the routinely screened group. While this reduction was dramatic, it was not statistically significant since the trial was not powered to identify differences in the multiple gestation subgroup. A 10-year study of routine ultrasonography in Europe involving over 22,000 women and 249 multiple gestations also revealed improved perinatal outcomes associated with routine earlier detection by ultrasound. Ultrasound is critical to the management of both twin and triplet gestations. In the second half of gestation, fetal growth should be assessed periodically by serial ultrasound examinations. Most clinicians repeat these ultrasounds on a monthly basis although the appropriate interval between scans has not been determined. This interval can likely be extended if previous examinations suggest appropriate fetal growth, especially in dichorionic gestations.

Selective Multifetal Pregnancy Reduction Gestational age and birth weight at delivery are the two most important factors determining perinatal morbidity and mortality and both are inversely proportional to the number of fetuses present. According to the U.S. Vital Statistics, the average birth weight and gestational age for singletons is 3,358 g at 39.3 weeks, compared to 2,500 g at 36.2 weeks for twins and 1,698 g at 32.2 weeks for triplets. Data from smaller reviews suggest that the average birth weight and gestational age is about 1,455 g at 30.5 weeks for quadruplets and 980 g at 29 weeks for quintuplets. These higher order multiples are at significant risk of delivery prior to viability and for those who reach viability, an appreciable risk of serious long-term morbidity. Expectantly managed triplets and quadruplets have a 20% to 30% risk of delivery prior to 24 weeks and an 8% to 12% risk of delivery between 24 to 28 weeks. Multifetal pregnancy reduction has emerged as a procedure meant to improve the chances of survival and health in higher order multiple gestations. The overall pregnancy loss rate prior to 24 weeks gestation following multifetal pregnancy reduction has dropped from initially reported rates of 15% to 20% to approximately 5% to 8% as experience with the procedure has increased. The risks of pregnancy loss and early preterm birth following multifetal pregnancy reduction have also been described based on the accumulated experience of a consortium of national and international centers. The loss rate prior to 24 weeks is related to both the starting and finishing number of fetuses. A higher starting number is associated with a greater pregnancy loss rate. The loss rate under 24 weeks gestation fell from 15.4% to 11.4%, 7.3%, 4.5%, and 6.2% with six or more, five, four, three, and two fetuses present, respectively, at the start of the procedure. The optimal finishing number of fetuses appears to be twins with loss rates at =24 weeks of 10.9%, compared with 13.7% and 18.0%, respectively, for singletons and triplets. The preferred technique is the transabdominal, ultrasound-guided, fetal intracardiac injection of potassium chloride. It was initially believed that women with quadruplets or more would be ideal candidates for multifetal pregnancy reduction. A meta-analysis of the effect of multifetal pregnancy reduction on pregnancy outcome demonstrated that reduction to twins is associated with longer gestations, higher birth weights, and lower NICU admission rates. The incidence of maternal antenatal hospitalization, preterm labor, and cesarean birth are also reduced although incidences of preeclampsia, gestational diabetes, and other pregnancy complications are not. Somewhat more controversial has been the value of multifetal pregnancy reduction in triplets. Smaller series have not identified an improvement in perinatal mortality in reduced versus nonreduced triplets. Several investigators have reported a significant reduction in early preterm births (24–32 weeks) among triplets reduced to twins compared to nonreduced triplets. Because early preterm birth is a known risk factor for disability, reduction of triplets to twins may reduce the rate of serious morbidity and improve the quality of life for those remaining. Two relatively large databases that have specifically addressed the issue of reduction of triplets to twins have identified better outcomes for the reduced triplets including decreased fetal loss prior to 24 weeks, decreased severe prematurity, increased gestational age at delivery, increased birth weights, decreased perinatal mortality, decreased neonatal respiratory morbidity, and decreased interventricular hemorrhage. It is also important to be aware of the psychological implications for mothers undergoing multifetal pregnancy reduction. Follow-up studies of the emotional responses of women undergoing this procedure revealed that 70% mourned for the reduced fetus(es), but most of the depressive symptoms were mild and lasted only 1 month. For a few however, moderately severe sadness and guilt continued for a longer period. Ultimately, over 90% of the women concluded they would make the same decision again. In addition to multifetal pregnancy reduction, selective fetal termination can sometimes be offered in order to allow a pregnancy to continue following identification of a serious or life-threatening malformation in one twin. The most common indications for selective fetal termination include dizygotic twins discordant for fetal chromosome abnormality, serious fetal structural malformation, or one twin affected by a single gene disorder. Multifetal pregnancy reduction of triplet and higher order multiple gestations is associated with longer gestations, higher birth weights, and lower rates of perinatal morbidity. Multifetal pregnancy reduction of quadruplets or quintuplets would also be associated with significant reductions in perinatal mortality. Multifetal pregnancy reduction should be included in the counseling of all women with triplets and higher order multiples.

Serial Digital Cervical Examination The value of antepartum digital cervical examination lies in its ability to provide ongoing risk assessment. One cervical score is

calculated as follows: cervical length (cm) minus cervical dilation at the internal os (cm). A cervix that is 2 cm long with a closed internal os gives a score at +2. A cervix that is 1 cm long, dilated 1 cm at the internal os gives a score of zero. A cervix that is 1 cm long with an internal os dilated 3 cm gives a score of -2. A cervical score =0 on any single examination predicted preterm labor within 14 days in 69% of those women. When only multiparous women were considered, the predictive value rose to 80%. Newman and Ellings performed weekly digital cervical examinations on 86 twin and 7 triplet gestations as part of routine antepartum surveillance. There was a progressive fall in cervical score throughout the latter half of gestation, most notable after 30 weeks gestation. A cervical score =0 on or before 34 weeks gestation had a positive predictive value of 75% and a four-fold increase relative risk of delivery =37 weeks. The earlier in gestation that a cervical score =0 is detected, the greater the positive predictive value ascribed to it. Only two (2.6%) women experienced spontaneous preterm labor or PPROM within 1 week of having a cervical score greater than 0. A cervical score =0 is a marker of abnormal cervical status and increased preterm delivery risk. Conversely, women who maintain a cervical score greater than 0 are good candidates for continued observation without obstetric intervention. Ideally, these examinations should be done by a consistent examiner on an every 1- to 2-week basis between 24 to 36 weeks gestation. There are no prospective studies or cohort series that demonstrate that antepartum digital cervical examination is associated with obstetric complications or adverse perinatal outcomes.

Corticosteroid Administration Corticosteroids should be administered to women with multiples experiencing preterm labor prior to 34 weeks gestation. The National Institutes of Health also recommends corticosteroid therapy for women with PPROM at less than 30 to 32 weeks gestation. Corticosteroids have been shown to induce fetal lung maturity and reduce perinatal complications in twin gestations as well as singletons. Evaluation of the clinical characteristics and outcomes of twin gestations complicated by PPROM reveals that the nonpresenting twin was more likely to develop hyaline membrane disease, respiratory complications, and require more oxygen therapy than the presenting infant. As a consequence, the nonpresenting twin was at greater risk for infant mortality.

Fetal Surveillance Although no prospective trials exist, all retrospective reviews indicate that the nonstress test has equivalent efficacy in multiples to that seen in singletons. Both the nonstress test and the biophysical profile have been shown to be effective in identifying the growth-retarded multiple, the multiple at risk for hypoxic/asphyxic injury, and the multiple at risk for perinatal mortality. One retrospective cohort study compared 230 twins who received third trimester nonstress tests to 435 twins who did not. Although the differences did not achieve statistical significance, there was only a single intrauterine fetal demise in the nonstress test group compared to nine in the control group. Similar findings have been reported in smaller retrospective studies involving triplet and higher order gestations. While the routine use of antepartum fetal surveillance in uncomplicated multiples has not been shown to be of benefit, surveillance is certainly indicated in those gestations identified as being at higher risk. These would include those with intrauterine growth restriction, abnormal fluid volumes, growth discordance, pregnancy induced hypertension, fetal anomalies, monoamnionicity, or any other pregnancy complications placing one or more of the fetuses at increased risk. Other recommended methods of fetal surveillance include fetal kick counting, although some patients may find it difficult to distinguish the movements of one fetus from those of another. Umbilical cord Doppler velocimetry may be of help in evaluating growth-retarded fetuses. Ultrasonography obviously contributes to both the risk assessment and surveillance of multiple gestations. The limitations of ultrasound for both the diagnosis of intrauterine fetal growth restriction as well as for fetal growth discordance would be the major indication for some clinicians to recommend routine surveillance of all multiples. At present, antepartum fetal surveillance in multiples is recommended in all situations for which one would perform similar surveillance in a singleton pregnancy. Further studies are needed to determine if routine antepartum fetal surveillance provides objective benefit in either twin or triplet gestations.

Controversial Interventions

Reduced Activities/Rest Activity restriction and increased rest at home is commonly recommended for women with multiples although there are no prospective randomized data evaluating this intervention. Existing data are both dated and limited by study design. Studies evaluating the role of prescribed rest in both twin and triplet gestations compared to similar pluralities with unrestricted activities typically date from time periods when the unrestricted multiples were in reality undiagnosed. Maternal rest has been associated with reduced baseline uterine contraction frequency, and restricted activity has been generally accepted as a reasonable approach to the prolongation of pregnancy. Other studies have suggested that the birth weights of both twins or triplets may be increased if reduced activity and home bed rest is introduced in the mid-trimester. Further research is needed to define the impact of restricted activity and rest on both the duration of pregnancy, fetal growth, and the risk of pregnancy-induced hypertension.

Home Uterine Activity Monitoring Few issues are as controversial as home uterine activity monitoring (HUAM). HUAM has been advocated for multiples due to their increased risk of premature labor combined with observations that multiples may be less accurate in the self-detection of their own prelabor uterine activity compared to women with singleton gestations. Prospective randomized trials evaluating the efficacy of HUAM in multiples have provided conflicting results. Dyson and colleagues performed a prospective randomized trial of high-risk pregnancies allocated to one of three interventions. The first group received standard care including instruction in the signs and symptoms of preterm labor. The second group was in the education/palpation group who performed daily HUAM but transmitted the data so that it could not be analyzed. The education/palpation group was contacted at least 5 days per week by a study nurse to elicit their signs and symptoms of preterm labor and record the number of contractions detected by palpation. The third group received the same education/palpation instruction and also underwent daily HUAM, which was interpreted by a study nurse. Of the entire study group, 189 were twin gestations that were analyzed separately. The incidence of preterm birth less than 36 weeks was significantly decreased in the education/palpation group (29.8%; $P < .05$) and markedly decreased in the HUAM group (23.1%; $P < .01$) compared to the standard care group (46.3%). The infants in the HUAM group had the best neonatal outcomes with significant improvements in all measures compared to standard care. The HUAM infants were also significantly less likely to be of very low birth weight, to be admitted to the NICU, and had shorter hospital stays compared to the infants in the education/palpation group. Following their initial publication, Dyson and colleagues embarked on a second prospective, randomized, multicentered trial of HUAM involving 2,422 pregnant women including 844 twins who all received preterm birth prevention education. This educational program was then combined by a random assignment to three subsequent levels of surveillance:

1. Weekly contact by a perinatal nurse.
2. Daily contact by a perinatal nurse.
3. Daily contact with a perinatal nurse and daily HUAM.

Among the twins, there were no differences in the frequency of preterm birth less than 35 weeks gestation between those women receiving weekly contact (22%), daily contact (24%), or HUAM (24%). At the time that preterm labor was diagnosed, 75% of the weekly contact patients, 76% of the daily contact patients, and 80% of the HUAM patients were =2 cm with no differences in the mean cervical dilation. There was also no difference in the frequency of low–birth-weight or very low–birth-weight (VLBW) deliveries, mean number of days gained with tocolysis, or number of unscheduled visits. HUAM in twins has been associated with improved outcomes in two prospective, randomized trials that included a standard care control group. No benefit could be ascribed to HUAM when the comparison group received intensive education and was provided with frequent perinatal nursing contact. At present, the benefits of HUAM in twins remain controversial and its use should be highly individualized. There are no prospective data addressing the use of HUAM in triplets.

Endovaginal Ultrasound Cervical Length Measurements Endovaginal sonography to measure cervical length has been studied to determine its predictive value for spontaneous preterm delivery in twin gestations. In a large, multicentered study sponsored by the NICHD (National Institute of Child Health and Human Development), predictors of preterm delivery were evaluated in both singleton and twin gestations. A cervical length of =25 mm was significantly more common in twin gestations compared to singletons at both 24 and 28 weeks. Of all the potential predictors of preterm delivery, a cervical length =25 mm at 24 weeks gestation was the best predictor of preterm labor before 32, 35, or 37 weeks gestation in twin pregnancies. Shortened cervical length measurements by endovaginal sonography correlate with preterm delivery risk in twin gestations. Alternatively, normal mid-trimester cervical length measurements are associated with low rates of early preterm delivery. Again, there is no evidence that endovaginal sonography improves outcome, nor have there been any successful intervention trials based on endovaginal cervical length measurements. Currently there is insufficient evidence to recommend cerclage placement for an abnormally short cervix, although this is clearly an area for future investigation.

Cervical/Vaginal Fetal Fibronectin Fetal fibronectin is a high–molecular-weight, extracellular matrix glycoprotein that is normally found in amniotic fluid, fetal membranes, and placental tissues. Observational trials involving singleton gestations have demonstrated that cervical/vaginal fetal fibronectin at concentrations over 50 ng per mL between 21 to 37 weeks gestation is predictive of impending preterm delivery. Several observational trials have specifically investigated the predictive capability of cervical/vaginal fetal fibronectin in multiple gestations. In the NICHD Preterm Prediction Study, 147 twins underwent serial assessment for cervical/vaginal fetal fibronectin in addition to endovaginal ultrasound cervical length measurements. Positive fetal fibronectin results at 28 and 30 weeks gestation were associated with an increased risk of delivery prior to 32 weeks. However, the association of fetal fibronectin with preterm delivery was no longer significant after controlling for cervical length with logistic regression analysis. In one study of asymptomatic women with twins, fetal fibronectin in at least one sample was associated with a relative risk of 2.0 for birth prior to 35 weeks, and a relative risk of 18.0 for birth prior to 35 weeks if all samples were positive. A positive fetal fibronectin test at 24 weeks gestation had a sensitivity of 37%, a specificity of 91%, a positive predictive value of 54%, and a negative predictive value of 84% for delivery less than 35 weeks. Fetal fibronectin in cervical/vaginal secretions in the late second and early third trimester is associated with an increased risk of preterm birth in multiples. Data are conflicting as to whether fetal fibronectin has predictive value in addition to endovaginal cervical length measurements. Alterations in clinical management based on fetal fibronectin results have not yet been evaluated, and improved pregnancy outcomes have not yet been demonstrated.

Tocolytic Therapy Tocolytic therapy has generally been found to be of limited benefit in terms of prolonging pregnancy. In most investigations, singleton or multiple, tocolytic therapy can only be relied on to provide a short-term prolongation of pregnancy. Even a short-term prolongation, however, may be beneficial in terms of allowing tertiary care transport, administration of corticosteroids for enhancement of fetal lung maturity, and in some cases, a modest extension of gestation. Tocolytic use in multiples must be accompanied by very careful monitoring of both maternal and fetal condition. Women pregnant with multiples are at higher risk for a number of tocolytic-related complications, most notably pulmonary edema. Contributing to this risk is a proportionately increased maternal blood volume, lower colloid oncotic pressure, and anemia in many cases. Tocolytic factors that increase the risk of pulmonary edema include the use of ß-adrenergic agents and prolonging tocolytic therapy for more than 24 hours. Both myocardial ischemia and cardiac arrhythmias have also been reported as a rare consequence of tocolytic therapy. Beta-adrenergic agents are also known to increase maternal glucose levels, aggravating either overt or gestational diabetes of pregnancy.

Nonbeneficial Interventions

Prophylactic Cerclage Two prospective randomized trials have assessed the value of prophylactic cervical cerclage in twin pregnancies and neither revealed any

improvement in preterm birth rate or perinatal mortality. Unfortunately both studies lack substantial power due to small sample sizes. The two studies also suggest that cerclage imparts some risk, specifically an increased risk of maternal infection and PPROM. These findings are also supported by several retrospective studies, none of which reveal any improvement in mean gestational age at delivery or the proportion of preterm deliveries. In triplet pregnancies, the literature consists of small retrospective studies. One study reported a benefit, whereas two others found none. Sufficient evidence is lacking to support the elective placement of cervical cerclage in either twin or triplet pregnancies. Cerclage should be reserved for patients with a significant clinical suspicion of cervical incompetence. While a shortened endovaginal cervical length measurement correlates with preterm delivery risk in twins, there is insufficient evidence at present to conclude that cerclage placement for an abnormally short cervix will improve outcome, although this is clearly an area for future investigation.

Prophylactic Tocolysis Prescribing prophylactic oral ß-mimetics in twins to reduce the risk of preterm birth has been evaluated in seven prospective randomized trials. Evaluation of these trials is difficult due to their heterogenicity. While all studies used oral ß-mimetic agents, a variety of different drugs were used as well as various dosages and gestational ages at which the medications were started. Despite this heterogeneity, a meta-analysis of these trials failed to show any consistent effect on the risk of preterm birth, birth weight, or neonatal mortality. Other tocolytic agents, such as prostaglandin synthetase inhibitors, calcium channel blockers, and oral magnesium sulfate have not been studied in multiples. The potential risks of prolonged fetal exposure to ß-mimetic agents or other tocolytics are not completely known. Little evidence of efficacy of prophylactic tocolysis in triplets exists, although these data are obtained solely from retrospective review. The lack of efficacy in these retrospective studies may be biased if prophylactic tocolysis was used more often in triplets perceived to be at greater risk. The prophylactic use of oral tocolytic agents has not been associated with improved outcome or meaningful prolongation of pregnancy in either twin or triplet gestations.

Routine Hospitalization Four prospective randomized trials of hospitalized bed rest for women with an uncomplicated twin pregnancy have been conducted. The *Cochrane Database of Systematic Reviews* of these trials showed that neither stillbirth, neonatal death, or preterm birth were reduced by elective hospitalized bed rest (Fig. 14.4). In fact, significantly more women delivered VLBW infants and infants prior to 34 weeks gestation in the hospitalized cohort. This was also associated with an increased risk of early neonatal demise among the women routinely hospitalized with uncomplicated twins. Those patients at hospitalized bed rest did experience a lower frequency of maternal hypertension. One further study evaluated elective hospitalization using a prospective sequential study design. A policy of elective hospitalization until 34 weeks was used between 1983 and 1985 encompassing 134 twin deliveries, followed by a policy of outpatient management between 1985 and 1987 encompassing 177 twin deliveries. There were no differences in prematurity or perinatal morbidity between the two groups. There was a higher mortality rate and significantly higher costs associated with elective hospitalization. A final study by Crowther in 1989 prospectively randomized 139 women with twins whose pregnancies were complicated by preterm cervical dilation (cervical score -2 at or before 34 weeks gestation). Despite the higher risk nature of this cohort, there were no differences seen in the risk of preterm birth, perinatal mortality, fetal growth, or other neonatal outcomes.

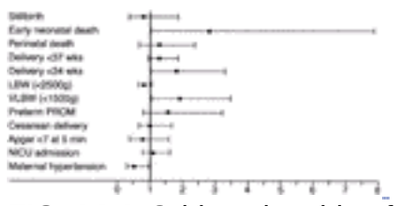

FIG. 14.4. Odds ratio table of the effect of routine hospitalization for bed rest on obstetric outcomes among women with uncomplicated twin pregnancies. (Adapted from Crowther CA. Hospitalization for bedrest in multiple pregnancy. In Neilson JP, Crowther CA, Hodnett ED, et al (eds). Pregnancy and childbirth module. *Cochrane Database of Systematic Reviews* [updated 03 June 1997] 1997:3.)

In triplets, there is a single small prospective trial involving 19 women randomized at 29 weeks gestation. The hospitalized group had a longer duration of pregnancy, fewer VLBW infants, and decreased neonatal morbidity. However due to the small sample size, the observed differences were compatible with chance variation. A retrospective sequential cohort study of 34 triplets managed by elective hospitalization at 24 weeks between 1985 and 1993 were compared to 32 triplets managed by bed rest at home between 1993 and 1996. Routine hospitalization increased gestational age at delivery by one week although this difference was not statistically significant. There is no obvious benefit of routine hospitalization in twin gestations. In triplet gestations, there is a single prospective randomized trial, which suggested improved outcome with routine hospitalization but included too few patients to draw definitive conclusions. Definitive benefits will be necessary to outweigh the social and financial costs associated with routine hospitalization.

INTRAPARTUM MANAGEMENT

Safe and successful intrapartum management of multiples requires attention to several important principles necessary to their care (Table 14.4). Most important is the presence of experienced and skilled obstetric, pediatric, anesthesia, and nursing personnel. Intrapartum management plans for twin gestations will depend to a great degree on their relative presentations. During labor, both fetuses should be continuously monitored as multiple gestations are at increased risk for several intrapartum complications which may manifest as abnormal fetal heart rate tracings. Ultrasonography should be available to ascertain presentation, estimate relative fetal weights, and to assist with fetal assessment during the interval between deliveries. When vaginal delivery is attempted, the delivery room should be doubly set up for a possible emergency cesarean section including immediate availability of anesthetic and neonatal services. Due to the relatively frequent need for emergency operative or manipulative obstetric procedures, continuous epidural anesthesia is preferred. Familiarity on the part of the obstetric attendants with the use of both obstetric forceps (Piper forceps if breech delivery is planned) and vacuum extractor is recommended. A variety of medications should also be available in the delivery suite including a premixed oxytocin infusion for stimulation of labor since uterine inertia is frequently encountered following delivery of the first twin. Tocolytic agents such as subcutaneous terbutaline and intravenous nitroglycerine should be available for uterine relaxation. Women with multiple gestations also experience an increased mean blood loss with delivery, an increased cesarean section rate, and are at increased risk of postpartum uterine atony. As a consequence, uterotonic agents such as methylergonovine maleate or 15-methyl prostaglandin F_2 should be immediately accessible and the availability of blood products should be insured.

Presence of skilled obstetric attendants for labor and delivery
Sufficient nursing and neonatal care personnel
Dual monitoring cardiotocograph
Intrapartum ultrasonic scanning capability
Intravenous access (16–18 gauge)
Premixed oxytocin infusion
Nitroglycerin or terbutaline for uterine relaxation
Methergine or 15-methyl $PGF_{2\alpha}$ to induce uterine contractions
Obstetric forceps and vacuum extractor available
Immediate availability of blood and blood products
Anesthesiologist available at delivery and capability for emergency cesarean

$PGF_{2\alpha}$, prostaglandin F2-alpha.

TABLE 14.4. *Principles of intrapartum care for the multiple gestation*

Timing of Delivery

The ideal time for delivery of uncomplicated multiple gestations is uncertain but an important issue in terms of optimizing perinatal outcome. A retrospective population-based analysis of all live births and fetal deaths in the United States from 1983 to 1988 revealed that the lowest fetal death rate per 1,000 conceptions for singletons was 0.9 at 3,700 to 4,000 g between 40 to 41 weeks. The lowest fetal death rate for twins was 3.3 per 1,000 conceptions at 2,500 to 2,800 g at 36 to 37 weeks gestation. The lowest fetal mortality rate for triplets was 5.2 per 1,000 conceptions at 1,900 to 2,200 g at 34 to 35 weeks gestation. A large retrospective, population-based study of almost 89,000 multifetal pregnancies and over 6 million singleton pregnancies delivered between 1989 and 1993 in Japan revealed similar findings. The incidence of stillbirth and early neonatal death gradually declined until 37 to 38 weeks gestation for multiples and increased thereafter. In singletons, the same parameters declined until 39 weeks before increasing. The lowest incidence of perinatal death (stillbirth plus early neonatal death) for multiples occurred at 38 weeks gestation. Most of the excess fetal mortality in twins was confined to infants with birth weights less than the 10th percentile. By 38 weeks gestation, overt asymmetric growth restriction encompasses nearly half of twin pregnancies and an even larger percentage of triplets. Obviously, these population-based analyses should be supplemented by clinical studies determining the neonatal and post-neonatal risks of prematurity-related morbidity among multiples born during these presumed optimal birth-weight and gestational age windows (i.e., 2,500 to 2,800 g at 36 to 38 weeks for twins and 1,900 to 2,200 g at 34 to 36 weeks for triplets).

Available data do not support the prolongation of a twin or triplet pregnancy beyond 38 or 36 weeks, respectively, in hopes of improving outcome. Beyond these points, multiples begin to experience increased combined fetal and neonatal morbidity and mortality primarily related to growth restriction. To safely prolong pregnancy requires reliable ultrasonographic evidence of adequate fetal growth, normal amniotic fluid volumes, and reassuring fetal testing, as well as a stable maternal condition. The identification of intrauterine growth restriction, significant discordance, oligohydramnios, maternal preeclampsia, or any other significant maternal–fetal complication at these gestational age limits should be a specific indication for delivery, which, in turn, will improve perinatal outcome. Unfortunately, this presumption has not been subjected to prospective randomized analysis. In the absence of any of these maternal or fetal complications and with reassuring fetal testing, there is no contraindication to continued observation beyond 38 weeks for twins or beyond 36 weeks for triplets while awaiting spontaneous labor or a more favorable cervix. Most agree that there are little data to suggest any value to prolonging a multiple gestation beyond 40 weeks.

Route of Delivery

The preferred route of delivery for multiples is controversial, particularly for the vertex/nonvertex presenting twins. The preferred route of delivery is usually determined based on presentation, which for twins is generally categorized into three large groups:

1. Twin A vertex, twin B vertex
2. Twin A vertex, twin B nonvertex
3. Twin A nonvertex.

Twin A Vertex/Twin B Vertex Approximately 40% of twin gestations will present with both in a vertex presentation. Vaginal delivery should be anticipated for this group of twins with high likelihood of success anticipated. More than 80% of vertex/vertex presenting twin gestations are successfully delivered vaginally. The presentation of the second twin should be reconfirmed following delivery of the first as a change in the presentation may occur in as many as 20% of cases.
Twin A Vertex/Twin B Nonvertex Opinions diverge regarding the optimal mode of delivery for vertex/nonvertex presenting twins, which represent another 40% of twins in labor. Reports of depressed Apgar scores and increased perinatal mortality during the 1970s and 1980s led to cesarean delivery being advocated by some whenever the second twin was in a nonvertex presentation. Since the early 1980s, however, there has been a significant accumulation of primarily observational, nonrandomized clinical experiences which have not found an increased risk of adverse neonatal outcome when the nonvertex second twin is delivered vaginally. Only one prospective randomized trial (by Rabinovici and colleagues) has been conducted. Sixty women in labor with twins at 35 to 41 weeks in which the first twin was vertex and the second a nonvertex were enrolled. Of the 33 women assigned to vaginal delivery, two underwent cesarean deliveries, four aftercoming twins spontaneously converted to vertex, 14 had assisted breech extraction, and 13 had total breech extractions. There were no differences between the groups in Apgar scores or neonatal morbidity and there was no birth trauma, stillbirth, or early neonatal death in either group. Women assigned to cesarean delivery had a significantly higher incidence of febrile morbidity and a trend toward greater receipt of general anesthesia (Fig. 14.5).

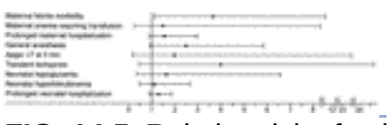

FIG. 14.5. Relative risk of selected obstetrical outcomes and the effect of cesarean delivery for the second twin. (Adapted from Rabinovici J, et al. Randomized management of the second nonvertex twin: vaginal delivery or cesarean section. *Am J Obstet Gynecol* 1987;156:52–56.)

Supporting the Rabinovici trial, there have been at least ten observational studies that have looked at the outcomes for the nonvertex second twin. Although each study is limited by its lack of prospective randomization, and in some cases by size, none have found that the nonvertex second twin was disadvantaged by vaginal delivery, especially if the birth weight was greater than 1,500 g. Maternal morbidity is routinely higher and length of stay longer for the groups undergoing cesarean delivery. Although not specifically studied, most clinicians would not recommend attempted breech extraction if the second twin was anticipated to be significantly larger (>500 g) than the presenting twin. Vaginal delivery of the nonvertex second twin by breech extraction or assisted breech delivery appears to be the best approach for infants over 1,500 g. There is no evidence that the increased maternal morbidity associated with routine cesarean delivery is offset by improved neonatal outcome. A policy of routine cesarean whenever the second twin is not presenting as a vertex can be expected to increase maternal morbidity and increase the need for general anesthesia without beneficial effects in terms of maternal or infant outcome. Recommendations for route of delivery for a nonvertex twin B whose birth weight is estimated to be less than 1,500 g is not so clear. A population-based study in Sweden encompassing 10 years of recorded deliveries allowed an assessment of 862 infants weighing less than 1,500 g delivered from 539 twin pairs. There was no significant difference in intrapartum or neonatal mortality related to the mode of delivery nor was there a difference of the subset of nonvertex second twins. Zhang and colleagues used a similar methodology in the United States but found somewhat different results. After controlling for maternal characteristics with multiple logistic regression, cesarean delivery was associated with a reduction in neonatal and infant death rates among all infants with a birth weight less than 1,000 g. The benefit of cesarean delivery was found primarily among second twins, whether vertex or nonvertex. Decisions on cesarean birth versus vaginal delivery for nonvertex second twins less than 1,500 g should be based on the specific clinical situation and the experience of the staff involved. In the absence of an experienced operator, cesarean delivery should be primarily performed. External cephalic version for the nonvertex second twin after delivery of the first has been described. This approach has been popular among physicians less comfortable with breech extraction. Although no prospective trials have been performed comparing the efficacy and safety of second twin version versus breech extraction, several retrospective studies have addressed this issue. Chauhan and co-workers reviewed this literature assembling 118 cases of external cephalic version of the nonvertex second twin. They found that despite a high rate of successful version, the rate of successful vaginal delivery of the second twin was highly variable between reports (46% to 80%) with an overall success rate of 58%. There was a combined complication rate of 10% including six cord prolapses, four episodes of fetal distress, one abruption, and one compound presentation. By way of comparison, the authors reviewed 683 second twin breech extractions in 11 published reports and reported a successful vaginal delivery rate of 98% with an overall complication rate of only 1%, which translated into three fractured humeri, two episodes of fetal distress, and two cord prolapses.
Twin A Nonvertex In approximately 20% of cases twin A presents as a nonvertex. Vaginal delivery of twins with a nonvertex presentation of twin A is problematic as little data exist evaluating its safety. Older retrospective reviews suggest an increased risk of perinatal loss when twin A delivers as a breech although other relatively small retrospective reviews have found no significance difference in perinatal outcome between breech/vertex twins delivered vaginally and similar groups delivered abdominally. For twins presenting breech/vertex, the possibility of interlocking exists. While this complication is extremely rare, it is typically catastrophic. While not so dramatic, fetal collision may also lead to cesarean delivery due to failure of the presenting breech to descend. When the first twin is presenting breech, the most commonly employed mode of delivery is cesarean. Vaginal delivery may be an option based on the experience of the staff and the capability for emergency cesarean delivery.
Triplets and Higher Order Multiples Cesarean is the most commonly recommended mode of delivery for triplets. A nationwide review of triplet births between 1985 and 1988 revealed that 94% of the deliveries were by cesarean, 4.5% were vaginal, and 1.5% were a combined vaginal/abdominal approach. Triplets and higher order multiples are at significant risk for prematurity, growth retardation, and malpresentation, and as a result, most clinicians prefer to deliver these pregnancies by cesarean section rather than attempt a vaginal delivery, which may require complex manipulation of preterm infants. Successful vaginal delivery of triplets has been reported in several small series without any apparent compromise of neonatal outcome. If a vaginal delivery is planned, it is imperative that an experienced obstetric team be available, malpresentation anticipated, and preparations made for emergency cesarean delivery if necessary. It would seem that optimal cases would be those with triplets estimated to weigh more than 1,500 g each and with at least the first two triplets in a vertex presentation.

Interval Between Deliveries

Previous data have suggested that time intervals between twin deliveries of more than 30 minutes would be associated with compromised outcomes. With the development of continuous electronic fetal monitoring and the intrapartum use of real-time ultrasonography, this no longer appears to be the case. Much of the data suggesting higher perinatal morbidity and mortality associated with long delays between deliveries are from an era when the presence of the second twin was frequently not apparent until after delivery of the first. Delays of more than one hour have not been associated with adverse outcomes for the second twin as long as continuous fetal heart rate monitoring is employed.

In some cases, there will be deterioration of the fetal condition following delivery of twin A. Both premature placental separation and prolapse of the umbilical cord are complications known to occur with increased frequency following the delivery of the first twin. Distress of the second twin should usually be managed by immediate cesarean or operative vaginal delivery. Internal podalic version and breech extraction should only be considered when emergency delivery is mandated and cesarean delivery is not immediately available. There are no current series documenting the safety of internal podalic version in cases of fetal distress. Due to the ever-present possibility of intrapartum fetal distress, the capability of immediate cesarean delivery should be considered the standard of care for multiples.

In the absence of any of the aforementioned complications, labor management for the second twin can be fairly aggressive. There is often a period of hypocontractility following delivery of the first twin. If labor has not resumed within a short period of time following delivery of twin A, a previously prepared oxytocin infusion can be started and the dosage escalated in relatively rapid fashion until adequate uterine contractions are achieved. Once effective uterine contractions are reestablished, the woman is encouraged to bear down in order to achieve further descent. Once the vertex is in the pelvic inlet, amniotomy can be performed during a contraction with moderate fundal pressure to help fix the vertex within the pelvis. The amniotic sac can be ruptured grossly if the fetal head is well applied to the cervix or leaked with a spinal needle if the vertex is not well applied.

Delayed Interval Delivery Due to an increased risk of both extremely preterm if not previable delivery, multiple gestations occasionally present the opportunity for delayed interval delivery. The optimal situation occurs in a diamniotic/dichorionic twin gestation where the loss of the presenting fetus is the consequence of extrusion following either PPROM or true cervical incompetence. Other reported cases in which delayed interval delivery has been successfully employed have been with separate implantations associated with müllerian anomalies, such as didelphic uterus. Less favorable circumstances would include those deliveries complicated by advanced preterm labor or vaginal bleeding suggestive of placental abruption. Contraindications to delayed interval delivery include significant hemorrhage, hemodynamic instability, intraamniotic infection, and monochorionic placentation. Although life-saving prolongation of pregnancy has been reported in case reports and small series, the patient should be informed of a relatively high failure rate associated with the procedure and risks including intrauterine infection, maternal sepsis, hemorrhage, and prolonged hospitalization. Successful delayed interval delivery has been achieved without the use of a rescue cerclage. However, based on available case reports, adjunctive rescue cerclage appears to offer a better chance of greatly prolonging the interval between deliveries. Most protocols make use of aggressive perioperative tocolysis and broad-spectrum antibiotic coverage, although there are no data to establish either the necessity or efficacy of either of these interventions in

this circumstance. Specific pathogens such as gonorrhea, chlamydia, and group B streptococci should be identified and treated. Following delivery of the first fetus, the umbilical cord is tied, cut short, and allowed to retract back into the uterus. At that point, most clinicians place a 5-mm Merseline band using the McDonald technique as a rescue cerclage procedure. Tocolytic therapy, antibiotic coverage, and hospitalized observation are continued for variable periods of time along with intensive maternal and fetal surveillance. At its most successful, delayed interval delivery has allowed prolongation of pregnancy from a previable stage of maturation to well within the third trimester, if not term.

POSTPARTUM MANAGEMENT

Because of the potential risk of uterine atony and postpartum hemorrhage, the other should be closely monitored during the initial hours after delivery. Adequate oxytocin should be administered and the uterine fundus should be regularly assessed to ensure that appropriate uterine tone is maintained. Lactation consultation may be useful to assist the mother in initiating breast-feeding of her twins or triplets. The maternal task of caring for multiple infants is often overwhelming. Follow-up and support for the mother in the early weeks after delivery are important, especially if the neonates require intensive care unit admission. Postpartum depression is likely more common in women delivering multiples and surveillance for this important complication should be ongoing.

SUMMARY POINTS

- Although multiples account for only a small percentage of all live births, they are responsible for a disproportionate share of all perinatal morbidity and mortality suffered in the United States.
- The dramatic increase in the frequency of dizygotic twinning in the United States is due, in part, to a national trend toward delayed childbearing but the majority is a consequence of ovulation induction therapy and recently developed assisted reproductive technologies.
- Women pregnant with multiples are more likely to be hospitalized antenatally for both an increased frequency and severity of pregnancy-related complications including preterm labor, PPROM, maternal anemia, placental abruption, preeclampsia, and urinary tract infections.
- The factors strongly correlated with both length of gestation and birth weight in multiples are maternal height, pregravid body mass index, maternal fat deposition, and weight gain, especially early weight gain in underweight women.
- Data do not support prolongation of a twin or triplet pregnancy beyond 38 or 36 weeks, respectively, due to the increased combined fetal and neonatal morbidity and mortality associated primarily with high rates of intrauterine growth restriction.
- There is no evidence that the increased maternal morbidity associated with routine cesarean delivery is offset by improved neonatal outcomes for the nonvertex second twin over 1,500 g; therefore, vaginal delivery by breech extraction or assisted breech delivery is the preferred method of delivery in these cases.

INTRODUCTION

The discovery of insulin in 1921 brought about a significant improvement in the overall outlook for women with diabetes and their reproductive potential. The incidence of both maternal and perinatal mortality has decreased markedly over the past 80-plus years as a result of this discovery as well as a multitude of other scientific advances, including fetal heart rate and blood glucose monitoring and neonatal intensive care. However, despite these advances, women with diabetes and their offspring remain at increased risk for a number of complications. The increased morbidity is directly related to the severity of maternal hyperglycemia. Therefore, the management goal of these pregnancies is strict glycemic control prior to conception and throughout gestation. This is best accomplished through the provision of multidisciplinary team care and targeted self-management education.

FUEL METABOLISM

Pregnancy is recognized as having a profound effect on maternal fuel metabolism. These pregnancy-related alterations in maternal metabolism are necessary to meet the demands of the developing fetus. Studies in lean healthy pregnant women have demonstrated a greater than normal sensitivity to the blood glucose–lowering effect of exogenously administered insulin during early pregnancy as compared with late gestation. In addition, insulin responses to an oral glucose load have been demonstrated to be increased in early pregnancy as compared with the nonpregnant state in the same glucose-tolerant women.

These increases in serum insulin levels and insulin sensitivity produce a milieu during early gestation that favors maternal fat accumulation in preparation for the rise in energy requirements associated with the rapid growth of the fetal–placental unit during late pregnancy. Moreover, the increases in plasma concentrations of estrogen, progestins, and cortisol observed during early pregnancy are also likely to stimulate fat accumulation.

Late gestation is characterized by accelerated growth of the fetoplacental unit, rising plasma concentrations of several diabetogenic hormones including human placental lactogen and estrogens, and increasing insulin resistance. Several investigators have demonstrated increased first- and second-phase insulin release during late gestation, as well as increased plasma insulin-to-glucose ratios. Studies using the euglycemic-hyperinsulinemic clamp and minimal model techniques have reported that peripheral insulin sensitivity is reduced by 33% to 50% during late gestation. During the third trimester of pregnancy, insulin-stimulated carbohydrate oxidation is reduced out of proportion to the decrease observed in insulin-stimulated glucose uptake. Endogenous glucose production is also significantly less inhibited during the third trimester when compared with either the second trimester or the nonpregnant state. Thus, there appears to be general agreement that the second half of pregnancy is associated with increasing insulin resistance, both in the periphery (muscle) and at the hepatic level.

The cause or causes of the increased insulin resistance during late pregnancy are not entirely clear. The parallel development of insulin resistance and increases in blood levels of human placental lactogen, a hormone with strong lipolytic and anti-insulin action, suggests that human placental lactogen and perhaps other diabetogenic hormones, including cortisol, progesterone, and estrogens, may be responsible for much of the observed insulin resistance. In addition, there is also evidence to support a role for plasma free fatty acids in the development of insulin resistance during late pregnancy.

The development of peripheral and hepatic insulin resistance after midpregnancy can be seen as an effort of the mother to adapt to the fuel needs of the rapidly growing fetus. During the third trimester of pregnancy, glucose uptake by the fetus has been estimated to be approximately 33 µmol/kg per minute. To satisfy this additional need, peripheral insulin resistance increases in pregnant women, thus reducing maternal glucose utilization. In addition, hepatic insulin resistance increases, which increases hepatic glucose production. Moreover, by decreasing carbohydrate oxidation, much of the glucose entering muscle is shunted into alanine or lactate, which can be recycled into glucose.

CLASSIFYING DIABETES

Diabetes mellitus generally is classified into the following categories: type 1 or insulin-dependent diabetes mellitus, type 2 or non–insulin-dependent diabetes mellitus, and gestational diabetes mellitus (GDM). Approximately 10% of all individuals with diabetes mellitus have type 1 diabetes. Beta-cell destruction, with resulting insulin deficiency, is the hallmark of this disorder. Onset is generally before the age of 30 and, as a result, this type of diabetes frequently is encountered in women of childbearing age. It is estimated that type 1 diabetes complicates approximately 0.2% of all pregnancies in the United States annually.

Type 2 diabetes is the most common form of the disease, affecting nearly 90% of all individuals with diabetes. Type 2 diabetes is characterized by defects in both insulin action and secretion. It typically is seen in individuals over the age of 40 and, therefore, in the past was felt to be uncommon in women of childbearing age. However, the incidence of type 2 diabetes has been increasing steadily among younger individuals, and data from the National Maternal and Infant Health Survey indicate that type 2 complicates 0.3% of all pregnancies in the United States. GDM is defined as carbohydrate intolerance of variable severity, with onset or first recognition during the index pregnancy.

If the abnormality in glucose tolerance persists after pregnancy, the patient's diagnosis is revised to type 1, type 2, or impaired glucose tolerance.

GESTATIONAL DIABETES MELLITUS

Gestational diabetes is a common problem, complicating approximately 2% to 5% of all pregnancies in the United States. The likelihood of developing gestational diabetes is increased significantly among certain subgroups, and these include individuals with a positive family history of type 2 diabetes, advancing maternal age, obesity, and nonwhite ethnicity. Excess risks for both gestational diabetes and impaired glucose tolerance have been demonstrated in African American, Hispanic, and Native American women, as well as in women from the Indian subcontinent and the Middle East.

Screening and Diagnosis for Gestational Diabetes

Screening of pregnant women for gestational diabetes remains a topic of great debate both in this country and throughout the world. In 1998, the Fourth International Workshop-Conference on GDM acknowledged that there were certain populations of low-risk women in whom it may not be cost effective to screen routinely for GDM. This low-risk group includes women who were not members of ethnic minorities, were less than 25 years of age, had no first-degree relatives with diabetes, and are of normal body weight. Although selective screening may be appropriate in certain populations with a low prevalence of type 2 diabetes, universal screening is still advocated in most centers. The American College of Obstetricians and Gynecologists recommends that all pregnant patients be screened for GDM whether by patient's history, clinical risk factors, or a laboratory screening test. However, the American, Canadian, and British diabetes associations recommend biochemical screening.

Screening should be performed between weeks 24 and 28 of gestation, although women with significant risk factors may benefit from being screened earlier in pregnancy. A 50-gram glucose challenge test is performed without regard to the time of day or interval since the last meal. A venous plasma glucose level is measured 1 hour later, with a value of =140 mg/dL indicating the need for a 3-hour, 100-gram oral glucose tolerance test (OGTT). However, lowering the cut-off value to 130 to 135 mg/dL increases the yield of cases of gestational diabetes by 10%. The use of either threshold is acceptable.

The OGTT is performed after an overnight fast and 3 days of an unrestricted carbohydrate diet. A fasting blood glucose level is drawn, and a 100-gram glucose load is then administered. Plasma glucose levels are drawn 1, 2, and 3 hours following ingestion of the glucose solution. Diagnosis requires that at least two of the four glucose levels of the OGTT meet or exceed the upper limits of normal. Two sets of diagnostic criteria are in use in the United States: those of the National Diabetes Data Group and those of Carpenter and Coustan. The Fourth International Workshop-Conference participants believed there was sufficient evidence to suggest that the Carpenter-Coustan criteria, with its lower cut-off values, more accurately predict neonatal risks and have recommended the use of these criteria. American College of Obstetricians and Gynecologists guidelines support the use of either set of criteria.

In addition, the Fourth International Workshop-Conference acknowledged an alterative to the two-step screening-diagnostic procedure described above. The evaluation of glucose intolerance during pregnancy may be made using a one-step approach or 2-hour 75-gram OGTT. This approach is considered most applicable in high-risk populations. Studies are underway to establish the relationships among the various diagnostic criteria and perinatal outcomes in these pregnancies.

Women with gestational diabetes should be evaluated at the first postpartum visit by a 2-hour OGTT using a 75-gram load. More than 90% of women will convert to normal glucose tolerance following delivery. However, studies indicate that the risk for overt diabetes may be as high as 20% to 50% in this population. Long-term annual follow-up is therefore indicated. GDM is greatly influenced by body weight, with the highest rate occurring in obese patients. Women with a history of GDM should be counseled regarding the use of lifestyle changes such as weight loss and regular exercise to reduce this risk.

PREGNANCY COMPLICATIONS

Despite improvements in pregnancy outcomes, women with both gestational and pregestational diabetes are at greater risk for a number of pregnancy-related complications (Table 15.1). These include preterm labor, infectious morbidities, hydramnios, and hypertensive disorders. In addition, multiple investigators have reported a significant association between poor glycemic control and hypertensive disorders, preterm labor, and infections. Furthermore, women with pregestational diabetes are at risk for the acute complications of diabetes because of the metabolic alterations associated with pregnancy, as well as the effects of strict glycemic control. The vascular alterations associated with long-term diabetes also contribute to the higher morbidity rates observed in women with diabetes. Both diabetic nephropathy and retinopathy may progress during pregnancy and should be monitored closely.

TABLE 15.1. *Pregnancy complications in diabetes*

Current data would seem to indicate that pregnancy is an independent risk factor for diabetic retinopathy. Hypertension, poor control early in pregnancy, and rapid normalization all appear to be associated with the potential to accelerate retinal deterioration. Furthermore, women with more advanced forms of retinopathy and a longer duration of diabetes are at highest risk for progression. All women who have had type 1 diabetes for 5 years or more or type 2 diabetes at diagnosis require a thorough dilated ophthalmologic evaluation. This may necessitate preconception fluorescein angiography, because dye studies generally are contraindicated during pregnancy. These evaluations ideally should be completed prior to attempting conception. Laser therapy, if indicated, also needs to be completed prior to conception.

In contrast, most studies of the effects of pregnancy on diabetic nephropathy have suggested that pregnancy is not associated with either the development or progression of preexisting nephropathy in women with mild to moderate disease. However, diabetic nephropathy is the complication of diabetes most likely to affect pregnancy outcomes. There are increased risks for pregnancy-induced hypertension or a progression of already existing hypertension, intrauterine growth retardation resulting in small-for-gestational-age infants, preterm deliveries secondary to fetal distress, and a ten-fold increase in the incidence of stillbirth over women with diabetes but without nephropathy. Preeclampsia is the most frequent, serious complication of maternal nephropathy, with implications for both mother and fetus. Close monitoring of blood pressure, with addition or adjustment of antihypertensive agents as needed, is recommended. The drugs of choice are methyldopa, calcium channel blockers, and ß blockers. Select calcium channel inhibitors, such as diltiazem, induce mild reductions in blood pressure but have a potent effect on decreasing excess protein excretion.

NEONATAL COMPLICATIONS

The offspring of women with diabetes remain at increased risk for a number of complications, which include congenital anomalies, fetal macrosomia, respiratory distress syndrome (RDS), metabolic abnormalities, as well as long-term sequelae (see Table 15.1).

Perinatal Mortality

The two major causes of perinatal mortality are unexplained fetal death and congenital malformations. The causes of unexpected death are not well understood. In animal models sustained hyperglycemia has been associated with increased insulin secretion, elevated fetal oxygen consumption, acidosis, and death. It has been postulated that fetal polycythemia and increased platelet aggregation could explain the increased incidence of intravascular thrombosis in infants of diabetic mothers and that thrombotic episodes could be the underlying cause for late unexplained intrauterine deaths.

Approximately 40% of perinatal deaths that occur among infants of women with diabetes can be attributed to malformations. Diabetes mellitus is one of the most common maternal conditions that results in anomalous offspring. The frequency of major congenital anomalies is increased two-fold to three-fold over that of the general population. Great diversity is seen in the types of malformations associated with insulin-dependent diabetes mellitus. The most frequent types of malformations involve the central nervous system, cardiovascular, gastrointestinal, genitourinary, and skeletal systems, with cardiac malformations being the most common.

The defects most often associated with diabetes occur during organogenesis before 7 weeks gestation. Clinical series in humans have shown an association between malformations and glucose control early in pregnancy. In addition, other investigators have demonstrated that tight glucose control either prior to conception or very early during pregnancy can effectively reduce the rate of major malformations. As a result of these and other studies, the management goal for diabetic pregnancies has become the establishment and maintenance of near euglycemia beginning with the preconceptual period and continuing throughout gestation.

Altered Fetal Growth

Macrosomia is a classic hallmark of the pregnancy complicated by diabetes and is reported to occur in 20% to 25% of pregnancies complicated by diabetes. Macrosomia is defined as excessive birth weight (>90%) for gestational age or as a birth weight over 4,000 grams. Increased adiposity is the primary cause of the increased birth weight seen in the offspring of diabetic women. Numerous studies have established a relationship between the level of maternal glucose control and macrosomia. Mothers of macrosomic infants usually have significantly elevated plasma glucose levels at term, indicating increased glucose availability to the fetus, with hyperinsulinemia a likely intermediate step, during the third trimester. Other factors associated with an increased risk for fetal macrosomia include increased maternal weight, increased parity, previous delivery of a macrosomic infant, and insulin requirements greater than 80 units/day.

Macrosomic fetuses have higher perinatal and neonatal mortality and morbidity rates. Approximately 10% of infants weighing over 4,500 grams at birth will require admission to a neonatal intensive care nursery. In addition, the reported perinatal mortality is 2 to 5 times higher in this group of children than in average-sized children. Delivery of a macrosomic infant is dangerous because of the risk for birth trauma to the head and neck. Fetal asphyxia and meconium aspiration may occur as a result of prolonged labor secondary to unrecognized cephalopelvic disproportion and shoulder dystocia.

At the other extreme, women with type 1 diabetes are also at increased risk for delivering a small-for-gestational-age infant. In general, the risk of growth retardation increases with the severity of the mother's clinical diabetes. Vascular complications, such as retinopathy and nephropathy, are believed to be associated with uteroplacental insufficiency in pregnant women with diabetes. Poor maternal renal function, hypertension, and placental lesions all have been associated with intrauterine growth retardation in the offspring of diabetic mothers. However, more recent evidence suggests that the growth retardation may be related to disturbances in maternal fuels during organogenesis.

Metabolic Abnormalities

Hypoglycemia occurs when plasma glucose levels fall below 35 mg/dL in the term infant and 25 mg/dL in the preterm infant. Infants of diabetic mothers can develop hypoglycemia during the first few hours of life, particularly in cases of poor glycemic control. Macrosomic infants and infants with elevated cord blood C-peptide or immunoreactive insulin levels are also at increased risk. The incidence of hypoglycemia is reported to range from 25% to 40% in infants of mothers with diabetes. Both poor glycemic control during pregnancy and high maternal plasma glucose levels at the time of delivery increase the risk of its occurrence.

The incidence of hypocalcemia also is increased significantly in the infants of women with diabetes. Hypocalcemia generally occurs in association with hyperphosphatemia and occasionally with hypomagnesemia. Neonatal hypocalcemia is defined as a calcium level at or below 7 mg/dL. Serum calcium levels are usually lowest on the second or third day of life. Polycythemia is defined as a venous hematocrit that exceeds 65% and is reported to occur in one third of neonates born to diabetic women. The polycythemia is believed to occur as a result of chronic intrauterine hypoxia, which leads to an increase in erythropoietin and results in an increase in red blood cell production. Neonates born to women with diabetes also have a higher incidence of hyperbilirubinemia as compared with nondiabetic controls. Neonatal hyperbilirubinemia develops in approximately 20% to 25% of cases. Animal studies have demonstrated an association between fetal insulin levels and elevated levels of erythropoietin, which is the major regulator of erythropoiesis in the neonate.

Other Infant Morbidities

Offspring born to women with diabetes mellitus are also at increased risk of developing various hypertrophic types of cardiomyopathy and congestive heart failure. The exact incidence is not known, but one study reported that 10% of infants born to women with diabetes may have evidence of myocardial and septal hypertrophy. Thickening of the interventricular septum and of the left or right ventricular wall can occur, and it is felt to be a result of the fetal hyperinsulinemic state. In the majority of cases the infants are asymptomatic, and the myocardial changes are detectable only by electrocardiogram or echocardiogram. In severe cases, left ventricular outflow obstruction can result and may lead to reduced cardiac output and congestive heart failure during the first few days of life. The abnormalities do not appear to damage the myocardium permanently and in most cases regress by 6 months of age.

RDS is another common complication associated with diabetes. In the past, offspring born to women with diabetes had a four-fold to six-fold greater incidence of RDS at every week of gestation. This incidence was decreased dramatically with the initiation of strict metabolic control. More recent studies seem to indicate that stringent metabolic control may reduce the incidence of RDS in neonates of women with diabetes to near background level in the population.

Lastly, there are long-term consequences of diabetic pregnancies. These include childhood obesity, neuropsychological deficits, and an increased tendency to develop overt diabetes.

PRECONCEPTION CARE

Care of women with type 1 or type 2 diabetes ideally begins before conception. Although numerous clinical trials have demonstrated that strict glycemic control prior to and during early gestation can reduce the rate of structural defects, the vast majority of women with diabetes still seek medical care only after they learn they are pregnant. Consequently, the rate of congenital malformations in infants of mothers with diabetes has continued to remain significantly higher than that of the general population.

A prepregnancy assessment should be undertaken to document a woman's overall fitness for pregnancy. This includes a careful history and thorough physical examination to assess the patient's vascular status. Baseline creatinine clearance and protein excretion levels should be evaluated and an electrocardiogram performed. These women also should be referred for an ophthalmologic consultation. Optimization of blood glucose control should be achieved before the woman is advised to become pregnant. Women should receive appropriate contraceptive therapy while they are preparing for pregnancy. For patients who are not already following an intensive regimen, an extensive period of education and the institution of self–blood glucose monitoring is also necessary.

Prepregnancy counseling for women with gestational diabetes should begin immediately after delivery. These women need to be advised that they are at significant risk for developing GDM in subsequent pregnancies and that they are at increased risk for developing type 2 diabetes as they age.

DIABETES MANAGEMENT

The main goal of management for pregnancies complicated by either gestational or pregestational diabetes is to achieve and maintain euglycemia throughout gestation. The treatment approach requires a combination of diet, exercise, intensive insulin regimens, and daily multiple blood glucose determinations.

Diet

Diet therapy is the cornerstone of diabetes management in pregnancy, just as it is in the nonpregnant state. The goal of diet therapy is to meet the additional nutrition requirements of pregnancy while at the same time maintaining good glycemic control.

All pregnant women with diabetes should be seen by a nutritionist for individualized diet counseling. There are no universal recommendations for determining the number of calories required during pregnancy. Most experts advocate an additional intake of 300 to 400 kcal/day to meet the needs of pregnancy. Recommendations regarding total caloric intake often are based on the mother's pregravid weight: 30 kcal/kg of body weight per day for normal-weight women with diabetes, 40 kcal/kg per day for underweight women, and 24 kcal/kg per day for overweight women (Table 15.2). Although it is generally agreed that pregnancy is not the time for weight reduction, obese women with type 2 or GDM should be encouraged to achieve weight gain of no more than 15 pounds. Modest caloric restrictions have not been associated with either ketonuria or elevated plasma ketone concentrations.

Determination of Calories	
Normal weight	30 kcal/kg/day
Underweight	40 kcal/kg/day
Overweight	24 kcal/kg/day
Components of Diet	
Carbohydrate	40%–45% of calories
Fat	Up to 40% of calories, with saturated fat limited to one third of calories
Protein	About 60 g, accounting for 12%–20% of calories

TABLE 15.2. *Preparation of a diet for a pregnant diabetic woman*

The most current guidelines suggest that the composition of the diabetic diet be based on an individualized nutrition assessment. Because the postprandial blood glucose level has been shown to be a major factor in the development of neonatal macrosomia, a goal of nutrition therapy is to blunt postprandial hyperglycemia. The postprandial blood glucose level is most influenced by the carbohydrate content of the meal (see Table 15.2). Carbohydrate levels of 40% to 45% of total calories are considered appropriate during pregnancy. To achieve euglycemia, dietary fat can be liberalized up to 40% of calories. Saturated fats should be limited to one third of fat calories or less. The remaining calories should come from either monounsaturated or polyunsaturated fats. The recommended dietary allowance for protein in pregnancy is 60 grams per day, and this typically ranges from 12% to 20% of total calories.

A number of different approaches to meal planning can be used and range from general guidelines for good nutrition to structured meal planning strategies. The most appropriate approach will depend on the patient's type of diabetes, educational level, lifestyle, habits, motivation, and economic restraints. Although the nutrition needs and distribution of calories for women with gestational diabetes and pregestational diabetes are similar, the number and timing of snacks will vary. Two or more snacks generally are recommended for women with type 1 diabetes, while women with type 2 diabetes or gestational diabetes require only a bedtime snack. The bedtime snack should include a complex carbohydrate and protein to prevent late-night hypoglycemia and early morning starvation ketosis. Artificial sweeteners are considered safe to use during pregnancy, although no specific recommendations concerning intake levels exist.

Exercise

Although exercise has been demonstrated to be beneficial in nonpregnant individuals, evidence regarding the risk and benefits of either periodic or regular exercise in pregnant women with diabetes is limited. Little has been published regarding exercise during pregnancy complicated by preexisting diabetes, either type 1 or type 2. However, walking is possible for most women and has been reported to improve lipid profiles and blood glucose control.

Pregnancy is not a time to initiate a new exercise program, although women who have been exercising regularly prior to pregnancy can be counseled to continue. Appropriate exercises are those that use upper body muscles and place little mechanical stress on the trunk region. Women should be taught to palpate their uterus during exercise and stop the exercise if they detect contractions. Until additional studies are completed, however, medical supervision is recommended for all pregnancies complicated by diabetes. Women with type 1 diabetes are vulnerable to exercise-related hypoglycemia and, therefore, should monitor their blood glucose levels closely and always have a readily available source of glucose. Women should be cautioned against becoming dehydrated, overheated, tachycardic, or dyspneic. Exercise should not be prescribed for patients with hypertension or an autonomic dysfunction with a diminished counter-regulatory response.

In regard to gestational diabetes, exercise has been recommended as an adjunct to nutrition therapy. Regular aerobic exercise has been shown to lower fasting and postprandial glucose concentrations. Several randomized controlled trials have demonstrated that upper extremity exercise for 20 minutes 3 times a week can lower blood glucose levels significantly in women with gestational diabetes. In addition, these trials found no significant increase in either maternal or neonatal complications related to exercise.

Insulin Therapy

Other than diet, insulin is the only therapy recommended to treat diabetes during pregnancy. The safety of all available oral agents has not been established in pregnancy and could lead to prolonged neonatal hypoglycemia. Therefore, they not recommended. However, a study in women with GDM has found glyburide to be a safe and clinically effective alternative to insulin.

The goal of insulin therapy is to achieve blood glucose levels that are nearly identical to those observed in healthy pregnant women. Therefore, multiple injections of insulin usually are required. Human insulin is the least immunogenic of all insulins and is recommended exclusively in pregnancy. Insulin requirements may change dramatically throughout the various stages of gestation. In the first trimester, the maternal insulin requirement is approximately 0.7 U/kg of body weight per day. This is increased in the third trimester to 1.0 U/kg per day.

Several different approaches to insulin administration can be used during pregnancy. The superiority of one regimen over another never has been fully demonstrated. The new rapid-acting insulin analogs, with peak hypoglycemic action 1 to 2 hours after injection, offer the potential for improved postprandial glucose control. However, their safety during pregnancy and their ability to improve perinatal outcomes has yet to be established. Studies in women with gestational diabetes have demonstrated that these agents do not cross the placenta.

The continuous subcutaneous insulin infusion pump is another treatment option which has been used successfully during pregnancy. Insulin therapy delivered by this mode more closely resembles that of physiologic insulin release. The pump delivers a continuous basal rate of insulin infusion, with pulse-dose increments before meals. In published studies, researchers have demonstrated that comparable glucose control and pregnancy outcomes can be achieved by both conventional insulin therapy and pump therapy. However, it has been reported that hemoglobin A_{1C} (HbA_{1C}) levels were significantly lower 1 year after delivery in women who elected to remain on pump therapy after delivery compared with women who had continued to use conventional insulin treatment. Other advantages of insulin pump therapy during pregnancy include more rapid and predictable insulin absorption, enhanced lifestyle flexibility, and simplified morning sickness management.

Insulin therapy should be initiated in all women with GDM who fail to maintain euglycemia with diet. Women typically are started on a dosage of 20 U of NPH and 10 U of regular insulin daily. Insulin dosage is adjusted according to blood glucose levels, and an evening injection is added if fasting hyperglycemia persists. Some investigators have advocated the use of prophylactic insulin in GDM to reduce the risk of macrosomia. However, the advantages of this therapy must be weighted against the disadvantages.

MONITORING METABOLIC STATUS

Self-monitoring of Blood Glucose

Self-blood glucose monitoring has become the mainstay of management for pregnancies complicated by diabetes mellitus. A variety of small, battery-powered blood glucose reflectance meters are available for home use. Accurate readings depend on performing the test correctly; however, most of the newest models are less technique dependent. Some models are extremely sophisticated, having memories that permit the storage of results with the date and time they were collected, whereas others can even be downloaded onto a personal computer. Each woman should be seen by a qualified nurse educator to ensure that her technique is accurate. Ongoing education also is important to help the woman make necessary changes in her treatment plan to maintain euglycemia throughout gestation.

Although it has been shown that, in general, self-monitored blood glucose values correlate very well with those measured in automated laboratories, reports have shown that sometimes patients report blood glucose levels falsely both during and outside of pregnancy. These findings are worrisome, because accurate information is essential for optimal management of the pregnancy complicated by diabetes. Therefore, verified blood glucose determinations (i.e., the use of blood glucose meters with memory) are recommended to enhance the reliability and accuracy of self-monitored blood glucose results.

Blood glucose measurements should be obtained at least 4 times a day (fasting and 1–2 hours after meals) in women with gestational diabetes and 5 to 7 times a day in women with preexisting diabetes (Table 15.3). In addition to this regular monitoring, patients also should test whenever they feel symptoms of either hyperglycemia or hypoglycemia. Detailed record keeping helps to identify glucose patterns. Daily urine ketone testing should be performed to ensure early identification of starvation ketosis or ketoacidosis. Ketone testing also should be performed anytime the blood glucose level exceeds 200 mg/dL, during illness, or when the patient is unable to eat.

Maternal Surveillance
Self-blood glucose monitoring 4–7 times daily
Hemoglobin A_{1C}
Urinary ketones
Blood pressure
Retinal and renal status (for women with preexisting diabetes)
Fetal Surveillance
Level II ultrasonography and fetal echocardiogram (for women with preexisting diabetes)
Serial assessment (4–6 wks) of fetal growth
Daily fetal movement counts
Weekly NST or BPP

BPP, biophysical profile; NST, nonstress test.

TABLE 15.3. *Monitoring the diabetic during pregnancy*

Blood glucose levels are measured in both the fasting and postprandial states. A randomized controlled trial compared the efficacy of preprandial and postprandial glucose determinations in reducing the incidence of neonatal macrosomia and other complications in women with gestational diabetes. Women requiring insulin treatment were randomly assigned to have their diabetes managed according to the results of preprandial self–blood glucose monitoring or postprandial monitoring performed 1 hour after meals. Both groups had similar success in achieving blood glucose level targets and demonstrated similar degrees of adherence with the monitoring schedule. Nevertheless, the women in the postprandial monitoring group received significantly more insulin and achieved a greater decrease in glycosylated hemoglobin values during treatment than those in the preprandial monitoring group. In addition, there was significantly less macrosomia and neonatal hypoglycemia among the offspring of the mothers in the postprandial monitoring group. These data suggest that adjustment of insulin therapy according to the results of postprandial blood glucose values improves glycemic control and pregnancy outcomes.

Previous studies in pregnant women with pregestational diabetes also have found that postprandial blood glucose levels are better predictors of fetal macrosomia than are fasting blood glucose levels. The Diabetes in Early Pregnancy Study demonstrated that third-trimester nonfasting glucose levels to be the strongest predictors of percentile birth weight in infants of diabetic mothers. Similar results have been reported by Combs and colleagues, who found that the incidence of macrosomia rose progressively with increasing postprandial glucose levels. Postprandial glucose levels of less than 130 mg/dL reduced the incidence of macrosomia, but levels of less than 120 mg/dL totally eliminated this complication. They recommended 130 mg/dL as a reasonable target for 1-hour postprandial glucose levels.

Although it is widely accepted that the level of metabolic control achieved in the pregnancy complicated by diabetes significantly affects perinatal outcome, what constitutes optimal control has not been established. Emerging evidence suggests that a continuum of risk exists between carbohydrate intolerance and both perinatal and neonatal morbidity. In theory, then, the target ranges for blood glucose values during pregnancy should be based on maternal plasma glucose levels in normal pregnancy. The logical approach is to achieve as near-to-normal glucose levels as possible without undue severe hypoglycemia. Current recommendations are that whole blood glucose levels should not exceed 95 mg/dL in the fasting state and 120 mg/dL after meals.

Although the current data demonstrate a relationship between metabolic control and neonatal complications, maternal glycemia may not be the sole parameter of optimal control. Buchanan and colleagues have suggested the use of fetal ultrasonography in women with gestational diabetes to identify pregnancies at risk for fetal macrosomia and related morbidity. They have found that during the late second trimester or early third trimester, a fetal abdominal circumference under or over the 75th percentile for gestational age can distinguish pregnancies at low risk from those at high risk, respectively, for producing large-for-gestational-age infants. Their data suggest that maternal glucose concentrations alone may not accurately predict which fetuses are at high risk for excessive fetal growth and support the use of fetal criteria to direct metabolic therapies in GDM.

Glycosylated Hemoglobin

The glycosylated hemoglobin assay is an accurate, objective measure of long-term glycemic control in diabetes. It can be measured either as total glycohemoglobin or as the particular configuration known as HbA_{1C}. Proteins undergo a nonenzymatic, postsynthetic modification that results in the attachment of glucose to various amino acids. This process, which is known as glycosylation, occurs slowly and is irreversible. The amount of hemoglobin that becomes glycosylated depends on the concentration of glucose over the time of the exposure and, therefore, is not influenced significantly by recent or transient blood glucose excursions. Because erythrocytes in the peripheral circulation have a half-life of 100 days, the glycosylated hemoglobin level reflects glycemic control over the preceding 2 to 3 months. Most studies have found positive correlation between HbA_{1C} values and other parameters of glucose control during gestation, similar to findings in the nonpregnant state.

Several investigators have reported an association between malformations and glucose control early in pregnancy. The higher the woman's glycosylated hemoglobin level, the greater is her risk of having a severely affected infant. The risk of miscarriage also has been shown to be increased with marked elevations in first-trimester glycosylated hemoglobin. Ideally, glycosylated hemoglobin levels should be measured before conception, and pregnancy should be delayed until normal levels are reached. Unfortunately, the majority of pregnancies in women with and without diabetes are not planned. Therefore, the HbA_{1C} level can be obtained at the first prenatal visit and reassessed every 4 to 6 weeks to document the degree of glycemic control maintained throughout the pregnancy. Although elevations in first-trimester glycosylated hemoglobin levels indicate an increased risk for congenital malformations, an elevation during the second half of pregnancy appears to identify infants at risk for perinatal morbidity and mortality. Several investigators have demonstrated an association between HbA_{1C} and neonatal hypoglycemia, neonatal hyperbilirubinemia, perinatal death, and macrosomia. In women with gestational diabetes, however, HbA_{1C} levels have not been found useful as either a screening or diagnostic tool.

FETAL ASSESSMENT

All pregnancies complicated by diabetes require additional fetal evaluation and assessment (see Table 15.3). Ultrasonography provides the clinician with essential information about the fetus and its development. A first-trimester scan should be performed to date the pregnancy and establish viability. All women with pregestational diabetes should also be evaluated for possible fetal anomalies. Although the risk for delivering an anomalous infant cannot be fully determined by a glycosylated hemoglobin level, an elevated HbA_{1C} should alert the practitioner to an increased risk for structural defects. Evaluation includes targeted ultrasonography to survey general fetal anatomy and fetal echocardiography at approximately 20 to 22 weeks gestation. In addition, the maternal serum a-fetoprotein screening test should be performed at 16 to 18 weeks gestation because of the increased risk of neural tube defects.

Because women with diabetes are at risk for fetal growth aberrations, frequent ultrasonographic scans are recommended to identify states of altered growth. Ultrasonographic examinations should be performed at 4- to 6-week intervals during the second and third trimesters of pregnancy to assess not only fetal growth, but amniotic fluid volume as well.

Fetal death is more common in pregnancies complicated by diabetes than in the general population. The goal of antepartum surveillance is avoidance of intrauterine death by early detection of fetal compromise. The nonstress test (NST) has become the preferred antepartum fetal heart rate test for screening the fetal condition in pregnancies complicated by diabetes. The NST evaluates the presence of accelerations from the baseline fetal heart rate. An alternative fetal test is the fetal biophysical profile (BPP), which also is used to evaluate the significance of a nonreactive NST. Because the BPP employs ultrasonography, it permits evaluation of amniotic fluid volume and may detect major fetal malformations in patients who have not been studied earlier in pregnancy. Maternal evaluation of fetal movement counts should be integrated into the surveillance program. Women with diabetes are instructed to count fetal movements beginning as early as 28 weeks of gestation. Although the false-positive rate is high, the technique is inexpensive and simple and augments the total antepartum surveillance program.

Most perinatal centers institute a program of weekly fetal monitoring beginning at 32 to 34 weeks gestation. Because fetal death is more common in women with poor glycemia control, hydramnios, fetal macrosomia, hypertension, or vasculopathy, these women receive twice weekly NST testing. Patients with diet-controlled gestational diabetes who maintain normal fasting and postprandial glucose levels are probably at low risk for an intrauterine fetal death and are not tested as early or as frequently. However, women with gestational diabetes and chronic hypertension, a previous stillbirth, preeclampsia, and who require insulin therapy receive more intense surveillance.

Timing and Mode of Delivery

It is generally accepted that if a pregnant diabetic patient is in good metabolic control and is receiving fetal surveillance on a regular basis, delivery may be delayed safely until term or the onset of spontaneous labor. Women with poor metabolic control, worsening hypertensive disorders, fetal macrosomia, growth retardation, or polyhydramnios may be delivered electively after fetal lung maturity has been confirmed. If an elective delivery is planned before 38 weeks gestation, amniocentesis should be performed for confirmation of fetal lung maturity. Fetal lung maturation is better predicted by the amniotic fluid phosphatidylglycerol content than by the lecithin/sphingomyelin ratio.

Cesarean delivery should be performed on most patients with an estimated fetal weight of greater than 4,500 grams to prevent shoulder dystocia and birth trauma. Management should be individualized for patients with an estimated fetal weight between 4,000 and 4,500 grams. The decision is based on the size of the pelvis and progress of labor, as well as the patient's obstetric history. A history of shoulder dystocia is often an indication for repeat caesarean section.

During labor and delivery, good blood glucose control should be maintained to prevent neonatal hypoglycemia. Blood glucose levels should be maintained below 100 mg/dL with the use of an insulin infusion. After delivery, insulin requirements tend to fall dramatically as a result of the significant decrease in levels of placental hormones. Once the patient is able to eat regular meals, she should receive subcutaneous insulin at approximately one half of her prepregnancy dose.

CONTRACEPTION AND FAMILY PLANNING

The use of contraception in all women with diabetes or a history of GDM cannot be emphasized strongly enough. This is the only way to ensure that preconception care can be provided. A variety of contraceptive methods are available. Barrier methods of contraception create mechanical or chemical barriers, or both, to fertilization

and include diaphragms, male condoms, spermicidal foam or jelly, cervical caps, and female condoms.

Although these methods pose no health risks to women with diabetes, they are user dependent, require correct application or insertion before intercourse, and have a high failure rate of 12% to 28% during the first year because of improper use. With experience and motivation, these failure rates may be reduced to levels of 2% to 6%.

Oral contraceptives remain the most popular form of birth control despite controversy over potential side effects. The main reasons for their popularity are their failure rate of generally less than 1% and ease of use. Low-dose formulations are preferred and are recommended only for patients without vascular complications or additional risk factors, such as smoking or a strong family history of myocardial disease. Progestin-only (“mini-pill”) oral contraceptives are an option for women with contraindications to the estrogen component, such as hypertension or thrombosis.

An intrauterine device is the most effective nonhormonal device. It should be offered only to women with diabetes who have a low risk of sexually transmitted diseases, because any infection might place the patient with diabetes at risk for sepsis and ketoacidosis. Patient education should include the early signs of sexually transmitted diseases, such as increased and abnormal vaginal discharge, dyspareunia, heavy or painful menses, lower abdominal pain, and fever.

Depo-Provera is a long-acting progestin that provides highly effective pregnancy prevention. Depo-Provera is administered intramuscularly every 3 months and works by inhibiting ovulation. The high efficacy and long period of action of Depo-Provera makes it an attractive option for women with diabetes, especially women with a history of poor medication compliance. Unfortunately, this long-acting progestin has not been studied in women with diabetes.

Permanent sterilization, including tubal ligation and vasectomy, may be considered by the patient or her partner when they desire no more children.

CONCLUSION

The diagnosis of diabetes mellitus during pregnancy has certain implications for the well-being of both the mother and the fetus. Advances in medical and obstetric care have dramatically improved the outlook for women with diabetes and their offspring. However, both mother and child remain at increased risk for a number of complications. Research indicates that the majority of these complications are associated with hyperglycemia. The achievement and maintenance of euglycemia has, therefore, become the major focus of management.

SUMMARY POINTS

- The development of insulin resistance during late pregnancy is a normal physiologic adaptation that shifts maternal energy metabolism from carbohydrate to lipid oxidation and thus spares glucose for the growing fetus.
- All pregnant women should be screened for GDM between 24 and 28 weeks gestation.
- Women with diabetes and their offspring are at greater risk for a number of pregnancy-related complications.
- Strict blood glucose control prior to conception and throughout gestation can reduce and or eliminate the excess risk for both mother and baby.
- All diabetic women of childbearing age should be counseled regarding the importance of preconception care and planning their pregnancies.

SUMMARY POINTS

RECOMMENDED READINGS

Hypertensive disorders are the most common medical complications of pregnancy, affecting 5% to 10% of all pregnancies. These disorders are responsible for approximately 15% of maternal mortality. This includes hypertension preceding pregnancy, known as *chronic hypertension*, and the group of hypertensive disorders unique to pregnancy, called *gestational hypertension and preeclampsia.* Preeclampsia, eclampsia, and transient hypertension fall under the broad category of gestational hypertension. Approximately 30% of hypertensive disorders in pregnancy are due to chronic hypertension and 70% are due to gestational hypertension. The spectrum of disease ranges from mildly elevated blood pressures with minimal clinical significance to severe hypertension and multiorgan dysfunction. The incidence of disease is dependent upon many different demographic parameters including maternal age, race, and associated underlying medical conditions. Understanding the disease process and the impact of hypertensive disorders on pregnancy is of the utmost importance, because these disorders remain a major cause of maternal and perinatal morbidity and mortality worldwide.

DEFINITIONS AND CLASSIFICATIONS

Making an appropriate diagnosis can at times be difficult in the gravid patient, however adhering to the following definitions and classification schemes will help to eliminate confusion. Hypertension is defined as a systolic blood pressure of 140 mm Hg or greater or a diastolic blood pressure of 90 mm Hg or greater. These measurements must be present on at least two occasions at least 6 hours apart, but no more than a week apart. No longer in use are the criteria of increase in blood pressure above baseline measurements of =30 mm Hg systolic, =15 mm Hg diastolic, or =20 mm Hg mean arterial pressure. It is important to note that choosing the appropriate size cuff will help to eliminate falsely lowered or elevated blood pressure measurements and render more accurate readings.

Abnormal proteinuria in pregnancy is defined as the excretion of 300 mg or more of protein in 24 hours. The most accurate measurement of proteinuria is obtained with a 24-hour urine collection. However, in certain instances, semiquantitative dipstick measurement may be the only mode available to assess urinary protein. A value of 1+ or greater correlates with 30 mg/dL. Proteinuria by dipstick is defined as 1+ or more on at least two occasions at least 6 hours apart but no more than 1 week apart. The accuracy of semiquantitative dipstick measurements on spot urine samples as compared with 24-hour urine collections is highly variable. Therefore, should time allow, a 24-hour urine collection should be performed as part of the diagnostic criteria to define proteinuria. Care should be taken when obtaining urine protein measurements to use a clean sample, because blood, vaginal secretions, and bacteria can increase the amount of protein in urine.

Edema is a common finding in the gravid patient, occurring in approximately 50% of women. Lower extremity edema is the most typical form. Pathologic edema is seen in nondependent regions such as the face, hands, or lungs. Excessive, rapid weight gain of 5 pounds or more per week is another sign of fluid retention.

The classification system of hypertension in pregnancy was proposed originally by the American College of Obstetricians and Gynecologists Committee on Terminology in 1972. Further modifications by the National High Blood Pressure Education Program Working Group in 2000 arrived at the classification scheme used today, which offers simple, concise, and clinically relevant features for each of the four categories. This system recognizes four major categories of hypertension in pregnancy—gestational hypertension, preeclampsia or eclampsia, chronic hypertension, and preeclampsia superimposed on chronic hypertension. Table 16.1 lists these categories and the features of each.

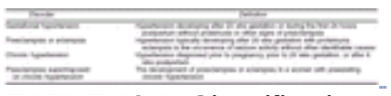

TABLE 16.1. *Classification of hypertension in pregnancy with definitions*

Gestational Hypertension

Gestational hypertension is the elevation of blood pressure during the second half of pregnancy or in the first 24 hours postpartum without proteinuria and without symptoms. Normalization of blood pressure will occur during the postpartum period, usually within 10 days. Treatment generally is not warranted, because most patients have mild hypertension. Gestational hypertension in and of itself has little effect on maternal or perinatal morbidity or mortality. However, approximately 46% of patients diagnosed with preterm gestational hypertension will develop proteinuria and progress to preeclampsia. Women with gestational hypertension are likely to have elevated blood pressure with subsequent pregnancies and to develop essential hypertension later in life.

Preeclampsia and Eclampsia

The syndrome of preeclampsia is defined by the classic triad of hypertension, proteinuria, and symptoms. Hypertension is defined as a blood pressure of 140 mm Hg systolic or 90 mm Hg diastolic on two separate occasions 6 hours apart. Significant proteinuria is defined as 300 mg or more in 24 hours. The symptoms of

preeclampsia are headaches, visual changes, and epigastric or right upper quadrant pain.

Preeclampsia may be subdivided further into mild and severe forms. The distinction between the two is made on the basis of the degree of hypertension and proteinuria, and the involvement of other organ systems. The criteria for mild preeclampsia and severe preeclampsia are presented in Table 16.2 and Table 16.3, respectively. Close surveillance of patients with either mild or severe preeclampsia is warranted, because either type may progress to fulminant disease. A particularly severe form of preeclampsia is the HELLP syndrome, which is an acronym for hemolysis, elevated liver enzymes, and low platelet count. This syndrome is manifest by laboratory findings consistent with hemolysis, elevated levels of liver function, and thrombocytopenia. The diagnosis may be deceptive, because blood pressure measurements may be elevated only marginally. A patient diagnosed with HELLP syndrome is automatically classified as having severe preeclampsia. Another severe form of preeclampsia is eclampsia, which is the occurrence of seizures not attributable to other causes.

Blood pressure ≥140 mm Hg systolic and ≥90 mm Hg diastolic on two occasions at least 6 hours apart, typically occurring after 20 wks gestation (no more than 1 wk apart)
Proteinuria of 300 mg in a 24-hour urine collection or ≥1+ on two random sample urine dipsticks at least 6 hours apart (no more than 1 wk apart)

TABLE 16.2. *Criteria for the diagnosis of mild preeclampsia*

Blood pressure ≥160 mm Hg systolic or ≥110 mm Hg diastolic on two occasions at least 6 hours apart
Proteinuria of ≥5 g/24 hours
Oliguria ≤500 cc/24 hours
Thrombocytopenia—platelet count ≤100,000/mm^3
Elevated liver function test results with persistent epigastric or right upper quadrant pain
Pulmonary edema
Persistent severe cerebral or visual disturbances

TABLE 16.3. *Criteria for the diagnosis of severe preeclampsia*

Chronic Hypertension

Hypertension complicating pregnancy is considered chronic if a patient was diagnosed with hypertension before pregnancy, if hypertension was present prior to 20 weeks gestation, or if it persists longer than 6 weeks after delivery. Women with chronic hypertension are at risk of developing superimposed preeclampsia. Superimposed preeclampsia is defined as an exacerbation of hypertension with new onset of proteinuria.

PREECLAMPSIA

Preeclampsia is a hypertensive disorder unique to human pregnancy. The incidence of preeclampsia is reported to be between 2% to 7%, depending on the population. Preeclampsia occurs more frequently in primigravidas and usually occurs after 20 weeks gestation. The reported rate of preeclampsia ranges from 6% to 7% in primigravidas and from 3% to 4% in multiparous patients. Several risk factors for preeclampsia have been identified and are listed in Table 16.4. Neonatal outcome in patients with preeclampsia relates largely to the gestational age at delivery. Risk to the mother can be significant and includes the possible development of disseminated intravascular coagulation, intracranial hemorrhage, renal failure, retinal detachment, pulmonary edema, liver rupture, abruptio placentae, and death. Therefore, astute and experienced clinicians should be caring for women with preeclampsia.

Nulliparity
Pregestational diabetes
Thrombophilia
Nephropathy
Connective tissue disease
Molar pregnancy
Fetal hydrops
Multifetal gestation
Chronic hypertension
Obesity
Prior pregnancy complicated by preeclampsia
Antiphospholipid antibody syndrome
Family history of preeclampsia or eclampsia
Fetal aneuploidy

TABLE 16.4. *Risk factors for preeclampsia*

Etiology

The etiologic agent responsible for the development of preeclampsia remains unknown. The syndrome is characterized by vasospasm, hemoconcentration, and ischemic changes in the placenta, kidney, liver, and brain. These abnormalities usually are seen in women with severe preeclampsia. Theories as to the causative mechanisms include placental origin, immunologic origin, and genetic predisposition, among others. A list of etiologic theories is shown in Table 16.5. A great deal of research is dedicated to solving the etiologic enigma of preeclampsia. Without a definitive etiology, predicting patients at risk for the development of preeclampsia and effecting a treatment for this morbid disease remain difficult.

Abnormal or increased immune response
Genetic predisposition
Abnormal coagulation or thrombophilias
Alterations in prostaglandin activity
Endothelial cell injury
Alterations in nitric oxide levels
Increased oxygen free radicals
Abnormal cytotrophoblast invasion
Abnormal calcium metabolism
Dietary deficiencies

TABLE 16.5. *Etiologic theories in preeclampsia*

Pathophysiology

Cardiovascular The hypertensive changes seen in preeclampsia are attributed to intense vasospasm thought to be due to increased vascular reactivity. The underlying mechanism responsible for the increased vascular reactivity is presumed to be alterations in the normal interactions of vasodilatory (prostacyclin, nitric oxide) and vasoconstrictive (thromboxane A_2, endothelin) substances. Another vascular hallmark of preeclampsia is hemoconcentration. Patients with preeclampsia have lower intravascular volumes and have less tolerance for the blood loss associated with delivery.

Hematologic The most common hematologic abnormality in preeclampsia is thrombocytopenia (platelet count <100,000/mm ^{3}). The exact mechanism for thrombocytopenia is unknown. Another possible hematologic abnormality is microangiopathic hemolysis, as seen in HELLP syndrome, and can be diagnosed by schistocytes seen on peripheral smear and increased lactate dehydrogenase (LDH) levels. Interpretation of the baseline hematocrit in a preeclamptic patient may be difficult. A low hematocrit may signify hemolysis, and a falsely high hematocrit may be due to hemoconcentration.

Renal Vasospasm in preeclampsia leads to decreased renal perfusion and subsequent decreased glomerular filtration rate (GFR). In normal pregnancy the GFR is increased up to 50% above prepregancy levels. Because of this, serum creatinine levels in preeclamptic patients rarely rise above normal pregnancy levels (0.8 mg/dL). Close monitoring of urine output is necessary in patients with preeclampsia, because oliguria (defined as <500 cc/24 hours) may occur due to renal insufficiency. Rarely, profound renal insufficiency may lead to acute tubular necrosis. The pathognomonic renal lesion in preeclampsia is called glomerular capillary endotheliosis, which is swelling of the glomerular capillary endothelial and mesangial cells.

Hepatic Hepatic damage associated with preeclampsia can range from mildly elevated liver enzyme levels to subcapsular liver hematomas and hepatic rupture. The latter usually are associated with HELLP syndrome. The pathologic liver lesions seen on autopsy are periportal hemorrhages, ischemic lesions, and fibrin deposition.

Central Nervous System Eclamptic convulsions are perhaps the most disturbing central nervous system (CNS) manifestation of preeclampsia and remain a major cause of maternal mortality in the third world. The exact etiology of eclampsia is unknown, but is thought to be attributed to coagulopathy, fibrin deposition, and

vasospasm. Radiologic studies may show evidence of cerebral edema and hemorrhagic lesions, particularly in the posterior hemispheres, which may explain the visual disturbances seen in preeclampsia. Other CNS abnormalities include headaches and visual disturbances including scotomata, blurred vision and, rarely, temporary blindness.

Fetus and Placenta The hallmark placental lesion in preeclampsia is acute atherosis of decidual arteries. This is due in part to the abnormal adaptation of the spiral artery–cytotrophoblast interface and results in poor perfusion. This may lead to poor placental perfusion, resulting in oligohydramnios, intrauterine growth restriction, placental abruption, fetal distress, and ultimately fetal demise.

Prediction

No good screening test for the prediction of preeclampsia exists. Several methods have been proposed but have not been found to be cost effective or reliable (Table 16.6). Given that nulliparity has a 5% to 7% risk of preeclampsia and multiparity carries only a 3% risk, an accurate and thorough maternal history with identification of risk factors is the most cost-effective screening method available.

Maternal serum uric acid levels
Uterine artery Doppler determinations
Roll-over test
Angiotensin II infusion test
Elevated second-trimester MSAFP, β-hCG levels
Plasma fibronectin values
Midpregnancy blood pressure measurements
Urinary calcium excretion
Urinary kallikrein concentration
Platelet activation
Excessive weight gain
Calcium-to-creatinine ratio

β-hCG, β-human chorionic gonadotropin; MSAFP, maternal serum α-fetoprotein.

TABLE 16.6. *Proposed methods of prediction of preeclampsia*

Prevention

Preventive interventions for preeclampsia could impact maternal and perinatal morbidity and mortality worldwide. As a result, during the past decade there have been many studies done to find a method for the prevention of preeclampsia. Consideration has been given to low-salt diets, diuretics, bed rest, and strict control of weight gain, but none of these is beneficial. Disappointingly, studies using low-dose aspirin (Table 16.7), calcium supplementation (Table 16.8), magnesium supplementation, and fish oil supplementation have shown no reduction in the rates of preeclampsia. Antioxidant use with vitamin C and E supplementation has shown promise in one study but will require further confirmation by larger studies.

TABLE 16.7. *Prevention of preeclampsia with aspirin—summary of randomized trials*

TABLE 16.8. *Prevention of preeclampsia with calcium—summary of randomized trials*

MILD PREECLAMPSIA

Diagnosis of Mild Preeclampsia

The diagnosis of mild preeclampsia requires the presence of hypertension and proteinuria in pregnancy. The diagnosis may be suspected also in the presence of hypertension and maternal symptoms. The diagnosis is considered to be mild preeclampsia if systolic blood pressure remains less than 160 mm Hg and diastolic blood pressure remains less than 110 mm Hg and urinary protein remains below 5 g/24 hours. The criteria for severe preeclampsia are listed in Table 16.3.

Because the spectrum of disease in preeclampsia is variable, it is important to monitor patients for the development of severe preeclampsia. Patients with mild preeclampsia are at risk of developing eclampsia, potentially suddenly, without warning, and with minimal blood pressure elevations. Another risk is abruptio placentae. However, both of these risks are less than 1%.

Management of Mild Preeclampsia

Any patient suspected of having preeclampsia should be hospitalized while confirming the diagnosis. Management of the patient with mild preeclampsia should include baseline laboratory evaluation including 24-hour urine collection for protein, hematocrit, platelet count, serum creatinine value, and aspartate aminotransferase (AST) level. At the time of diagnosis, ultrasonography should be performed to evaluate amniotic fluid volume and estimated fetal weight.

The only definitive cure for preeclampsia is delivery. In patients diagnosed with mild preeclampsia at term (>37 weeks), the general consensus is delivery. For the patient who is preterm (<37 weeks), controversy arises regarding management with respect to level of activity, diet, antihypertensive medications, and delivery. Usually these patients do not require immediate delivery and expectant management is warranted. Hence, the clinical decision making in patients with mild preeclampsia is two-fold. If expectant management is chosen, the second question then becomes where to manage the patient, in the hospital or at home?

In the past, once diagnosed with mild preeclampsia, a woman was either delivered immediately or managed in the hospital for the remainder of the pregnancy. Several studies have shown that a management plan including immediate delivery may not be justified. Sibai and colleagues studied 200 women with preeclampsia who were managed as inpatients with unrestricted activity, but they were randomized to receive labetalol or no medications. The mean pregnancy prolongation was 21 days. The rate of placental abruption was 1.1% and the perinatal mortality rate was 5.4 per 1,000. Another study by Matthews and colleagues evaluated the effect on preeclampsia of bed rest versus unlimited activity. They, also, found no significant difference in maternal or fetal outcomes.

At-home management of these patients or use of a day care setting is appropriate in most cases, provided the patient is compliant, has readily available transportation, and is reliable with follow-up. Using this approach, it is important to educate patients regarding the signs and symptoms to report (Table 16.9). They should be advised to return immediately to the hospital should any of these arise. Should the disease progress from mild to severe, or if there is any indication of fetal compromise, including non-reassuring fetal heart rate test results, oligohydramnios, or growth restriction, the patient should be hospitalized and evaluated for delivery. Serial laboratory evaluation of platelet counts and liver enzyme values should be performed every 3 to 7 days to monitor for worsening disease. Significant abnormalities in any of these laboratory criteria warrants hospitalization. Antenatal surveillance should include at least twice-weekly nonstress tests. Patients should also be instructed to monitor fetal movement. Given the slightly increased risk of intrauterine growth restriction, it is also appropriate to perform an ultrasonographic examination for fetal growth every 3 to 4 weeks.

Nausea and vomiting
Persistent severe headache
Right upper quadrant or epigastric pain
Scotomata
Blurred vision
Decreased fetal movement
Rupture of membranes
Vaginal bleeding
Regular contractions

TABLE 16.9. *Signs and symptoms of preeclampsia that warrant prompt evaluation*

Optimal timing of delivery is dependent on maternal and fetal status. In the preterm pregnancy, the sole benefit of expectant management is for the fetus. Once a pregnancy reaches term, the plan should be for delivery. Induction of labor is indicated in those patients with a favorable cervix. At 37 weeks or beyond, if the cervix is unfavorable, there are two options: either cervical ripening and delivery or continued expectant management with maternal and fetal evaluation. The preferred mode of delivery remains vaginal. A cesarean section should be performed for obstetric indications only.

While in labor, patients may receive intravenous magnesium sulfate ($MgSO_4$) for seizure prophylaxis. A regimen for $MgSO_4$ administration is presented later in this chapter. The exact point in labor at which to start the $MgSO_4$ remains unknown. There is no support in the literature for the need or the optimal timing to begin the $MgSO_4$ infusion, and this should be left to the discretion of the individual physician. Pain management in labor should be individualized, also. Intravenous narcotics and regional anesthesia are both appropriate options. Close monitoring of blood pressure intrapartum is necessary. Antihypertensive medications may be needed in order to keep blood pressure values below 160 mm Hg systolic and below 110 mm Hg diastolic. The most commonly used intravenous medications for this purpose are labetalol and hydralazine. The recommended dosages of medications for the immediate treatment of hypertension are listed in Table 16.10. Care should be taken not to drop the blood pressure too rapidly, because a marked decrease in mean arterial pressure may lead to reduced renal perfusion and reduced placental perfusion. Preeclamptic women receiving $MgSO_4$ are also at risk for postpartum hemorrhage due to uterine atony.

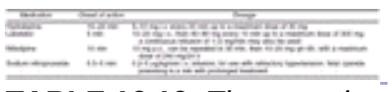

TABLE 16.10. *Therapeutic options in the acute treatment of hypertension*

Patients should be monitored closely for at least 12 to 24 hours postpartum. Postpartum eclampsia occurs in 25% of patients. It is not clear if $MgSO_4$ should be continued in the postpartum period. There is no need for continued seizure prophylaxis beyond 24 hours postpartum.

SEVERE PREECLAMPSIA

Management of Severe Preeclampsia

Any patient with severe preeclampsia should be admitted and observed initially in a labor and delivery unit. Workup should include assessment for fetal well-being, monitoring of maternal blood pressures and symptomatology, and laboratory evaluation. Laboratory evaluation should include 24-hour urine collection for total protein, hematocrit, platelet count, and serum creatinine and AST levels. An initial ultrasonographic examination for fetal growth and amniotic fluid index should be obtained, also.

It is well accepted that delivery is considered in all women with severe preeclampsia at >34 weeks, because prolonging the pregnancy may be hazardous to the mother with little benefit to the fetus. In patients at a gestational age of 33 to 34 weeks, steroids should be administered and delivery planned within 48 hours.

In patients with severe prematurity (=32 weeks), expectant management significantly improves neonatal outcome. The goal in these patients is to gain at least 48 hours so that antenatal glucocorticoids can be administered for fetal benefit. Patients should be selected carefully to undergo expectant management. They should be counseled regarding the risks and benefits of expectant management. Guidelines for expectant management are outlined in Table 16.11. Fetal well-being should be assessed on a daily basis by nonstress testing and weekly amniotic fluid index determinations. The patient should also be instructed on fetal movement assessment. Ultrasonography for fetal growth should be performed every 2 to 3 weeks. Maternal laboratory evaluation should be done daily or every other day. If a stable maternal and fetal course is maintained, expectant management may be continued until 34 weeks. The development of any worsening change in maternal or fetal status warrants delivery regardless of gestational age, as in Table 16.12. A woman with a nonviable fetus should be presented with the option of pregnancy termination. In the United States, it typically is accepted that the fetus is potentially viable at 23 weeks, and at this gestation expectant management may be considered. Consultation with the neonatology team may aid in making this decision.

Controlled hypertension (blood pressures below severe range)
Urinary protein of any amount
Oliguria that resolves with fluid challenge or oral intake
Elevated liver enzyme levels without symptoms
Reassuring fetal status—including biophysical profile ≥4, normal amniotic fluid volume, and appropriate fetal weight (>5th percentile for gestational age)

TABLE 16.11. *Criteria for expectant management of severe preeclampsia*

Uncontrolled severe hypertension
Eclampsia
Persistent oliguria (<500 cc/24 h)
Abruptio placentae
Platelet count <100,000/mm^3
Elevated liver enzyme levels with epigastric pain or right upper quadrant tenderness
Pulmonary edema
Persistent severe headache or visual changes
Fetal death
Spontaneous labor
Rupture of membranes
Gestational age ≥34 wks
Evidence of fetal distress including repetitive late decelerations, biophysical profile <4 on two occasions 4 hours apart, severe oligohydramnios, intrauterine growth retardation (<5th percentile for gestational age)

TABLE 16.12. *Criteria for delivery in severe preeclampsia*

Maternal blood pressure control is essential during either expectant management or during delivery. Medications can be given either orally or by the intravenous route, as necessary, to maintain a desired blood pressure range between 140 and 160 mm Hg systolic and 90 and 110 mm Hg diastolic. Drugs typically used in the management of acute hypertension are hydralazine and labetalol. The dosage of each is presented in Table 16.10. Once again, care must be taken to avoid a sudden drop in maternal blood pressure precipitating cerebral ischemia, decreased renal perfusion, and decreased placental perfusion. These patients typically do not require invasive hemodynamic monitoring. However, in patients with pulmonary edema and those with underlying cardiac disease, consideration should be given to the use of invasive hemodynamic monitoring.

Intrapartum management should include close blood pressure control, continuous fetal monitoring, and intravenous $MgSO_4$ administration. An indwelling urinary catheter should be placed in order to closely monitor fluid balance. Urine output should be =100 cc/ 4 hours. A trial of labor is indicated in patients with severe preeclampsia. However, an appropriate time frame should be established during which to achieve active labor. Pain management should be dealt with on an individual basis. Epidural anesthesia is a reasonable option provided the patient is without a coagulopathy. Patients with preeclampsia tolerate blood loss poorly due to volume contraction, and type-specific blood should be readily available for transfusion if needed. Appropriate steps should be taken to minimize postpartum hemorrhage in patients who develop uterine atony while receiving continuous $MgSO_4$ infusion. Methylergonovine (Methergine) is contraindicated in these patients.

$MgSO_4$ infusion should continue for 24 hours postpartum. The patient should be kept under close observation for 24 hours after delivery to monitor blood pressure, reflexes, and fluid status. Most patients will show improvement in the disease process within the first 24 hours postpartum. On the other hand, approximately 30% of

HELLP cases develop postpartum, and all patients with severe preeclampsia should be monitored for the development of HELLP syndrome after delivery. If hypertension persists after delivery, the patient may need to continue taking antihypertensive medication after being discharged to home. Patients should be seen every week or two as a outpatients until they become normotensive. If the hypertension persists beyond 6 weeks postpartum, the diagnosis of chronic hypertension should be entertained.

HELLP SYNDROME

Diagnosis of HELLP Syndrome

The term *HELLP syndrome* is used to describe preeclampsia in association with hemolysis, elevated liver enzyme levels, and low platelet count. It is found in about 10% of pregnancies complicated by severe preeclampsia. The diagnosis is not always clear and the syndrome may be confused with other medical conditions. Any patient diagnosed with HELLP syndrome should be considered to have severe preeclampsia.

In the past, the diagnostic criteria for HELLP syndrome were variable and led to inconsistent diagnoses. The newer criteria used for the diagnosis of HELLP syndrome are those reported by Sibai and include specific laboratory abnormalities demonstrating hemolysis, elevated liver enzyme levels, and low platelet count as shown in Table 16.13.

Hemolysis
Abnormal peripheral smear
Lactate dehydrogenase >600 U/L
Bilirubin ≥1.2 mg/dL
Elevated Liver Enzyme Levels
Serum aspartate aminotransferase >70 U/L
Lactate dehydrogenase >600 U/L
Low Platelets
Platelet count <100,000/mm³

Source: Sibai BM. The HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets): much ado about nothing? *Am J Obstet Gynecol* 1990;162:311–316, with permission.

TABLE 16.13. *Criteria for the diagnosis of HELLP syndrome*

The clinical picture of patients with HELLP syndrome is highly variable. However, in general, patients with HELLP are multiparous white females who will be diagnosed at less than 35 weeks gestation. The typical symptomatology of these patients consists of vague complaints, further skewing the diagnosis. A large percentage of patients will have a history of general malaise for the few days prior. Other complaints include epigastric or right upper quadrant pain (67%), nausea or vomiting (30%), and nonspecific viral syndrome–like complaints. Thus, any pregnant woman with suspected preeclampsia who makes these complaints should undergo a minimum workup of a complete blood count with platelet count and liver enzyme levels.

Sibai has noted that hypertension may be absent (20%), mild (30%), or severe (50%) in women diagnosed with HELLP syndrome. Therefore, the diagnosis of HELLP syndrome cannot necessarily be ruled out in the normotensive patient who has other signs and symptoms consistent with preeclampsia.

Differential Diagnosis of HELLP Syndrome

HELLP syndrome may be easily confused with many other medical conditions, particularly when the patient is normotensive. It is important to be aware of the differential diagnosis of HELLP and be able to discern this condition from others. A list of the differential diagnosis is found in Table 16.14.

Acute fatty liver of pregnancy
Appendicitis
Cerebral hemorrhage
Diabetes insipidus
Gallbladder disease
Gastroenteritis
Glomerulonephritis
Hemolytic uremic syndrome
Hyperemesis gravidarum
Idiopathic thrombocytopenia
Pancreatitis
Pyelonephritis
Systemic lupus erythematosus
Thrombophilias
Thrombotic thrombocytopenic purpura
Viral hepatitis including herpes

Source: Sibai BM. The HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets): much ado about nothing? *Am J Obstet Gynecol* 1990;162:311–316, with permission.

TABLE 16.14. *Differential diagnosis of HELLP syndrome*

HELLP syndrome can easily be confused with two other specific medical conditions, acute fatty liver of pregnancy and thrombotic thrombocytopenic purpura–hemolytic uremic syndrome (TTP/HUS). The differentiation among the three entities is made largely based on specific laboratory findings. Table 16.15 presents detailed laboratory comparisons among the three disorders.

	HELLP	TTP/HUS	AFLP
Edema	Normal	Normal	Elevated
Anemia	Present	Severe	Normal
Antithrombin III	May be reduced	Normal	Decreased in all cases
Aspartate transaminase	Elevated	Usually normal	Elevated
Bilirubin	Elevated, mostly indirect	Elevated	Elevated, mostly direct
Creatinine	May or may not be elevated	Significantly elevated	Significantly elevated
Fibrinogen	Normal	Normal	Decreased in all cases
Glucose	Normal	Normal	Decreased
Hypertension	Present	May or may not be present	May or may not be present
Liver enzymes	Elevated	Significantly elevated	Elevated
Proteinuria	Present	May or may not be present	May or may not be present
Thrombocytopenia	Present	Present	May or may not be present

AFLP, acute fatty liver of pregnancy; HELLP, hemolysis, elevated liver enzymes, low platelets; HUS, hemolytic uremic syndrome; LDH, lactate dehydrogenase; TTP, thrombotic thrombocytopenic purpura.

TABLE 16.15. *Clinical and laboratory findings in HELLP syndrome, TTP/HUS, and AFLP*

Management of HELLP Syndrome

The initial evaluation of women diagnosed with HELLP syndrome should be like that for severe preeclampsia. The patient should be cared for at a tertiary care center. Management initially should include maternal and fetal assessment, control of severe hypertension, if present, initiation of $MgSO_4$ infusion, correction of coagulopathy, if present, and maternal stabilization. A potentially life-threatening complication of HELLP syndrome is a subcapsular liver hematoma. If the suspicion for a subcapsular liver hematoma is high, then it is appropriate to proceed with obtaining a computed tomography scan.

Immediate delivery should be performed in patients =34 weeks gestation. In patients less than 34 weeks and without proven fetal lung maturity, glucocorticoids should be given for fetal benefits and delivery planned in 48 hours provided no worsening of maternal or fetal status occurs. Multiple studies have been done using steroids, volume expanders, plasmapheresis, and antithrombotic agents in patients with HELLP to attempt to prolong gestation. These studies show only marginal results. Some evidence exists as to the benefit of steroid therapy for improvement in maternal condition. In a study by O'Brien and colleagues, the antepartum use of glucocorticoids showed a dose-dependent prolongation in latency, reduction in liver enzyme abnormalities, and improvement in platelet count in patients with HELLP syndrome. Conservative management of HELLP syndrome has significant risk, including abruptio placentae, pulmonary edema, adult respiratory distress syndrome (ARDS), ruptured liver hematoma, acute renal failure, disseminated intravascular coagulation (DIC), eclampsia, intracerebral hemorrhage, and maternal death. It is the author's opinion that expectant management longer than 48 hours after glucocorticoid administration is not warranted for the potential minimal fetal benefits when weighed against the profound maternal risk.

Patients with a favorable cervix and a diagnosis of HELLP syndrome should undergo a trial of labor, particularly if they arrive in labor. HELLP syndrome does not automatically mandate cesarean delivery. An operative delivery in some situations may even be harmful. Any patient with a favorable cervix, regardless of length of gestation, should undergo induction of labor with either oxytocin or prostaglandins. Elective cesarean section should be considered in patients in very early gestation

who have an unfavorable cervix. A management paradigm is presented in Table 16.16 for patients with HELLP undergoing cesarean section.

1. Control severe hypertension
2. Initiate intravenous magnesium sulfate infusion
3. Glucocorticoids for 24–48 hours for fetal benefit if <34 wks
4. General anesthesia for platelet count <75,000/mm^3
5. Platelets 5–10 units before surgery if platelet count <50,000/mm^3
6. Leave vesicouterine peritoneum (bladder flap) open
7. Subfascial drain
8. Secondary closure of skin incision or subcutaneous drain
9. Postoperative transfusions as needed
10. Intensive monitoring for at least 48 hours postpartum

TABLE 16.16. *Perioperative management of a patient with HELLP syndrome requiring cesarean section*

Pain management of the patient with HELLP during labor should be discussed between the obstetrician and the anesthetist. The anesthetist should be made aware of the patient's condition due to the potential of laryngeal edema and difficulties with intubation or extubation. Typically the decision of whether to use epidural anesthesia is at the discretion of the anesthetist. Regional anesthesia should be used with caution in patients with particularly low platelet counts. A study by O'Brien and co-workers supported the use of glucocorticoids to improve platelet counts and to allow a more liberal use of regional anesthesia in patients with HELLP syndrome. The anesthetist should be updated as to the trend in platelet count of patients with HELLP. Intravenous narcotics can be given to achieve analgesia. Local infiltration can be used without concern during vaginal deliveries and for perineal repairs. Pudendal blocks should be avoided due to the potential for unrecognized bleeding into this area.

Should a patient with HELLP syndrome require cesarean delivery, precautions should be taken to minimize adverse outcomes. Platelet transfusion of approximately 5 to 10 units should be done en route to the operating room for patients with severe thrombocytopenia. Platelet consumption is rapid with a platelet transfusion, and the effects are temporary. Intraoperative considerations should include drain placement, either subfascial, subcutaneous, or both, due to anticipated generalized oozing. The choice of skin incision should be made entirely on the surgeon's best clinical judgment. In a study by Briggs and colleagues, patients with HELLP syndrome undergoing cesarean section were evaluated for wound complications. No statistical difference was found between midline incision versus Pfannenstiel, whether primary or delayed closure.

Another potential life-threatening complication of HELLP syndrome is a subcapsular liver hematoma. Clinical findings consistent with subcapsular hematoma include physical examination with peritoneal irritation and hepatomegaly and referred pain from the phrenic nerve. Pain to the pericardium, peritoneum, pleura, shoulder, gallbladder, and esophagus are consistent with referred pain from the phrenic nerve. Confirmation of the diagnosis can be made by computed tomography, ultrasonography, or magnetic resonance imaging. Conservative management in a hemodynamically stable patient with an unruptured subcapsular hematoma is an appropriate plan, provided that close hemodynamic monitoring, serial evaluations of coagulation profiles, and serial evaluation of hematoma status by radiologic studies are performed. Should the patient decompensate hemodynamically, the diagnosis of ruptured subcapsular hematoma should be entertained.

If rupture of a subcapsular liver hematoma is suspected, immediate intervention is necessary. Liver hematoma rupture with hemodynamic shock is a life-threatening surgical emergency. Treatment at this point is from a multidisciplinary approach and should involve general surgeons and vascular surgeons to perform a laparotomy. Furthermore, correction of coagulopathy and massive blood product transfusion is essential. The rupture typically involves the right lobe of the liver. Maternal and fetal mortality is over 50% with immediate intervention. The recommendation in the literature for rupture of a subcapsular liver hematoma in pregnancy is packing and drainage. According to a study by Smith and co-workers, overall survival reached 82% with this method.

Postpartum management of the patient with HELLP should include close hemodynamic monitoring for at least 48 hours. Serial laboratory evaluations should be done to monitor for worsening abnormalities. Most patients will show reversal of laboratory parameters within 48 hours postpartum. Small studies have shown a more rapid reversal in laboratory abnormalities with postpartum administration of plasma exchange and steroids.

ECLAMPSIA

The rate of eclampsia in the United States is 0.05% to 0.1%. The rate is much higher in developing countries. Eclampsia continues to be a major cause of maternal and perinatal morbidity and mortality worldwide. The maternal mortality rate is approximately 4.2%. The perinatal mortality rate is higher, ranging from 13% to 30%. Eclampsia can occur antepartum (50%), intrapartum (25%), or postpartum (25%). Patients with eclampsia can exhibit a wide spectrum of signs and symptoms, from mild isolated hypertension to multiorgan failure. Prevention of eclampsia is one of the goals in treating preeclamptic patients with $MgSO_4$.

Management of Eclampsia

During the eclamptic seizure, the main therapy is supportive care. This includes avoiding injury, maintaining oxygenation, and minimizing the risk of aspiration. An outline to the specific steps to care for an eclamptic patient are in Table 16.17. Most seizures are self-limited, lasting 1 to 2 minutes. However, some patients may have repeated convulsions, which can result in hypoxia or acidosis both in mother and fetus. $MgSO_4$ is the drug of choice for the prevention of eclamptic seizures and should be used for the prevention of recurrent seizures. Approximately 10% of eclamptic women receiving $MgSO_4$ will have further seizures.

1. Avoid injury
a. Padded bedside rails
b. Physical restraints
c. Padded tongue blade
2. Maintain oxygenation to mother and fetus
a. Oxygen at 8–10 L/min by face mask
b. Monitor oxygenation and metabolic status with transcutaneous pulse oximetry or arterial blood gas measurements
3. Minimize aspiration
a. Lateral decubitus position
b. Suctioning of vomitus and oral secretions
c. Obtain chest x-ray after cessation of convulsion to rule out aspiration
4. Initiate $MgSO_4$ to prevent recurrent seizures
5. Control severe hypertension
6. Initiate the delivery process

$MgSO_4$, magnesium sulfate.

TABLE 16.17. *Management of the eclamptic patient*

Immediately following an eclamptic seizure, it is common to see abnormalities in the fetal heart rate pattern. These include fetal bradycardia, decreased variability, late decelerations, and reflex tachycardia. These abnormalities typically resolve within 5 to 10 minutes after the convulsion. It is important not to proceed directly to cesarean delivery after a seizure. Stabilization of the mother is the number one priority. Generally the fetus will respond favorably once the mother is treated. If prolonged signs of fetal compromise occur indicating possible abruptio placentae, consideration should be given to proceed with operative delivery.

Vaginal delivery is the preferred route after an eclamptic seizure. Cesarean delivery should be performed for obstetric indications only. Induction of labor should be performed with oxytocin or prostaglandins. The patient should be maintained on $MgSO_4$ throughout her labor. Careful attention must be made to the overall fluid status of the patient. Patients with eclampsia have profound hemoconcentration. Because of this, close hemodynamic monitoring is required with the use of epidural anesthesia and in case of severe blood loss. Patients who are hypovolemic will not respond well to acute blood loss, in contrast to healthy parturients. It is also important to limit fluids, because these patients have capillary leakage and are predisposed to developing pulmonary edema.

$MgSO_4$ should be continued for 24 hours postpartum. Intracranial imaging typically is not warranted unless coma or focal neurologic signs persist or the diagnosis is uncertain. Most patients are normotensive at discharge and do not require medication. Eclamptic patients should be evaluated in the outpatient setting within 1 week of discharge.

Postpartum eclampsia offers a diagnostic dilemma. Any woman seizing in the postpartum period should be considered to have a diagnosis of eclampsia, although other disorders must be ruled out. Late postpartum eclampsia, defined by Sibai as occurring more than 48 hours after delivery, happens in 56% of postpartum eclampsia. Patients who develop postpartum eclampsia usually will have symptoms prior to seizure activity, including severe persistent headache, blurred vision, photophobia, epigastric pain, nausea and vomiting, and transient mental status changes. Therefore, it is important to educate patients about reporting these symptoms to health care providers. All such women should receive preeclamptic evaluation. These patients should receive $MgSO_4$ for 24 hours after seizure activity. If the

patient has normal laboratory values and hypertension is controlled, she can be discharged after $MgSO_4$ treatment to return in 1 week for outpatient evaluation.

MAGNESIUM SULFATE

$MgSO_4$ is used in the management of preeclamptic patients for the prevention of eclamptic seizures. The exact mode of action of $MgSO_4$ for preventing seizures is unknown, although it has been in use since the early 1900s. Multiple studies have been done which show $MgSO_4$ to be superior to both phenytoin and diazepam for the prevention of seizures. Most notable of these is the Collaborative Eclampsia Trial, in which women with eclampsia were randomized to receive $MgSO_4$, phenytoin, or diazepam. The trial found that $MgSO_4$ was superior to both phenytoin and diazepam in the prevention of recurrent seizures and of maternal and perinatal death.

The administration of $MgSO_4$ is usually intravenous. The therapeutic range is considered a serum plasma level from 4 to 8 mg/dL. Multiple regimens have been prescribed to achieve these levels. The recommended regimen is presented in Table 16.18. The intravenous route is the preferred method, because intramuscular injections of $MgSO_4$ are very painful and occasionally can cause gluteal abscess formation. Lidocaine at the injection site may decrease discomfort. The intramuscular route should be reserved for rare situations when intravenous infusions may not be possible, such as lack of intravenous access, unavailability of infusion pumps, or during patient transport.

Loading dose: 6 g i.v. over 20–30 min (6 g of 50% solution diluted in 150 cc D5W)
Maintenance dose: 2–3 g i.v. per hr (40 g in 1 L D5LR at 50 cc/hr)
Additional 2 g over 5–10 min (1–2 times) can be given with persistent convulsions
If convulsions persist (2% of cases), give 250 mg sodium amobarbital i.v. over 5 min
In status eclampticus: intubation and muscular paralysis
Intramuscular dose: 10 g i.m. (20 mL of 50% $MgSO_4$, one half of the dose in each buttock)

$MgSO_4$, magnesium sulfate.

TABLE 16.18. *Recommended regimens of magnesium sulfate in the treatment of eclamptic convulsions*

$MgSO_4$ is not an entirely benign medication. Any member of the health care team caring for a patient receiving $MgSO_4$ should be familiar with potential side effects and complications of its administration. Patients receiving $MgSO_4$ are at increased risk for postpartum hemorrhage due to uterine atony. This should be anticipated and steps taken to prepare cross-matched blood if the need arises. Monitoring patients for signs of magnesium toxicity should be done throughout the course of administration. This includes eliciting deep tendon reflexes, assessing mental status, and checking respiratory rate. Table 16.19 lists the clinical findings associated with various serum magnesium levels. If a patient develops signs of magnesium toxicity, the infusion should be stopped immediately. The patient should then be evaluated for respiratory compromise by examination and pulse oximetry, oxygen administered, and a serum magnesium level obtained. If magnesium toxicity is diagnosed, the patient should be treated with 10 cc of 10% calcium gluconate (1 g) slow push intravenously. Calcium competitively inhibits magnesium at the neuromuscular junction and decreases the effect of the magnesium. The effect of the calcium is transient, and the patient should be monitored closely for continued magnesium toxicity. Should respiratory or cardiac arrest occur, immediate resuscitation including intubation and mechanical ventilation should be performed. A summary of the treatment of magnesium toxicity is seen in Table 16.20.

Clinical finding	Serum level
Loss of patellar reflex	8–12 mg/dL
Feeling of warmth, flushing	9–12 mg/dL
Double vision	
Somnolence	10–12 mg/dL
Slurred speech	10–12 mg/dL
Muscular paralysis	15–17 mg/dL
Respiratory difficulty	15–17 mg/dL
Cardiac arrest	30–35 mg/dL

TABLE 16.19. *Serum magnesium levels and associated clinical findings*

Discontinue magnesium sulfate infusion
Begin supplemental oxygen administration
Obtain serum magnesium level
Administer 1 g calcium gluconate (10 cc of 10% calcium gluconate) by slow intravenous push
Repeat calcium gluconate administration if necessary
If respiratory arrest occurs, begin cardiopulmonary resuscitation

TABLE 16.20. *Management of magnesium toxicity*

Counseling

Any patient diagnosed with preeclampsia is at significantly greater risk of having an underlying medical condition than is a normotensive gravidae. A study by Dekker and Sibai found 39% of patients with a history of early-onset severe preeclampsia developed chronic hypertension. Another study by Nisell and co-workers found that 37% of patients with a history of pregnancy-induced hypertension and 20% of patients with a history of preeclampsia were noted to have hypertension at 7-year follow-up. It is thus essential that women diagnosed with preeclampsia receive close follow-up.

With regard to future pregnancies, patients with preeclampsia are at increased risk of developing preeclampsia during subsequent gestations. The risk is dependent on severity of preeclampsia, as well as gestational age at onset in the index pregnancy. The recurrence rate is 65% if preeclampsia develops in the midtrimester and 20% if it develops at term. Sibai and associates reviewed recurrence rates of preeclampsia and HELLP in patients who had pregnancies complicated by HELLP syndrome. Their findings noted that the recurrence risk for preeclampsia in the otherwise normotensive group was 19% and the risk for recurrence of HELLP was 3%. This is in contrast to a group of patients with underlying chronic hypertension who had recurrence rates of preeclampsia and HELLP of 75% and 5%, respectively. The rate of recurrence of eclampsia is about 1% to 2%.

CHRONIC HYPERTENSION

Chronic hypertension is defined by elevated blood pressure occurring prior to pregnancy or elevated blood pressure measurements prior to 20 weeks gestation. The rate of chronic hypertension is 1% to 5% in pregnancy. This number is effected by many factors, including maternal age and race. The incidence of chronic hypertension among African Americans is 2.5% in comparison with 1% among other racial groups. The Third National Health and Nutrition Examination Survey, 1988 to 1991, studied the incidence and stratification of patients with chronic hypertension. The results of this study showed that the rate of chronic hypertension among women ages 18 to 29 was 2.0% for African Americans, 0.6% for Caucasians, and 1.0% for Mexican Americans. In the 30 to 39 age category, the rates were 22.3%, 4.6%, and 6.2%, respectively. And from 40 to 49 years of age, the prevalence was 30.5%, 12.7%, and 10.6% for each group. Given the trend in delayed childbearing as women pursue career and educational goals, increasing numbers of pregnancies will be complicated by chronic hypertension.

Determination of associated underlying medical conditions and the classification of hypertension is important in the management and counseling of patients with chronic hypertension in pregnancy. Chronic hypertension can be classified as either mild or severe, depending on blood pressure criteria. Systolic blood pressure =160 mm Hg or diastolic blood pressure =110 mm Hg, or both, constitute severe chronic hypertension. The etiology of chronic hypertension can be either primary or secondary. Primary hypertension, also referred to as idiopathic hypertension or essential hypertension, occurs in 90% of pregnancies. Secondary hypertension occurs in the remaining 10% of pregnancies and is associated with the following underlying medical conditions: renal disease, endocrine disease, collagen vascular disease, and coarctation of the aorta.

Women with chronic hypertension in pregnancy are at increased risk for the development of superimposed preeclampsia, abruptio placentae, intrauterine growth restriction, and preterm delivery. The rate of superimposed preeclampsia in women with chronic hypertension is 25%. If the patient has chronic hypertension of over 4 years' duration, renal insufficiency, or had hypertension in a prior pregnancy, the rate of superimposed preeclampsia increases. Overall, abruptio placentae occurs in 1.5% of pregnancies complicated by chronic hypertension. This rate varies from 1% in women with uncomplicated chronic hypertension to 3% in women with superimposed preeclampsia. Proteinuria is an independent risk factor for adverse perinatal outcome, regardless of the development of superimposed preeclampsia. A

maternal serum creatinine greater than 1.4 mg/dL at conception is another risk factor for increased fetal loss and progressive worsening of maternal renal disease. Fetal loss is increased 10-fold in women with uncontrolled chronic hypertension and impaired renal function at conception as compared with normotensive women and women with well-controlled hypertension. Therefore, management of women with chronic hypertension should begin prior to conception.

Women with chronic hypertension should be counseled regarding the increased risk of adverse maternal and fetal outcomes as above. These patients should also be evaluated for end-organ damage such as retinopathy, renal disease, and left ventricular hypertrophy. The possibility of worsening maternal condition during pregnancy must be discussed with the patient. Blood pressure control prior to pregnancy should be optimized and lifestyle changes initiated, if possible. Patients should be discouraged from tobacco or alcohol use, because both of these may exacerbate hypertension, not to mention other known obstetric risks. Daily salt intake should be limited to 2 g. Appropriate antihypertensive medications should be prescribed. This would include the discontinuation of angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor antagonists, if the patient was previously taking these medications. In addition, atenolol should be discontinued early in pregnancy.

The diagnosis of superimposed preeclampsia may be difficult to make in the patient with chronic hypertension, particularly with baseline nephropathy. To make the diagnosis, the patient should have increasing or difficult-to-control blood pressure, HELLP syndrome, new-onset proteinuria, or significant increase in preexisting proteinuria. Any patient with chronic hypertension who develops headache, right upper quadrant pain, or visual disturbances requires further evaluation for superimposed preeclampsia. If superimposed preeclampsia is suspected in a patient with chronic hypertension, she should be hospitalized for close maternal and fetal evaluation.

MANAGEMENT

The management of pregnancies complicated by chronic hypertension differs for the low-risk group versus the high-risk group. Patients considered in the low-risk group have, by definition, mild hypertension without evidence of organ damage. The high-risk group has either severe hypertension (systolic blood pressure =160 mm Hg or diastolic blood pressure =110 mm Hg) or mild hypertension with evidence of organ involvement.

Patients with low-risk chronic hypertension who do not develop superimposed preeclampsia have pregnancy outcomes similar to those of the general population. Studies have shown that antihypertensive treatment in this group does not effect perinatal outcome and is not necessary, provided they remain in the mild hypertension range by blood pressure criteria. Antihypertensive use may be discontinued at the first prenatal visit in any patient with mild hypertension. These patients should be observed closely throughout gestation, because they may become high risk at any time. Pharmacologic agents should be reinstituted if systolic blood pressures reach 160 mm Hg or diastolic pressures reach 105 mm Hg or target organ damage develops. Prenatal care should include 24-hour urine collection for total protein determination in the first trimester and at least monthly visits in the first and second trimester. Visits should be every 1 to 2 weeks after 32 weeks, looking carefully for the development of superimposed preeclampsia. Fetal surveillance should include interval ultrasonography for fetal growth and amniotic fluid assessment every 4 weeks beginning at 32 weeks, unless there is suspicion of poor fetal growth, and then testing should be started earlier. Weekly fetal heart rate testing with nonstress tests should begin at 34 weeks. Fetal well-being assessment should be increased to twice weekly with evidence of growth restriction or oligohydramnios. The patient should also be instructed on fetal movement counts. Timing of delivery should be determined on an individual basis. Patients in the low-risk group may continue their pregnancies up to 41 weeks, provided that blood pressure remains controlled and no evidence of superimposed preeclampsia or fetal growth restriction develops.

Central to the management of the high-risk chronic hypertensive pregnancy is the use of antihypertensive pharmacotherapy. The choice of agent is dependent on their pharmacologic actions and will be covered in the next section. Prenatal care of the high-risk patient includes a first-trimester 24-hour urine collection for total protein level. The frequency of visits in the first and second trimesters should be every 2 to 3 weeks, and weekly in the third trimester if clinically indicated. Fetal surveillance should include ultrasonography for estimated fetal weight and amniotic fluid volume every 4 weeks starting at 26 weeks. Weekly nonstress testing or biophysical profile assessments should begin at 28 weeks. The frequency of prenatal care visits and fetal testing may need to be increased dependent upon clinical findings such as increasing hypertension, superimposed preeclampsia, decreased amniotic fluid volume, or fetal growth restriction. If superimposed preeclampsia is suspected or uncontrolled hypertension develops, the patient should be hospitalized, preferably at a tertiary care center. The timing of delivery is dependent upon the development of confounding complications and gestational age. In general, pregnancies in patients with high-risk chronic hypertension should not be continued past 40 weeks.

ANTIHYPERTENSIVE AGENTS

Many agents are available for the control of hypertension. It is important to be familiar with the maternal and fetal side effects, as well as mode of action, in order to choose the most effective agent for your patient. Antihypertensive agents exert their activity through the following five methods: they decrease cardiac output, decrease peripheral vascular resistance, decrease blood pressure centrally, diurese, and inhibit angiotensin production. Commonly used drugs in pregnancy are listed in Table 16.21 and we will discuss them in this section. For the postpartum patient who is breast-feeding, little information is known for most drugs regarding excretion in breast milk and neonatal effects. In general, ACE inhibitors are discouraged secondary to potential renal effects on the neonate.

Medication	*Dosage*	*Maximum*	*Half-life*
Methyldopa	250–500 mg p.o. q6–12h	4 g/24 h	2 h
Labetalol	100 mg p.o. b.i.d.	2,400 mg/24 h	5–8 h
Thiazide Diuretic	12.5 mg p.o. b.i.d.	50 mg/24 h	3 h
Nifedipine	10–20 mg p.o. q4–6h	240 mg/24 h	2 h

TABLE 16.21. *Antihypertensive drugs commonly used in pregnancy*

Centrally Acting Drugs

Methyldopa Methyldopa is the most commonly used antihypertensive in pregnancy. Its mode of action is by central inhibition of the sympathetic drive. The safety and efficacy of methyldopa is well established. Studies have documented no known congenital malformations or adverse long-term follow-up of children exposed in utero. Maternal side effects include tiredness, dry mouth, and somnolence. In addition, about 5% to 10% may have elevated liver enzyme values. Methyldopa is the agent of choice for long-term, nonemergent oral therapy.
Clonidine Clonidine is not commonly used and there is limited data regarding safety and efficacy of its use. Limited studies regarding congenital defects associated with the use of clonidine reveal no increased risk.

Beta Blockers

The main mode of action of ß-adrenergic blockade is through the reduction in cardiac output. The drugs in this group are a heterogeneous mixture exerting their effects dependent upon receptor selectivity, lipid solubility, and intrinsic sympathomimetic activity. Fetal effects of ß blockers may include growth restriction and neonatal hypoglycemia. Atenolol in the first trimester in particular has been linked to intrauterine growth restriction. Labetalol is a nonselective ß blocker and a postsynaptic ß-1 blocker. It has lower ß blocking effect than other ß blockers, which does not reduce cardiac output. It is probably, thus, less responsible for fetal growth restriction. The side effects are tremors, headache, and scalp tingling. The use of labetalol should be avoided in patients with asthma and congestive heart failure.

Calcium Channel Blockers

Calcium channel blockers act by inhibiting extracellular calcium influx into cells through slow calcium channels. This, then, reduces peripheral vascular resistance. Studies have found no increase in congenital malformations associated with the long-term use of calcium channel blockers. However, adverse maternal and fetal outcomes have been associated with sublingual use of nifedipine, including maternal myocardial infarction and profound hypotension. Maternal side effects are flushing, headache, and palpitations.

Vasodilators

Hydralazine Hydralazine works through direct and potent vasodilatation. It may be used orally but is most effective as an intravenous agent to control hypertensive crisis. No congenital defects have been associated with hydralazine. It may cause hypotension in hypovolemic patients, so giving intravenous fluids may be warranted. Side effects include fluid retention, tachycardia, palpitations, headache, lupuslike syndrome, and neonatal thrombocytopenia.

Diuretics

Diuretics, in general, are not contraindicated in pregnancy. There is no increased risk of congenital defects with their use, but their efficacy is uncertain. It is recommended that women receiving diuretics prior to pregnancy be continued on them throughout pregnancy. However, diuretics should be discontinued in patients with preeclampsia or oligohydramnios or if there is evidence of reduction in uteroplacental flow.

Thiazide The thiazide diuretics have minimal effect on lowering blood pressure in pregnancy and are rarely used. Limited studies show no increased congenital anomalies with the use of thiazide. The side effect profile includes maternal and fetal hyponatremia and acute pancreatitis, rise in blood uric acid levels, and neonatal thrombocytopenia. It can also precipitate hyperglycemia and glycosuria in the diabetic patient.
Furosemide Furosemide is rarely used as a sole pharmacologic agent but is useful in conjunction with other antihypertensives. Studies showed no increase in congenital anomalies with use in the second and third trimesters, but first trimester use may be associated with hypospadias. Furosemide use in pregnancy should be limited to postpartum management of fluid overload and pulmonary edema in the preeclamptic patient.

Angiotensin-converting Enzyme Inhibitors

ACE inhibitors act by inhibiting the production of angiotensin II and by reducing peripheral vascular resistance. The use of ACE inhibitors has been associated with an increased risk of intrauterine demise, renal dysgenesis, oligohydramnios, pulmonary hypoplasia, fetal growth restriction, and neonatal renal dysfunction. The mechanism of action is thought to be due to continuous inhibition of the renin-angiotensin system, leading to the development of tubular dysfunction. Therefore, ACE inhibitors are contraindicated in pregnancy, mainly during the second and third trimesters. However, ACE inhibitors may be an excellent choice for hypertensive control in the postpartum period.

Contraception

Women with hypertensive diseases in pregnancy, whether preeclampsia or chronic hypertension, will seek advice regarding contraceptive methods postpartum. It is important to be familiar with options available to patients and be able to discuss potential risk factors.

No contraindications exist with the use of barrier methods with regard to hypertension. The user failure rate, however, may be significant if failure results in a pregnancy with increased morbidity due to hypertensive disease. There are no contraindications for hypertensive patients desiring to use an intrauterine device. It is important to be aware of any associated underlying medical problems or therapies that the patient may have that would prohibit the use of an intrauterine device. Natural family planning continues to be an acceptable form of contraception when used appropriately.

The greatest concern in finding appropriate contraception for the hypertensive patient is with regard to hormonal contraception. Oral contraceptive pills are the most widely used reversible form of birth control in the United States. Combination oral contraceptives are known to elevate blood pressure minimally, increase clotting factors, and increase total cholesterol levels. Once again, it is extremely important to be familiar with any coexisting disease in a hypertensive patient. Hypertension may have associated underlying antiphospholipid syndrome, for example, which would be a contraindication to combination oral contraceptives given the increased risk for thromboembolic phenomena. Progestin-only contraceptive methods may be a suitable alternative for women with underlying hypercoagulability, because they do not interfere with coagulation. Overall, the contraceptive choices afforded hypertensive patients are basically the same as in normotensive patients. The risks and benefits of contraception must be weighed and patients counseled accordingly. Avoiding the morbidity associated with pregnancy in some patients may be a benefit that outweighs the risk of contraceptive use.

SUMMARY POINTS

- Making an appropriate diagnosis is essential in caring for women with hypertensive disease in pregnancy.
- There is no known etiology, prevention, or screening method for preeclampsia.
- The use of $MgSO_4$ is warranted in patients with preeclampsia and eclampsia to prevent seizures.
- Fetal outcome in patients with preeclampsia is based largely upon gestational age at delivery; as such, prolonging pregnancies in patients with preeclampsia should be done with close maternal and fetal observation.
- Blood pressure =170 mm Hg systolic and =110 mmHg diastolic requires intervention.
- Any patient with symptoms of HELLP syndrome should have laboratory evaluation performed, regardless of blood pressure measurements.
- Evaluation of a patient with chronic hypertension should include monitoring for target organ damage. Management of these patients is dependent upon the degree of hypertension.
- Any patient with chronic hypertension is at increased risk of developing superimposed preeclampsia.

Anemias

Anemia is defined as a hemoglobin (Hb) concentration of less than 12 g/dL in nonpregnant women. Anemia can be acquired or inherited. During pregnancy, plasma volume expands proportionately more than Hb or red blood cell volume, resulting in Hb dilution, such that anemia is defined as a Hb concentration of less than 10 g/dL. In addition to blood loss, anemia can result from decreased production or increased destruction of red blood cells. The initial workup consists of a history and physical examination, as well as an examination of the red blood cell indices and a peripheral smear, with additional tests as indicated (Fig. 17.1).

FIG. 17.1. Workup of anemia in pregnancy.

Acquired Anemias

Iron Deficiency Anemia Iron deficiency is an acquired anemia and is the most common cause of anemia in gravid women, occurring in 15% to 25% of all pregnancies. Iron deficiency is suspected when the mean corpuscular volume (MCV) is less than ã80/µm ^{3} and is confirmed by demonstrating an elevated total iron-binding capacity (TIBC), a low serum iron level, a serum iron-to-TIBC ratio less than 20%, or a low ferritin level. Effects of iron deficiency on the fetus are usually minimal, although neonatal anemia is increased. Iron is transported actively across the placenta, and fetal iron and ferritin levels are 3 times higher than maternal levels. However, iron deficiency anemia has been weakly associated with preterm birth, and when maternal anemia is severe (Hb less than 6 g/dL), intrauterine growth restriction (IUGR) may occur. In pregnant women, iron deficiency can cause symptoms including fatigue, headache, lightheadedness, and reduced exercise tolerance. Blood loss at delivery may be tolerated poorly in anemic patients, and postpartum tissue healing may be compromised. For these reasons, treatment during pregnancy is recommended. The total iron requirement of pregnancy is 1,000 mg: 500 mg increases the maternal red blood cell mass, 300 mg is transported to the fetus and placenta, and 200 mg compensates for blood loss at delivery. The iron requirements of pregnancy increase steadily toward term but average 3.5 mg per day. Even though iron absorption efficiency increases during pregnancy, excess iron must be ingested to ensure sufficient dosage. Recommended supplementation for nonanemic gravidas is 300 mg of ferrous sulfate per day, which contains 60 mg of elemental iron. Anemic gravidas (Hb of 8 or 9 g/dL) should take 300 mg ferrous sulfate 2 or 3 times a day. Patients who cannot tolerate iron tablets may take an enteric-coated tablet or a liquid suspension (Table 17.1). Vitamin C facilitates iron absorption. Therapeutic results can be expected after 3 weeks of therapy.

TABLE 17.1. *Iron preparations and dosages*

The severely anemic patient (Hb less than 8 g/dL) may require parenteral therapy in the form of intramuscular or intravenous iron dextran. Because 0.2% to 0.3% of patients have an anaphylactic response to iron dextran, all patients should receive a small test dose 1 hour before the initiation of treatment, and therapy should be provided in an area with ready access to resuscitative medication and equipment. The total dose of iron required can be calculated using this formula: Total dose of iron dextran (mL) = (0.0476 × body weight in kg × [desired Hb concentration - observed Hb concentration]) + 1 mL/5 kg of body weight up to a maximum of 14 mL This dose can be given intramuscularly or intravenously (by slow push), 2 mg per day, until the total dose has been given, or the entire dose can be given diluted in 500 to 1,000 mL of 0.9% saline and administered intravenously over 1 to 6 hours. Adequate parenteral therapy should result in a marked increase in the reticulocyte count within 7 to 14 days.

Megaloblastic Anemia Megaloblastic anemia is characterized by red blood cells with increased MCV and white blood cells with altered morphology (hypersegmented neutrophils, anisocytosis, and poikilocytosis). It complicates up to 1% of pregnancies and usually is caused by folate deficiency, although it can occur after exposure to sulfa drugs or hydroxyurea or, rarely, because of vitamin B $_{12}$ deficiency. Folate deficiency can develop over a relatively short time, because liver stores of folate are sufficient to meet the body's needs for only 1 to 2 months. Malnutrition (e.g., alcoholism), malabsorption, anticonvulsant therapy, oral contraceptive use, or pregnancy can rapidly deplete the body's folate stores. Hypersegmented neutrophils (more than 5% of neutrophils having five or more lobes) appear after 7 weeks of deficiency, red blood cell folate is reduced after 18 weeks, and anemia occurs after 20 weeks. The daily folate requirement for a nonpregnant individual is 50 to 100 µg; a pregnant woman needs 300 to 400 µg. This dosage may be difficult to achieve through dietary manipulation, because folate is found primarily in fresh fruits and vegetables and is destroyed by cooking. As a separate issue, it now seems apparent that some women require excess folate to overcome a relative enzyme deficiency leading to high blood and amniotic fluid levels of homocysteine and an increased risk for fetal neural tube defects. For these reasons, women contemplating pregnancy should be advised to ingest a daily folic acid supplement (0.4 mg per day if there is no family history of neural tube defects; 4 mg per day if there is a family history) beginning before conception and continuing throughout the first trimester of pregnancy. In contrast, vitamin B $_{12}$ deficiency is rare, because very little of the body's stores is used each day. Ingested vitamin B $_{12}$ is bound to intrinsic factor produced by the parietal cells of the stomach and then absorbed through the mucosa of the distal ileum. Patients who have had a gastrectomy, ileitis, or ileal resection, or who have pernicious anemia, pancreatic insufficiency, or intestinal parasites eventually may become vitamin B $_{12}$ deficient. When megaloblastic anemia is suspected, the history should be reviewed for predisposing factors. The peripheral smear should be examined both to confirm altered cell morphology and to rule out a mixed (i.e., folate and iron) deficiency. Serum folate and vitamin B $_{12}$ levels should be measured. A fasting folate level less than 3 ng/mL or a vitamin B $_{12}$ level less than 80 pg/mL indicates deficiency. Folate deficiency responds to 0.5 to 1.0 mg folate orally per day, while a B $_{12}$ deficiency requires vitamin B $_{12}$, 1 mg intramuscularly, weekly for 6 weeks.

Hereditary Anemias The most commonly encountered hereditary anemias in pregnancy are the thalassemias and sickle cell variants. Hb is a tetramer composed of two copies each of two different polypeptide chains; the identity of the chains determines the type of Hb produced. During embryonic and fetal life, genes directing production of different types of polypeptide chains and, thus, different types of Hb, are switched on and then off sequentially. At birth, a normal individual produces a and ß chains, along with very small quantities of d and t chains (Fig. 17.2). Normal adults produce primarily hemoglobin A (HbA), composed of two a and two ß polypeptide chains.

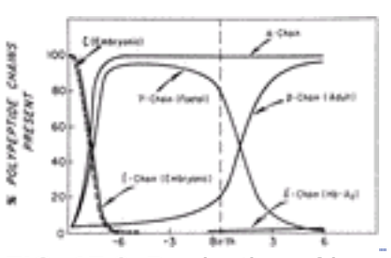

FIG. 17.2. Production of hemoglobin polypeptide chains in relationship to gestational age. (From Rucknagel DL, Laros RK. Hemoglobinopathies: genetics and implications for studies of human reproduction. *Clin Obstet Gynecol* 1969;12:4, with permission.)

Thalassemias Thalassemias are characterized by impaired production of one or more of the peptide chains. Thalassemia has a high incidence in certain ethnic groups, especially those originating in the Mediterranean basin, the Middle East, Africa, Asia, and India. Four clinical syndromes are associated with a-thalassemia, and two syndromes are associated with ß-thalassemia. Two genes direct ß-chain production, one on each copy of chromosome 11. Over 100 different gene mutations have been identified that prevent or reduce ß-chain transcription; if one gene carries such a mutation, ß-chain production will be reduced by one half, and abnormally low quantities of Hb will be produced. This results in ß-thalassemia minor. The excess a chains combine, instead, with d chains, producing a molecule called HbA $_2$, or with ? chains, producing fetal hemoglobin (HbF). If ß-thalassemia minor is suspected because the patient has microcytic anemia without iron deficiency, Hb electrophoresis should be performed. Levels of HbA $_2$ greater than 3.5% and HbF greater than or equal to 2% confirm the diagnosis (Table 17.2). The gravid patient with ß-thalassemia minor generally tolerates pregnancy well. She should receive folic acid supplementation, but not iron supplementation unless iron deficiency is diagnosed, also.

TABLE 17.2. *Hemoglobin electrophoresis findings in various hemoglobinopathies*

Patients with mutations preventing transcription of both ß-chain genes have ß-thalassemia major (ß-thalassemia), or Cooley anemia. Erythropoiesis is ineffective because there is no ß-chain production, and the a chains precipitate, causing red blood cell destruction. Occasionally, the mutations allow some ß-chain production, resulting in a less severe reduction of Hb synthesis (ß-thalassemia). Aggressive intervention in infancy using transfusion therapy ultimately leads to iron overload and hemosiderosis, with multiple organ system dysfunction and infertility. Increasing numbers of pregnancies in this population are being reported by virtue of aggressive transfusion and iron chelation therapy. Such pregnancies can be complicated by an increased risk of cardiac arrhythmias and congestive heart failure secondary to severe anemia, chronic hypoxemia, and myocardial hemosiderosis. Folate supplementation is routine. The safety of iron-chelating agents such as deferoxamine has not been established in pregnancy. Prenatal diagnosis is available, and such pregnancies show improved outcome with stable maternal disease. An entity designated *thalassemia intermedia* has been described also, in which the clinical course is milder than with homozygous ß-thalassemia. Some individuals with this condition produce large quantities of t chains that combine with a chains to produce fetal HbF; the presence of 17% to 35% HbF defines hereditary persistence of HbF. Alternatively, these individuals may have some degree of a-thalassemia in addition to ß-thalassemia, resulting in less ß-chain precipitation and hemolysis. Patients with

thalassemia intermedia have severe hemolytic anemia but generally are not transfusion dependent. Before genetic counseling is provided to the patient with ß-thalassemia minor, MCV screening, followed by Hb electrophoresis if the MCV is low, should be offered to the father of the fetus. If the father has normal Hb, the fetus has a 50% chance to have ß-thalassemia minor and a 50% chance to have normal Hb. If the father has ß-thalassemia minor, the fetus has a 25% chance to have ß-thalassemia major, which is associated with increased morbidity and mortality, a 50% chance of thalassemia minor, and a 25% chance of having normal hemoglobin. Prenatal testing of the fetus should be offered to high-risk women; at least 20% of ß-chain mutations can be detected by chorionic villus sampling (CVS) or amniocentesis. Alpha-chain production is directed by four genes, two on each copy of chromosome 16. Mutation of only one gene results in no clinical or laboratory abnormalities and is thus referred to as the silent carrier state. Mutations in two of the four genes results in ß-thalassemia minor, a condition characterized by mild microcytic hypochromic anemia. Patients with ß-thalassemia minor have a low MCV but normal levels of HbA_2. The patient with these laboratory results should be referred for genetic evaluation and family studies to confirm the diagnosis, but typically they tolerate pregnancy fairly well. Mutation of three of the four a genes results in hemoglobin H (HbH) disease. Affected patients have some HbA and a large percentage of HbH (four ß chains). The clinical course is characterized by chronic hemolytic anemia that may worsen during pregnancy. Loss of all four ß-chain genes causes ß-thalassemia major, resulting in fetal hydrops and perinatal death. As with ß-thalassemia, testing of the father is crucial for accurate genetic counseling. Consideration of the patient's ethnic background is also important. Asians with ß-thalassemia minor usually have the two mutant genes on the same chromosome (*cis* position) and thus have a 50% risk of passing on both affected genes with each conception. In contrast, patients of other ethnic origins usually carry the mutant genes on opposite chromosomes (*trans* position), so that only one affected gene can be transmitted with each conception. All forms of ß-thalassemia can be detected by CVS or amniocentesis.

Hemoglobinopathies Hemoglobinopathies involve Hb gene mutations. Over 400 have been identified that alter polypeptide function instead of preventing production. These Hb variants generally have either reduced oxygen transport capabilities or cause hemolytic anemia. Hemoglobin S (HbS) and hemoglobin C (HbC) are the most frequent variants and can occur in association with thalassemia, as well (Table 17.3).

Hemoglobinopathy	*Frequency*
Sickle cell trait (HbSA)	1:10
Sickle cell disease (HbSS)	1:400
Hemoglobin SC disease (HbSC)	1:800
Hemoglobin S/ß-thalassemia	1:1,250
Hemoglobin C trait (HbAC)	1:35
Hemoglobin C disease (HbCC)	1:4,800

TABLE 17.3. *Frequency of sickle hemoglobinopathies in African Americans*

Sickle Disease A mutation causing a single amino acid substitution of valine for glutamic acid at position 6 on the ß chain changes normal Hb to sickle Hb. An individual who is homozygous for this mutation has sickle cell anemia, producing only HbS and a small quantity of HbF, but no HbA. Sickle Hb functions well in the oxygenated state but aggregates, forming rod-shaped polymers, in the deoxygenated state. Polymerized Hb precipitates in the red blood cell, changing the cell from a biconcave disc to an elongated crescent or sickle shape. Sickled red blood cells are not deformable and cannot squeeze through the microcirculation. Microvascular obstruction results in local hypoxia that leads to a vicious cycle of further sickling and obstruction. Localized schemia and infarction cause tissue damage. Patients with sickle cell anemia usually produce increased quantities of HbF. HbF is not distributed uniformly among all red blood cells but is present at levels of zero to 20% per cell. In cells containing HbF, restoration of normal oxygen tension may reverse the sickling and halt the destructive process. Cells containing little or no HbF become irreversibly sickled and are rapidly cleared from the system in a process leading to hemolytic anemia. Patients with homozygous HbS typically have hematocrits of 20% to 30% and reticulocyte counts of 10% to 25%. Hydroxyurea therapy has been shown to increase both the number of red blood cells containing HbF and the quantity of HbF per cell. Unfortunately, there are few data regarding the safety of hydroxyurea use in pregnancy. It is a category D drug. Any pathologic state causing acidosis, dehydration, or hypoxemia can precipitate sickling, hemolysis, vasoocclusion, and infarction. Pregnancy often is characterized by an increase in sickle crises and associated problems (e.g., pneumonia, pyelonephritis, pulmonary emboli, congestive heart failure) and by pregnancy complications such as IUGR, preterm birth, and preeclampsia. The goal of pregnancy management should be to maintain adequate hydration and oxygen delivery to the tissues, and to avoid or rapidly control infections or other stressors that could precipitate a crisis. Patients with sickle cell anemia should ingest 1 mg of folate per day to support increased erythropoiesis in the face of chronic hemolysis and should receive the polyvalent pneumococcal vaccine, because chronic splenic infarction leads to functional asplenia by adulthood. Iron supplementation should not be given prophylactically but should be prescribed if there is laboratory evidence of iron deficiency anemia. All sickle cell patients should undergo a funduscopic examination, with laser therapy as needed, because they are at increased risk for proliferative retinopathy. Asymptomatic bacteriuria (ASB) and other infections should be treated aggressively. One controversy concerns the possible benefit of antepartum prophylactic exchange transfusions. Available data indicate that although some women with sickle cell anemia may escape prophylactic transfusion because they have no associated organ damage, very few crises, and a high percentage of HbF, many will require antepartum transfusion. Even those patients who avoid transfusion during pregnancy should be transfused prior to delivery, because the stresses of labor, anesthesia, operative delivery, and any associated complications (e.g., preeclampsia, chorioamnionitis) can precipitate a serious crisis. Transfusions should be planned to achieve a hematocrit above 30% and HbA above 50%. Unless complications dictate otherwise, delivery can be at term, with cesarean section for obstetric indications only. Substitution of lysine for glutamic acid at the sixth position of the a chain results in the production of HbC. HbC is less soluble than HbA and can cause a mild hemolytic anemia, but it is more stable than HbS under hypoxic conditions. Nonpregnant women who are compound homozygotes for HbS and HbC generally have less severe anemia and fewer pain crises than women with HbSS, but under the stress of pregnancy, they experience the same maternal morbidity and pregnancy complications. Additionally, severe bone pain frequently occurs in individuals with HbSC, and acute respiratory compromise as the result of embolization of necrotic bone marrow has been reported. The antenatal management of women with HbSC should be the same as that of women with HbSS. If one ß-chain gene carries the sickle cell mutation and the other gene is functionally deleted, the patient has sickle cell ß-thalassemia. Pregnancy-related morbidity in these patients is the same as for sickle cell anemia, and they should be managed similarly. Patients with HbCC or C-ß-thalassemia have a very mild anemia and usually do not experience hemoglobinopathy-related pregnancy complications. Heterozygotes for the sickle Hb mutation have sickle cell trait. Individuals with sickle trait have red blood cells that sickle under conditions of markedly reduced oxygen tension (i.e., the sickle Dex test), but Hb electrophoresis confirms the presence of 55% to 60% HbA, in addition to 35% to 40% HbS. Sickling does not occur in vivo, except under conditions of severe stress and hypoxia. Because the renal medulla is especially sensitive to reduced oxygen tension, patients with sickle trait may have episodes of painless, self-limited hematuria. During pregnancy they exhibit an increased susceptibility to urinary tract infections. There are also reports of increased preeclampsia in these patients. Patients with sickle trait should be offered genetic counseling. The father of the fetus should be tested so that the precise risk to the fetus can be provided. Prenatal diagnosis is possible by CVS or amniocentesis. No special therapy is required generally during labor and delivery.

Congenital Hemolytic Anemias

Hereditary Spherocytosis, Elliptocytosis, and Pyropoikilocytosis Hemolytic anemia can occur for a variety of reasons. It may result from a hemoglobinopathy, may be autoimmune, drug induced, or pregnancy induced (very rarely), or may occur as the result of inherited red blood cell membrane abnormalities. Hereditary spherocytosis, elliptocytosis, and pyropoikilocytosis result from congenital defects of different red blood cell membrane proteins. All are autosomal dominant disorders occurring at an incidence of 1 in 4,000 to 5,000. All result in variant red blood cell shapes, such that affected red blood cells cannot pass readily through the spleen. While trapped in the spleen, the cell membranes are damaged, leading to red blood cell lysis, hemolytic anemia, jaundice, and splenomegaly. Splenectomy is the treatment of choice and effectively eliminates the anemia. Most women of reproductive age will already have undergone splenectomy. Although the abnormality of red blood cell shape persists, affected women tolerate pregnancy, labor, and delivery well, with few associated problems. The rare patient who has not undergone splenectomy may experience hemolytic anemia sufficient to require red blood cell transfusions. All patients should receive the polyvalent pneumococcal vaccine and should ingest a folic acid supplement throughout pregnancy. Infection should be treated aggressively, because it may cause hemolysis. The offspring of affected individuals have a 50% chance of inheriting the condition. Affected neonates may experience severe neonatal jaundice requiring exchange transfusion or splenectomy.

Glucose-6-phosphate Dehydrogenase Deficiency Glucose-6-phosphate dehydrogenase (G6PD) deficiency is an inherited defect of an enzyme essential to the hexose monophosphate shunt. Because of this defect, when under oxidant stress, Hb sulfhydryl groups become oxidized and Hb precipitates in the red blood cell, leading to hemolytic anemia. The gene is most prevalent among individuals of African, Asian, Mediterranean, or Middle Eastern origin. Known stressors include viruses, bacteria, toxins, fava beans, and certain drugs such as antimalarial agents, sulfa drugs, and nitrofurantoin. Over 400 different gene mutations leading to G6PD deficiency have been described; the A variant is most common and is present in 1 in 20 black men and 1 in 10 black women in the United States. Although G6PD deficiency is X linked and males are affected preferentially, women with this gene defect can be symptomatic. Some heterozygotes have markedly reduced G6PD levels because unfavorable lyonization can lead to a large proportion of cells expressing the defect, and homozygosity for G6PD deficiency can occur (in at least 1 in 400 black women). Precipitating drugs should be avoided in known carriers.

Platelet Disorders

Thrombocytopenia, defined as a platelet count less than 150,000/mm^3, occurs relatively frequently in pregnancy, complicating 7% to 8% of all pregnancies. The diagnosis of benign or essential gestational thrombocytopenia is one of exclusion, however, requiring that other pathologic forms of thrombocytopenia be ruled out. Thrombocytopenia in pregnancy can be caused by defective platelet production (bone marrow pathology such as leukemia, lymphoma, metastatic disease), sequestration (splenomegaly), or accelerated platelet destruction. Accelerated destruction occurs most commonly. Destructive processes may be nonimmunologic and unique to pregnancy (e.g., preeclampsia, placental abruption), may occur as part of sepsis or disseminated intravascular coagulation, or may result from immune dysfunction (e.g., systemic lupus erythematosus, immune thrombocytopenic purpura). These causes of thrombocytopenia are discussed elsewhere.

Thrombotic Thrombocytopenic Purpura Thrombotic thrombocytopenic purpura (TTP) is a disorder characterized by the pentad of thrombocytopenia, hemolytic anemia, fever, neurologic abnormalities, and renal failure. It is rare and of unknown etiology. TTP affects individuals of all ages, although most commonly young women. The untreated mortality rate exceeds 90%. Patients typically experience bleeding (uterine, gastrointestinal, or other) along with a mild Coombs-negative hemolytic anemia, thrombocytopenia, and mild jaundice. Hypertension and renal failure occur later in the course of the disease. All disease signs and symptoms result from microvascular damage caused by platelet thrombi, fibrin deposition, and microaneurysms in arterioles. Endothelial cell function, including prostaglandin production, is abnormal, although it is not known whether this causes TTP or results from it. Immune dysfunction may play a role. When TTP manifests in the third trimester, it may be difficult to distinguish from preeclampsia or the syndrome of hemolysis, elevated liver enzymes, and low platelets (HELLP syndrome). One distinguishing feature is that tests of coagulation (prothrombin time, partial thromboplastin time, fibrinogen, fibrin dimers) usually have normal results in TTP. The

advent of a fever of unknown origin or transient neurologic symptoms, as well as nonspecific complaints of arthralgias, nausea, or abdominal pain, may aid in the diagnosis of TTP. End-organ damage worsens as the disease persists. Delirium, seizures, hemiparesis, visual field defects, and coma indicate a very poor prognosis and an increased risk of mortality. Distinguishing TTP from preeclampsia in its various forms is vital, because management is dramatically different. TTP responds only to plasmapheresis or exchange transfusion, although delivery is eventually curative for preeclampsia. Steroids, heparin, splenectomy, and antiplatelet drugs have had only variable success in management of TTP. Plasmapheresis should be initiated as soon as the diagnosis is made, regardless of the clinical severity. If the patient is at or near term, magnesium sulfate therapy and delivery should also be initiated because of the possibility that the true diagnosis is preeclampsia. Cesarean delivery should be for obstetric indications only.

Hemolytic Uremic Syndrome Hemolytic uremic syndrome (HUS) is similar to TTP, with similar microangiopathy, except that the kidneys are primarily affected in HUS. The patient usually manifests hemolytic anemia, thrombocytopenia, and oliguric renal failure. Laboratory evaluation reveals a normal coagulation profile and hemoglobinuria. Most patients are hypertensive. The pathologic process usually is confined to the kidney, although some patients have mild neurologic symptoms. Postpartum renal failure is probably the same entity, except that the pregnancy has already ended. Treatment in both cases consists of dialysis and red blood cell transfusions to maintain the hematocrit above 20%. Maternal morbidity and mortality are significant, with death frequently resulting from uncontrollable hemorrhage.

Coagulation Defects

Von Willebrand Disease Von Willebrand disease is an inherited defect of von Willebrand factor (vWF), one of the proteins in the coagulation cascade. vWF is a large glycoprotein synthesized by endothelial cells and megakaryocytes and serves two functions: it is the plasma carrier for factor VIII, and it allows normal platelet aggregation at sites of endothelial injury. These two functions are directed by two different regions of the molecule, and several different mutations in both of these domains have been identified. There are three forms of von Willebrand disease. Type I (approximately 75% of cases) and type II von Willebrand disease (25%) are inherited as autosomal dominant traits. Affected individuals have one normal vWF gene in addition to the abnormal gene, and some normal vWF will, therefore, be produced. As a result, individuals with type I disease usually are mildly affected, exhibiting easy bruising or bleeding only after dental procedures. Individuals with type II disease usually experience more severe bleeding problems, such as menorrhagia or corpus luteum hemorrhage. Type III disease is autosomal recessive and extremely rare. It usually is associated with severe symptoms, because affected patients have no normal allele and thus produce no vWF. Clinical manifestations in Type III disease are similar to those associated with hemophilia. The many different known mutations and heterozygosity in the majority of cases account for the variability observed in symptoms and in laboratory test results. If the diagnosis is not made before pregnancy, it may be considered after excessive bleeding from a surgical or episiotomy site. Retrospectively, the patient may describe easy bruising or heavy menses. The pedigree is likely to include other similarly affected family members. The diagnosis is confirmed by all or some combination of the following laboratory tests: a prolonged bleeding time, decreased vWF concentration, reduced ristocetin cofactor activity, and reduced factor VIII activity. Women with von Willebrand disease usually tolerate pregnancy well, in large part because the production of all coagulation factors is increased and vWF factor levels can reach near-normal levels. Despite this, the bleeding time may still be prolonged, and treatment may be required. If the bleeding time is prolonged at term, levels of vWF must be increased so that postpartum or surgical hemorrhage can be avoided. One way to increase the vWF level is to administer desmopressin acetate (DDAVP) for 48 hours prior to planned delivery. Patients with type I disease have the best response to desmopressin; those with type III disease usually do not respond at all. Thus, a trial of the therapy should be conducted in the second trimester. Alternatively, vWF replacement can be provided. Fresh frozen plasma contains all coagulation factors in equal proportions, cryoprecipitate contains factor VIII, vWF, and fibrinogen, and lyophilized factor VIII contains only that protein. For patients with von Willebrand disease, the recommended therapy is 15 to 20 U of cryoprecipitate given twice daily just prior to delivery and for 2 to 3 days afterward. Factor VIII concentrate can be administered instead. Effective treatment should normalize the bleeding time. Women with type I or type II von Willebrand disease have a 50% risk of having an affected child; those with type III disease have minimal risk, unless they are related to their spouses. Prenatal diagnosis is possible but, unless termination is a consideration, is unlikely to affect labor and delivery management, because affected neonates experience minimal bleeding difficulties.

Hemophilias A and B Hemophilias A and B result from X-linked deficiencies of two different coagulation proteins. Female carriers of hemophilia A have a mutation in one factor VIII gene, while carriers of hemophilia B have a mutation in one gene for factor IX; levels of these factors are thus reduced by one half or more. These decreased factor levels are adequate for normal hemostasis, and carrier women usually are clinically unaffected. In rare circumstances, a woman may exhibit all the classic features of hemophilia (i.e., if she is homozygous for the mutation or if she is a carrier and has unfavorable lyonization leading to preferential expression of the X chromosome carrying the mutation); such patients benefit from factor replacement. Carrier mothers should be offered genetic counseling. One half of their daughters will be carriers, and one half of their sons will have hemophilia. Prenatal diagnosis is available. Knowledge of fetal hemophilia status allows consideration of pregnancy termination. In ongoing pregnancies, knowledge that a male fetus carries a hemophilia gene allows the obstetrician to plan to avoid placing a scalp electrode during labor and to avoid vacuum-assisted or forceps-assisted vaginal delivery. Cesarean delivery should be for obstetric indications only, because atraumatic spontaneous vaginal delivery does not entail additional risk for the affected fetus.

GASTROINTESTINAL DISEASE

Nausea and Vomiting

Mild and self-limited nausea and vomiting in the first trimester of pregnancy occur in 60% to 80% of women. Chronic nausea and vomiting, or hyperemesis gravidarum, complicates 1 in 200 to 300 pregnancies. This disorder is characterized by dehydration, electrolyte imbalance, and nutrition depletion and prompts medical intervention.

The etiology of hyperemesis is unclear. Theories have suggested the influence of human chorionic gonadotropin, the pituitary–adrenal axis, transient hyperthyroidism, and psychogenic factors. Regardless of the cause, intervention is appropriate, ranging from intravenous hydration and antiemetic medications (e.g., droperidol, metoclopramide, and prochlorperazine) to nasogastric enteral feeding and hyperalimentation. Pregnancies complicated by mild or severe hyperemesis are not at increased risk for growth abnormalities, congenital anomalies, or prematurity (Table 17.4).

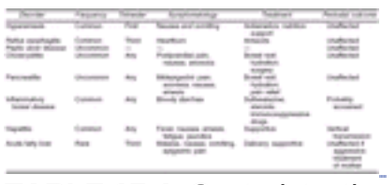

TABLE 17.4. *Gastrointestinal disease in pregnancy*

Gastrointestinal Reflux Disease

One half of all pregnant women complain of gastroesophageal reflux disease (GERD), commonly known as heartburn, sometime during pregnancy and particularly in the third trimester. Complaints include burning substernal discomfort with or without radiation, dysphagia exacerbated by meals, and increased intraabdominal pressure, all worsening in the recumbent position. The differential diagnosis includes angina, achalasia, and structural or functional causes of dysphagia.

Risk factors for gestational GERD include heartburn prior to or in previous pregnancies, multiparity, and advanced gestational age. There is no association between GERD and race, prepregnancy weight, or weight gain during pregnancy. Treatment options are similar to treatment of the nonpregnant population, depend on the severity of symptoms, and are initiated sequentially beginning with lifestyle modifications and antacids. In severe refractory cases, cimetidine and metoclopramide are appropriate therapeutic interventions.

Peptic Ulcer Disease

Gastric secretion and motility are reduced and mucus secretion is increased during gestation. As a result, peptic ulcer disease (PUD) is uncommon in pregnancy, and its complications, such as hemorrhage and perforation, quite rare. Patients with PUD often experience considerable improvement, if not remission, of disease in pregnancy. However, PUD recurs in most women within 2 years of delivery.

Upper Gastrointestinal Bleeding

Hyperemesis can be accompanied by gastrointestinal bleeding. Although gastrointestinal bleeding prompts a concern for PUD with hemorrhage, most pregnant women with hematemesis will prove to have Mallory-Weiss tears. These small, linear mucosal tears near the gastroesophageal junction respond to iced saline lavage, antacids, and intravenous cimetidine. Endoscopy can be performed during pregnancy and will detect esophageal rupture with bleeding (Boerhaave syndrome), a much more serious diagnosis for which surgery and gastroenterology consultations are appropriate.

Cholelithiasis and Biliary Disease

Studies using serial ultrasonographic examinations over the course of pregnancy confirm that the risk of gallstones is increased, to an incidence of 2% to 10%, because pregnancy is characterized by decreased gallbladder motility and increased biliary sludge. Many women with cholelithiasis are relatively asymptomatic during pregnancy and require no intervention. However, acute cholecystitis complicates about 1 in 1,000 to 1,600 gestations. It is heralded by postprandial pain in the right upper quadrant or epigastric area, with radiation to the back or shoulder. This type of pain, with anorexia, nausea, emesis, low-grade fever, and leukocytosis, suggests stone obstruction of a duct. Ultrasonographic examination is very helpful, detecting approximately 95% of stones.

Management is the same as in a nonpregnant individual. Three fourths of patients with acute cholecystitis will respond to medical therapy consisting of bowel rest, nasogastric suction, intravenous hydration, antibiotics, and analgesics. The remainder will require surgical intervention for persistent pain, empyema, gangrene, or perforation. Open laparoscopic cholecystectomy during pregnancy is becoming more widely accepted. Although the second trimester is considered optimal for any surgical procedure, delay in treatment should be avoided regardless of gestational age.

Pancreatitis

Pancreatitis occurs with an incidence of 1 in 1,500 to 4,000 during pregnancy, with the majority of cases due to cholelithiasis. Other far less common etiologies include ethanol abuse, certain medications, trauma, and hypertriglyceridemia. Symptoms include midepigastric pain with back radiation, anorexia, nausea, and emesis. In normal pregnancy, serum amylase and lipase levels tend to increase only slightly with advancing gestation. The upper limits of normal for amylase and lipase in the first two trimesters are 100 U/dL and 200 U/dL, respectively. Significant elevations of these enzymes are, therefore, consistent with pancreatitis, although the degree of elevation does not correlate with disease severity. As in the nonpregnant population, pancreatitis is managed by bowel rest, nasogastric suction, analgesia, and intravenous hydration.

In most patients, inflammation subsides within 2 to 7 days. In the minority, abscess or pseudocyst formation prompts abdominal exploration. In this population, perinatal morbidity ranges from 5% to 15%, and perinatal mortality can be as high as 38%, most likely resulting from accompanying hypovolemia, hypoxia, and acidosis.

Inflammatory Bowel Disease

The term *inflammatory bowel disease (IBD)* refers to two forms of intestinal inflammation, namely, Crohn disease and ulcerative colitis. These diseases share many features but usually can be differentiated. IBDs are genetic diseases with complex nonmendelian patterns of inheritance. The greatest risk factor for IBD is a family history of IBD. When both parents have IBD, the risk to the offspring is as high as 36% and is unaffected by disease activity in either parent at the time of conception. Figures for healthy offspring, congenital abnormalities, spontaneous abortions, and fetal demise are the same in pregnancies complicated by IBD as in the control population. Some report an increased risk of low birth weight in patients with Crohn disease, particularly if there is ileal disease, a history of bowel resection, or current tobacco abuse.

Ulcerative Colitis Ulcerative colitis is a mucosal disease, almost always involves the rectum, and extends proximally and continuously for a variable distance. Symptoms include diarrhea, often with bleeding, and some degree of abdominal pain. Affected individuals may also have arthritis, uveitis, or erythema nodosum. Colon cancer occurs in 1% per year. The clinical course is one of exacerbations and remissions. The most serious complication is toxic megacolon, which can necessitate an emergency colectomy. Medical management includes sulfasalazine, 5-aminosalicylic acid, and prednisone. If ulcerative colitis is quiescent at the time of conception, only one third to one half of patients will experience reactivation, often in the first trimester. Active disease at the time of conception has a worse prognosis. When the disease is active, aggressive medical management, including parenteral nutrition, is essential.
Crohn Disease Crohn disease is a transmural granulomatous inflammatory process, which involves the rectum about 50% of the time. It may involve any part of the gastrointestinal tract but most often involves the terminal ileum and colon. “Skip” areas are common. Diarrhea and hematochezia can occur, and abdominal pain is almost always a problem. Nutritional deficiencies are more common than with ulcerative colitis. Complications include toxic megacolon and fistula formation, which is problematic for vaginal delivery if the perineum is involved. Eighteen percent of patients develop de novo perineal involvement after vaginal delivery, most often if an episiotomy was performed. As in ulcerative colitis, the patient may also have arthritis, and the risk of cancer is increased. Cancer risk correlates with the extent of mucosal pathology (pancolitis confers the highest risk) and the duration of the disease. In patients with long-standing disease, the risk exceeds 1% per year. Quiescent disease at conception carries a good prognosis. Prednisone, sulfasalazine, and immunosuppressant drugs help control disease activity. Surgery is necessary in about 5% of such pregnant patients.

Hepatitis

Acute viral hepatitis in pregnancy is a systemic illness with fever, nausea, emesis, and fatigue. Jaundice is common initially, and liver function tests are elevated markedly. With the exception of hepatitis E viral (HEV) infection, viral hepatitides do not occur more frequently or with greater severity in pregnancy. HEV infection is more dangerous in a pregnant patient, with a mortality of 15% to 20%. It is transmitted by the fecal-oral route and occurs most frequently in countries with poor sanitation (e.g., the Middle East, Africa, and India). Infection in the third trimester often is associated with fulminant hepatitis, as well as preterm delivery, and neonatal and maternal death.

Hepatitis A Hepatitis A virus (HAV) is an RNA virus, with fecal-oral transmission and an incubation period of 15 to 50 days. This highly contagious disease is self-limited, with resolution over 2 to 3 weeks. Acute HAV infection is confirmed by a positive anti-HAV immunoglobulin M (IgM) antibody test. There are no chronic sequelae, and HAV does not cross the placenta. A single dose of hepatitis immune globulin is recommended as soon as possible after exposure. If the exposed pregnant patient becomes infected, close contacts, including the neonate, should be offered passive immunotherapy.
Hepatitis B Hepatitis B virus (HBV) is a double-stranded DNA virus with worldwide distribution, transmitted by parenteral and sexual contact. Risk factors include multiple sexual partners, intravenous drug abuse, and receipt of blood products. Its incubation period is 40 to 100 days, and it can be recovered from all body fluids, most importantly, blood, breast milk, and amniotic fluid. HBV surface antigen (HBsAg) and anti-HBc IgM antibody are seen in the early clinical phase of infection, before icteric changes or elevations in liver function tests. They indicate infectivity (Fig. 17.3). The presence of HBe antigen (HBeAg) denotes active viral replication. Although HBeAg usually indicates acute infection, its persistence correlates both with the chronic carrier state and with the ultimate development of hepatocellular carcinoma. The risk of maternal–fetal transmission increases dramatically to 90% when acute infection occurs in the third trimester or in the presence of both HBsAg and HBeAg positivity, and is a consequence of intrapartum exposure to blood and genital secretions. If the mother develops HBV infection remote from delivery and has developed anti-HB antibodies, the risk of fetal or neonatal infection is considerably less. The neonate's risk of active or chronic disease is reduced significantly by HB immune globulin and the HBV vaccine; these should be given at delivery. Breast-feeding does not increase the risk of infection in these infants. The absence of HBsAg excludes active or chronic infection, and there is no risk for neonatal transmission. In the at-risk patient who is HBsAg negative and antibody negative, vaccination should be offered, because it is not contraindicated in pregnancy.

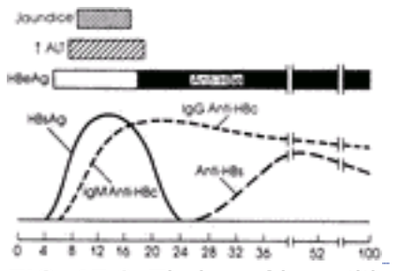

FIG. 17.3. Timing of hepatitis B antigen and antibody production in acute hepatitis B infection. (From Dienstag JL, Isselbacher KJ. Acute hepatitis. In: Isselbacher KJ, Braunwald E, Wilson JD, et al., eds. *Harrison's principles of internal medicine*, 13th ed. New York: McGraw-Hill, 1994:1458, with permission.)

Hepatitis C Hepatitis C virus (HCV) is the agent primarily responsible for non-A, non-B (posttransfusion) hepatitis. HCV is a single-stranded RNA virus. Principal risk factors for HCV transmission are blood product transfusion and intravenous drug use. Acute HCV infection follows an incubation period of 3 to 60 days, and only 25% of infected patients will be symptomatic. The presence of HCV antibody indicates chronic infection and does not confer immunity; approximately one half of those infected develop chronic liver disease. No specific therapy has been shown to be efficacious in decreasing the morbidity of the disease. Coinfection with HCV and human immunodeficiency virus (HIV) is thought to accelerate the progression of hepatic injury. Seroprevalence studies in pregnant patients in the United States indicate an incidence of HCV of 2% to 4%. Vertical transmission is proportional to the maternal HCV RNA titer, and approximately 8% of patients transmit the disease to their offspring. Coinfection with HIV is associated with an increased rate of perinatal transmission to 23% to 44%. Breast-feeding in the HCV-positive patient is not contraindicated by virtue of the 4% transmission rate in breast and bottle-fed infants.
Hepatitis D Hepatitis D virus (HDV) is an RNA virus that is dependent on coinfection with HBV for replication. HDV is acquired as a coinfection with HBV or as a superinfection in a chronic HBV carrier. Coinfection rarely leads to chronic disease, whereas superinfection is associated with an 80% likelihood of chronic hepatitis. Perinatal transmission of HDV can be prevented by the immunoprophylaxis used for HBV.

Pregnancy Following Liver Transplantation

Following liver transplantation, most authorities recommend that pregnancy be avoided for at least 12 months, so that graft viability can be assessed and immunosuppression can be achieved and maintained with the lowest possible medication dosages. Thirty-eight percent of liver transplant patients are hypertensive; pregnancy does not increase this incidence or hasten graft rejection. The incidence of spontaneous abortion is similar to that of the general pregnant population, and the incidence of preeclampsia is 13.5%. Anemia complicates 31% of pregnancies in liver transplant patients, and rejection develops or worsens in 9%. Fifty-eight percent deliver at term, and the majority deliver appropriately-grown babies vaginally.

Acute Fatty Liver

Acute fatty liver of pregnancy (AFLP) has an incidence of 1 in 13,000 deliveries. AFLP accounts for a large percentage of severe liver disease in pregnancy and is accompanied by a mortality of up to 25%. Primiparity, male fetal sex, and multiple gestation appear to confer a higher risk. The etiology is unknown, and liver biopsy reveals microvesicular fatty infiltrates.

Symptoms typically appear in the late third trimester and include malaise, persistent nausea, and vomiting. Right upper quadrant or epigastric pain is noted in 50% to 80%. Laboratory abnormalities include elevated liver function tests, increased ammonia and uric acid levels, hemolysis, hypoglycemia, and coagulopathy. Early recognition is essential; if untreated, AFLP progresses to multiorgan system failure and death. Once it is diagnosed, intensive supportive care is provided, and delivery is necessarily accomplished. Under these circumstances, maternal and fetal mortality are less than 20%. Survivors have no long-term sequelae, and recurrence in subsequent pregnancies is a rarity.

CARDIOVASCULAR DISEASE

Physiologic Changes in Pregnancy

Normal pregnancy entails many physiologic changes that can stress the cardiovascular system. Plasma volume increases are measurable by 6 to 8 weeks gestation and 45% greater by 30 to 34 weeks. Red blood cell volume increases about 25%, resulting in a physiologic anemia. Cardiac output increases by 30% to 50% during the first half of pregnancy (as the result of an increase in both stroke volume and heart rate), by a further 30% during active labor, and by 45% during pushing. Systemic vascular resistance decreases during pregnancy, with both systolic and diastolic blood pressures falling during the second trimester and then returning to prepregnancy values in the third trimester. During labor, each uterine contraction results in an autotransfusion of 300 to 500 mL of blood. Cardiac output during this time is influenced by maternal vascular volume, maternal position, pain, and the method of pain relief (epidural anesthesia, spinal anesthesia, or intravenous narcotics). Cardiac output rapidly increases at delivery as the result of autotransfusion and relief of caval compression by the involuting uterus.

Women with cardiovascular disease may tolerate these physiologic changes poorly. Knowledge of the pregnancy-associated risks and complications associated with each type of heart disease allows the physician to choose management that optimizes the chances for a good pregnancy outcome. For each patient, the prepregnancy cardiovascular status should be established and used as a reference in assessing any pregnancy-related cardiac changes. The New York Heart Association (NYHA) classification scheme is useful for quantifying symptomatology:

- Class I: patients are asymptomatic in all situations.
- Class II: patients are symptomatic with greater-than-normal exertion.
- Class III: patients are symptomatic with normal activities.
- Class IV: patients are symptomatic at rest.

Although useful for categorizing symptoms, this classification scheme does not necessarily predict pregnancy outcome. In one large retrospective study, for example, the majority of cases of pulmonary edema and maternal death occurred in women who were functional class I or class II. However, this scheme can be used to assess changes in cardiac function. Any change in cardiac classification during the pregnancy, even if only from class I to class II, can be ominous and should prompt a thorough evaluation and aggressive management. Bed rest or hospitalization often is required.

Rheumatic Heart Disease Approximately 4% of reproductive-age women have heart disease. Although this number has remained fairly constant, the relative incidence of the various forms of heart disease has changed dramatically during the last few decades. During most of the 20th century, the majority of heart disease resulted from rheumatic fever (group A ß-hemolytic *Streptococcus*); the ratio of rheumatic heart disease to congenital heart disease was 20 to 1. During the last few decades, however, the prevalence of rheumatic heart disease has decreased significantly, while the number of adult survivors with congenital heart disease has increased; the ratio is now 3 to 1 or less. Nevertheless, rheumatic valvular disorders still account for a substantial proportion of heart disease in reproductive-age women.

Mitral Stenosis Mitral stenosis is the most common form of rheumatic heart disease in women. Rheumatic fever typically occurs at ages 6 to 15 years. If myocarditis is present, mitral insufficiency will develop, followed in approximately 5 years by mitral stenosis. Symptoms usually do not begin for another 15 years after that, with severe complications such as right-sided heart failure occurring in another 5 to 10 years. The mean age for the initiation of symptoms is thus 31, with incapacity occurring at age 38 if the condition is not treated. Initial symptoms include fatigue and dyspnea on exertion, which progress to dyspnea at rest and hemoptysis. Atrial arrhythmias, infection, or pulmonary embolism can lead to heart failure. The stenotic mitral valve impairs left ventricular filling and thus limits any increase in cardiac output. Pregnancy-mediated cardiovascular changes, especially increased intravascular volume and increased heart rate, can exacerbate the impaired filling and lead to decompensation during pregnancy and especially during labor, delivery, and the puerperium. Left atrial volume and pressure increase, pulmonary venous pressure increases and, eventually, features of pulmonary hypertension and right ventricular hypertrophy and failure can develop. The goals of management are to optimize cardiac output by preventing rapid ventricular rates and avoiding decreases in systemic vascular resistance, and to reduce stress on the right ventricle by minimizing increases in blood volume and avoiding situations in which pulmonary artery pressure is increased (i.e., hypercarbia, hypoxia, or acidosis). Two serious complications associated with mitral stenosis are atrial fibrillation and pulmonary edema. Both have been associated with maternal death. During pregnancy, tachyarrhythmias should be treated, because a rapid heart rate prevents adequate ventricular filling and decreases cardiac output. Beta blockers should be considered for the patient with a heart rate above 90 beats per minute. Digoxin and heparin may be required for the patient with atrial fibrillation. Rarely, surgery becomes necessary during the pregnancy, including balloon valvuloplasty and surgical commissurotomy. During labor, bedside cardiac monitoring is routine; central hemodynamic monitoring is routine if the patient is in NYHA class III to IV or the valve diameter is less than 2.5 cm^2. Pain must be managed effectively. Epidural anesthesia can be used if care is taken not to overload the patient with fluid beforehand and not to decrease systemic vascular resistance during the infusion. Fluid management must be meticulous, with extra attention given to the patient during the immediate postpartum period, when autotransfusion rapidly increases the central blood volume. Pulmonary function must be followed closely for pulmonary edema. A pulmonary artery catheter may assist in the management of patients with severe disease. Because the pulmonary capillary wedge pressure (PCWP) may not accurately reflect left ventricular filling pressure in severe mitral stenosis, the PCWP should be maintained in the high-normal to elevated range. If general anesthesia becomes necessary, agents that produce tachycardia (e.g., atropine, meperidine, ketamine) should be avoided. The high-risk period for severe decompensation continues for 24 to 48 hours postpartum. Although the American Heart Association recommends antibiotic prophylaxis only for women who have a vaginal delivery in the presence of an infection or who undergo urethral catheterization, many clinicians provide prophylaxis to all cardiac patients. Subacute bacterial endocarditis (SBE) prophylaxis usually includes ampicillin 2 g and gentamicin 1.5 mg/kg intravenously, 30 minutes before delivery, and ampicillin 1 g intravenously or amoxicillin 1 g orally 6 hours after delivery. Penicillin-allergic patients should receive vancomycin 1 g before delivery and again 8 hours later, instead of ampicillin.

Mitral Insufficiency Mitral insufficiency results in regurgitation of blood from the left ventricle back into the left atrium, with resulting left atrial enlargement. Most patients tolerate mitral insufficiency well and remain asymptomatic for 30 to 40 years. However, because pulmonary edema or embolism, atrial tachycardia, and infective endocarditis can occur during pregnancy, patients with mitral insufficiency should be monitored closely. Anything that stresses or impairs the function of the left ventricle should be avoided. Increases in systemic vascular resistance, atrial fibrillation, bradycardia, or myocardial depressants can all result in left ventricular decompensation. During labor, pain should be treated effectively and fluid management calculated to maintain left ventricular volume without increasing it. Epidural anesthesia can be very effective, as long as preprocedure hydration is conducted cautiously. SBE prophylaxis should be given. Occasionally, surgical valve replacement is necessary during pregnancy.

Aortic Insufficiency Aortic insufficiency (AI) usually occurs 7 to 10 years after an episode of rheumatic fever myocarditis and the patient remains asymptomatic for another 7 to 10 years. The regurgitant valve causes a chronic increase in left ventricle volume, eventually leading to increased compliance, increased end-diastolic pressure, and pulmonary congestion and edema. Most pregnant women with AI are relatively asymptomatic. This is, in part, because the decreased systemic vascular resistance and increased heart rate typical of pregnancy tend to increase forward flow through the insufficient valve. However, cardiovascular changes occurring during labor and delivery can lead to decompensation, especially if intravascular volume is increased markedly or systemic vascular resistance is increased by pain or other stressors. Epidural anesthesia is ideal for such patients, because it eliminates pain and decreases systemic vascular resistance. However, care must be taken not to reduce diastolic blood pressure or provoke a bradycardic episode, because left ventricular output will decrease as a result. Myocardial depressants should be avoided, and fluids must be managed carefully to maintain adequate volume but not overload the left side of the heart. Frequent pulmonary examinations to rule out pulmonary congestion may be helpful. SBE prophylaxis should be given.

Aortic Stenosis Aortic stenosis (AS) resulting from rheumatic fever rarely complicates pregnancy, because the time lag between the rheumatic fever episode and the occurrence of stenosis is usually 35 to 40 years. However, AS can occur in reproductive-age women, and those who are symptomatic (e.g., angina, syncope,

shortness of breath) have a risk of sudden death out of proportion to the severity of their symptoms; left ventricular failure and infective endocarditis are other serious complications. The normal cross-sectional area of the aortic valve is 2.6 to 3.5 cm^2; an orifice less than 2.6 cm^2 usually is heralded by a loud systolic murmur, while an orifice less than 1 cm^2 produces symptoms of dyspnea, chest pain, and syncope. AS results in a relatively fixed stroke volume that is dependent on both adequate diastolic filling and heart rate. Although some increase in heart rate helps to maintain an adequate cardiac output, tachycardia greater than 140 beats per minute, bradycardia, and decreased systemic vascular resistance are poorly tolerated. For these reasons, epidural anesthesia may be a poor choice for pain relief during labor, and the patient could instead be managed with parenteral narcotics and pudendal block. Fluid management must be meticulous, taking care to maintain an adequate intravascular and thus end-diastolic volume. A pulmonary artery catheter may be very helpful in directing fluid management. Because hypovolemia is a far greater threat to this patient than is pulmonary edema, the pulmonary artery wedge pressure should be maintained in the range of 14 to 16 mm Hg to provide a margin of safety against unexpected peripartum blood loss.

Congenital Heart Disease Congenital heart disease accounts for the majority of all heart disease in reproductive-age women. Many women now reach adulthood without surgical correction of their lesions, while for others, early surgery has been lifesaving. Women who have undergone surgical correction, have normal hemodynamics, and are completely asymptomatic generally tolerate pregnancy, labor, and delivery well without special considerations. Women with uncorrected lesions, however, require special management. The most common uncorrected heart abnormalities seen in pregnancy are atrial septal defect (ASD), patent ductus arteriosus (PDA), ventricular septal defect (VSD), pulmonic stenosis, congenital AS, coarctation of the aorta, and tetralogy of Fallot. Both maternal and fetal outcomes depend on the nature of the cardiac lesion, the patient's functional capacity, the history of surgical repair (if any), and the presence or absence of pulmonary hypertension or cyanosis. In the presence of cyanosis, there is an increased risk of functional deterioration, congestive heart failure, maternal mortality, IUGR, preterm birth, miscarriage, and stillbirth. In one series, only 55% of pregnancies in cyanotic mothers resulted in a live birth. A woman with congenital heart disease should receive genetic counseling regarding the etiology of the lesion and risks to her fetus. Isolated congenital heart malformations are considered multifactorial in origin and, thus, have a general recurrence risk of 3% in first-degree relatives. However, a more precise recurrence risk can be provided if the heart defect is categorized according to the aspect of cardiac development that went awry: Cell migration abnormalities, defective cell death, extracellular matrix abnormalities, targeted growth defects, and blood flow-related lesions. However, only flow-related heart defects have a significant risk of recurrence of approximately 11% to 13.5%. Many structural cardiac defects can be identified by second-trimester ultrasonographic examination or fetal echocardiogram.

Mitral Valve Prolapse Mitral valve prolapse (MVP) is the most common congenital valvular lesion, with an incidence of 5% to 10% in the general population. The majority of patients with MVP are asymptomatic and tolerate pregnancy, labor, and delivery well. Occasionally, arrhythmias occur. Although the patient's cardiovascular status should be monitored closely, usually no special therapy is required other than SBE prophylaxis.

Left-to-right Intracardiac Shunts Left-to-right intracardiac shunts can result from ASDs, VSDs, or PDAs. Small shunts often are well tolerated for many years. If there is no pulmonary hypertension and the patient is asymptomatic, pregnancy does not impose significant increased risk and may actually improve cardiac hemodynamics, because the decreased systemic vascular resistance encourages forward flow. Increased systemic vascular resistance or increased maternal heart rate may increase the shunt and should be avoided; epidural anesthesia for labor and delivery can be very helpful. Patients with ASDs are at increased risk of developing supraventricular dysrhythmias that should be controlled with medication. If, however, the shunt is substantial, resulting in many years of increased pulmonary blood flow, pulmonary hypertension and right heart failure can develop, and the shunt reverses. The combination of pulmonary hypertension and right-to-left shunt through any communication between the systemic and pulmonary circulation is known as Eisenmenger syndrome. This condition is life threatening in the pregnant patient, with a maternal mortality of 40% to 60%. Death is due to congestive heart failure and thromboembolic phenomena. The outcome for the fetus is also exceptionally poor, with a perinatal mortality exceeding 28% and a 55% incidence of preterm birth. Women with Eisenmenger syndrome should be strongly discouraged from becoming pregnant or carrying a pregnancy. Management of the gravid patient with this condition includes hospitalization, oxygen therapy, prophylactic anticoagulation, and treatment of heart failure with digoxin and diuretics. Delivery usually requires pulmonary artery catheterization, intrathecal morphine provides excellent analgesia without significant motor or autonomic effects, and shortening of the second stage of labor with forceps delivery is common. SBE prophylaxis is routine and many consider minidose heparinization postpartum.

Tetralogy of Fallot Right-to-left shunting is seen also in tetralogy of Fallot. This term describes the combination of VSD, right ventricular outflow tract obstruction, right ventricular hypertrophy, and overriding aorta. The amount of right-to-left shunting is determined by both the size of the VSD and the degree of right ventricular outflow tract obstruction. Uncorrected tetralogy of Fallot is a cyanotic condition characterized by decreased arterial oxygen saturation and polycythemia. Pregnancy can cause further decompensation, because the decreased systemic vascular resistance increases the right-to-left shunt; shunting is increased also by a rise in the pulmonary vascular resistance resulting from the stress of labor. With uncorrected tetralogy of Fallot, 40% of women develop heart failure during pregnancy, and 12% die; the fetal mortality rate is 36%. Pregnancy is discouraged in those with uncorrected tetralogy. Poor prognosis is associated with several factors, including a prepregnancy hematocrit of over 65%, a history of syncope or congestive heart failure, electrocardiographic evidence of right ventricular strain, and a peripheral oxygen saturation of less than 80%. Pregnancy management includes bed rest, oxygen therapy, and isotopic support as necessary. Because any decrease in systemic vascular resistance can be life threatening, epidural or spinal anesthesia should be avoided. Intravenous medication and pudendal block can be used, and the second stage of labor should be shortened.

Congenital Aortic Stenosis Congenital AS accounts for 5% of all congenital heart disease, with bicuspid aortic valve being the most common malformation. Many patients with bicuspid aortic valve are completely asymptomatic and tolerate pregnancy, labor, and delivery well. For those who are symptomatic, management considerations are the same as for AS resulting from rheumatic heart disease.

Coarctation of the Aorta Coarctation of the aorta rarely complicates pregnancy because most affected women undergo surgical correction as children. During pregnancy, patients with uncorrected coarctation face an increased risk of aortic dissection and rupture, and thus an increased risk of maternal (up to 9%) and fetal (20%) death, as well as bacterial endocarditis and cerebral hemorrhage (associated with intracranial aneurysms). Because the coarctation results in a fixed stroke volume, management is similar to that for AS.

Pulmonic Stenosis Pulmonic stenosis can be either valvular, which usually does not progress until late in life, or subvalvular, which can become steadily worse during the reproductive years. The right ventricle becomes hypertrophic to maintain output but eventually decompensates, leading to left ventricular failure, as well. Right ventricular output is dependent on preload and heart rate, and systemic vascular resistance typically increases to compensate for any reduction in left ventricular output. During labor and delivery, fluids must be managed carefully so that preload is neither increased nor decreased, and bradycardia must be avoided. Because increased systemic vascular resistance is an important compensatory mechanism, epidural or spinal anesthesia should be used very cautiously, if at all.

Other Cardiac Abnormalities

Primary Pulmonary Hypertension Primary pulmonary hypertension leads to right ventricular hypertrophy and eventually to right ventricular and then left ventricular failure. Pregnancy exacerbates this condition, resulting in a maternal mortality rate as high as 50%. Management is similar to that for Eisenmenger syndrome.

Hypertrophic Cardiomyopathy and Asymmetric Septal Hypertrophy Hypertrophic cardiomyopathy and asymmetric septal hypertrophy are relatively well tolerated in pregnancy. The increased intravascular volume of pregnancy tends to distend the left ventricle and reduce the degree of outflow obstruction. However, decreased systemic vascular resistance may increase the left ventricular ejection force and thus increase outflow obstruction. Management goals include avoiding significant increases or decreases in intravascular volume, avoiding tachycardia, avoiding any decrease in systemic vascular resistance, and avoiding anything that increases myocardial contractility. Pain relief during labor can best be provided with intravenous medication or pudendal block or both.

Peripartum Cardiomyopathy Peripartum cardiomyopathy is a global congestive heart failure characterized by dilation of all four chambers of the heart, low cardiac output, and pulmonary edema. Arrhythmias may develop, along with pulmonary or systemic embolism. By definition, peripartum cardiomyopathy arises in the last month of pregnancy or in the first 5 months postpartum, and there is no other discernible etiology. The patient may complain of orthopnea, dyspnea, edema, weakness, and palpitations. The chest radiograph, echocardiogram, and electrocardiogram (ECG) are all consistent with cardiomegaly. The left ventricle and left atrium are enlarged, the ejection fraction is markedly reduced, and pulmonary congestion is often present. Up to 50% show evidence of pulmonary or systemic embolic phenomena. Management consists of aggressive treatment of heart failure with digitalis, diuretics, and vasodilators as necessary, strict bed rest, and full anticoagulation. The prognosis is poor. If heart size and function do not return to normal within 6 months, the mortality rate is high (up to 85% in some series), and survivors often are left with a dilated cardiomyopathy that imposes significant morbidity. A proportion of patients experience a complete normalization of heart size and function within 6 months of the onset of disease and then remain at NYHA cardiac functional class I or II status. These patients should be counseled that the risk of recurrence of cardiomyopathy in future pregnancies approaches 50% and that complete recovery from a second episode cannot be assured.

Myocardial Infarction The risk of myocardial infarction (MI) in a reproductive-age woman is low (1 in 10,000). Contributing factors include atherosclerosis, thrombosis, and vasospastic disease. The risk of death is highest at the time of the MI and is gestational-age dependent; maternal morality is approximately 23% in the first and second trimesters but 50% in the third. The risk of death is also high if delivery occurs within 2 weeks of the infarction. In the event of a cardiac arrest in a pregnant patient, cardiopulmonary resuscitation (CPR) should be administered. Uterine displacement toward the left, maintenance of PaO_2 greater than 70 mm Hg, cardioversion (having removed all metal monitoring devices from mother and fetus), and consideration of a cesarean section to increase the effectiveness of resuscitative efforts are appropriate. Management of a pregnant woman with an MI includes bed rest to minimize cardiac workload and myocardial oxygen consumption. Nitrates, aspirin, ß blockers, and calcium channel blockers have been used successfully. Epidural anesthesia should be provided during labor and delivery, along with supplemental oxygen and left lateral tilt position. Troponin should be used to document an MI, because myoglobin, creatine kinase, and creatine kinase myocardial bands are increased two-fold after delivery. Patients should be advised not to become pregnant for at least 1 year after an MI, and then only if normal ventricular function is confirmed by echocardiography, coronary angiography, or radionuclide studies.

Thromboembolic Disease

Venous thromboembolism occurs in 1 in 1,000 to 2,000 pregnancies and is a leading cause of maternal mortality in the United States. Venous stasis, which is aggravated by uterine compression of the pelvic veins, is a major predisposing factor. Levels of coagulation proteins are also altered unfavorably in pregnancy. Factors II, VII, and X and fibrin increase, levels of protein S decrease, and the fibrinolytic system is inhibited. Years ago, when postpartum ambulation was discouraged, the majority of thromboses occurred after delivery. Now, however, 50% or more of all thromboses occur during the antepartum period, making diagnosis and therapy a

challenge.

Superficial Thrombophlebitis Superficial thrombophlebitis involves only the superficial saphenous veins and is a relatively benign condition, often associated with varicosities. It is treated symptomatically with analgesia, rest, and elastic support.
Deep Venous Thrombosis Deep venous thrombosis (DVT) is a pathologic condition that can be life threatening, with an absolute risk of symptomatic DVT during pregnancy of 0.5 to 3.0 per 1,000 women. It occurs most commonly in the iliofemoral region or in the veins of the calf and is characterized by edema and lower extremity aching and limb discoloration. Most DVT in pregnancy occurs on the left side, can complicate an otherwise unremarkable pregnancy, with diagnosis requiring a search for predisposing factors and a high index of suspicion. Most DVTs can be accurately diagnosed noninvasively. Impedance plethysmography is both highly sensitive and specific for identifying obstruction of the proximal veins (iliac, femoral, and popliteal). Likewise, real-time sonography and duplex Doppler sonography reliably detect proximal vein thrombosis, although they may fail to identify calf vein obstruction. During any examination after the late second trimester, the uterus should be displaced off the vena cava to prevent lower extremity engorgement leading to false-positive results. If ultrasonography is performed properly, however, a positive result after any of these three tests should be considered confirmatory and sufficient to warrant the initiation of therapy. If these studies are equivocal or negative and suspicion is high, venography can be performed and findings are considered highly accurate. The amount of fetal radiation exposure associated with unilateral venography without an abdominal shield is 0.3 rad (0.003 Gy); a limited venogram requires less than 0.05 rad (0.0005 Gy).
Pulmonary Thromboembolism Pulmonary thromboembolism (PTE) is characterized by dyspnea, tachypnea, tachycardia, pleuritic chest pain, cough, and anxiety. In pregnancy, PTE usually is caused by emboli from a DVT and appears to occur more frequently in the postpartum period. Arterial blood gases confirm hypoxemia and hypocapnia, the ECG shows tachycardia with right heart strain, and the chest radiograph reveals subsegmental atelectasis. If there is a strong clinical suspicion of PTE, intravenous heparin therapy should be initiated immediately. The patient is thus protected from further compromise while awaiting confirmation of the diagnosis with a ventilation-perfusion (V/Q) scan. Perfusion defects that are unmatched by ventilation defects indicate a high probability of PTE, while a normal V/Q scan excludes the diagnosis. Intermediate results, however, do not rule out a PTE and must be resolved by pulmonary angiography. Pulmonary angiography can be performed while the patient is receiving heparin. As with DVT, necessary diagnostic procedures should not be withheld because the patient is pregnant. The combination of chest radiograph, V/Q scan, and pulmonary angiography exposes the fetus to a radiation dose of only 0.5 rad (0.005 Gy). Risk factors for a thromboembolic event include a history of DVT, a mechanical heart valve, atrial fibrillation, trauma, prolonged immobilization, major surgery, the antiphospholipid antibody syndrome, and several hereditary thrombophilias. Some individuals carry a gene mutation that predisposes them to a thromboembolic event. Women who are heterozygotes for protein C or protein S deficiency have an approximately 3% to 10% risk of antepartum thromboembolism and an 7% to 19% risk postpartum. The risk for heterozygotes for antithrombin III deficiency is 12% to 60% during pregnancy and 11% to 33% during the puerperium. A mutation in the gene for factor V—the factor V Leiden mutation—produces a single amino acid substitution that prevents factor V destruction and causes activated protein C resistance. Women carrying this mutation have a 28% incidence of pregnancy-associated thromboembolism. These mutations are all dominant with variable expressivity. Most carriers have affected family members who display varying degrees of pathology. Laboratory tests to diagnose all these deficiencies are available and should be considered in the workup of a patient with a history of thromboembolism, especially if there is a strong family history and no clear predisposing factors. Tests for protein C, protein S, and antithrombin III deficiencies cannot be performed while the patient is anticoagulated. Factor V Leiden mutation is identified by molecular analysis, however, and can be diagnosed at any time. Although knowledge of such mutations would not affect management of an acute thromboembolic event, it would have a profound effect on the patient's future medical management. Many authorities recommend continued anticoagulative prophylaxis once such mutations have been identified. As noted previously, antiphospholipid antibody syndrome also imposes an increased risk of thromboembolism and should be considered in the workup for hromboembolic disease. Treatment for PTE with unfractionated heparin consists of intravenous administration for 5 to 10 days, followed by subcutaneous heparin every 12 hours or 3 times a day for the remainder of the pregnancy. Heparin is a large molecule that does not cross the placenta and has few reported side effects (mild thrombocytopenia or reversible osteoporosis after long-term therapy). The dosage should be titrated to achieve a midinterval activated partial thromboplastin time (aPTT) 1.5 to 2.5 times normal or a plasma heparin level of 0.1 to 0.2 IU/mL within 24 hours of the acute event; failure to do so increases the risk of recurrent thromboembolism by a factor of 15. Most patients require a minimum of 24,000 IU per 24 hours (Table 17.5). Unfractionated heparin also can be administered by continuous subcutaneous pump. Fractionated or low-molecular-weight heparin has a longer half-life than ordinary heparin and thus can be administered once daily, and it is associated with reduced bleeding, osteoporosis, and thrombocytopenia that can complicate standard heparin administration. Low-molecular-weight heparin does not cross the placenta, and experience in pregnant patients is increasing. It is necessary to monitor peak antifactor Xa levels periodically when twice-daily dosing is used, because the aPTT does not correlate well with the anticoagulant effect of low-molecular-weight heparin. Warfarin sodium derivatives are not recommended during pregnancy, because they readily cross the placenta and have pathologic effects on the fetus. First-trimester exposure imposes the highest risk, resulting in some or all of the features of warfarin sodium embryopathy, including midfacial hypoplasia, central nervous system (CNS) abnormalities (e.g., microcephaly, hydrocephalus, or agenesis of the corpus callosum), optic atrophy, epiphyseal stippling, low birth weight, mental retardation, and seizures. Exposure beyond the first trimester may cause hemorrhage and secondary disruption of CNS and skeletal structures.

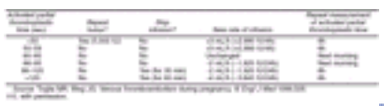

TABLE 17.5. *Protocol for adjustment of intravenous heparin dose*

Unfractionated heparin has a short half-life (60 to 90 minutes) and can be reversed with protamine sulfate. Because the half-life of low-molecular-weight heparin is much longer, most practitioners convert their anticoagulated patients to unfractionated heparin therapy in the last month of pregnancy. When delivery is planned or the patient enters labor, heparin should be discontinued and the aPTT checked. Most patients can undergo epidural anesthesia or cesarean section within 4 to 6 hours of their last unfractionated heparin dose, and protamine can be administered if reversal of anticoagulation is required sooner. Heparin should be resumed 6 to 12 hours postpartum, depending on the type of delivery and the occurrence of any complications, with warfarin sodium administered simultaneously. Once a therapeutic level is reached, warfarin alone should be continued for at least 6 weeks. The recurrence risk of PTE in a subsequent pregnancy is 4% to 15%; the risk is much higher if the patient has a predisposing gene mutation or other risk factor. Prophylactic heparin therapy should, therefore, be provided in subsequent pregnancies, although the ideal heparin dosage and duration of treatment remain to be determined. Some authors recommend a dosage of 5,000 to 10,000 IU every 12 hours, increasing as the pregnancy progresses, while others believe the dosage should be adjusted to maintain a plasma heparin level of 0.1 to 0.2 IU/mL. Prophylactic heparin therapy usually is initiated in the midtrimester or earlier if the patient has a thrombophilic gene mutation.
Mechanical Heart Valves Women with mechanical heart valves require therapeutic anticoagulation during pregnancy. As noted above, coumarin derivatives should be avoided during embryogenesis. Women with mechanical valves can be switched to therapeutic subcutaneous heparin before attempting conception or can be switched immediately after conception is verified (i.e., 1 to 2 weeks after the first missed period). The optimal agent for anticoagulation from 14 to 39 weeks is controversial. The advantages of heparin include its inability to cross the placenta and its rapid reversibility. Disadvantages include difficulty in maintaining a therapeutic dosage and failure to prevent all valve thromboses. Although coumarin may provide more consistent anticoagulation, its effects cannot be readily reversed and extend to the fetus. Consultation with the patient's cardiologist may be helpful.

PULMONARY DISEASE

Asthma

Asthma manifests as a spectrum of illness from infrequent, spontaneously resolving symptoms to repetitive, severe, life-threatening attacks. Symptomatic asthma involves fluctuating degrees of wheezing, dyspnea, chest tightness, and cough associated with reversible obstructive airway disease or bronchial hyperreactivity. Reversibility is defined objectively as an increase in forced expiratory volume in 1 second (FEV_1) of 12% and at least 200 mL after inhalation of a short-acting $ß_2$ agonist.

Pathophysiologic mechanisms suspected as causal in asthma include genetic predisposition and airway hyperreactivity with a tendency toward bronchoconstriction, airway inflammation, and abnormal mucociliary function. Triggering factors include allergen exposure, respiratory infections, exercise, aspirin, nonsteroidal antiinflammatory drugs (NSAIDs), and environmental irritants (e.g., tobacco smoke, pollutants).

Asthma may improve, worsen, or remain unchanged during pregnancy. Typically, the more severe the disease, the more likely it is to worsen. The course of asthma in a previous pregnancy is fairly predictive of the course in a subsequent pregnancy in about 60% of women. The peak incidence of asthma exacerbations is 24 to 36 weeks gestation, with relative improvement during the last month of pregnancy. Severe or uncontrolled asthma is associated with an increased risk of preeclampsia and maternal mortality, as well as IUGR, preterm delivery, and perinatal mortality. Potential mechanisms may include hypoxia and medication exposure. It is apparent that perinatal outcome is much improved when optimal control is achieved.

Therapy of this chronic disease characterized by acute exacerbations should include education in the use of a peak flow meter, the importance of compliance with medications, and the avoidance of known triggers. Mild intermittent disease, with symptoms fewer than 2 times per week, is treated with an inhaled $ß_2$ agonist such as albuterol, two puffs every 4 hours, when needed. Use of a spacer improves drug delivery. Mild persistent asthma, with symptoms more than 2 times per week, is treated with an inhaled glucocorticoid, such as triamcinolone (100 µg/puff) 2 puffs t.i.d. to q.i.d. or 4 puffs b.i.d. A long-acting $ß_2$ agonist or a leukotriene antagonist are second-line additive therapies to inhaled glucocorticoids for moderate and severe persistent asthma with daily or continuous symptoms. Systemic glucocorticoids for refractory severe exacerbations in the form of oral prednisone, 40 to 60 mg per day, is recommended until acute symptoms resolve, followed by tapering for 10 to 14 days.

Acute asthma attacks in pregnancy should prompt a thorough evaluation. Blood gas analysis in the normal pregnant woman typically reveals a pH of 7.35 and a higher PO_2 (102 to 106 mm Hg) and lower PCO_2 (28 to 30 mm Hg) than in nonpregnant patients. During the early stages of an asthma attack, the blood gas results are often consistent with hyperventilation, with an even lower PCO_2 and an elevated pH. After a prolonged attack, the patient will tire and may eventually hypoventilate. Therefore, a PCO_2 greater than 35 mm Hg or a PO_2 less than 70 mm Hg indicates severe respiratory compromise.

In addition to arterial blood gas analysis, the evaluation should include a complete blood cell count, electrolyte levels, spirometry, and a chest radiograph (Table 17.6). A respiratory therapist should be involved. Initial management consists of intravenous hydration and inhaled oxygen to maintain a PO_2 greater than 70 mm Hg and adequate urine output (in the face of alkalosis), followed by a nebulized ß $_2$ agonist, such as albuterol, up to three doses in the first 60 to 90 minutes and then 1 to 2 hours thereafter. Next, intravenous methylprednisolone 1 mg/kg every 6 to 8 hours is added, with tapering as clinical improvement occurs. Some clinicians also give intravenous aminophylline, a 6 mg/kg loading dose and 0.5 mg/kg per hour maintenance dose, to keep blood levels between 8 and 12 mg/mL. Patients should receive intravenous antibiotics in the event that an infection is confounding. Finally, terbutaline, 0.25 mg per hour subcutaneously for three doses, is offered. In the absence of clinical response, transfer to an intensive care setting is considered, because respiratory support may become necessary.

1. Arterial blood gas, complete blood cell count, electrolytes, peak flow meter, chest radiograph
2. Call respiratory therapy
3. Intravenous hydration, supplemental oxygen therapy to maintain PO_2 >70 mm Hg; monitor urine output
4. Albuterol, nebulized, 3 doses in initial 60–90 min
5. Methylprednisolone 1 mg/kg i.v. q6h
6. Aminophylline 6 mg/kg i.v. loading dose, then 0.5 mg/kg/h maintenance
7. Antibiotic i.v.
8. Terbutaline 0.25 mg s.c.
9. Transfer to intensive care for respiratory support in absence of improvement

TABLE 17.6. *Treatment of acute asthma attack*

Antepartum management in patients with well-controlled mild to moderate asthma should be like that of an uncomplicated pregnant patient. In those patients with poorly controlled severe asthma, however, the pregnancy should be monitored for IUGR and preeclampsia, and weekly tests of fetal well-being should be instituted if these complications occur. Of treated asthmatic women, 10% experience pulmonary symptoms in labor, in which case they are treated as outlined above. For those patients on a maintenance glucocorticoid or those who received a steroid course during the pregnancy, supplemental hydrocortisone, 100 mg intravenously every 8 hours for three doses, is recommended to avoid the unlikely occurrence of an Addisonian crisis.

Medications to be avoided in the asthmatic patient include ß blockers and prostaglandins. NSAIDs should be avoided in aspirin-sensitive patients. Magnesium sulfate and calcium channel blockers are well tolerated. Epidural anesthesia is preferred to general anesthesia.

Tuberculosis

Pregnancy does not worsen the course of tuberculosis (TB), and TB does not alter the overall outcome of pregnancy. However, it is important to diagnose and treat infected patients aggressively, because congenital TB can develop if a tubercular infection and bacteremia develop in a pregnant patient.

TB screening consists of the purified protein derivative (PPD) tuberculin test or Mantoux test. Forty-eight to 72 hours following intradermal injection, the presence or absence of induration at the injection site is determined. In patients with immunologic dysfunction (e.g., HIV infection), no reaction may be elicited. Therefore, a control skin test, such as for *Candida*, is placed, also. Most women have been exposed, and those who are not anergic will react. Reaction at the site of the control, and not at the site of the PPD test, indicates a negative PPD result. Induration greater than or equal to 5 mm is considered positive in an HIV-positive patient, in anyone in recent contact with an active TB case, or in anyone with clinical or radiologic evidence of TB. Induration greater than or equal to 10 mm is considered positive in health care workers, chronic alcoholics, or institutionalized individuals. Finally, induration greater than or equal to 15 mm on the PPD test is considered positive in all low-risk patients. When a skin test is positive, a chest radiograph should be done; with shielding, this procedure involves minimal fetal radiation exposure. If the chest radiograph result is normal, or abnormal but inconsistent with TB, the patient is offered treatment to prevent disease development: isoniazid (INH) 300 mg every day for 6 months. Pyridoxine (vitamin B_6) at 50 mg daily is recommended, also, to decrease the incidence of peripheral neuropathy and to protect the fetus from the neurotoxic effects of INH. Liver function tests are checked at baseline and then monthly to detect INH-induced hepatitis. If values increase two-fold, the medication is discontinued. Patients on INH are instructed to avoid alcohol and acetaminophen. If the chest radiograph is consistent with old TB and further evaluation fails to reveal active TB, the patient should receive INH 300 mg every day for 12 months after delivery.

If the chest radiograph findings are consistent with TB (adenopathy, multinodular infiltrates, upward medial retraction of hilar markings), further workup to confirm the diagnosis is necessary. The workup should include a thorough history, physical examination, drug sensitivity testing, and a sputum smear and culture. The sputum test results confirm the diagnosis. Treatment for 6 to 9 months with two or more drugs is required, as in nonpregnant patients. INH and rifampin are the drugs of choice. If there is suspicion of drug resistance, ethambutol and pyrazinamide are considered. Household contacts of any patient with active TB should be identified, evaluated, and treated as necessary.

Maternal treatment does not treat the infant. Recognition of congenital TB can be difficult, and unrecognized active disease has significant mortality. Treatment in infants is similar to that in adults. Isolation of the uninfected infant from any potential close infectious contact is recommended until effective treatment is underway, although the infant may breast-feed.

Viral Pneumonia

Influenza Pneumonia Influenza pneumonia is the most commonly occurring viral pneumonia, with type A being the most common antigenic type. Previous reports of increased mortality in the pregnant population have not been substantiated in more recent studies. Treatment is supportive, because antiviral agents are not well studied in this population. Influenza is not associated with an increased incidence of congenital anomalies, and there is no indication for influenza vaccine in the low-risk population.
Varicella Pneumonia Varicella pneumonia can complicate 0.3% to 50% of all primary varicella infections in adults. Pregnant women are at increased risk of this complication, which has a mortality of up to 40%. Respiratory symptoms typically develop 2 to 5 days after the onset of fever, rash, and malaise. The physical examination findings can be unimpressive. Any pregnant woman with varicella and respiratory symptoms should be thoroughly evaluated and hospitalized if pneumonia is suspected. Aggressive treatment with intravenous acyclovir (Zovirax), a DNA polymerase inhibitor, has decreased mortality in the pregnant population by 50%, without an increase in fetal anomalies. Two to five percent of primary varicella infections occurring at less than 20 weeks gestation are associated with congenital varicella syndrome. This syndrome includes microphthalmia, hypoplastic limbs, nasal hypoplasia, and skin lesions. Infants born within 5 days of the development of maternal rash can develop disseminated neonatal varicella, with a 60% to 70% morbidity rate and a 5% to 20% mortality rate. In such cases, delivery should be delayed, if possible, to allow maternal antibodies to reach the fetus.

Cystic Fibrosis

Experience with pregnant patients with cystic fibrosis (CF) is increasing, because the median age of survival is now 27 to 28 years. Most patients with CF have chronic obstructive pulmonary disease and pancreatic insufficiency, but this heritable, autosomal recessive disorder has a broad spectrum of clinical manifestations. Progressive bronchopulmonary disease is the predominant cause of morbidity and mortality in CF. It is characterized by exacerbations of chronic endobronchial infection, bronchiectasis, and airway obstruction. *Pseudomonas* is the most common organism to colonize the respiratory tracts of patients with CF.

Prospective controlled studies of CF in pregnancy are lacking. Counseling regarding the effects of pregnancy on the disease process is therefore difficult. In general, progressive pulmonary deterioration with hypercapnia-hypoxemia with or without cor pulmonale or pulmonary hypertension contraindicate pregnancy. Several reports indicate that patients with good nutritional status and pancreatic sufficiency tolerate pregnancy well. The perinatal mortality rate is increased in patients with CF secondary to preterm delivery reported at 5.9% to 35%. This increased rate is felt to be due to poor weight gain, low maternal prepregnancy weight, and chronic hypoxia. Management of the pregnant patient with CF stresses nutrition, maintenance of baseline pulmonary and cardiovascular status, and prompt treatment of exacerbations and deterioration. Counseling is essential; the patient with CF should understand that the fetus will carry the gene. Paternal testing will reveal the fetal risk of disease. Unaffected couples also should be counseled regarding the risk of disease according to American College of Obstetricians and Gynecologists guidelines.

Sarcoidosis

Pulmonary sarcoidosis rarely complicates pregnancy. If it changes during pregnancy, it usually improves, although the disease can relapse or exacerbate postpartum. No special management is necessary for the pregnant patient with sarcoidosis. Angiotensin-converting enzyme levels do not vary with disease activity, so following such levels is without benefit. If an exacerbation occurs, such as worsening pulmonary symptoms, deterioration in chest radiograph findings, CNS or ophthalmic involvement, or hypercalcemia, systemic steroids are recommended.

RENAL DISEASE

Urinary tract infections are a common complication in pregnancy, occurring in 10% to 15% of women. Pregnancy-associated urinary stasis, glucosuria, and vesicoureteral reflux are predisposing factors. Responsible organisms include *Escherichia coli* (75% to 90%), *Klebsiella* (10% to 15%), and *Proteus* (5%) species. *Pseudomonas, Streptococcus*, and *Staphylococcus* species are present infrequently.

Renal Infections

Asymptomatic Bacteriuria ASB is defined as greater than 10,000 organisms per milliliter of urine in an asymptomatic woman. The incidence of ASB in the pregnant population is 6%, the same as in nonpregnant, sexually active women. The incidence is twice as high in women with sickle cell disease trait. Failure to identify and treat pregnant women with ASB will result in an incidence of pyelonephritis of 25% to 40%, but treatment reduces this 10-fold. Treatment typically consists of empiric antibiotic therapy, such as 10 to 14 days of ampicillin or nitrofurantoin, or therapy based on in vitro bacterial sensitivities. A culture should be repeated 1 week following therapy completion, because 30% of infections recur.
Cystitis Cystitis is symptomatic bacteriuria without flank pain or fever. Urinary urgency, frequency, and dysuria are the most common complaints. Diagnosis and treatment do not differ from those of ASB. Occasionally, the same symptoms are associated with sterile urine; in this situation, the infecting agent is likely to be *Chlamydia trachomatis* and will respond to erythromycin therapy.
Pyelonephritis Renal parenchymal infection, or pyelonephritis, complicates 1% to 3% of pregnancies. Patients with acute pyelonephritis are typically febrile. Symptoms can include chills, urgency, dysuria, and nausea and vomiting. Other signs include costovertebral angle tenderness, pyuria, and bacteriuria. Most cases of pyelonephritis are right sided or bilateral. Disease limited to only the left side suggests an anatomic abnormality. Bacterial endotoxins and cytokines produced by activated macrophages are responsible for many of these symptoms. Hospitalization is recommended routinely, although outpatient management may be effective and safe in selected pregnant women. The risk of preterm labor is increased with pyelonephritis. Once a urine culture is obtained, intravenous antibiotic therapy and vigorous intravenous hydration are started. The antibiotic of choice is usually a cephalosporin, because a large proportion of *E. coli* strains are ampicillin resistant. If the patient is afebrile within 24 hours, oral antibiotic treatment is started. If she remains afebrile for another 24 hours, she can be discharged home to complete a 10-day antibiotic course. If she remains febrile, changing or adding antibiotics to the regimen must be considered. If the urine culture and sensitivity results are available, they can be used to guide selection of drugs. If the organism is sensitive to the original antibiotic, gentamicin should be added. If no clinical improvement is seen, a renal ultrasonographic examination should be performed to rule out calculi or abscess. Recurrent pyelonephritis occurs in 10% to 18% of patients. To reduce this risk, chronic suppressive therapy consisting of nitrofurantoin 100 mg each night often is recommended. Urine is obtained for culture and sensitivity every month, or with patient complaints. Documented recurrent infection is treated with a 10-day course of antibiotics. For the patient with recurrent or persistent disease, a urologic evaluation, including intravenous pyelogram and voiding cystogram, is recommended 3 months postpartum.

Urinary Calculi

Urinary calculi occur in 1 in 1,000 pregnancies. Pregnancy does not affect the risk or severity of calculi formation. However, calculi do increase the incidence of urinary tract infections to 20% to 45%. Patients with known calculi typically are placed on suppressive nitrofurantoin therapy throughout the pregnancy. Urine cultures are performed every month, and infection is treated aggressively.

Urolithiasis should be suspected if the patient experiences colicky flank pain, tenderness, hematuria, or unresolved bacteriuria. The diagnosis can be confirmed by ultrasonography in 60% of patients and in 96% using a single-view intravenous pyelogram, which exposes the fetus to minimal radiation (about 50 mrad). Acute urolithiasis is treated with analgesia and vigorous intravenous hydration. If infection is documented, antibiotic therapy is instituted. A ureteral stent or percutaneous nephrostomy may be required to relieve persistent obstruction.

Chronic Renal Disease

The effect of pregnancy on chronic renal disease varies with the degree of renal insufficiency. Mild renal insufficiency, defined as a serum creatinine less than 1.4 mg/dL, can be associated with a decline in renal function, increased proteinuria, and hypertension. However, renal function typically returns to prepregnancy levels after delivery (Table 17.7).

TABLE 17.7. *Renal disease prognosis*

Moderate renal insufficiency is defined as a creatinine greater than 1.4 mg/dL but less than 2.5 mg/dL. Several series suggest that 10% of women with moderate renal insufficiency experience accelerated deterioration of renal function during pregnancy; women whose prepregnancy creatinine is greater than 2 mg/dL are at greatest risk. Hypertension typically escalates, and its control is essential for good outcome. Although methyldopa is prescribed frequently, the lag between dose and effect may make it a suboptimal choice. Beta blockers, such as labetalol, and calcium channel blockers, such as nifedipine, have been shown to be effective.

Less information is available regarding pregnant patients with severe renal insufficiency (creatinine greater than 2.5 mg/dL). Thirty to forty percent of these patients experience a decline in renal function to end-stage disease within 12 to 24 months postpartum.

Patients with renal insufficiency are at high risk of perinatal mortality (up to 15%), preeclampsia (more than 50%), preterm delivery (30% to 80%), and IUGR (up to 57%). Monitoring of baseline and subsequent laboratory values, routine urine cultures with prompt treatment for infection, serial ultrasonographic examinations for fetal growth, and formal tests of fetal well-being are indicated.

Acute Renal Failure

Acute renal failure is a rare but potentially devastating complication of pregnancy. It has many causes, including preeclampsia, hemorrhage, and placental abruption. Although typically characterized by persistent oliguria, diuretic therapy is not helpful, because it does not correct the cause of the renal failure. In the presence of azotemia and severe oliguria, dialysis usually is initiated and continued until renal function returns. Fortunately, morbidity and mortality from renal failure have decreased as obstetric recognition and intervention have become more prompt, and intensive supportive therapy has become more widely available.

Dialysis

Although most women with severely impaired renal function are infertile, chronic hemodialysis or peritoneal dialysis may make pregnancy possible. Hemodialysis usually is initiated earlier in the pregnant patient than in the nonpregnant, because the risk for intrauterine fetal demise increases at a blood urea nitrogen (BUN) level above 80 mg/dL. The goal of dialysis is to maintain the BUN at 50 to 60 mg/dL, while limiting volume changes and episodes of hypotension. Peritoneal dialysis may be superior to hemodialysis because it minimizes fluid shifts and does not require maternal anticoagulation, although data to support its preferential use in pregnancy are limited. Because dialysis often is accompanied by contractions, magnesium sulfate can be added to the dialysate to maintain a serum level of 5 mEq/L. Increased numbers of hours on hemodialysis and increased frequency of treatments are recommended, because these improve management of weight and diet issues.

Renal Transplantation

Most pregnancies after renal transplantation are successful. Patients typically are advised to avoid pregnancy for 2 years following surgery to allow recovery,

stabilization of graft function, and confirmation of graft survival on maintenance doses of immunosuppressive agents (prednisone up to 15 mg/day, azathioprine up to 2 mg/kg per day). Once pregnancy is achieved, maternal–fetal complications can include an increased incidence of preeclampsia, infection (both viral [CMV, herpes, hepatitis] and urinary tract [40%]), parathyroid dysfunction, and preterm birth. The incidence of prematurity is 45% to 60% and, of these babies, about 20% are growth restricted. Preterm premature rupture of the membranes is more common, as well, likely due to long-term steroid therapy. However, pregnancy outcome is considered successful in 80% to 90% of these patients. Pregnancy management can be intense. Suspicion of graft rejection is high in the presence of fever, oliguria, graft enlargement, tenderness, and decline in renal function. Because the differential diagnosis also includes severe preeclampsia, pyelonephritis, and recurrence of glomerulopathy, renal biopsy may be necessary to confirm rejection. The immunosuppressive agents typically prescribed, including prednisone, azathioprine, and cyclosporine, are considered to be safe in pregnancy.

NEUROLOGIC DISORDERS

Neurologic diseases occur frequently in the general population (Table 17.8) and in reproductive-age women, and pregnancy can provoke or exacerbate certain neurologic abnormalities.

Disorder	*Prevalence*
Migraine	2,000
Epilepsy	650
Cerebral palsy	250
Multiple sclerosis	100
Spinal cord injury	50
Subarachnoid hemorrhage	50
Myasthenia gravis	4
Genetic disorders (excluding congenital central nervous system malformations)	<10

TABLE 17.8. *Prevalence of neurologic disorders*

Headache

Headache is a common complaint during pregnancy, and the overwhelming majority are tension headaches. Tension headaches typically persist for hours and are characterized by a tight, sore feeling in the back of the head and neck. The pain usually responds to rest, application of heat or ice packs to the neck, massage, antiinflammatory drugs, or a mild tranquilizer such as chlordiazepoxide. Strategies to relieve stress are important to prevent recurrence. Depression headaches usually occur in association with other symptoms of depression and respond to antidepressant medication and counseling.

Migraine Headache

Migraine headaches are seen commonly in pregnancy, and 15% of women with migraines experience their first one when pregnant. However, 64% of women with a history of menstrual migraine headaches experience a dramatic improvement in symptoms during pregnancy. Migraines are noteworthy for cerebral artery vasoconstriction and decreased blood flow. There is a 3-fold to 6-fold increased incidence of ischemic stroke in the population with migraines, which is increased to 10-fold to 14-fold with tobacco abuse.

There are at least four types of migraine headaches. Common migraine is characterized by a frequently unilateral headache lasting several hours, nausea and vomiting, and scalp tenderness. There is often a family history of similar headaches. Classic migraine has the same symptoms but is preceded by premonitory sensory phenomena, such as visual scotomata or hallucinations. Basilar migraine includes symptoms of vertigo, dysarthria, or diplopia, while complicated migraine involves more serious neurologic symptoms, mimicking an ischemic event.

The diagnosis of new-onset migraine headaches during pregnancy is usually one of exclusion. Other disorders such as brain tumor, stroke, and epilepsy need to be ruled out. The patient can undergo the same evaluation as a nonpregnant individual, usually consisting of a thorough history and neurologic examination and sometimes including computed tomography (CT) or magnetic resonance (MR) imaging or awake and asleep electroencephalograms. Immediate treatment is also very similar in the pregnant patient and can include aspirin or acetaminophen, with or without caffeine or butalbital, narcotics, phenothiazine antiemetics, or sumatriptan succinate (Imitrex). Ergotamine should not be given during pregnancy, because it is a potent vasoconstrictor that can adversely affect uterine and placental blood flow. NSAIDs should be avoided in the third trimester. If headaches are chronic, the patient may benefit from suppressive amitriptyline or nortriptyline, propranolol, or verapamil. Valproic acid (Depakene) may be prescribed after the first trimester, when the fetal neural tube is completely formed.

Epilepsy

Epilepsy affects 0.5% to 2.0% of the population and complicates 1 in 200 pregnancies. Seizures usually are classified according to whether they are idiopathic or acquired (e.g., trauma, infection, space-occupying lesion, metabolic disorder), are partial or generalized, as well as by a description of the seizure itself. Absent seizures, or petit mal, involve loss of consciousness without any accompanying motor activity. Although both progesterone and estrogen have been shown to influence seizure activity, the relationship of pregnancy and seizure activity is unclear; 46% of women experience no change in seizure frequency, 20% experience a reduction, and 34% experience an increase in seizure activity during gestation. Factors that increase the frequency of seizures during pregnancy include discontinuation of antiepileptic medication in the belief that it harms the fetus, subtherapeutic drug levels because the dosage was not adjusted to compensate for expanding maternal vascular volume, inability to ingest medication because of nausea and vomiting, and lowering of the seizure threshold by sleep deprivation and stress.

The new onset of seizures during pregnancy is concerning. Although gestational epilepsy is probably a distinct entity, it is a diagnosis of exclusion. A complete workup should be performed as for a nonpregnant individual. Status epilepticus is a medical emergency, and the pregnant woman should be treated in the same manner as a nonpregnant individual. The airway must be secured and protected, and intravenous fluids, along with a glucose bolus and thiamine 100 mg, should be given. Intravenous phenytoin, phenobarbital, or diazepam should be administered. If possible, a wedge should be placed under one hip to displace the uterus off the vena cava. Although fetal heart rate abnormalities may be present during the seizure, the mother should be stabilized before any fetal intervention is contemplated. In most cases, resuscitation of the mother resuscitates the fetus. A thorough workup, including a toxicology screen and anticonvulsant drug levels, should be initiated following maternal stabilization.

Most epileptic women require seizure medication to remain seizure free. For many anticonvulsant drugs, the benefit of preventing seizures outweighs any potential risks to the fetus. Other medications are clearly teratogenic and should be avoided, if possible; these include valproic acid before 8 weeks gestation and trimethadione (Tridione). However, women with epilepsy are at increased risk for fetal malformations, whether or not they ingest anticonvulsant medication. Although women taking multiple medications are at highest risk, it is not clear whether the increased risk is due to fetal drug exposure or whether it correlates with severity of maternal disease. Fetal factors play a role, as well. For example, fetuses with epoxide hydrolase deficiency are at high risk for fetal hydantoin syndrome. The epileptic gravida should be counseled that her disease increases the risk of birth defects from the background rate of 3% to approximately 7%.

The lowest medication dosage associated with seizure prevention should be prescribed. Stressors should be minimized, and the patient should ingest a multivitamin with folate. Some authors advocate prescribing oral vitamin K in the last month of pregnancy to women taking phenytoin, although this is controversial, because it is not clear that vitamin K crosses the placenta, and exposed fetuses usually are given vitamin K neonatally. A second-trimester targeted ultrasonographic examination, with other ultrasonographic examinations as needed to assess fetal growth, is warranted. During labor, antiseizure medications should be continued, and pain relief should be excellent, so that hyperventilation with pain does not lead to a respiratory alkalosis that could lower the seizure threshold. The patient may breast-feed. The anticonvulsant content of breast milk is inversely proportional to the degree of protein binding. However, even drugs that are not highly protein bound (e.g., carbamazepine, phenobarbital, primidone [Mysoline]) are present at low levels, so that the total dosage ingested by the infant is usually negligible.

Subarachnoid Hemorrhage

Intracranial vascular anomalies can become symptomatic during pregnancy. Rupture of such malformations, resulting in subarachnoid hemorrhage, occurs in 1 in 75,000 pregnancies. Subarachnoid hemorrhage is heralded by sudden intense headache, visual changes or cranial nerve abnormalities, focal neurologic deficits, or an altered level of consciousness. In addition, the patient often complains of nausea, vomiting, and photophobia. The examination reveals signs of meningeal irritation, tachycardia, hypertension, slight fever, and mild leukocytosis and proteinuria. Subarachnoid hemorrhage may result from a ruptured cerebral angioma, saccular aneurysm, or arteriovenous malformation (AVM); aneurysm rupture reportedly occurs 3 times more often than rupture of an AVM. The mortality rate is reported to be as high as 35%.

If intracranial hemorrhage is suspected during pregnancy, the patient should undergo a CT scan to confirm the hemorrhage and localize the bleeding. If the CT scan is normal but hemorrhage is strongly suspected, examination of the cerebrospinal fluid to confirm the presence of blood followed by angiography to locate the lesion may be indicated. Treatment consists of bed rest, sedation, and analgesia; surgical correction often is recommended. Aneurysms that have bled once are very likely to bleed again within weeks of the first bleed, and 5% to 7% of AVMs bleed again during the first year. Therapy should not be withheld from the patient because she is pregnant. Hypothermia during neurosurgery usually is well tolerated by the fetus, although hypotension should be avoided if at all possible. If the patient requires neurosurgery near term, cesarean section just prior to the craniotomy may avoid fetal compromise if the fetus is mature. Otherwise, there is usually no maternal benefit to terminating the pregnancy. Patients who experience an intracranial hemorrhage within 2 months of delivery or who have an unrepaired aneurysm should not perform the Valsalva maneuver during labor. Epidural anesthesia and assisted vaginal delivery are indicated.

Ischemic or Thrombotic Stroke

Ischemic (thrombotic) stroke is uncommon in reproductive-age women, occurring in 1 in 7,000 to 11,000 pregnancies; however, it can occur in association with hypertension, diabetes, hyperlipidemia, antiphospholipid antibody syndrome, sickle cell disease, rheumatic heart disease, septicemia, and tobacco abuse. Cerebral artery thrombosis most often is associated with atherosclerosis and may be preceded by transient ischemic attacks. Cerebral artery embolism usually is associated with cardiac arrhythmia. In either case, the affected patient experiences the sudden onset of severe headache, hemiplegia or other neurologic deficits, or new-onset seizures. A thorough workup should be performed, including complete blood cell count, sedimentation rate, serum lipid profile, ECG or echocardiogram, and head CT scan or cerebral angiography, as necessary. Therapy includes rest, analgesia, aspirin, and heparin. Heparin may be discontinued prior to vaginal delivery and restarted postpartum. Cesarean section should be for obstetric indications.

Cerebral Venous Sinus Thrombosis

Cerebral venous sinus thrombosis is usually a puerperal complication, occurring in association with preeclampsia, sepsis, or a coagulation defect. The patient complains of severe headache, drowsiness, and confusion, and may have convulsions, focal neurologic deficits, hypertension, or papilledema. The diagnosis is made by CT scan or angiography. Treatment consists of mannitol or dexamethasone to reduce intracranial edema, along with antiepileptic medication if seizures have occurred. Heparin may be given if hemorrhage has been ruled out. If sepsis is a cofactor, the source must be identified and the infection treated aggressively. The mortality rate can be as high as 30%; poor prognostic factors include obtundation, coma, accompanying subarachnoid hemorrhage, or rapid deterioration. However, the prognosis for survivors is excellent.

Primary CNS malignancies occur in 3 to 5 per 100,000 people per year. Although pregnancy does not alter this incidence, intracranial malignancies account for 10% of all maternal deaths. The malignancy may arise during pregnancy, or the physiologic changes of pregnancy may induce symptoms in a previously asymptomatic tumor. Symptoms typically include headache, vomiting, altered levels of consciousness, seizures, and hypertension. The presence of papilledema helps to distinguish intracranial pathology from other entities such as preeclampsia. Diagnosis is by CT or MR imaging. If an operable tumor of high malignant potential is suspected (e.g., high-grade gliomas, choroid plexus papillomas, posterior fossa tumors) or if there are significant neurologic complications such as seizures or progressive hydrocephalus, surgery should be performed without delay. Intraoperative hypothermia usually is well tolerated by the fetus, although hypotension should be avoided, if possible. In contrast, minimally symptomatic lesions of low malignant potential (e.g., meningioma) may be followed and treated definitively postpartum.

It should be kept in mind that a proportion of intracranial malignancies are metastatic from other sites, primarily breast, lung, or gastrointestinal or genitourinary tracts. A complete history and physical examination is, therefore, crucial. Choriocarcinoma may manifest intracranial findings, and pituitary tumors may become symptomatic in pregnancy.

If intracranial malignancy is diagnosed early in pregnancy, pregnancy termination is not indicated routinely but might be appropriate in patients with uncontrollable seizures or progressive loss of consciousness. Patients who have undergone craniotomy within 2 months of delivery should not perform the Valsalva maneuver during labor. Epidural anesthesia and assisted vaginal delivery are indicated. Cesarean section should be for obstetric indications only.

Pseudotumor Cerebri

Pseudotumor cerebri is defined by increased intracranial pressure, papilledema, and headache without focal neurologic abnormalities. The etiology is unknown. Although pregnancy does not increase the incidence, the majority of cases occur in obese women of reproductive age. Pregnancy complications experienced by such women are likely to be related to their obesity and not their neurologic diagnosis. Women with pseudotumor cerebri should be followed with serial visual field and acuity testing. Treatment typically consists of repeated lumbar punctures, shunting, glucocorticoids, or acetazolamide (Diamox); all can be safely used in pregnancy. Although weight loss and diuretics may also be helpful, they should be deferred until postpartum.

Multiple Sclerosis

Multiple sclerosis (MS) is a multifocal demyelinating disease of CNS white matter, characterized by chronic inflammation, selective demyelination, and scarring. The etiology is unknown but may involve a virus-triggered autoimmune phenomenon in a genetically susceptible individual. There are three forms of MS: relapsing MS, which is defined by recurrent attacks of neurologic abnormality followed by greater or lesser degrees of recovery; chronic progressive MS, which gradually worsens from the onset without remission; and inactive MS, in which patients have fixed neurologic deficits that neither progress nor resolve. Because it is most commonly seen in 20- to 40-year-old white women and does not impair fertility, MS can first manifest coincidentally with pregnancy. Symptoms and signs include weakness, hyperreflexia, paresthesia, hypesthesia, ataxia, visual loss resulting from optic neuritis, diplopia, facial nerve palsy, vertigo, urinary urgency, or incontinence. None of the symptoms or signs can be explained by a single anatomic lesion. The diagnosis is one of exclusion, with MS confirmed by cerebrospinal fluid abnormalities and MR imaging. In many patients, MS has been diagnosed before conception, and medical therapy in the form of corticotropin and glucocorticoids was initiated. Patients with chronic progressive MS or severe relapsing MS may require more aggressive therapy with immunosuppressive drugs such as cyclosporine, azathioprine, or cyclophosphamide. All of these drugs may be continued during pregnancy if there is clear maternal benefit. Affected patients may also require an antispasmodic agent, urinary tract infection prophylaxis, and physical therapy.

Women with MS should be counseled that pregnancy increases the likelihood of urinary tract infections and constipation and may exacerbate fatigue and mobility problems. Women with paraplegia or quadriplegia are at risk for unmonitored, precipitous delivery. Women with a lesion at or above T6 are at risk for autonomic dysreflexia. Although some women experience relatively little symptomatic progression during pregnancy, flares are common during the first 3 postpartum months. Flares may preclude breast-feeding, and the patient may require assistance with infant care.

Myasthenia Gravis

Myasthenia gravis is a chronic autoimmune neuromuscular disease characterized by easy fatigability of facial, oropharyngeal, extraocular, and limb muscles. The primary defect is immunoglobulin G (IgG)-mediated destruction of striated muscle acetylcholine receptors. The diagnosis is made with the edrophonium chloride test (edrophonium inhibits acetylcholinesterase, which allows acetylcholine levels to increase and improves strength in myasthenic muscles), nerve stimulation tests, and measurement of acetylcholine receptor antibodies. The incidence of myasthenia gravis is 1 in 10,000. Women are affected more often than men and experience a peak occurrence in their 20s and 30s. Symptoms typically wax and wane and are not altered by pregnancy, although postpartum exacerbation is common. Thymectomy usually is performed shortly after diagnosis, because it results in symptomatic improvement and may ultimately eliminate the need for medical therapy.

Pregnant women with mild disease usually require only adequate rest and the avoidance of strenuous activities. More seriously affected women require medical therapy in the form of pyridostigmine bromide or neostigmine bromide, glucocorticoids, or immunosuppressive drugs. Plasmapheresis can relieve acute symptoms by mechanically removing the pathologic antibodies and can be performed during pregnancy, if care is taken to avoid maternal hypotension or hypovolemia. Because the disease does not affect smooth muscle, labor and delivery proceed normally. The patient may receive oxytocin and analgesics, but care should be taken to avoid extensive regional blocks that could compromise maternal respiration. Certain drugs are tolerated poorly and should be avoided. These include magnesium sulfate, aminoglycosides, certain antiarrhythmic agents (e.g., quinine, quinidine, and procaine), procaine anesthetics, curare, succinylcholine, and large doses of narcotics. Because the antireceptor IgG antibody easily crosses the placenta, the neonate will be transiently symptomatic in approximately 10% of cases and will require tertiary care.

Myotonic Dystrophy

Myotonic dystrophy is an autosomal dominant, multisystem disease characterized by muscle stiffness (myotonia), progressive dystrophic changes in muscles of the face, neck, and distal limbs, and posterior subcapsular cataracts. It occurs in 3 to 5 per 100,000 individuals and usually is diagnosed in late childhood or early adulthood, with the development of progressive muscle weakness and atrophy. Affected patients have characteristic facies (drooping eyelids, bitemporal wasting, and weakness, with diminished expressivity of the mouth known as a *flattened smile*), weakness and atrophy of small hand muscles, and respiratory and gastrointestinal

difficulties. Although menstrual irregularities and infertility are common, affected patients can become pregnant. Such pregnancies can be complicated by polyhydramnios, preterm labor, dysfunctional labor, and postpartum hemorrhage. Maternal deaths related to aspiration pneumonia or cardiac failure have been reported. Symptoms are usually worse in the last half of pregnancy and often improve after delivery.

The molecular defect is a region of CTG trinucleotide repeats in the myotonin gene on the long arm of chromosome 19. The number of repeats in this region determines the severity of the symptoms; expansion of the region, along with an increase in symptom severity, can occur with each generation. The fetus of an affected mother is thus at risk of inheriting an expanded form of the gene and having the severe congenital form of the disease. Infants with congenital myotonia are floppy at birth, have diminished suck and cry reflexes, and have serious respiratory compromise. Prenatal diagnosis is available. Severely affected women and their affected infants usually require tertiary care.

Spinal Cord Injury

Spinal cord injury resulting in paraplegia or quadriplegia occurs in 1 in 10,000 individuals per year in the United States. Reproductive-age women with spinal cord injuries generally tolerate pregnancy well, although pregnancy may exacerbate bowel dysfunction or pressure necrosis of the skin and may increase the incidence of urinary tract infections. Women with lesions below T10 to T12 feel uterine contractions normally. Women with lesions above this level, however, usually do not feel their contractions and are at risk for a precipitous, unattended delivery. Such women should be taught to palpate their uterus for contractions on a regular basis during the third trimester.

Women whose lesion is above T6 are at risk for autonomic hyperreflexia. In this condition, any number of stimuli (labor, urethral catheterization, cervical or rectal examination) can provoke afferent nerve impulses that enter the cord and initiate focal segmental reflexes that are not modulated or inhibited by higher centers, resulting in stimulation of the sympathetic nervous system. Symptoms include pilomotor erection, excessive sweating, facial flushing, dilated pupils, severe headache, paroxysmal hypertension, and bradycardia. Epidural anesthesia can prevent or control such sympathetic stimulation and is, therefore, a crucial component of planned labor management. Vaginal delivery is possible for some patients with spinal cord injury, because the expulsive forces of the uterus are sufficient to bring down the fetal head for an assisted vaginal delivery. If cesarean section is required, regional anesthesia is ideal.

ENDOCRINOLOGY

Pituitary Tumors

The pituitary gland normally enlarges by 30% during pregnancy, and compression of the optic chiasm infrequently results in bitemporal hemianopsia. Pituitary secretions are altered by pregnancy: follicle-stimulating hormone and luteinizing hormone levels are decreased, and corticotropin and prolactin are increased. Thyroid-stimulating hormone (TSH) concentrations, however, vary with gestational timing.

Pituitary adenomas are benign neoplasms of anterior pituitary cells. Adenomas can secrete hormones, such as prolactin or ACTH, and cause hypopituitarism or headache or visual problems. They are classified by size as microadenomas or macroadenomas, with the former being less than 10 mm. They also can be classified by the hormone they secrete, with prolactin-secreting adenomas being the most prevalent at 26%. Diagnosis is confirmed by MR imaging or CT scan. Hyperprolactinemia can manifest as galactorrhea, menstrual disorders, infertility, hirsutism, headache, and visual field defects.

Treatment options include medical, surgical, or radiation therapy. Medical treatment is with the dopamine agonist bromocriptine, which decreases prolactin levels to normal in up to 90% of treated patients. Bromocriptine is not known to be teratogenic, but treatment during pregnancy typically is discontinued. As the normal pituitary enlarges during pregnancy, the potential for enlargement of an adenoma exists, as well. Pregnant women should be educated about and monitored for the symptoms of expansion, such as headaches and visual field changes. This occurs infrequently, because only 2% of microadenomas and 15% of macroadenomas show signs or symptoms of tumor growth during pregnancy. An initial visual field examination early in the pregnancy is routine, but serial exams typically are not useful because visual field losses are acute. Instead, the patient should be made aware of the possibility of visual field loss, with the recommendation made to seek prompt evaluation if it occurs. Surgery and radiation are alternative treatment modalities for adenomas, with surgery reserved for patients with very large tumors in whom medical therapy fails. Breast-feeding is unaffected by hyperprolactinemia. Bromocriptine is reinstituted at its completion.

Diabetes Insipidus

Diabetes insipidus (DI) involves water loss secondary to inadequate renal tubule reabsorption. Polyuria, polydipsia, and excessive thirst are characteristic. There are three causes of DI (Table 17.9). Hypothalamic (central) DI results from inadequate arginine vasopressin (AVP) secretion in response to stimuli and can be genetic (rare) or acquired. Acquired central DI occurs as the result of tumor, trauma, infection, Sheehan syndrome, or autoimmune disease. Nephrogenic DI results from decreased renal sensitivity to normal or elevated AVP levels and can be familial or acquired. Lithium also causes this type. Primary polydipsia, typically psychogenic in origin, involves excessive fluid intake and AVP suppression.

Hypothalamic
Genetic
Acquired
Nephrogenic
Primary polydipsia

TABLE 17.9. *Causes of diabetes insipidus*

DI is diagnosed with a water deprivation test. In a pregnant patient with a viable fetus, this test is performed with continuous fetal monitoring. Dehydration in DI will be accompanied by rising serum osmolality and an inability to concentrate the urine. Intranasal administration of desmopressin acetate prompts urine concentration and confirms the diagnosis. Its use is not associated with maternal or fetal complications.

Thyroid Disease

Maternal Thyroid Function During Normal Pregnancy Normal pregnancy results in modest thyroid enlargement, detectable on physical examination. Serum levels of TSH and thyroid-releasing hormone (TRH) are the same in the pregnant patient as in the nonpregnant, while levels of thyroid-binding globulin (TBG) increase due to estrogen-enhanced hepatic production. Because total thyroxine (T_4) and triiodothyronine (T_3) are increased, also, free biologically active T_3 and T_4 concentrations are unchanged in normal pregnant women. Human chorionic gonadotropin has the same a chain as TSH, so there is an inverse relationship between these hormone levels during pregnancy.
Maternal Hypothyroidism Most pregnant patients treated for hypothyroidism during pregnancy are diagnosed before pregnancy and are already on replacement therapy. In these patients, the dosage should be maintained initially. A patient may also develop hypothyroidism during pregnancy. The most common cause of hypothyroidism is Hashimoto thyroiditis, which is confirmed by demonstrating the presence of circulating antithyroglobulin and antimicrosomal antibodies. Women who have undergone thyroid ablation for Graves disease and are receiving inadequate replacement may also be hypothyroid. Symptoms include excessive fatigue, dry skin, cold intolerance, constipation, bradycardia, and irritability. Myxedema is rare. Laboratory evaluation reveals low free T_4 and high TSH levels. The goal of therapy is to provide enough T_4 to normalize the TSH and the pulse rate, which should be checked every 2 to 3 weeks. A typical replacement dosage is 150 µg of levothyroxine per day. At least 75% of all hypothyroid patients will require a higher dosage during pregnancy. The dosage typically is increased in 50 µg increments. Unrecognized or inadequately treated hypothyroidism is associated with an increased risk of miscarriage, preeclampsia, intrauterine fetal demise, and postpartum hemorrhage.
Maternal Hyperthyroidism Hyperthyroidism complicates 1 in 500 pregnancies. Causes include Graves disease, acute or subacute thyroiditis, toxic nodular goiter, toxic adenoma, and gestational trophoblastic disease (Table 17.10). Patients with Hashimoto thyroiditis also may exhibit signs of hyperthyroidism if they make antithyroid antibodies (a combination of Graves disease and Hashimoto thyroiditis, or Hashitoxicosis) or if they make anti-TSH receptor antibodies.

Graves disease
Acute (subacute) thyroiditis
Hashimoto disease
Toxic nodular goiter
Toxic adenoma
Gestational trophoblastic disease

TABLE 17.10. *Causes of hyperthyroidism*

The most common cause of hyperthyroidism in pregnancy is Graves disease. The diagnosis is based on a triad of manifestations, including hyperthyroidism with diffuse goiter, ophthalmopathy (particularly exophthalmos), and dermopathy. Graves disease is an autoimmune disorder in which circulating thyroid-stimulating

immunoglobulins (TSIs) bind to thyroid follicular cell TSH receptors, stimulating excess thyroid hormone synthesis and secretion. The patient may have other autoimmune diseases, including systemic lupus erythematosus, myasthenia gravis, and immune thrombocytopenia. The diagnosis of hyperthyroidism can be difficult, because the patient may report symptoms that are seen commonly in a normal pregnancy. These include shortness of breath, palpitations, and heat intolerance. Signs and symptoms of hyperthyroidism that are not typical of pregnancy, and thus aid in its diagnosis, include weight loss or poor weight gain and increased bowel frequency. Laboratory evaluation confirms the diagnosis. Free T_4 level is high in hyperthyroid patients. Rarely (in 3% to 5%), T_4 level may be normal and free T_3 elevated. TSH is suppressed. Autoantibodies confirm the autoimmune nature of the disease and may have fetal implications. Hyperthyroidism can be treated with antithyroid medications, surgery, or radioactive sodium iodine (^{131}I). All medications have some contraindications in pregnancy. Propylthiouracil (PTU) and methimazole (Tapazole) are thioamides that inhibit thyroid hormone biosynthesis. PTU lowers T_4 levels faster than methimazole, giving it an advantage for therapy. The recommended dose of PTU is 300 to 450 mg initially, followed by a 50- to 300-mg daily maintenance dose, usually divided into a 3-times-a-day dosage regimen. Both PTU and methimazole cross the placenta and can have inhibitory effects on fetal thyroid function. Once a high-normal free T_4 level has been achieved, the PTU dosage should be reduced to the smallest amount that maintains this level, thus decreasing the risk of fetal hypothyroidism. During therapy, maternal thyroid function should be evaluated every 3 to 4 weeks to guide dosage adjustments. Before initiation of therapy, a baseline white blood cell count and differential should be obtained. Adverse reactions to PTU include skin rash (2% to 8%), bronchospasm, drug fever, hepatitis, oral ulcers, and idiopathic agranulocytopenia. Idiopathic agranulocytopenia usually occurs during the first 3 months of therapy (1 in 500 patients) and is reversible after stopping the PTU. An adverse reaction to one thioamide does not necessarily predict a similar reaction to another. Both PTU and methimazole are taken up by the fetal thyroid gland after the first trimester. At PTU dosages of 300 mg or greater daily, fetal goiter and hypothyroidism have been reported; at dosages lower than 300 mg daily, fetal clinical outcome is usually improved; and at dosages lower than 200 mg daily, fetal T_4 levels can be normal. Aplasia cutis has been described in some fetuses exposed to methimazole, which may make PTU preferable during pregnancy. After birth, women taking these antithyroid medications may pass physiologically significant dosages of the medication into their milk. However, PTU is more strongly plasma protein bound, and therefore preferable for the patient who desires to breast-feed. The patient should be reminded to take the medication after feeding or pumping and to notify their pediatrician that she is taking the medication. The infant's thyroid function should be checked eriodically to prevent undiagnosed neonatal hypothyroidism. Beta blockers may be useful in decreasing the sympathetic-like symptoms of hyperthyroidism, while thyroid hormone levels are being reduced by other forms of therapy. In addition, propranolol has an inhibitory effect on the peripheral conversion of T_4 to T_3 and thus lowers circulating thyroid hormone levels. This action is additive to the effects of the thioamides. The recommended propranolol dose for this indication is 20 to 40 mg orally 3 to 4 times a day. Surgical thyroid ablation, or thyroidectomy, may be necessary during pregnancy if very high dosages of PTU (greater than 300 mg daily) are needed long term to control maternal hyperthyroidism. Medical thyroid ablation with ^{131}I should not be considered during pregnancy because of the possibility of simultaneous fetal thyroid ablation. Antenatal treatment with ^{131}I at the usual dosage results in 0.75 to 1.5 rad (0.0075 to 0.015 Gy) of fetal radiation exposure. Patients with inadvertent first-trimester exposure can be reassured that the fetal thyroid gland does not begin concentrating iodine until 10 to 12 weeks gestation, and maternal thyroid ablation before this time would not be expected to affect the fetus. Exposure after 12 weeks gestation, however, may result in congenital hypothyroidism. Theoretically, 10 days of maternal PTU administration after accidental exposure may benefit the fetus by decreasing uptake of ^{131}I iodine into the fetal thyroid gland. Adequate treatment of hyperthyroidism is important to decrease the risk of preeclampsia and preterm delivery, as well as that of fetal demise, growth restriction, and fetal or neonatal thyroid dysfunction. The patient with a very serious complication of Graves disease, thyroid storm or crisis, can experience tachycardia, hyperpyrexia, circulatory collapse, and death. Thyroid storm involves a massive release of thyroid hormones and often is recipitated by a stressor, such as infection (e.g., pyelonephritis), thyroid gland palpation, or labor and delivery. Thyroid storm is an emergency and must be treated aggressively to prevent maternal decompensation. Treatment may require the administration of multiple agents for up to 1 to 2 weeks (Table 17.11). PTU should be given in large doses: 600 mg orally initially followed by 300 mg orally every 6 hours. The thioamides can be administered through a nasogastric tube if the patient cannot tolerate oral medications. In addition, sodium iodide, 1 g in 500 mL of fluid, should be given daily to inhibit the release of stored hormone. Propranolol may be added for control of tachycardia and other sympathetic-like symptoms if there is no evidence of cardiac failure. The initial propranolol dosage is 40 to 80 mg orally every 4 to 6 hours, or 1 mg per minute intravenously for 2 to 10 minutes with concurrent maternal cardiac monitoring. The dosage may be adjusted, depending on the patient's cardiac response. Dexamethasone, 1 mg orally or intramuscularly every 6 hours, or hydrocortisone, 100 mg intravenously every 8 hours, can further inhibit peripheral T_4 to T_3 conversion. Oxygen, digitalis, fluid replacement, and acetaminophen (as an antipyretic) should be given as needed.

Propylthiouracil: 600 mg p.o. (n.g.), then 300 mg q6h
Sodium iodide: 1 g/500 empc i.v. q.d.
Propranolol: 40–60 mg p.o. q4–6h
Dexamethasone: 1 mg p.o. i.m. q6h
Oxygen, acetaminophen, fluid replacement

n.g., nasogastric tube administration.

TABLE 17.11. *Treatment of thyroid storm*

Thyroid Nodules and Cancer Evaluation of thyroid nodules discovered during pregnancy should begin with a complete physical exam, evaluation of thyroid function tests, and ultrasonography to document the nodule's presence and size. This is followed by a fine-needle aspiration, and if elected, surgical removal, preferably in the mid-second trimester. Thyroid cancer is suspected if there is rapid growth unaccompanied by tenderness or hoarseness. Thyroid function test results are usually normal. Thyroid cancer is more likely in a population irradiated in childhood; in this group, 30% of those with a thyroid nodule will have thyroid cancer at the time of surgery. In the pregnant patient, papillary cancer predominates and is no more aggressive than in the nonpregnant patient. Importantly, a delay in surgery does not alter outcome. In the presence of either a hyperfunctioning benign nodule or documented papillary carcinoma, thyroid function typically is suppressed with levothyroxine until definitively treated. In the presence of a more malignant cell type, such as medullary or undifferentiated carcinoma, or lymphoma, some practitioners recommend pregnancy termination to pursue aggressive management with surgery, adjuvant radiation, and chemotherapy. There is no evidence that pregnancy affects the progression of thyroid cancer or that thyroid cancer affects the outcome of pregnancy. As a result, thyroid cancer or a history of it is not an absolute contraindication to pregnancy. Although pregnancy is not a contraindication to thyroid surgery, it is a contraindication to ^{131}I treatment.

Fetal Thyroid Function The fetal thyroid gland is first capable of hormonal activity by the end of the first trimester, and there is normally a gradual increase in fetal T_4 concentrations during pregnancy. This increase represents fetal production rather than transplacental transfer, because both T_3 and T_4 cross the placenta only minimally. However, iodides, antithyroid medications, and TSIs cross the placenta easily. Thyroid hormone deficiency during fetal development or during the first 2 years of life can cause irreversible brain damage, with the degree of disease related to the severity, duration, and gestational age at which the hypothyroidism occurs. Although neonatal hypothyroidism is not common (1 in 4,000 live births in the United States), it is a potentially treatable cause of mental retardation and thus is now included in most newborn blood screening programs. Fetal hypothyroidism can be treated antenatally by direct hormone injection of the fetus via amniocentesis. Fetal hyperthyroidism can also be diagnosed before birth and may respond to prenatal treatment. Fetal or neonatal thyrotoxicosis occurs in 1 of 70 thyrotoxic mothers. It results from the transplacental transfer of TSIs and is a potentially serious disease, with mortality rates of 10% to 16% due to prematurity and congestive heart failure. Hyperthyroid pregnant patients should be evaluated frequently for fetal tachycardia, and appropriate interval fetal growth should be confirmed. Fetal goiter may be identified on ultrasonographic examination, and fetal thyroid function can be assessed with fetal blood sampling. Because PTU and methimazole cross the placenta, maternal dosage can be adjusted to correct the fetal hyperthyroidism; replacement T_4 can then be given to the mother, if necessary. The diagnosis of neonatal thyrotoxicosis is usually clinically apparent, because the infant may have a goiter, exophthalmos, tachycardia, irritability, and growth restriction. The mother likely has a history of hyperthyroidism and may have had previous infants affected by this disease. Mild cases of neonatal thyrotoxicosis require no treatment; the symptoms resolve as maternal TSIs are cleared from the infant's system. Severely symptomatic babies are treated with propranolol and PTU.

Parathyroid Conditions The parathyroid glands function to maintain maternal calcium and phosphate homeostasis. Total calcium levels decline during pregnancy because the binding protein albumin declines, but the level of ionized, biologically active calcium is unchanged. The fetus contains approximately 30 mg of calcium, which is transported actively across the placenta. Maternal calcium requirements increase from 0.5 mg per day to 1.5 mg per day at term. Serum parathyroid hormone (PTH) levels gradually increase during pregnancy, reflecting the increased calcium transfer to the fetus plus the increases in extracellular fluid volume and glomerular filtration rate.

Hyperparathyroidism Hyperparathyroidism is a condition caused by excessive PTH production, often due to a clinically inapparent parathyroid adenoma. Hypercalcemia results and causes symptoms of fatigue, weakness, polyuria, polydipsia, nausea, anorexia, and constipation. During pregnancy, affected women may have prolonged nausea and vomiting. Increased renal excretion of calcium may predispose to nephrocalcinosis, renal calculi, and symptomatic bony resorption. Although serum calcium measurements remain the best single diagnostic test, the physiologic changes of pregnancy may make the diagnosis of hyperparathyroidism difficult. A total calcium concentration of 10.5 mg/dL or greater in late pregnancy must be considered suspicious, and a total calcium concentration of 12.0 mg/dL or greater is definite evidence of hyperparathyroidism. Palpable parathyroid adenomas are extremely uncommon. Hyperparathyroidism is associated with an increased incidence of perinatal morbidity and mortality; therapy is recommended. Up to 50% of infants of untreated mothers will develop hypocalcemia and tetany, which may be the first indicator of maternal disease. If the diagnosis is first established during pregnancy, surgical resection of the adenoma generally is indicated, although oral phosphate therapy (1 to 1.5 g daily in divided doses) may occasionally be attempted. Pregnancy termination need not be considered except in the rare case of advanced renal involvement.

Hypoparathyroidism Hypoparathyroidism results from inadequate production of PTH and is characterized by weakness, fatigue, mental status changes, numbness and paresthesias of the extremities, muscle cramps, and tetany. It must be distinguished from pseudohypoparathyroidism, in which parathyroid function is normal but end organs do not respond to PTH. The signs and symptoms of hypoparathyroidism are the result of a decreased serum ionized calcium level and increased neuromuscular irritability. It occurs most commonly as the result of parathyroid gland injury or removal in association with thyroid surgery or irradiation, but it can be idiopathic. The increased calcium requirements of pregnancy may make patients with hypoparathyroidism more symptomatic. In addition, relative unavailability of calcium for the fetus may lead to secondary neonatal hyperparathyroidism. Symptomatic hypocalcemia can be prevented with calcitriol (1,25-dihydroxyvitamin D_3), dihydrotachysterol, large doses of vitamin D, and calcium gluconate or lactate. The patient should be on a low-phosphate diet and might benefit from consultation with an endocrinologist and a dietitian.

Adrenal Disease

In normal pregnancy, plasma concentrations of adrenal steroid hormones typically increase with advancing gestation. Because the amount of cortisol bound to nuclear receptors actually is decreased slightly (due to competition by progesterone), both total plasma cortisol and cortisol-binding globulin levels increase. Free cortisol levels are increased, and a diurnal variation is maintained. Aldosterone levels also rise, although the factor(s) responsible remain unclear; no consistent correlations exist with observed elevations in angiotensin II or progesterone. Adrenal function tests are unaltered. As with other endocrine disorders, abnormalities in adrenal function are usually associated with infertility. However, adrenal insufficiency and hyperfunction can complicate pregnancy.

Adrenal Insufficiency Inadequate production of adrenal corticosteroids can be either chronic or acute. Although most cases of adrenal insufficiency are diagnosed outside of pregnancy, the disease may first occur during pregnancy and present a diagnostic challenge. The chronic form may become apparent with numerous nonspecific signs and symptoms, whereas the acute form may manifest as vascular collapse. The signs and symptoms of chronic adrenocortical insufficiency during pregnancy are identical to those in the nonpregnant state and include fatigue, hyperpigmentation, weakness, anorexia, nausea, vomiting, and weight loss. Because all of these problems may be encountered during the course of an otherwise normal gestation, the clinical diagnosis of adrenocortical insufficiency in pregnancy may be difficult. However, persistent weight loss or nausea and vomiting beyond the first trimester, particularly in association with any of the aforementioned signs or symptoms, should raise suspicions. The diagnosis and appropriate treatment of adrenocortical insufficiency during pregnancy are important because of the risks associated with the added stress of pregnancy and delivery and because of the increased likelihood of adrenal crisis, particularly during the puerperium. Adrenal insufficiency can be primary (Addison disease), due to autoimmune adrenal destruction or tuberculosis, or secondary, due most often to exogenous glucocorticoid intake (Table 17.12). When Addison disease is suspected, a blood sample for plasma cortisol and ACTH levels should be obtained (Table 17.13). A cortisol level less than 20 µg/dL is consistent with Addison disease. Treatment should be started promptly, consisting of intravenous hydrocortisone 100 mg every 6 hours. When chronic adrenal insufficiency is suspected or confirmation of the diagnosis of acute adrenal insufficiency is needed, an ACTH challenge test can be performed and a 24-hour urinary free cortisol level determined. Long-term replacement thereafter consists of hydrocortisone 12 to 15 mg/m ^{2} per day and, if necessary (as guided by serum potassium), fludrocortisone acetate (Florinef) 100 g per day for mineralocorticoid activity.

Primary (Addison Disease)
Autoimmune
Tuberculosis
Secondary
Exogenous glucocorticoids

TABLE 17.12. *Causes of adrenal insufficiency*

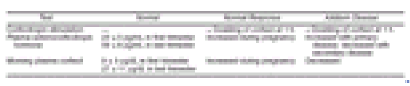

TABLE 17.13. *Laboratory diagnosis of adrenocortical insufficiency*

Additional cortisol replacement is recommended during periods of major stress, with criteria being fairly vague and liberal (e.g., injury, fever, surgery). In these instances, the dosage is increased to at least 200 mg per day until the stress has passed. For periods of minor stress (e.g., nausea, vomiting, low-grade fever), the routine daily dosage is doubled. Because glucocorticoids cross the placenta, transient suppression of the newborn hypothalamic-pituitary-adrenal axis may be observed, and the neonate may require cortisol replacement and treatment of hypoglycemia. Neonatal outcome is otherwise unaffected.

Cushing Syndrome or Hypercortisolism Elevated levels of glucocorticoids can result from bilateral adrenal hyperplasia, benign or malignant adrenal adenomas, or exogenous corticosteroid therapy. If adrenal hyperplasia occurs in response to an ACTH-producing pituitary tumor, the diagnosis is Cushing disease. Affected individuals are obese, hypertensive, and hirsute, with common complaints of weakness, easy bruising, and emotional lability. Classically described features of Cushing syndrome include round faces and full cheeks, with increased centripetal fat distribution. Glucose intolerance, acne, and osteoporosis are also common in untreated patients. The diagnosis of Cushing syndrome in pregnancy may be difficult, because many of the previously mentioned signs and symptoms may be seen in normal pregnancy. However, hirsutism and acne tend to be particularly prominent. These patients have elevated plasma cortisol levels, without diurnal variation, that are not suppressed with dexamethasone (Table 17.14). Because of the possibility of adrenal carcinoma, any such patient must be evaluated carefully by appropriate laboratory and radiographic means. With Cushing symptomatology, adrenal cancers are typically very large (6 cm) and easily detectable on CT scan.

TABLE 17.14. *Laboratory diagnosis of hypercortisolism*

Cushing syndrome in pregnancy is associated with an increased incidence of miscarriage, premature labor, diabetes, hypertension, and stillbirth. Consequently, careful fetal surveillance is mandatory.

Congenital Adrenal Hyperplasia Congenital adrenal hyperplasia (CAH) is the result of one of several enzyme defects in cortisol biosynthesis. The majority of patients have 21-hydroxylase deficiency, although 11ß-hydroxylase deficiency or 18-hydroxysteroid dehydrogenase deficiency may be encountered rarely. Because these enzyme deficiencies are autosomal recessive, the patient with this diagnosis has a negligible chance to have an affected child, unless she is related to the child's father. Approximately 90% of patients with CAH during pregnancy have a partial or complete deficiency of the 21-hydroxylase enzyme. The resultant decrease in cortisol production leads to increased ACTH stimulation, which then results in both increased production of androgenic cortisol precursors (e.g., 17ß-hydroxyprogesterone) and decreased production of aldosterone. Because these androgenic steroids readily cross the placenta, pregnancies complicated by significant maternal 21-hydroxylase deficiency are at increased risk for fetal virilization. Such virilization is most apparent in female infants, although male infants also may have somewhat enlarged external genitalia. The risk of fetal virilization is reduced if pregnant patients with CAH receive adequate basal glucocorticoid replacement, together with additional glucocorticoid in times of stress. Mineralocorticoid replacement should be continued, as well. Sometimes the pregnant patient, herself, does not have CAH but has had a previous child with the disorder. The diagnosis of CAH in the fetus historically has been made on the basis of amniotic fluid measurement of 17ß-hydroxyprogesterone. However, molecular genetic techniques are available for evaluation of fetuses at risk by sampling of chorionic villus cells or amniocytes. The affected fetus will produce high levels of androgenic steroids that can cause virilization. Fetal treatment consisting of maternal oral dexamethasone twice daily, beginning at 6 to 7 weeks, may prevent this. The treatment is discontinued if CVS or amniocyte analysis confirms that the fetus does not carry the enzymatic defect. A newborn with ambiguous genitalia requires rapid diagnosis, treatment, and gender assignment. The karyotype, electrolytes, 17ß-hydroxyprogesterone, and urinary 17-ketosteroids should be evaluated expeditiously. The clinical manifestations of cortisol and aldosterone deficiency can include hypoglycemia, hyperpigmentation, apneic episodes, seizures, emesis, hyperkalemia, dehydration, hypotension, vascular collapse, and shock. Resuscitation requires hydrocortisone administration and saline-glucose hydration. Elevated plasma renin activity indicates the need for mineralocorticoid replacement, as well. Eventually, maintenance therapy with hydrocortisone (glucocorticoid) and fludrocortisone (mineralocorticoid) is guided by 17ß-hydroxyprogesterone and plasma renin activity measurements, respectively. Under-treatment is accompanied by premature skeletal maturation, whereas over-treatment leads to slowing of skeletal maturation. It is hoped that using clinical variables such as height velocity and weight to guide replacement therapy will improve the mean adult height in patients with this disorder (i.e., 4th percentile for men and 25th percentile for women).

Pheochromocytoma Pheochromocytoma is a rare, but extremely serious, complication of pregnancy, with increased maternal and perinatal morbidity and mortality rates. Hypertension is present in the majority of patients and may be either paroxysmal or sustained. Only a minority of patients have classic pheochromocytoma episodes, characterized by extreme hypertension, headache, diaphoresis, weakness, tremor, and palpitations. Such patients often are initially considered to have hyperthyroidism. The diagnosis of pheochromocytoma is best made by measurement of 24-hour urinary catecholamine levels; normal values are unaffected by pregnancy. If the diagnosis is established by laboratory criteria, the tumor should be localized, using whatever combination of abdominal CT scan and selective venous sampling is clinically indicated. Eighty percent of these tumors are located in one adrenal gland, 10% to 15% are bilateral, and 10% are found in other locations, including the renal hilus, the organ of Zuckerkandl, and the periaortic sympathetic chain. Because of the high morbidity and mortality associated with this condition, surgical removal during pregnancy is indicated when the diagnosis is established. The patient should be pretreated with a and ß blockers, usually phenoxybenzamine and propranolol, for 1 to 2 weeks before surgery to increase the likelihood of intraoperative symptomatic control. Multidisciplinary management is essential to maximize maternal and fetal outcomes.

DERMATOLOGIC DISEASE

Physiologic Changes During Pregnancy

The systemic changes of pregnancy affect the skin in many ways. Effects can be transient or permanent. Striae gravidarum, or stretch marks, develop in the majority of women and, although they may fade postpartum, they seldom disappear. Ninety percent of all pregnant women experience some degree of hyperpigmentation, the cause of which is unknown. It may involve melanocyte-stimulating hormone and estrogens, or other factors. Hyperpigmentation is more marked in darker skinned women, more often permanent in lighter skinned women, and involves the nipples, perineum, umbilicus, and the linea alba (nigra). Facial pigmentation, or melasma, is seen in at least 50% of pregnant women. It is melanin related and aggravated by sunlight. Benign or melanocytic nevi commonly enlarge and darken and can be

confused with malignant melanoma. Vascular changes are prominent and may manifest as spider angiomas, palmar erythema, and venous varicosities. Finally, scalp hair growth is altered, with an increased proportion of growing hairs to resting hairs. This is reversed after delivery with the onset of telogen effluvium, an abrupt hair loss 1 to 4 months postpartum. By 6 to 12 months, normal hair growth is restored.

Pregnancy-specific Dermatologic Disease

Intrahepatic Cholestasis of Pregnancy Intrahepatic cholestasis of pregnancy is the second most common cause of jaundice in pregnant women (hepatitis is the most common cause) and can produce intense pruritus (Table 17.15). There may be a several-fold increase in maternal serum bile salts, alkaline phosphatase, aspartate aminotransferase (serum glutamic-oxaloacetic transaminase), alanine aminotransferase (serum glutamic-pyruvic transaminase), and bilirubin. Treatment is symptomatic but not always effective. Topical antipruritics, antihistamines, dexamethasone, cholestyramine, and ursodeoxycholic acid have been used with variable success. The pruritus and laboratory abnormalities typically resolve promptly after delivery, but one half of patients will experience recurrence in subsequent pregnancies or with oral contraceptive use. Cholestasis is associated with an increased risk of adverse fetal outcome. Antepartum tests of fetal well-being and consideration of delivery upon documentation of fetal lung maturity are recommended.

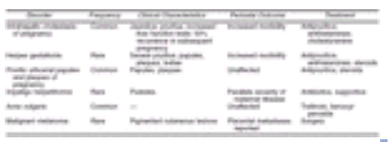

TABLE 17.15. *Dermatologic diseases in pregnancy*

Herpes Gestationis Herpes gestationis, or pemphigoid gestationis, is a rare, serious, autoimmune dermatologic disease seen in pregnancy. The onset is typically in mid to late pregnancy but occasionally occurs postpartum. It is characterized by severe pruritus, with urticarial papules, plaques, erythema, and vesicles and bullae involving the abdomen and extremities. It is occasionally generalized, and exacerbations and remissions are common. Treatment for these pruritic lesions typically includes antihistamines and topical steroids, with oral steroids considered in severe cases. Biopsy with histologic examination reveals subepidermal edema with inflammatory infiltrate, and immunofluorescent staining confirms complement and IgG deposition at the basement membrane. This complement-fixing IgG can cross the placenta and cause dermatologic manifestations in about 5% of newborns; these typically resolve within several weeks. Herpes gestationis has been associated with adverse fetal outcome, so fetal well-being testing is appropriate. Recurrence is seen in subsequent pregnancies, and it is often more severe and occurs earlier in gestation.

Pruritic Urticarial Papules and Plaques of Pregnancy Pruritic urticarial papules and plaques (PUPP) of pregnancy is the most common pruritic dermatosis of pregnancy. An intensely pruritic disorder, PUPP appears late in pregnancy, with a frequency as high as 1%. It is more common in nulliparas and is not known to recur. The papules and plaques can be generalized or patchy, involving the abdomen, buttocks, thighs, and arms. On biopsy and immunofluorescent staining, the absence of antibody or complement deposition distinguishes PUPP from herpes gestationis; instead, there is a nonspecific lymphocytic perivasculitis. Treatment consists of antipruritics and topical steroids. In severe cases, oral steroids may be considered. There is no associated increase in perinatal morbidity.

Impetigo Herpetiformis Impetigo herpetiformis, which some consider to be pustular psoriasis, is a rare disease with an onset late in pregnancy. It initially involves intertriginous surfaces but can extend to involve the entire skin surface and mucous membranes. It classically appears as erythematous patches surrounded by sterile pustules that can become secondarily infected. Systemic symptoms and signs include fever, malaise, gastrointestinal distress, and hypocalcemia. Maternal sepsis is not uncommon. Treatment is supportive, with maintenance of fluid and electrolyte balance, correction of hypocalcemia, and antibiotic therapy, as needed. The utility of steroids is uncertain. Delivery is not necessarily accompanied by resolution. Perinatal morbidity and mortality parallel the severity of maternal disease and tests of fetal well-being are warranted in severe cases.

Non–pregnancy-specific Dermatologic Disease

Acne Vulgaris Some, but not all, women will note that their acne vulgaris improves with pregnancy. Topical treatments, such as tretinoin (Retin-A) and benzoyl peroxide, as well as oral erythromycin, can be useful for the pregnant patient. Isotretinoin (Accutane), prescribed for severe cystic acne, and etretinate (Tegison), prescribed for psoriasis, are contraindicated, because they are teratogenic.

Malignant Melanoma Malignant melanoma, a relatively common disease of women of childbearing age, complicates about 3 in 1,000 births. Melanoma should be considered if a skin lesion is enlarging and unusually colored, with bleeding or irregular borders. The most significant risk factor is sun exposure. Diagnosis is by biopsy. Pregnancy is not thought to affect survival and, as in the nonpregnant population, tumor size and thickness are the most important qualifiers for prognosis. Placental metastases have been reported. Treatment is primarily surgical, with adjuvant chemotherapy or immunotherapy. Because the majority of recurrences manifest within 5 years, most experts recommend a delay in future pregnancies.

ACUTE ABDOMEN AND SURGICAL DISEASE IN PREGNANCY

Excluding ectopic pregnancy, pregnancy does not increase the risk of surgical illness or malignancy and does not increase the risk of adverse outcome after an uncomplicated surgical procedure. Surgical diseases in the pregnant woman can be life threatening, however, because the physiologic changes of pregnancy and the presence of a gravid uterus may delay accurate diagnosis and can make many surgical procedures more technically difficult. Although elective surgery should be postponed until after delivery if at all possible, a surgical emergency in a pregnant woman should prompt the same aggressive treatment considered for the nonpregnant individual.

Appendicitis

Laparotomy is required during 1 in 500 to 1,000 pregnancies; appendicitis is the most common diagnosis. Pregnancy does not increase the risk of appendicitis. It occurs with equal frequency in all three trimesters, and appendectomy can be performed safely throughout pregnancy. However, acute appendicitis has been associated with a maternal mortality rate as high as 5% and an increased risk of preterm labor and fetal loss. These complications most often result from a delay in diagnosis.

Intraabdominal pathology can be difficult to diagnose in the gravid woman. Bowel is progressively displaced upward and backward as the gravid uterus grows during pregnancy. Because bowel sounds normally are heard only in the upper abdomen, the absence of bowel sounds may not be appreciated. The appendix also assumes an increasingly more cephalad position, and associated inflammation and pain are therefore not typically localized to the right lower quadrant after the first trimester. Anorexia, nausea and vomiting, a change in bowel habits, and even epigastric or abdominal pain can be part of normal pregnancy and thus may not suggest pathology. Laboratory evaluation may not be helpful, because a mild leukocytosis is common in pregnancy. Nevertheless, it is in the patient's best interest to have a high index of suspicion, because delayed diagnosis and therapy can be catastrophic.

The patient typically has periumbilical or right flank pain that is increased by uterine manipulation. Placing the patient on her left side allows the uterus to fall away from the right flank and may facilitate examination. Thirty percent of appendices are retrocecal in location; in this situation, the initial complaint may be right flank or leg pain or pain on rectal examination, and the patient may have psoas or obturator muscle symptoms. Anorexia, nausea, and vomiting usually are increased relative to normal pregnancy. The white blood cell count may be elevated significantly, and the patient may be febrile, especially if rupture or generalized peritonitis is present. Sonographic examination can help rule out other diagnoses but generally cannot confirm appendicitis itself, because ultrasound waves penetrate gas-filled structures poorly. A plain radiograph to identify air-fluid levels or free air in the abdomen can be very helpful and generally exposes the fetus to less than 300 mrad (0.0003 Gy) of radiation. Once appendicitis is suspected, laparotomy should be performed. A right paramedian vertical incision provides ideal visualization.

Intestinal Obstruction

The second most common nonobstetric indication for abdominal surgery is intestinal obstruction, which complicates 3 in 10,000 pregnancies. Risk factors include previous pelvic inflammatory disease and previous intraabdominal surgery. The incidence of intestinal obstruction increases as pregnancy advances because the enlarging uterus displaces the bowel upward and backward, placing preexisting adhesions on tension and increasing the risk of volvulus. As stated above, pregnancy makes assessment of bowel function difficult and may contribute to a delay in diagnosis. Maternal mortality as high as 10% to 20% has been reported, due primarily to maternal shock associated with unrecognized bowel infarction. As with appendicitis, once bowel obstruction unresponsive to conservative management has been diagnosed, surgical intervention should not be delayed.

Cholecystitis

Acute abdomen may be due to cholecystitis. Cholecystitis occurs in 1 in 1,000 to 1,600 pregnancies; over 90% of cases are caused by cholelithiasis. Patients typically seek treatment for nausea, vomiting, and the acute onset of colicky midepigastric pain. Laboratory evaluation and ultrasonographic examination are helpful in making the diagnosis. The treatment is primarily medical, especially in the first and third trimesters. Surgery is considered for the patient with repeated severe episodes of

cholecystitis and unremitting pain, systemic toxicity, or persistent or recurring pancreatitis. The second trimester is preferable for elective surgery, because the risks of surgery-associated fetal loss, preterm labor, or fetal compromise are lowest at this time. Further, although the pregnancy is well established, the uterus is still small enough to allow adequate visualization of the operative site without extensive uterine manipulation. Open laparoscopic second-trimester cholecystectomy has been reported with good results. Maternal mortality is minimal, and fetal mortality is usually less than 5%.

Pancreatitis

Pancreatitis can result in acute abdomen. In pregnancy, the most common cause of pancreatitis is cholecystitis, with alcohol abuse, viral infection, and hyperlipidemia accounting for a small proportion of cases. Treatment is primarily medical, as outlined earlier, with surgery considered only if symptoms do not improve rapidly (1 to 2 days) or an abscess or pseudocyst develops. As with cholecystitis, ultrasonographic examination may be helpful in making the diagnosis and ruling out other entities. The patient should be followed closely, with careful attention given to fluid management. Fetal loss can occur in complicated cases as a result of acidosis, hypovolemia, and hypoxia.

Liver Disease

Abdominal pain, particularly right upper quadrant pain, may be due to liver disease. Most commonly, liver pathology in pregnancy is due to preeclampsia, hepatitis, or acute fatty liver. Very rarely, pregnancy is complicated by cirrhosis or portal hypertension. Because pregnancy increases the risk of bleeding from esophageal varices, such patients may require endoscopic sclerotherapy during pregnancy.

Peptic Ulcer Disease

Although PUD can cause symptoms of acute abdomen, it is rare in gravid women because the hormonal milieu and other physiologic changes of pregnancy confer a protective effect. Endoscopy can be performed to confirm the diagnosis. Management is primarily medical.

MATERNAL TRAUMA

Physiologic Changes in Pregnancy

Accurate assessment of the pregnant trauma victim requires knowledge of the physiologic changes that normally occur during gestation. No organ system is unaffected, but the functions of the cardiovascular and respiratory systems are altered most dramatically. Plasma volume increases by 50%, while red blood cell mass increases by 25%, resulting in a physiologic anemia. Leukocytosis normally occurs, peaking in the third trimester with a white blood cell count of 12,000 to 18,000/mm^3 and 25,000/mm^3 in labor. Cardiac output increases by 4.5 to 6.0 liters per minute (30% to 50%), primarily as a result of a gradual increase in stroke volume to 50% above nonpregnant levels. The majority of pregnant women have a widely split first heart sound, a third heart sound, and a systolic ejection murmur. Over 10% of cardiac output goes to the uterus at term, and veins in the pelvis and lower extremities are engorged. Renal blood flow increases by 30%, leading to a 30% to 50% increase in the glomerular filtration rate. As a result, the BUN and creatinine fall and should not be higher than 13 mg/dL and 0.8 mg/dL, respectively, during pregnancy. A hormonally mediated decrease in vascular resistance leads to a midtrimester decrease in both systolic and diastolic blood pressure. All these changes are affected by maternal position. In the supine position, the uterus compresses the vena cava, resulting in decreased venous return, decreased cardiac output, a drop in blood pressure, bradycardia, and syncope.

Hyperventilation begins as early as the first trimester, probably in response to increased progesterone levels. Because of gradual elevation of the diaphragm by the enlarging uterus, functional residual capacity, residual volume, and expiratory reserve volume all decrease, while inspiratory reserve volume increases. The normal gravida at term has a chronic respiratory alkalosis with a resting carbon dioxide tension below 30 mm Hg. Seventy-five percent of gravidas experience dyspnea in the third trimester. Although arterial oxygen tension generally rises toward term, a moderate hypoxemia can occur in the supine position. Thus, the midtrimester gravida lying supine in the emergency room may be hypotensive, bradycardic, relatively hypoxemic, and anemic, all because of normal physiologic changes.

The ABCs

Taking into consideration the physiology of pregnancy, the pregnant trauma patient should be assessed initially as any trauma victim is assessed, according to the ABCs: airway, breathing, and circulation. In a rapid assessment of the patient's status, airway patency and adequacy of respirations should be established. Supplemental oxygen should be administered to all patients; the patient who is not breathing spontaneously should be intubated and mechanically ventilated. A wedge should be placed under the right hip to displace the uterus off the vena cava. Pregnancy significantly slows gastrointestinal motility, so all pregnant women should be assumed to have a full stomach. The conscious patient should be given sodium citrate or a similar antacid, while the airway of the unconscious patient should be protected.

If cardiac function is adequate, attention should be turned to maintaining adequate circulating volume. One or two large-bore intravenous lines should be established and Ringer's lactate solution given. Infusion of large volumes of sodium chloride should be avoided, because it can lead to hyperchloremic acidosis that would exacerbate lactic acidosis caused by poor perfusion. If the patient is bleeding, packed red blood cells should be ordered and administered as soon as possible.

If cardiac arrest has occurred, full resuscitation should be initiated as for any other patient. CPR at most generates only 30% of the normal cardiac output; CPR of a pregnant woman in left lateral tilt will be even less effective. The patient must therefore remain supine, and someone must be assigned to elevate the uterus manually off the vena cava. It can be assumed that perfusion to the uterus will be negligible during CPR. The general consensus is that a fetus can survive total asphyxia for at most 4 to 6 minutes. If cardiac function has not been restored within 4 minutes of arrest and the fetus is still alive, an emergent, nonsterile, classic cesarean section should be performed without anesthesia at the bedside, and the uterus and abdominal incisions closed as rapidly as possible. If cardiac arrest has persisted for more than 6 minutes but fetal cardiac activity continues, delivery should still be performed. In addition to possibly saving the fetus, evacuation of the uterus will facilitate CPR by improving cardiovascular dynamics.

The American College of Obstetricians and Gynecologists recommends that any pregnant woman sustaining trauma beyond 22 to 24 weeks gestation undergo fetal monitoring for a minimum of 4 hours. If more than four contractions per hour are observed, if rupture of membranes, bleeding, fetal arrhythmia, or fetal heart rate decelerations occur, or if the mother is seriously injured, the patient should be admitted with continuous fetal monitoring for at least 24 hours.

Abdominal Trauma

Motor vehicle accidents are the leading cause of blunt abdominal trauma (especially if the woman is unrestrained or is not wearing her lap belt as low as possible under her uterus), followed by falls and direct assaults. Placental abruption is the most common severe complication of blunt trauma, occurring with 1% to 5% of minor injuries and 20% to 50% of major injuries. Findings may include vaginal bleeding, uterine tenderness or contractions, as well as fetal tachycardia, decelerations, acidosis, and death. Direct fetal injury is less common but most often involves fetal skull and brain injury as a result of maternal pelvic fracture. Rupture of the liver or spleen can accompany blunt trauma, and rupture of the uterus occurs in less then 1% of cases. Bladder injury or rupture is more common after 20 weeks, when the bladder assumes an intraabdominal position and no longer is protected by the pelvis. Bladder injury may also result from pelvic fracture.

A patient with any signs of shock or peritoneal irritation is appropriately suspected to have major intraabdominal injury. Intraabdominal bleeding can be detected with intraperitoneal lavage, just as in the nonpregnant patient. Bladder injury is suspected when a urinary catheter cannot be passed, fails to return urine, or returns grossly bloody fluid. Bowel injury is uncommon, except at points of fixation. Uterine rupture usually results in vaginal bleeding, hypotension, absent fetal heart tones, and hematuria if the rupture involves the anterior uterine wall. If significant injury is suspected, the patient should be stabilized and a laparotomy performed as rapidly as possible. Extent of injuries, gestational age, and assessment of fetal well being are considerations for fetal delivery. Appropriate counseling should be provided regarding the possibility of hysterectomy, and blood products should obviously be available.

However, if the patient is stable and a CT scan or other radiologic studies are necessary for diagnostic purposes, they should be performed. If at all possible, the patient should be positioned with a wedge under one hip to deflect the uterus off the vena cava. The amount of radiation exposure resulting from standard radiologic procedures is less than the minimum dose associated with fetal teratogenicity or growth effects. The fetus is most susceptible before 15 weeks gestation, when radiation doses of 10 rad (0.1 Gy) or greater can cause mental retardation. At 16 to 25 weeks, the risk is considerably less, and radiologic procedures at 25 weeks or beyond pose minimal to no risk. Most authorities recommend limiting fetal exposure to less than 5 rad (0.05 Gy). Most plain radiographs entail doses of less than 1 rad (0.01 Gy); an abdominal CT scan exposes the fetus to 2 to 2.6 mrad (0.02 to 0.026 Gy). MR imaging does not require ionizing radiation and thus does not entail risk at any gestational age. Medical and surgical care should not be compromised in any way because the patient is pregnant. If the woman is Rh negative and unsensitized, Rh_0(D) immune globulin will protect her if there was fetal-maternal bleeding.

Penetrating Abdominal Trauma

Gunshot and knife wounds are responsible for most cases of penetrating abdominal trauma in pregnancy. As the uterus grows out of the pelvis, it becomes more likely that the uterus will be a site of injury. Penetration of the uterus results in maternal mortality in less than 5% of cases, but in fetal injury in 59% to 89% of cases, with fetal death in 41% to 71%. After penetrating abdominal trauma, the pregnant patient should be assessed as above and attempts made to determine the exact site(s) of injury and associated organ damage. The initial evaluation and subsequent surgical management should be the same as for the nonpregnant patient. If the uterus is the primary site of injury, exploratory laparotomy will likely be required. Bullet wounds must be explored surgically, because deflection of the bullet off intraabdominal structures can cause extensive damage and make it impossible to determine the projectile path. Knife wounds may require exploration, because the enlarged uterus compresses other intraabdominal organs and prevents structures underlying the stab wound from sliding away from the blade, as they would in the nonpregnant state. Ultrasonographic examination of the fetus to determine age and assess viability is essential.

Decisions about whether or not to empty the uterus should be individualized. If there is extensive intrauterine damage, if the pregnancy is near term, if there is a strong suspicion of fetal hemorrhage, or if uteroplacental insufficiency is present, the fetus should be delivered and the uterus thoroughly explored. If the uterus is uninjured or the injury can be repaired without entering the uterine cavity, if the fetus is previable or dead, and if uterine size does not preclude adequate exploration of the abdominal cavity, hysterotomy may be avoided as long as hemostasis is achieved.

Intraabdominal organs are compressed into the upper abdomen as pregnancy advances. Penetrating wounds in this area are especially traumatic, because multiple organs are injured. In decreasing order of frequency, small bowel, liver, colon, and stomach are damaged most often. For this reason, many authorities recommend that upper abdominal wounds be explored by laparotomy in all pregnant patients. Broad-spectrum antibiotics should be administered, and tocolytic therapy can be used with caution during the postoperative period. Beta mimetic agents have maternal and fetal cardiovascular effects that may confuse postoperative assessment, while magnesium sulfate is associated with maternal nausea, vomiting, and dizziness. Maintenance of normal intravascular volume and close attention to fluid balance are crucial.

Head Trauma

The gravida with head trauma should be evaluated and treated in the same way as the nonpregnant patient. Assessment begins with the ABCs. The head and neck should be immobilized as a unit in case there is cervical spine injury. In the stable patient, gestational age and viability should be assessed. Unless precluded by vertebral fractures, the uterus should be rolled off the vena cava by placing a wedge under the backboard. Mannitol, steroids, and other medications should be given, as necessary. Because fluid restriction, osmotic diuresis, maternal hypotension, and hypothermia induced during neurosurgery may reduce uteroplacental blood flow, the viable fetus should be monitored and therapeutic adjustments made as required.

Burns

Burns are described as being partial or full thickness and quantitated according to the percentage of surface area affected. Extensive full-thickness burns result in severe thermal instability and dramatic fluid loss. Hypovolemic shock can occur, especially within the first 36 hours. Airway management and treatment of the burn, itself, should be the same for pregnant and nonpregnant patients. The pregnant burn victim, however, requires meticulous attention to fluid management, with consideration of the expanded intravascular volume and altered cardiovascular dynamics associated with pregnancy (see above). Fetal status is related directly to the adequacy of uteroplacental perfusion; poor outcome is associated with inadequate fluid resuscitation. If more than 50% of the patient's surface area is affected, immediate delivery of the viable fetus should be considered. However, in some cases, aggressive fluid resuscitation and close fetal monitoring may allow delivery to be deferred.

Thermal injury causes elevated prostaglandin levels and increased susceptibility to infection. These factors often contribute to preterm labor. Because complications typically associated with tocolytic therapy may not be tolerated by the gravid burn victim, tocolytics should be used cautiously, if at all. Indomethacin (Indocin) may be the safest agent for use before 32 weeks. If fetal surveillance (24 or more weeks gestation) indicates fetal compromise despite optimal maternal resuscitation, the fetus should be delivered.

Electrical Injury

There are very few reports of electrical injury during pregnancy. Because the uterus and amniotic fluid offer low resistance, current entering an upper xtremity and exiting a lower extremity may traverse the uterus and fetus. Maternal cardiac and respiratory status should be assessed and treated as in any injured patient. Ultrasonographic examination and fetal monitoring should guide pregnancy management. Fetal survival without specific intervention has been reported, although immediate fetal death is also possible.

SUMMARY POINTS

- The obstetrician-gynecologist must be thoroughly familiar with the normal physiologic changes of pregnancy, because these changes affect the clinical pictures of many diseases, as well as their management.
- Although many disease processes are unchanged by pregnancy, the course of some diseases is altered. This alteration often affects diagnosis and therapy.
- Necessary radiologic procedures can be performed during pregnancy.
- Very few medications need to be restricted in pregnancy.
- In general, pregnant and nonpregnant women with a medical or surgical disease should receive comparable care, although fetal well-being must be kept in mind if fetal viability has been reached.

REPRODUCTIVE IMMUNOLOGY

The physiologic mechanisms that protect the fetus and its placenta from attack by the maternal immune system are complex, and many remain poorly understood. Nevertheless, the practicing obstetrician should be familiar with the immunologic aspects of the maternal–fetal relationship, as well as the profound impact that aberrations in immunologic function have on pregnancy outcome.

Fundamental Immunobiology

The primary function of the immune system is to protect against foreign pathogens, primarily by distinguishing biologic “self” from “nonself” (the clonal selection model of immunity). In the early stages of development, immune cell precursors are educated to recognize self. T cells that recognize self-antigens are killed or rendered inactive while T cells with specific receptor types against foreign pathogens continue to develop.

The immune system has two primary effector mechanisms classified as either innate or adaptive. Although they function through different mechanisms, they work together to defend the body from foreign pathogens. The innate immune response, also known as cellular immunity, is a continuous, nonspecific process that recognizes all foreign material as nonself. Components of the innate system include physical and biochemical barriers, primary effector cells such as mononuclear phagocytes, natural killer (NK) cells, and polymorphonuclear leukocytes, and circulating biochemical factors such as the complement system. Recognition of foreign pathogens by membrane receptors on effector cells is followed by phagocytic destruction and induction of apoptosis by NK cells (Fig. 18.1). One family of pathogen recognition receptors, called Toll-like receptors (Tlr), appears to play an important role in mediating the inflammatory responses in the reproductive tract. As membrane receptors on inflammatory cells, they initiate a nonspecific response to bacterial antigens and may also function to facilitate adhesion of immune cells on endothelium.

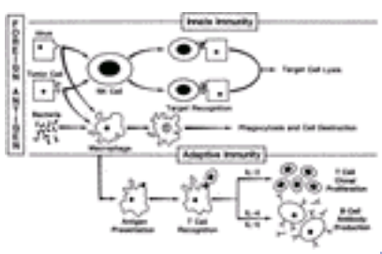

FIG. 18.1. Schematic view of innate and adaptive immune systems. Phagocytic cells of the innate immune system recognize foreign antigen. The foreign antigen can be a microbial pathogen, viral antigen, or tumor antigen. Innate immune responses result in direct cytotoxicity or destruction of the pathogen. Activation of the adaptive immune system depends on interaction with processed antigen provided by cells of the innate immune system. T-cell and B-cell activation results in T-cell clonal proliferation and B-cell antibody production, respectively. *IL*, interleukin; *NK*, natural killer. (From Dudley DJ. The immune system in health and disease. *Balliere's Clin Obstet Gynaecol* 1992;6:393.)

As proliferating T cells mature, they differentiate into an array of subtypes that have diverse functions. CD4+ helper cells help other cells proliferate and help B cells produce antibodies. CD4+ inducer cells control the subsequent development of other T cells. CD8+ cytotoxic cells lyse foreign or virus-infected cells, and CD8+ suppressor cells prevent uncontrolled proliferation. T-cell subsets destroy and remove foreign tissues and organisms by direct binding and secretion of cytokines that recruit and activate macrophages. Cytokines are a means of communication between immune cells. Interleukin (IL)-1 is produced by macrophages and monocytes and promotes multiplication and activation of lymphocytes. IL-2, produced in response to lymphocyte activation, is the major T-cell growth factor for the proliferation of activated T cells.

The hallmark of adaptive immunity is precise specificity of antigen recognition and memory so that repeated exposures to a specific antigen elicit an enhanced immune

response. The adaptive response includes several stepwise processes that occur in the lymphatic system (see Fig. 18.1). The primary adaptive effector cells are B cells, precursors of plasma cells that secrete specific antibodies that circulate through the bloodstream and destroy target cells in concert with complement or antibody-dependent cellular cytotoxic cells. Antibodies are heterogeneous proteins produced by gene rearrangement, a process that creates myriad possible immunoglobulin antigen-recognition sites. The first antibody to respond is immunoglobulin M (IgM), which is soon superseded by a predominantly immunoglobulin G (IgG) response.

Cells of the innate immune system act as secondary effector cells in the adaptive response through T-cell recognition of HLA antigens, which are products of the major histocompatibility complex (MHC) located on the short arm of chromosome 6 (Fig. 18.2). Class I MHC antigens are expressed by nearly all nucleated cells and are identified by cytotoxic T cells. Class II MHC antigen expression is restricted to B cells, monocytes, macrophages, and activated T cells but is important for presenting antigen to helper T cells.

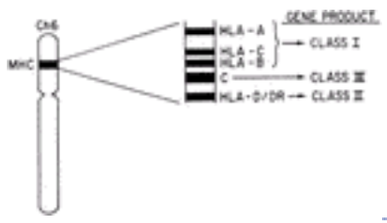

FIG. 18.2. Chromosomal location of the major histocompatibility complex. Within the complex are genes that encode as follows: for class I antigens (HLA-A, HLA-B, and HLA-C); for several components of the complement cascade, including complement components 2 and 4 and factor B, some of which are located at position C; and for class II antigens. (From Scott JR, Rote NS, eds. *Immunology in obstetrics and gynecology.* Norwalk, CT: Appleton-Century-Crofts, 1985:35.)

Embryologic Development of the Immune System

The development of the immune system begins at conception and continues throughout pregnancy and into the newborn period. During weeks 2 and 3 of gestation, pluripotential yolk sac stem cells form the precursors for all the blood cell series. The thymus develops in the human embryo at 6 weeks gestation, and lymphocyte differentiation proceeds in the absence of foreign antigens. Small lymphocytes appear in the peripheral blood at week 7 and around lymphocyte plexuses by week 8. As early as 13 weeks gestation, T cells that can respond to mitogens and recognize histoincompatible cells begin to appear. By 20 weeks gestation, the human fetus has the ability to respond to congenital infections by producing plasma cells and antibodies.

The presence of an intact trophoblastic cellular barrier prevents the movement of large numbers of immunocompetent cells into or out of the fetus during pregnancy. In contrast, maternal IgG, by virtue of its Fc fragment, is specifically selected for placental transfer (Fig. 18.3). Fetal IgG concentrations are about 10% of adult levels by the middle of the first trimester (Fig. 18.4). Adequate humoral immunity in the neonatal period depends on the circulating immunoglobulins that have crossed the placenta, and fetal blood levels of IgG reflect maternal levels. The specific antibody protection depends on the mother's own antigenic experience. The primary role of maternal antibodies is to protect the neonate from infections. However, several maternal autoimmune disorders are characterized by production of IgG antibodies and can be harmful to the infant.

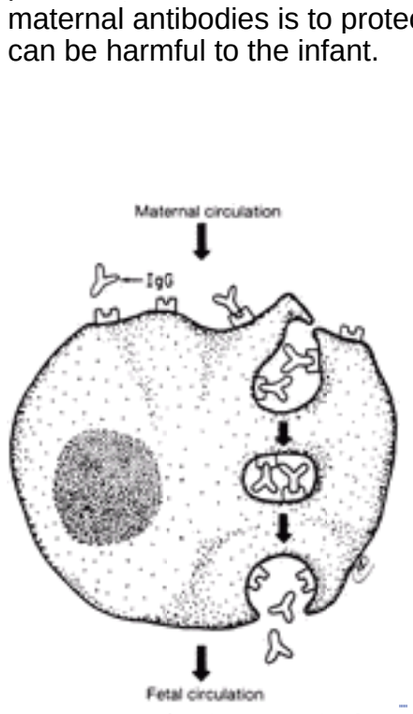

FIG. 18.3. The transport of maternal immunoglobulin G (IgG) across the trophoblast and into the fetal circulation is an active process. Maternal IgG binds to Fc receptors on the surface of the trophoblast and is internalized into vacuoles. These receptors are specific for the Fc portion of IgG and do not bind other classes of immunoglobulins. The interaction of IgG with the receptors probably protects the antibody from digestion during the transport of the vacuole across the cell. On the fetal side, IgG is released into the fetal circulation. (From Scott JR, Rote NS, eds. *Immunology in obstetrics and gynecology.* Norwalk, CT: Appleton-Century-Crofts, 1985:70.)

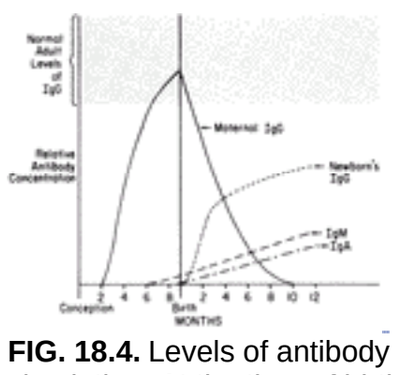

FIG. 18.4. Levels of antibody in the cord blood and neonatal circulation. Early in gestation, maternal immunoglobulin G (IgG) crosses the placenta and enters the fetal circulation. At the time of birth, the fetal circulation normally contains a near-adult level of IgG, which is almost exclusively maternal, and small amounts of fetal immunoglobulin M and immunoglobulin A. After delivery of the child, maternal IgG is rapidly catabolized, whereas neonatal IgG production increases. (From Scott JR, Rote NS, eds. *Immunology in obstetrics and gynecology.* Norwalk, CT: Appleton-Century-Crofts, 1985:69.)

Pathogenesis of Autoimmune Disease

The immune system is normally regulated so that cells capable of producing an immune response to self-antigens are suppressed. Activation of innate immunity requires two separate signals from a presenting antigen to T cells. The first signal is produced through the recognition of the MHC antigen on presenting cells. The second signal is through CD28 expressed on the T cell and CD80 or CD86, which are expressed on the activated antigen-presenting cell. If only one signal is received, the T cell is rendered anergic or unresponsive to further activation even if both signals are given at a later time.

Autoimmune diseases result from a breakdown in normal regulatory mechanisms that lead to an inability to discriminate between self and nonself. Autoimmunity is characterized by persistent activation of immunologic mechanisms that affect the function and integrity of certain cells and organs. The process may be initiated by environmental agents but is probably sustained by persistent T-cell activation that overrides normal tolerance of self-antigens. Autoimmune diseases have a predilection for women of reproductive age and are often encountered during pregnancy. The effects of pregnancy on autoimmunity appear to depend on whether the autoimmune disease is innate (cellular) or adaptive (humoral) in nature. Diseases with strong cellular pathophysiology, such as rheumatoid arthritis and multiple sclerosis, are associated with remission during pregnancy whereas diseases characterized by autoantibody production, such as lupus and Graves disease, are more

severe in pregnancy.

Maternal–Fetal Immunology

Maternal immunologic reaction to the genetically dissimilar cells of the conceptus begins at fertilization and continues throughout pregnancy as differentiated fetal trophoblast cells interact with maternal uterine tissue and blood. The normal relationship between mother and fetus appears to be healthy and growth-promoting rather than the usual allogeneic model of destruction.

Several mechanisms likely play a role in protection of the fetus from immunologic damage. Circulating blocking factors have been theorized to attenuate maternal immunologic reaction. One progesterone-induced blocking factor suppresses production of lymphocytes and pro-inflammatory cytokines. In addition, so-called blocking antibodies may prevent lymphocytic destruction by binding to receptors on fetoplacental tissues. Alternatively, blocking antibodies may be directed against antigen-specific combining sites (idiotypes) on maternally produced antibodies that prevent them from assisting lymphocytes in targeting cells on the conceptus. While the concept is appealing, the relevance of blocking antibodies and other alleged circulating pregnancy-maintaining factors remains unsettled. Not only do agammaglobulinemic women without antibody production have normal pregnancies, antibodies do not frequently appear until late in the first or second trimester of the first pregnancy.

Immunotolerance during pregnancy probably results from interactions at the local maternal–fetal interface rather than from generalized maternal immunosuppression. Before conception, endometrial stromal cells transform into decidual cells that contain T-cell subtypes with immunosuppressive activity. One T-helper cell subset secretes cytokines that are beneficial or neutral to the presence of the fetus. Another is thought to prevent colonization with microbial pathogens. Additional evidence suggests that some subsets of the decidual T cells promote growth of the placenta through the secretion of cytokines that suppress inflammation. Hormones, enzymes, growth factors, and endometrial proteins within maternal decidual tissue also have potent immunomodulatory properties that promote a favorable interaction between the conceptus and the mother.

The presence of large granular lymphocytes in luteal phase and early to mid-pregnancy deciduas has generated considerable interest among reproductive immunologists. Under normal circumstances, these nonspecific innate immune effector cells, similar to NK cells, kill standard NK cell targets with the notable exception of trophoblastic cells. Their absence or alteration has been associated with pregnancy loss.

The placenta also plays an active role in protection of the fetus from maternal immune responses. Villous cytotrophoblasts and syncytiotrophoblasts escape destruction because both express nonclassic MHC antigens that prevent trophoblast destruction through inhibition of lysis by activated NK cells, limitation of leukocyte cytotoxic activity, suppression of pro-inflammatory cytokine production, and induction of T-cell death. Nonclassic MHC antigens also promote trophoblast proliferation and invasion. Altered expression of nonclassic MHC antigens has been linked to recurrent miscarriage and preeclampsia.

Placental expression of a protein known as the Fas ligand may also play a role in pregnancy success through selective deletion of antifetal T-cell clones. In animal studies, binding to the Fas ligand causes death and removal of autoreactive T cells.

The placenta may also inhibit T-cell proliferation by sequestering nutrients. Placental indolamine 2,3-dioxidase (IDO) inactivates the amino acid tryptophan that is essential for the proliferation of T cells. The role of IDO in recurrent pregnancy loss in humans has not yet been widely investigated.

ERYTHROBLASTOSIS FETALIS

Though the first description of erythroblastosis fetalis (hemolytic disease of the newborn) dates back to the 1609, it was not until the early 1900s that the role of alloimmunization in the pathogenesis of erythroblastosis was established. The early investigators determined that an Rh–negative mother becomes alloimmunized by exposure to Rh–positive fetal erythrocytes during pregnancy or delivery. Maternally produced anti-erythrocyte antibodies pass through the placenta to the fetus where they react with the Rh–positive fetal erythrocytes, causing their destruction. In the past, Rh alloimmunization has also been referred to as sensitization and immunization. The terms *alloimmunization* and *sensitization* will be used interchangeable in this text.

Many other erythrocyte antigens have been described since the discovery of the Rh antigen but only a few are clinically important causes of maternal alloimmunization. However, with the widespread use of Rh–immunoglobulin prophylaxis and the decline in Rh-D alloimmunization, the overall importance of the “minor antigens” in red cell alloimmunization has increased.

Genetics of the Rh Antigen

The Rh blood group was so named because rabbits immunized with rhesus monkey erythrocytes produced an antibody that agglutinated erythrocytes from 85% of whites. The so-called Rh factor is actually an antibody directed against an erythrocyte surface antigen of the rhesus blood group system. The Rh blood group system has a high degree of polymorphism, with five major antigens and many variant minor antigens. While three systems of nomenclature have been suggested, the Fisher-Race system is probably best suited to understanding the inheritance of the Rh antigen and the clinical management of Rh alloimmunization. It assumes the presence of three genetic loci, each with two major alleles, lettered C, c, D, E, and e. No antiserum specific for a ?d? antigen has been found.

The Rh gene complex is described by the three appropriate letters with eight possible combinations (listed in decreasing order of frequency among whites): CDe, cde, cDE, cDe, Cde, cdE, CDE, and CdE. Genotypes are indicated as pairs of gene complexes, such as CDe/cde. Certain genotypes, and thus certain phenotypes, are more prevalent than others. Although the alleles are always written in the order C(c), D, E (e), the actual order on chromosome one is of the genes coding for the antigens D, C(c), E (e). Anti–C, anti–c, anti–D, anti–E, and anti–e designate specific antibodies directed against the respective antigens. Because the majority of Rh alloimmunization resulting in overt clinical disease results from incompatibility with respect to the D antigen, common convention holds that *Rh-positive* indicates the presence of the D antigen and *Rh-negative* indicates the absence of D antigen on erythrocytes.

Unique Rh antibodies have been used to identify more than 30 antigenic variants in the Rh blood group system, the most common of which is the D^u antigen, now commonly referred to as *weak D*. This heterogeneous group of clinically important D-antigen variants is most often found in blacks. At least some weak D–positive patients are capable of producing anti–D, which could presumably result in a weak D–positive mother becoming sensitized to her D–positive fetus, but such an occurrence is exceedingly rare.

The Rh-D antigen appears very early in embryonic life and has been demonstrated on the red blood cells of a 38-day-old fetus. Its precise function is unknown, though it may play a role in maintaining red cell membrane integrity or regulate the asymmetric distribution of different phospholipids through the red cell membrane.

Pathophysiology of Rh Alloimmunization

Rh alloimmunization can only occur in the presence of three conditions:

1. The fetus must have Rh–positive erythrocytes, and the mother must have Rh–negative erythrocytes.
2. The mother must have the immunogenic capacity to produce antibody directed against the D antigen.
3. A sufficient number of fetal erythrocytes must gain access to the maternal circulation.

Incidence of Rh-D Incompatibility and Subsequent Alloimmunization About 15% of whites, 5% to 8% of blacks, and 1% to 2% of Asians and Native Americans are Rh-D–negative. In terms of risk, an Rh–negative woman has about an 85% chance of mating with an Rh–positive man, 60% of whom are heterozygous and 40% of whom are homozygous at the D locus. Assuming that one-half of the conceptions of heterozygous men will be Rh-D–positive, the chance of an Rh–positive man producing an Rh–positive fetus is about 70%. An Rh–negative woman has about a 60% chance of bearing an Rh–positive fetus (0.85 × 0.70). About 10% of pregnancies are Rh-incompatible (0.15 × 0.60). However, fewer than 20% of Rh–incompatible pregnancies result in alloimmunization because fetomaternal hemorrhage sufficient to trigger a maternal antibody response does not occur in every case. About 16% of untreated Rh–negative women become alloimmunized in their first Rh–incompatible (ABO–compatible) pregnancy. Half produce detectable anti–D antibody within 6 months of delivery while the rest have undetectable amounts until early in the next incompatible pregnancy. Overall, even before the introduction of Rh–immunoglobulin prophylaxis, only about 1% of pregnant women had anti–D antibody.
Maternal Immunologic Response The probability and severity of Rh-D alloimmunization varies depending on individual patient characteristics. As many as 30% of Rh–negative individuals appear to be immunologic “nonresponders” who will not become sensitized. In addition, ABO incompatibility diminishes the risk of alloimmunization to about 1.5% to 2.0% after the delivery of an Rh–positive fetus. This is possibly due to rapid clearance of ABO–incompatible fetal cells from the maternal circulation or alteration or damage to the fetal Rh antigen so that it is no longer immunogenic. The effect is most pronounced if the mother is type O and the father is type A, B, or AB.

Fetomaternal Hemorrhage Fetal red cells may gain access to the maternal circulation during pregnancy, delivery, and the immediate postpartum period. Fetomaternal hemorrhage in a volume sufficient to cause alloimmunization is most common at delivery, occurring in 15% to 50% of births. The amount of fetal blood entering the maternal circulation is usually less than 0.1 mL but may be greater than 30 mL in 0.2% to 1% of cases. Risk factors for excessive postpartum fetomaternal hemorrhage include cesarean delivery, multiple gestations, bleeding placenta previa or abruption, manual removal of the placenta, and intrauterine manipulation. However, the majority of cases of excessive fetomaternal hemorrhage occur after uncomplicated vaginal delivery. Antepartum events can also result fetomaternal hemorrhage in sufficient volume to cause in alloimmunization in 1% to 2% of cases, even without obvious disruption of the choriodecidual junction (Table 18.1). Fortunately, asymptomatic antepartum sensitization rarely occurs before the third trimester.

Event or procedure	*Dosage of Rh Immune globulin*
First trimester miscarriage	50 µg
Ectopic pregnancy	50 µg
Threatened first trimester miscarriage[a]	50 µg
Molar pregnancy	50 µg
Induced first trimester abortion	50 µg
Induced second trimester abortion[b]	300 µg
Fetal death (>10 wks of gestation)[b]	300 µg
Amniocentesis	300 µg
Chorionic villus sampling	50 µg
External cephalic version[b]	300 µg
Abruption/previa[b]	300 µg
Abdominal trauma[b]	300 µg
Vaginal bleeding in the second and third trimester of unknown origin[b]	300 µg

[a]The risk of fetomaternal hemorrhage and alloimmunization is uncertain and the benefit of prophylaxis is uncertain in this situation.
[b]A test for the presence and volume of fetomaternal hemorrhage should be performed to determine the dosage of Rh immune globulin.

TABLE 18.1. *Antepartum events associated with fetomaternal hemorrhage*

Rh-D Immunoglobulin

The prevention of alloimmunization to a specific antigen by the passive administration of antibody is termed *antibody-mediated immune suppression*. In the case of Rh-D alloimmunization, a high degree of protection was first achieved by administering anti–D immunoglobulin (Rh-D immunoglobulin) to Rh–negative male volunteers who had been infused with Rh–positive red cells. It was later established that the amount of Rh-D immunoglobulin necessary to prevent alloimmunization varies according to the size of fetomaternal hemorrhage:

- 300 g of Rh-D immunoglobulin for exposure to 10 mL of fetal blood
- 20 g of Rh-D immunoglobulin for exposure to 1 mL of fetal erythrocytes
- 10 g of Rh-D immunoglobulin for 1 mL of whole fetal blood.

Postpartum Alloimmunization Prophylaxis The early Rh-D alloimmunization prevention trials found that administration of Rh-D immunoglobulin within 72 hours of delivery reduced alloimmunization to less than 1.5% in Rh–negative women, a seven- to ten-fold decrease in alloimmunization compared with untreated controls. Although 300 g of Rh immunoglobulin was used (and continues to be the standard in the United States), it has subsequently been shown that a dose of 100 g to 150 g is probably adequate for routine use. Rh-D immunoglobulin must be given as soon as possible after exposure to Rh-D–positive blood (delivery or other event associated with fetomaternal hemorrhage) before the primary immune response is established. While 72 hours is the standard recommendation, it is an artifact from the early studies performed using inmates, during which prison officials would allow visits only at 3-day intervals. Prophylaxis beyond 3 days has never been extensively studied but if for some reason Rh–immune prophylaxis does not occur within 72 hours after exposure, susceptible Rh-D–negative women should be treated up to 14 to 28 days. Further, if the neonatal Rh status is unknown 3 days after delivery, Rh immunoglobulin should be given rather than waiting for the neonatal results.
Antepartum Alloimmunization Prophylaxis One to two percent of susceptible Rh-D–negative women become sensitized during pregnancy in spite of postpartum Rh-D–immune prophylaxis. Most failures can be attributed to antepartum fetomaternal hemorrhage that is often not clinically apparent. Prophylactic administration of Rh-D immunoglobulin at 28 weeks gestation reduces the incidence of alloimmunization from 1.8% to 0.1%. Initial concerns about potential adverse effects of antenatal Rh-D–immune prophylaxis have been refuted by decades of experience with Rh-D immunoglobulin without reports of maternal or fetal complications. Further, routine antepartum prophylaxis is much less expensive than the neonatal intensive care required for severely anemic infants.

Management of the Unsensitized Rh–Negative Pregnant Woman

Prenatal care for Rh-D–negative women, without evidence of alloimmunization is straightforward (Table 18.2). Every woman should have her ABO blood group, Rh type, and antibody screen checked at the first prenatal visit of all pregnancies. If she is Rh-negative or weak D–negative and has no demonstrable antibody, she is a candidate for 300 g Rh–immunoglobulin prophylaxis at around 28 weeks gestation and again immediately postpartum. The American Association of Blood Banks recommends obtaining another antibody screen before administration of Rh immunoglobulin, including antepartum prophylaxis.

TABLE 18.2. *Evaluation and management of an unsensitized Rh-negative, pregnant woman*

After delivery, another antibody screen is routinely performed. If negative and the newborn is Rh-D–positive or weak D–positive, alloimmunized women should be given 300 g of Rh-D immunoglobulin. In addition, because up to 1% of deliveries result in a fetomaternal hemorrhage greater than 30 mL (the largest volume of fetal blood adequately covered by a standard 300-g dose of Rh immunoglobulin), a screen for “excessive” fetomaternal hemorrhage should be performed. Most laboratories use the erythrocyte rosette test, a simple and sensitive method for detecting fetomaternal bleeding. If the rosette test is positive, the volume of fetal red cells in the maternal circulation can be calculated using the Kleihauer-Betke test. If the volume of fetomaternal hemorrhage is greater than 30 mL whole blood, an additional 10g of Rh immunoglobulin should be administered for each additional milliliter of fetal blood.

A weak D–positive mother who delivers an Rh–positive infant is not at significant risk of Rh sensitization, probably because the weak D antigen is actually an incompletely expressed D antigen. Therefore, weak D–positive mothers usually do not require Rh immunoglobulin. Occasionally a woman previously typed as Rh-negative is unexpectedly found to be weak D–positive during pregnancy or after delivery. In this situation, the clinician should be suspicious that the patient's “new” weak D–positive status is actually due to a large number of Rh–positive fetal cells in the maternal circulation. Appropriate diagnostic studies should be performed, and if fetomaternal hemorrhage is found, the mother should be treated with Rh immunoglobulin.

Several antepartum complications and procedures may also result in fetomaternal hemorrhage (see Table 18.1). First trimester complications, including spontaneous miscarriage, elective abortion, and ectopic abortion, may result in fetomaternal hemorrhage sufficient to result in alloimmunization.

Fetomaternal hemorrhage has also been demonstrated in up to half of women with *threatened* first trimester miscarriage but is only occasionally associated with alloimmunization. Management is controversial with no clear consensus or evidence-based recommendation on use of Rh immunoglobulin.

An Rh–negative, unsensitized patient who has antepartum bleeding or suffers an unexplained second or third trimester fetal death should receive Rh–immunoglobulin prophylaxis and be evaluated for the possibility of massive fetomaternal hemorrhage. Several procedures may also result in fetomaternal hemorrhage sufficient to cause alloimmunization including chorionic villus sampling, amniocentesis, and external cephalic version.

For first trimester pregnancy complications and procedures, 50 g of Rh immunoglobulin is protective. Beyond 12 weeks, a full 300-g dose is indicated even if in the absence of detectable hemorrhage. In addition, because excessive fetomaternal hemorrhage may occur with any complication or procedures performed in the second and third trimester, an assessment of the volume of fetal whole blood should be performed and the appropriate amount of Rh-D immunoglobulin should be given.

Failure to administer Rh immunoglobulin when indicated is responsible for one-fourth of new cases of alloimmunization. This inexcusable oversight may be due to:

- failure to type the patient's blood at the first prenatal visit or to order Rh-D immunoglobulin when indicated
- error in transmitting the proper blood type to the mother's chart and to the physician
- error in typing the mother's, father's, or baby's blood

- failure to administer Rh-D immunoglobulin when ordered
- unrecognized fetomaternal hemorrhage during pregnancy
- inadequate Rh-D-immunoglobulin for the volume of fetomaternal hemorrhage
- patient refusal.

Management of the Rh-D–Alloimmunized Pregnancy

Obstetric History A well-documented obstetric history is essential to guide management of alloimmunized pregnancy. Fetal hemolytic disease tends to become more severe in subsequent pregnancies. If hydrops occurred in a previous pregnancy, the next Rh–incompatible fetus has an 80% to 90% chance of becoming hydropic as well. With this in mind, patients are grouped into one of three categories:

- mildly affected fetuses, which can be allowed to remain in utero until they have achieved pulmonary maturation
- moderately affected fetuses, which may need to be delivered before pulmonary maturity but who do not need fetal treatment
- severely affected fetuses, which require active intervention to reach a gestational age at which the risks of delivery and neonatal intensive care are less than the risks of in utero therapy.

In general, hemolysis and hydrops develop at about the same time or somewhat earlier in subsequent pregnancies; this can be used as a rough guide for timing initial fetal studies and transfusions. Fetal hydrops seldom develops in a first sensitized pregnancy.
Maternal Antibody Titers Severe erythroblastosis or perinatal death does not occur if antibody levels remain below 1:16. Some centers use an anti–D titer of 1:8 because of variations in reliability and methods of titration. In general, women with anti–D titers of 1:8 or less, and no history of a previously affected infant, can be safely followed with anti–D titers every 2 to 4 weeks and serial fetal ultrasound assessment. Those with anti–D titers of 1:16 or greater should be referred for amniocentesis. Once the critical anti–D antibody titer has been reached in a sensitized pregnancy, more antibody titers are not useful in the current pregnancy or subsequent pregnancies. Titers may remain stable in up to 80% of severely affected pregnancies. Variability between maternal antibody levels and severity of fetal disease is explained by the fact that antibody concentration is only one factor influencing the degree of anemia. Other factors include antibody subclass and degree of glycosylation, placental transfer of antibody, antigen expression on fetal erythrocytes, functional maturity of the fetal reticuloendothelial system, and the presence of HLA-related antibodies that inhibit fetal erythrocyte destruction.
Determination of the Fetal Antigen Status The possibility that the fetus is Rh-negative (not at risk) should always be considered. A reasonable first step in this process is to determine paternal Rh–antigen status and zygosity:

- If the father is Rh-negative, the fetus must also be Rh-negative and no further testing is necessary.
- If the father is Rh-positive, but has previously fathered Rh–negative children, he is heterozygous and the probability that this fetus is Rh-negative is 50%.
- If the father is Rh-positive without other Rh–negative children, zygosity can be established using either DNA analysis or Rh antisera. If the father is homozygous, this fetus is Rh-positive and no other testing is necessary.

In the past, determination of fetal blood type required direct analysis of fetal blood obtained by umbilical cord blood sampling with its attendant risks of fetal loss and fetomaternal hemorrhage. The development of DNA tests that use polymerase chain reaction (PCR) has made it possible to determine fetal Rh status from uncultured amniocytes obtained from as little as 2 mL of amniotic fluid or 5 mg of chorionic villi. Though highly accurate, DNA testing for fetal Rh status is equivocal in about 1% of cases, probably because of the presence of gene rearrangements near the Rh-D locus that can be missed by standard DNA primers used for PCR. Most laboratories recommend simultaneous testing of paternal blood and amniotic fluid. Fetal antigen testing from amniocytes has become routine at most centers in the United States. Most alloimmunized women have fetal antigen typing at the time of the first amniocentesis for amniotic fluid bilirubin analysis. Alloimmunized women having chorionic villus sampling (CVS) or second trimester amniocentesis for other unrelated conditions can have fetal antigen typing earlier. However, except for patients with severe Rh sensitization who would consider termination of an Rh–positive pregnancy, CVS and amniocentesis are not usually offered for detection of Rh-D fetal antigen status alone. If the DNA test indicates an Rh–negative fetus, the small likelihood of misdiagnosis should be discussed and the patients offered standard antenatal surveillance. In the future, fetal Rh–antigen status will likely be performed on fetal cells obtained from the maternal circulation or by preimplantation genetics.
Amniotic Fluid Optical Density Analysis Assessment of amniotic fluid in Rh alloimmunization is based on the original observations that spectrophotometric determinations of amniotic fluid bilirubin correlated with the severity of fetal hemolysis. A by-product of fetal hemolysis, bilirubin is excreted into the amniotic fluid through fetal pulmonary and tracheal secretions and by diffusion across the fetal membranes and the umbilical cord. Using a semilogarithmic plot, the curve of optical density of normal amniotic fluid is approximately linear between wavelengths of 525 and 375 nm. Bilirubin causes a shift in the spectrophotometric density with a peak at a wavelength of 450 nm. The amount of shift in optical density from linearity at 450 nm (the ?OD450) is used to estimate the degree of fetal red cell hemolysis (Fig. 18.5).

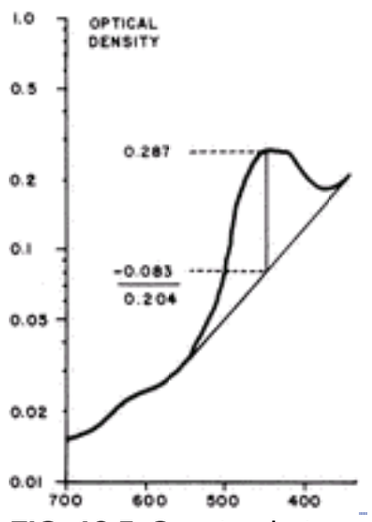

FIG. 18.5. Spectrophotometric scan of amniotic fluid containing bilirubin. An arbitrary line (*thick line*) has been drawn to show where the scan would have been traced if there had been no increase in bilirubin. The peak absorption of bilirubin occurs at 450 µm. The difference between the peak and the arbitrary line equals 0.204.

Liley was the first to correlate amniotic fluid ?OD450 values with newborn outcome by dividing a semilogarithmic graph of gestational age versus ?OD450 into three zones (Fig. 18.6). Unaffected fetuses and those with mild anemia had ?OD450 values in zone I (the lowest zone), while severely affected fetuses had ?OD450 values in zone III (the highest zone). Fetuses with zone II values (the middle zone) had disease ranging from mild to severe, indicated primarily by the trend of the determinations of amniotic fluid bilirubin. Because there is a tendency for amniotic fluid bilirubin to decrease as pregnancy advances, the boundaries of the zones slope downward as gestational age increases. Implementation of Liley's method reduced perinatal mortality from 22% to 9% over a 5-year period.

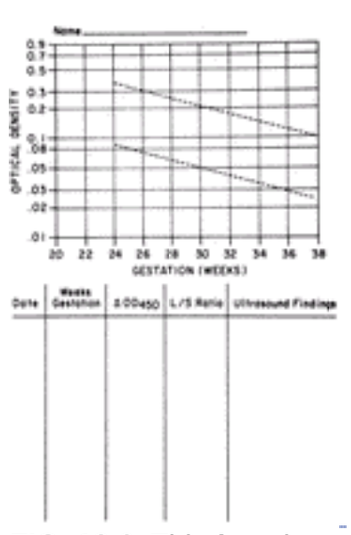

FIG. 18.6. This form is used to record serial data on each Rh-immunized patient. The modified Liley graph is divided into three zones to predict the outcome of the pregnancy in terms of umbilical cord blood hemoglobin, intrauterine deaths, or unaffected fetuses.

A single ?OD450 measurement is seldom helpful in the management of alloimmunized pregnancies unless it is very high or very low. Instead, serial amniocenteses should be performed to determine the trend of ?OD450 values over time. Amniotic fluid ?OD450 values trend downward in unaffected and mildly affected infants while values from severely affected fetuses show a mixed pattern of higher values. A horizontal or rising trend is ominous and indicates the need for intervention either by

intrauterine transfusion (IUT) or delivery. The usefulness of third trimester measurements of amniotic fluid bilirubin using ?OD450 determinations has been confirmed by decades of clinical experience. There have also been attempts to extrapolate Liley's original graph backward to assess fetal status before 27 weeks gestation. However, ?OD450 measurements in the second trimester tend to be less reliable predictors of true fetal anemia because of wide physiologic variation in concentrations of amniotic fluid bilirubin. Laboratory techniques, including chloroform extraction to remove blood and meconium from amniotic fluid, appear to improve the accuracy of second trimester ?OD450 measurements. Still, umbilical cord blood sampling remains the most accurate method of fetal assessment during the second trimester in severely alloimmunized pregnancies. Unfortunately, it is often impractical because of the technical expertise and clinical support required to avoid an unacceptably high rate of pregnancy loss. Enthusiasm for second trimester measurement of concentrations of amniotic fluid bilirubin has grown in recent years. One approach uses a curve developed by Queenan (Fig. 18.7), which, like Liley's original curve, plots ?OD450 measurements against gestational age. The Queenan curve has four outcome zones which predict the degree of fetal anemia and guide management. Alternatively, others have simply extended Liley's original zones backward with some success. Recognizing that this issue is not completely settled, one reasonable approach is to use the standard semilogarithmic Liley curve for amniotic fluid assessment, extrapolated linearly back to 24 weeks gestational age (see Fig. 18.6). Clinical management is then based on trends rather than single ?OD450 values, taking history and gestational age into consideration.

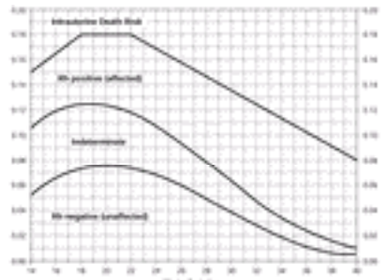

FIG. 18.7. The Queenan curve plots ?OD450 measurements against gestational age, dividing them into four zones of fetal risk. This curve allows prediction of the degree of fetal hemolysis from 14 weeks gestation until term. (Adapted from Queenan JT, Tomai TP, Ural SH, et al. *Am J Obstet Gynecol* 1993;168:1370–1376.)

Fetal Blood Analysis Ultrasound-guided umbilical cord sampling (cordocentesis) should be performed to assess the degree of fetal anemia in severely alloimmunized pregnancies. The procedure is successful in greater than 95% of cases with fetal loss rates between 0.5% and 2% per procedure. Fetomaternal bleeding may occur at the time of cordocentesis resulting in worsened maternal alloimmunization. Traversing an anterior placenta with the sampling needle is thought to result in increased sensitization in as many as 50% of cases. Other complications have also been described including acute refractory fetal distress, umbilical cord hematoma, amnionitis with maternal adult respiratory distress syndrome, and placental abruption. The role of cordocentesis in the management of alloimmunization is limited to assessment of those fetuses already known to be antigen-positive and who are suspected of having moderate to severe anemia. Because of the technical difficulty and increased hazard (both immediate and remote) associated with the procedure, umbilical cord blood sampling should be used with caution and performed only by properly trained personnel.
Ultrasound and Doppler Studies Ultrasonographic examination of the fetus has become an extremely important adjunct in the management of the Rh–alloimmunized pregnancy, primarily as a guide for amniocentesis, cordocentesis, and IUT. Sonographic fetal findings have also been studied in an effort to identify those with severe anemia and reduce the need for invasive procedures. However, other than identifying frank hydrops, ultrasound is not sufficiently reliable in distinguishing mild from severe hemolytic disease. Doppler flow velocity waveforms of fetal cardiac output and red cell flow in numerous fetal blood vessels have been extensively investigated as noninvasive predictors of fetal anemia. Doppler flow waveforms of the fetal middle cerebral artery (MCA) have shown the most promise in the management of Rh–alloimmunized pregnancies. Several investigators have reported that fetal MCA peak systolic velocity waveforms consistently identify fetuses with moderate or severe anemia when velocities are greater than 1.5 times the median of values derived from normal controls (Fig. 18.8). New protocols are emerging at many centers that use fetal MCA peak systolic velocity values to guide management of alloimmunized pregnancies in a manner similar to traditional amniotic fluid protocols using amniotic fluid ?OD450 values. As more clinical experience is gained, it seems likely that this noninvasive tool may become routinely employed to direct fetal management.

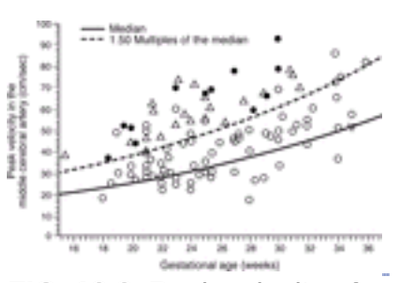

FIG. 18.8. Peak velocity of systolic blood flow in the middle cerebral artery in 111 fetuses at risk for anemia due to maternal red-cell alloimmunization. *Open circles* indicate fetuses with either no anemia or mild anemia (0.65 multiples of the median hemoglobin concentration). *Triangles* indicate fetuses with moderate or severe anemia (<0.65 multiples of the median hemoglobin concentration). The *solid circles* indicate the fetuses with hydrops. The *solid curve* indicates the median peak systolic velocity in the middle cerebral artery, and the *dotted curve* indicates 1.5 multiples of the median. (From Mari G, Deter RL, Carpenter RL, et al. *N Engl J Med* 2000;342:9–14.)

Intrauterine Transfusion in Rh–Alloimmunized Pregnancies

Determining the Need for Transfusion The goals of IUT are to correct fetal anemia in an effort to improve fetal oxygenation and to reduce extramedullary hematopoietic demand which, in turn, should result in a fall in portal venous pressure and improved hepatic function. The need for cordocentesis and IUT should be determined by obstetric history, clinical findings, and the experience and expertise of the management team. About one-half of susceptible infants of Rh–immunized pregnancies have mild to moderate hemolytic disease and do not require IUT or extensive extrauterine therapy. Reasonable management for these patients includes serial ultrasound examinations of the fetus every 2 to 4 weeks from 20 weeks gestation until delivery and serial amniotic fluid ?OD450 determinations, with the first amniocentesis at 24 to 28 weeks gestation. The timing of the next amniocenteses or need for IUT or delivery depends on the trend in ?OD450 values (Fig. 18.9). If ?OD450 values fall within the low zone or the lower half of the middle zone on the Liley graph, amniocentesis is repeated every 2 to 4 weeks. Severe anemia is suspected when the ?OD450 values rise into the upper fourth of the middle zone or into zone III, especially before 30 weeks gestation. Depending on the clinical situation, a single ?OD450 value in zone III may also be an indication of severe anemia. If ultrasound reveals any evidence of fetal hydrops, severe fetal anemia (hematocrit <15%) can be assumed and cordocentesis and IUT should be arranged immediately.

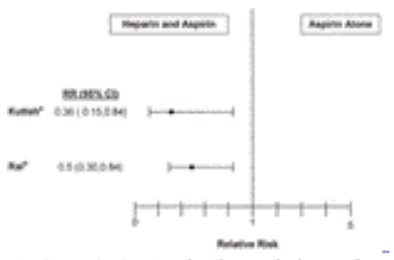

FIG. 18.9. Relative risks of pregnancy loss in women with antiphospholipid syndrome after treatment. *Closed circles* represent the relative risk of pregnancy loss after treatment with heparin and low-dose aspirin. *Horizontal lines* represent range of 95% confidence interval.

A history of severe alloimmunization with early hemolysis and fetal hydrops is predictive of a similarly bad outcome in the current pregnancy. Fetal survival may depend on identifying severe anemia earlier than 24 weeks gestation. Either the Queenan curve or extrapolation of the Liley curve can be used to guide management, understanding that single ?OD450 values between 18 and 24 weeks are difficult to interpret and that trends in ?OD450 determinations are more accurate indicators of fetal anemia. In general, ?OD450 values below 0.09 suggest an unaffected or mildly affected fetus while those greater than 0.15 suggest fetal anemia. In the occasional patient with a particularly ominous history of early second trimester disease or previous severe disease with misleading ?OD450 values, cordocentesis to determine the fetal hematocrit is a reasonable first step. At any gestational age, fetal hydrops should be considered evidence of severe fetal anemia and cordocentesis with immediate intravascular transfusion is indicated.
Intraperitoneal Intrauterine Transfusion Intraperitoneal transfusions were the mainstay of IUT therapy until the mid-1980s. Placement of erythrocytes in the fetal peritoneal cavity was found to reduce fetal anemia by gradual uptake of transfused red cells into the fetal circulatory system via subdiaphragmatic lymphatics. Success depended on the gestational age and the severity of fetal disease, particularly with regard to fetal hydrops (Table 18.3).

TABLE 18.3. *Neonatal survival of infants with severe Rh alloimmunization treated with intrauterine transfusions*

The routine use of ultrasound for needle guidance has dramatically reduced the procedure-related morbidity and mortality associated with intraperitoneal transfusion. Confirmation of appropriate needle placement is usually straightforward, but inadvertent transfusion into the bowel, liver, abdominal wall, and retroperitoneum may occur. Infection, premature rupture of the membranes, refractory preterm labor, and fetal distress necessitating immediate delivery are potential hazards of intraperitoneal IUT. The procedure should be performed only in well-equipped centers with appropriately trained personnel.

Intrauterine Intravascular Transfusion Direct access to the fetal circulation for transfusion offers several advantages over the intraperitoneal approach. The initial fetal hematocrit can be measured, allowing a more precise calculation of the volume of blood required for transfusion. In some cases, the fetus will have a higher hematocrit than expected and transfusion can be delayed. A post-transfusion hematocrit can also be obtained to determine whether the transfusion was adequate and when the next one should be scheduled. Further, transfusion into the fetal vascular system ensures complete uptake with a more rapid correction of fetal anemia, especially important for hydropic fetuses that often do not adequately absorb intraperitoneally transfused erythrocytes. Disadvantages of intravascular fetal transfusion include the rare possibility of volume overload in the compromised fetus, procedure-related complications, and the risk of increasing the severity of maternal sensitization due to fetomaternal hemorrhage. The perinatal survival of nonhydropic fetuses exceeds 90%, and approximately 75% of hydropic fetuses survive with intravascular transfusion (see Table 18.3). Several different methods of estimating the volume of blood needed for transfusion have been reported with a goal of keeping the post-transfusion hematocrit at 40% to 45%. Following intravascular transfusion, the decline in the donor hematocrit is most dependent on the life span of the donor erythrocytes, the rate of fetal growth (and increased vascular volume), and the ratio of fetal to donor erythrocytes (since the fetal erythrocytes are subject to continued hemolysis). The latter is most influential between the first and second intravascular transfusions, when the ratio of fetal cells to donor cells is greatest. On average, the decline in the fetal hematocrit following the first transfusion is about 1.5% per day; following subsequent transfusions, the decline in fetal hematocrit is about 1% to 2% per day. Follow-up intravascular transfusions are scheduled to keep the fetal hematocrit above 20% to 25%. Morbidity and mortality associated with intravascular transfusion are related to the technique of vascular access and transfusion. Fetal bradycardia is the most common problem, occurring in 8% to 12% of cases, though only rarely requires immediate delivery. Postprocedure infection and premature rupture of the membranes have also been reported. Overall, it appears that intravascular transfusion in experienced hands seems to have a procedure-related complication rate of around 10% to 15% and a perinatal mortality rate of 1% to 5%.

Other Therapies

A number of noninvasive alternatives to IUT have been investigated for the treatment of fetal hemolysis. Most have been aimed at modifying the maternal immune response. High-dose intravenous immunoglobulin (IVIG) has been used to treat women with severe Rh alloimmunization refractory to traditional treatment. Experience is limited to case reports and small case series, all with different dosing regimens. The mechanism of action is uncertain, but is most likely at the maternal or placental level since direct fetal administration is not effective. Plasmapheresis has also been tried in refractory Rh alloimmunization and has been associated with a transient reduction in the anti–D titer during or immediately after treatment. However, no long-term, clinically significant reduction in antibody titer has been achieved.

Timing of Delivery

The timing of delivery should be based on individual case circumstances, including obstetric history and severity of Rh-D alloimmunization. In mildly affected pregnancies, induction of labor at 37 to 38 weeks gestation is reasonable, unless fetal pulmonary maturity is documented earlier by amniocentesis. In severely sensitized pregnancies, the risks of continued cord blood sampling and transfusions must be weighed against the potential neonatal morbidity and mortality associated with preterm delivery. This has traditionally led to scheduling the last procedures around 30 to 32 weeks gestation, with delivery between 32 to 34 weeks after maternal steroid administration to enhance fetal pulmonary maturity. In an effort to limit neonatal morbidity, IUT can be continued up to 36 weeks gestation with delivery between 37 and 38 weeks. At the University of Utah, we generally time the last procedure so that delivery can be carried out at about 34 to 36 weeks. Using this approach, neonatal survival in our nursery approaches 100% and long-term morbidity from prematurity is exceedingly low.

Alloimmunization Caused by Minor Antigens

The reduction in Rh disease brought about by Rh–immunoglobulin prophylaxis has led to a relative increase in the number of cases of alloimmunization caused by other red blood cell surface antigens, known as “minor,” “atypical,” or “irregular” antigens (Table 18.4). Overall, alloimmunization due to minor antigens occurs in about 1.5% to 2.5% of obstetric patients though the frequency depends on ethnicity of the population under study. Most cases result from incompatible blood transfusion because blood banks do not routinely assess donor–recipient compatibility for antigens other than ABO and Rh-D. Some of the most common antibodies (i.e., anti–Lea, anti–Leb, and anti–I), do not cause fetal or neonatal hemolysis. However, other commonly encountered atypical antibodies (i.e., anti–E, anti–Kell, anti–c, anti-c + E, and anti–Fya [Duffy A]) may cause erythroblastosis fetalis and hydrops.

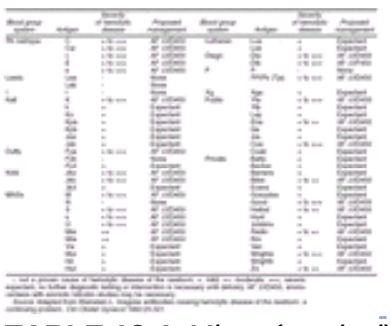

TABLE 18.4. *Minor (atypical) red blood cell antigens, their risk of hemolytic disease, and proposed management*

In general, management of pregnancies complicated by alloimmunization to one of the minor red cell antigens is similar to management of pregnancies complicated by Rh-D alloimmunization. An exception to this rule is alloimmunization to the Kell antigen, which requires special vigilance because of its unpredictability and potential for severe fetal anemia, hydrops, and death. Its virulence may be related to its ability to suppress fetal erythropoiesis and activate the complement cascade in addition to hemolysis. Fortunately, only 9% of whites are positive for the Kell antigen and only 0.2% of pregnancies are complicated by Kell alloimmunization.

Compared to Rh alloimmunization, maternal antibody titers and amniotic fluid ?OD450 values and trends do not predict the degree of fetal hemolysis in cases of Kell alloimmunization. Severe anemia seems to occur with lower antibody titers and in zones of the Liley curve rather than with Rh-D alloimmunization. Because of this, some authorities suggest routine umbilical cord blood sampling as early as 20 weeks gestation if the father is Kell-positive or of uncertain status. An alternative approach with less likelihood of perinatal morbidity and mortality is to perform early amniocentesis (20 weeks or less) and have a lower threshold to proceed with cordocentesis and IUT. In addition, noninvasive diagnostic modalities that detect fetal anemia, such as Doppler and ultrasound, may be well suited to management of pregnancies complicated by Kell alloimmunization.

ABO INCOMPATIBILITY

A comparison of Rh and ABO incompatibility is important because they are the most frequent causes of immune hemolytic disease in the neonatal period. In about 20% to 25% of pregnancies, ABO incompatibility exists between mother and infant, but a clinically recognizable hemolytic process in the infant occurs in only 10%. ABO hemolytic disease affects the firstborn child in about 50% of ases, and it is not uncommon for multiple siblings to be affected with comparable severity.

The pathophysiology involves the transplacental passage of maternal antibody and its interaction with fetal or neonatal red blood cell antigens, yielding erythrocyte destruction, variable anemia, and hyperbilirubinemia. Clinically, ABO hemolytic problems are confined almost exclusively to the A (specifically A1 rather than A2) or B infants of group O mothers. Anti–A and anti–B “natural” antibodies produced early in life by group A or B individuals are predominantly IgM. In contrast, group O individuals produce anti–A or anti–B that is predominantly IgG and capable of crossing the placenta. Yet, for reasons not completely understood, these antibodies seldom cause harm during pregnancy. There is no relationship between the antibody titer and the severity of hemolytic disease. The discordance between the high frequency of ABO–incompatible pregnancies and the low frequency of hemolytic disease as well as the broad spectrum of the severity has been attributed to such factors as immature, weak, nonspecific, or altered antigens on the fetal red blood cell; absorption of the antibodies by ABO antigens present in all body tissues; and the presence of soluble blood group substances in fetal plasma and tissue fluids that can neutralize maternal antibody. No single test exists that can forewarn the physician

of impending ABO hemolytic disease.

Because this problem does not occur until after birth, amniocentesis and preterm induction of labor are not justified. The most common manifestations of ABO incompatibility in the neonate are early-onset jaundice (i.e., within 24 hours) and a variable elevation of the indirect bilirubin fraction. In contrast to Rh disease, kernicterus and anemia are rare. The cornerstones of management of ABO incompatibility are bilirubin surveillance, phototherapy (required in about 10% of infants), and, occasionally, exchange transfusion.

PLATELET ALLOIMMUNIZATION

Like erythrocytes, platelets have specific surface antigens that occasionally result in maternal alloimmunization when there is an incompatibility between fetus and mother. In a situation analogous to Rh disease, fetal or neonatal alloimmune thrombocytopenia (NAIT) results from maternal production of antiplatelet antibodies followed by placental transfer of antiplatelet antibodies and subsequent platelet destruction. The maternal platelet count is normal but fetal/neonatal thrombocytopenia is often profound.

Several different bi-allelic antigen systems may cause platelet alloimmunization, but most cases (75%) are due to sensitization to the HPA-1a (PlA1) antigen. Approximately 2% of whites, 0.4% of blacks, and less than 0.1% Asians are negative for HPA-1a and thus at risk for NAIT. Though fetomaternal incompatibility to platelet antigens is relatively common, only about 1:1,000 to 1:2,000 births are complicated by NAIT, probably because maternal HLA-antigen class II type influences susceptibility. Clinically, about 90% of affected newborns have diffuse petechiae and 9% to 12% suffer intracranial bleeding with a neonatal mortality of 5% to 13%. Fetal thrombocytopenia has been detected as early as 20 weeks gestation with 50% of intracranial hemorrhages diagnosed at the time of prenatal ultrasound.

Unlike erythrocyte alloimmunization, platelet alloimmunization often occurs during the first pregnancy with diagnosis after delivery of severely affected firstborn children. Maternal platelet antibody titers are not beneficial in predicting the severity of NAIT. Routine testing for HPA-1a antibody status during pregnancy has been proposed but is probably not justified because of the wide variation in the clinical expression of maternal–fetal platelet incompatibility and because 25% of cases of NAIT are due to antigens other than HPA-1a. The incidence of recurrent NAIT following delivery of an affected newborn is approximately 90% to 95% and thrombocytopenia is generally equal or worse in severity.

Obstetric Management of Platelet Alloimmunization

Umbilical cord blood sampling and direct measurement of fetal platelet count is the only method that accurately predicts disease severity. However, serial cordocentesis and IUT are not recommended because of the high risk of procedure-related fetal loss. Based on the effectiveness of IVIG treatment for neonates with NAIT, antenatal protocols using maternally administered high-dose IVIG have been developed and widely accepted. Some centers also add dexamethasone if the response to IVIG treatment is not adequate. The mechanism of IVIG treatment probably involves Fc–receptor saturation in the placenta and blockage of antibody transfer to the fetus. Direct fetal administration has not been successful. The use of high-dose IVIG in pregnancies at risk for NAIT is not without risk. Treatment with IVIG is expensive (over $1,000 per weekly infusion), occasional shortages have occurred, and there have been sporadic reports of acute hepatitis C associated with IVIG use.

The management of pregnancies at risk for NAIT is directed at prevention of hemorrhage in the fetus and newborn. As in erythrocyte alloimmunization, the paternal antigen status can be determined using DNA diagnostic techniques. If the father is homozygous, the fetus is at risk and pregnancy management should proceed accordingly. If the father is heterozygous for the particular antigen, amniocentesis at 16 to 20 weeks can be performed to assess fetal antigen status. If the fetus is antigen-negative, there is no significant risk of thrombocytopenia or intracranial hemorrhage and no fetal blood sampling is performed. If the fetus is antigen-positive, a protocol involving a combination of cordocentesis and IVIG treatments should be offered. In all cases at risk for NAIT, maternal platelets should be available for transfusion after delivery, regardless of the antenatal treatment or previously obtained fetal platelet counts.

MATERNAL THROMBOCYTOPENIA

Maternal thrombocytopenia is one of the most common hematologic disorders in pregnancy. Most cases of maternal thrombocytopenia are immunologically mediated, though thrombocytopenia may also be part of other systemic illnesses as well (Table 18.5). Normal values for platelets are unchanged during pregnancy; the mean platelet count for healthy pregnant women is 246,000 per mL. Platelet counts less than 150,000 per mm ^{3} occur in up to 7.6% of pregnant women and counts less than 100,000 per mm3 occur in less than 1%. Thrombocytopenia may be categorized into mild (100,000–150,000/mL), moderate (50,000–100,000/mL), and severe (<50,000/mL). Clinically significant bleeding does not usually occur until platelet counts drop below 10,000 per mL. Excessive bleeding associated with trauma or surgery is uncommon unless the patient's platelet count is less than 50,000 per mL.

Gestational thrombocytopenia
Pregnancy-induced hypertension
HELLP syndrome
Pseudothrombocytopenia (laboratory artifact)
Human immunodeficiency virus (HIV) infection
Immune thrombocytopenic purpura
Systemic lupus erythematosus
Antiphospholipid syndrome
Hypersplenism
Disseminated intravascular coagulation
Thrombotic thrombocytopenic purpura
Hemolytic uremic syndrome
Congenital thrombocytopenias
Medications (heparin, quinine, quinidine, zidovudine, sulfonamides)

HELLP, hemolysis, elevated liver enzymes, low platelet count.

TABLE 18.5. *Causes of thrombocytopenia in pregnancy*

Gestational Thrombocytopenia

Gestational thrombocytopenia, also known as essential thrombocytopenia or incidental thrombocytopenia is the most common type of mild thrombocytopenia in pregnancy. It is often diagnosed at the time of routine prenatal screening. Characteristics of gestational thrombocytopenia include the following:

- Thrombocytopenia is mild, usually greater than 70,000 per mL.
- Women with thrombocytopenia are asymptomatic with no history of bleeding diathesis.
- There is no history of thrombocytopenia, except in prior pregnancies.
- Platelet counts return to normal 1 to 2 weeks following delivery.
- There are no serious maternal or fetal consequences.

The mechanism of gestational thrombocytopenia is unknown but may involve accelerated platelet consumption. Many women with gestational thrombocytopenia have antiplatelet antibodies but their presence is probably meaningless. Except for the addition of serial platelets counts, no change in prenatal care is necessary.

Autoimmune Thrombocytopenia

Autoimmune thrombocytopenia (ATP) is the most common autoimmune bleeding disorder encountered during pregnancy, affecting between 1 in 1,000 to 10,000 pregnancies. While acute ATP is a self-limited disorder of childhood, chronic ATP typically presents in the second or third decade of life with a female-to-male ratio of 3:1. Autoimmune thrombocytopenia is characterized by production of IgG antibodies directed against platelet membrane glycoproteins. The IgG antiplatelet antibodies bind to platelets, rendering them more susceptible to sequestration and premature destruction in the reticuloendothelial system. Thrombocytopenia occurs when the rate of destruction exceeds the ability of the bone marrow to produce new platelets. Though other sites are also involved, most antibody production and platelet destruction occur in the spleen.

The diagnosis of ATP should be based on clinical findings, after other causes of thrombocytopenia have been excluded. Characteristics include:

- Thrombocytopenia (platelet count <100,000/mL) is present before and after pregnancy with or without megathrombocytes on the peripheral smear.
- Bone marrow aspirates reveal normal or increased numbers of megakaryocytes.
- Patients usually, but not uniformly, have a history of bleeding, easy bruising, petechiae, menorrhagia, or other bleeding problems.

- Splenomegaly is absent.

The course of ATP is not substantially influenced by pregnancy. However, ATP may lead to complications in pregnancy, the most serious of which is maternal hemorrhage around the time of delivery. No maternal deaths from ATP in pregnancy have been recorded since the early 1980s, but peripartum bleeding may result in serious morbidity. Because the placenta selectively transports maternal IgG antiplatelet antibodies into the fetal circulation, fetal thrombocytopenia may also occur, sometimes leading to purpura, ecchymosis, or melena. Intracranial hemorrhage is only rarely reported and appears to be unrelated to the mode of delivery.

Many women with ATP have elevated levels of platelet-associated antibodies and sometimes circulating antiplatelet antibodies. Assays for these antibodies are commercially available but should not be routinely performed because they are nonspecific, poorly standardized, and subject to a large degree of interlaboratory variation. Furthermore, levels of antiplatelet antibodies do not correlate well with the degree of fetal thrombocytopenia.

Treatment Treatment of pregnant women with ATP are aimed at preventing bleeding by maintenance of the platelet count above 20,000 per mm ^{3} in the antepartum period and over 50,000 per mm ^{3} for delivery.
Glucocorticoids Glucocorticoid drugs are the cornerstones of therapy for ATP in pregnancy. Prednisone (1–2 mg/kg/d in divided doses) for 2 to 3 weeks is the most typical regimen. An increase in platelet count to more than 50,000 per mL, accompanied by a decrease in clinical bleeding, is usually achieved within 21 days. More than 70% of patients have some response and complete remission occurs in up to 25%. The prednisone dose is tapered by 10% to 20% decrements at 2-week intervals to a dose that maintains the platelet count above 50,000 per mm ^{3}. Dexamethasone and betamethasone also cause an increase in platelet count but both readily cross the placenta and have harmful fetal effects. The side effects of glucocorticoids in pregnancy include steroid-induced moon facies, gestational diabetes mellitus, psychosis, adrenocortical insufficiency, osteoporosis, aseptic necrosis, hypertension, and uteroplacental insufficiency.
Intravenous Immunoglobulin Given at high doses (i.e., 400 mg/kg/d for 5 days), IVIG usually induces a peak in platelet count within 7 to 9 days. More than 80% of patients achieve a platelet count greater than 50,000 per mm ^{3}, and the response lasts for more than 30 days in 30% of patients. Only 2 to 3 days of IVIG therapy may be needed in some patients, and doses greater than 800 mg or 1 g per kg may suffice as a single or double infusion. Although expensive, IVIG therapy initiated 1 to 2 weeks before delivery or surgery may be useful in some obstetric patients who must undergo operative procedures or who develop bleeding problems and require emergency treatment. The exact mechanism of action of IVIG is unclear, but may be related to decreased antiplatelet antibody production, interference with antibody attachment to platelets, inhibition of macrophage receptor-mediated immune complex clearance, or interference with platelet receptor mechanisms in the reticuloendothelial system. IgG is selectively transported across the placenta and the amount transferred increases with gestational age and dose so that after 32 weeks of gestation, maternally infused IgG sometimes has a beneficial effect on the fetal platelet count. No cases of human immunodeficiency virus (HIV) transmission have been reported with the use of IVIG, but adverse effects include thrombosis, alopecia, liver function disturbances, transient neutropenia, chills, nausea, flushing, tightness of the chest, wheezing, and anaphylactic reactions in patients with immunoglobulin A (IgA) antibodies.
Splenectomy Splenectomy serves to remove the site of destruction of damaged platelets as well as the major source of antibody production. During pregnancy, it is used only for patients with ATP who are refractory to or cannot tolerate glucocorticoids and IVIG. A complete remission is obtained in 80% of patients. The postsplenectomy platelet count increases rapidly and often is normal within 1 to 2 weeks. The surgery is associated with a modest risk of spontaneous abortion or preterm labor and is technically more difficult late in gestation. If splenectomy is unavoidable, it is best performed in the second trimester; it has also been combined safely with cesarean section at term. Splenectomy does not always protect the fetus from thrombocytopenia because antibodies to platelets are also produced in other lymphoid tissues.
Platelet Transfusions Platelet transfusions are used only as a temporizing measure to control life-threatening hemorrhage or to prepare a patient for splenectomy or cesarean section. The survival of transfused platelets is decreased in patients with ATP because antiplatelet antibodies also bind to donor platelets. In addition, patients with ATP do not respond as well as normal individuals to platelet transfusions but 6 to 10 U is usually sufficient to temporarily control hemostasis.
Other Treatments Other agents have been used with some success in patients who are refractory to glucocorticoids, IVIG, and splenectomy. Those most commonly used, such as azathioprine, cyclophosphamide, Vinca alkaloids, and danazol, are to be avoided in pregnancy because of their toxicity and potential adverse effects on the fetus. Plasmapheresis has also been tried, but the results of this treatment are variable.
Obstetric Management of Autoimmune Thrombocytopenia Management of pregnancies complicated by ATP is controversial largely because of uncertainties regarding the actual risk of fetal thrombocytopenia. In the past, cesarean delivery was advocated in all women with ATP because of anecdotal reports of intracranial hemorrhage associated with vaginal delivery. Prompted by the fact that clinically significant bleeding is extremely unlikely in fetuses with platelet counts more than 50,000 per mL, some authorities recommended cesarean delivery only if the fetal platelet count was less than 50,000 per mL. However, this required measurement of the fetal platelet count. Fetal scalp sampling during labor was the first and most commonly performed method of obtaining the fetal platelet count, allowing 80% of fetuses with acceptable platelet counts to be safely delivered vaginally. Unfortunately, the procedure is technically difficult to perform in early labor and falsely low platelets were sometimes obtained. Cordocentesis often replaced fetal scalp sampling because platelet counts were extremely accurate and the procedure could be performed before the onset of labor. However, cordocentesis is expensive and unavailable in centers without appropriate expertise and equipment. It also has several potentially serious complications including fetal bradycardia, hemorrhage at the puncture site, and cord hematoma. Both fetal scalp sampling and cordocentesis might be useful if there was any evidence that cesarean delivery reliably prevents intracranial hemorrhage in thrombocytopenic fetuses. However, it appears that early reports of ATP in pregnancy overestimated the risk of severe fetal thrombocytopenia and intracranial hemorrhage associated with vaginal delivery. In a recent, large, population-based study of almost 16,000 pregnancies, no infant born to a mother with ATP suffered intracranial hemorrhage, regardless of the route of delivery. Because it appears that fetal scalp sampling, cordocentesis, and cesarean delivery contribute to cost and morbidity without preventing intracranial hemorrhage, many obstetricians have abandoned antenatal measurement of fetal platelet counts and reserved cesarean delivery for the usual obstetric indications. Mothers with ATP do not require substantial alterations in prenatal care. Serial platelet counts should be obtained during the pregnancy. If the platelet count is less than 50,000 per mL in the weeks preceding delivery, patients with ATP should be treated with glucocorticoids or IVIG. Women requiring chronic glucocorticoid therapy during pregnancy should be carefully monitored for the development of gestational diabetes and should have serial ultrasounds to assess fetal growth. Women with prior splenectomy should be monitored for the development of infection. Delivery is best accomplished in a setting in which platelets, fresh frozen plasma, and IVIG are available. A neonatologist or pediatrician familiar with the disorder should be present to promptly treat any hemorrhagic complications in the neonate. In the puerperium, salicylates and nonsteroidal antiinflammatory drugs (NSAIDs) should be avoided. Though breast-feeding may theoretically induce neonatal thrombocytopenia because of the passage of antiplatelet antibodies in the colostrum, it is considered safe and reasonable by most pediatricians.

Other Causes of Thrombocytopenia in Pregnancy

Other than ATP, the most common serious condition associated with maternal thrombocytopenia late in pregnancy is preeclampsia or HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count). Other conditions that can result in maternal thrombocytopenia at any gestational age include acute HIV infection, systemic lupus erythematosus, antiphospholipid syndrome (APS), sepsis, cocaine abuse, thrombotic thrombocytopenic purpura, transfusion reaction, blood dyscrasias, or certain medications (see Table 18.5).

Pseudothrombocytopenia can result from laboratory artifacts such as platelet clumping induced by ethylenediaminetetraacetic acid (EDTA) in the collection tube, blood clotting related to techniques of blood withdrawal, and an inadequate amount of anticoagulant. These factors can be confirmed by examining a stained peripheral maternal blood smear. Once the diagnosis of pseudothrombocytopenia is established, no further treatment is needed for mother or infant.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is a chronic inflammatory condition affecting virtually every organ system of the body. With a predilection for women of reproductive age, it is the autoimmune disease most commonly encountered during pregnancy. No specific gene mutation for SLE has been identified. However, 5% to 12% of affected individuals have another relative with SLE and 25% to 50% of affected monozygotic twins are concordant for the disease. Several alterations in the HLA-antigen system have been linked to the development of SLE and homozygous carriers of inherited complement deficiency disorders also appear to be predisposed to development of the disease. With an increased awareness of the disease, more sophisticated diagnostic methods, and improved drug therapy, the 10-year survival rate now exceeds 90%.

Diagnosis of Lupus

Lupus may easily be overlooked because it often begins with mild and vague symptoms such as fatigue and is characterized by periods of exacerbation and remission. The presence of autoantibodies, characteristically against nuclear components, is a hallmark of the disorder. The American Rheumatism Association has set criteria for the diagnosis of SLE that incorporate immunologic abnormalities and improve disease classification for purposes of clinical studies (Table 18.6). The most common clinical manifestations include arthralgia or arthritis (90%), dermatologic involvement (70%–80%), renal disease (46%), hematologic abnormalities (50%), and cardiovascular disease (30%–50%). The most frequent laboratory findings are thrombocytopenia, leukopenia, and the presence of autoantibodies.

Finding	Frequency
Malar rash (fixed erythema over malar eminences)	85%
Discoid rash (erythematous, raised patches with scaling	15%
Photosensitivity	Common
Oral or pharyngeal ulcers	50%
Arthritis (nonerosive, involving two or more joints)	90%
Pleuritis or pericarditis	25%–46%
Proteinuria, 0.5 g/d, or cellular casts	50%
Seizures or psychosis	20%
Anemia, leukopenia, thrombocytopenia	>95%
Positive antinuclear antibody titer	>95%
Positive lupus erythematosus preparation, anti-DNA, anti-Sm, or false-positive test results for syphilis	>95%

[a]The presence of any four criteria, serially or simultaneously, in any given period of observation is sufficient to make the diagnosis of systemic lupus erythematosus.

TABLE 18.6. *Diagnostic criteria for systemic lupus erythematosusa*

Lupus should be suspected when a woman in her reproductive years presents with glomerulonephritis, nephrotic syndrome, hemolytic anemia, leukopenia, or thrombocytopenia. A positive antinuclear antibody (ANA) test is confirmatory in virtually all (98%) patients. However, this test does not have high specificity for SLE and many healthy women may test positive for low levels of ANA antibodies. High titers of antibodies to double-stranded DNA and antibodies to the Smith (Sm) antigen are most specific for SLE.

Systemic Lupus Erythematosus and Pregnancy

Lupus Flare During Pregnancy Considerable debate surrounds the incidence and severity of SLE flare during pregnancy. Studying SLE flare in pregnancy is difficult because many of the signs and symptoms typically associated with SLE flare are considered routine during pregnancy. In addition, studies have not consistently used the same criteria for flare or disease severity. Nevertheless, it appears that SLE flare occurs in 35% to 65% of pregnant women with well-controlled SLE. Most flares are mild-to-moderate in nature and easily treated with glucocorticoids. Flares occur with equal frequency in all three trimesters and the puerperium. Women at greatest risk for complications of SLE during pregnancy are undoubtedly those with preexisting lupus nephritis (LN). Approximately half of all SLE patients eventually develop LN as a result of immune complex deposition in the kidney with subsequent complement activation and inflammatory tissue damage. Patients typically present with proteinuria, hematuria, aseptic pyuria, and urinary sediment. Renal biopsy is necessary to confirm the diagnosis. Pregnancy places women with LN at risk for deterioration of renal function and increased proteinuria, especially if active nephritis or renal insufficiency is present at the time of conception. However, the risks of pregnancy may not be so serious for women with stable LN. About one-third of women with LN experience flare during pregnancy, fewer than 25% have worsening renal function, and 10% of have permanent deterioration. The incidence of maternal death attributed to renal failure during pregnancy is less than 2%.
Obstetric Complications in Women with Lupus Women with SLE are at risk for several obstetric complications. Between 20% to 30% of women with SLE have pregnancies complicated by preeclampsia. Women with secondary APS, underlying renal disease, chronic hypertension, or chronic steroid use are at particular risk. Uteroplacental insufficiency resulting in intrauterine growth restriction (IUGR) or neonates who are small for gestational age has been reported in 12% to 40% of pregnancies complicated by SLE. Renal insufficiency or hypertension increases the risk of IUGR. The risk of pregnancy loss for women with SLE is uncertain with reported rates ranging from 10% to 50%. There appears to be a predilection for the second and third trimester. Renal insufficiency increases the risk of fetal loss; live births occur in only 50% of pregnancies complicated by moderate to severe renal insufficiency (serum creatinine >1.5 mg/dL) and in 40% with preexisting proteinuria (>300 mg/24 h or creatinine clearance <100 mL/min). Coexisting APS poses the greatest risk for pregnancy loss in women with SLE. Only 50% of women with SLE and APS have live births; if they have previously experienced a fetal loss, 85% have recurrent loss in subsequent pregnancies.
Lupus Disease Activity and Risks of Pregnancy The degree of disease activity at conception dramatically affects the risk of SLE flare and other complications during pregnancy. The rate of SLE flare is lower for women with SLE in remission prior to conception. Renal deterioration is also less likely and less severe in women with inactive LN in the 6 months prior to conception. Furthermore, nearly 90% of women with inactive SLE at conception have live births compared to 64% of those with active disease. Women with SLE who plan their pregnancies after disease remission have outcomes similar to those of the general population.
Neonatal Lupus Erythematosus Neonatal lupus erythematosus (NLE) is a rare condition of the fetus and neonate, occurring in 1 of 20,000 of all live births and in fewer than 5% of all women with SLE. Dermatologic NLE is most common with lesions described as erythematosus, scaling annular or elliptical plaques occurring on the face or scalp, analogous to the subacute cutaneous lesions in adults. Lesions appear in the first weeks of life, probably induced by exposure of the skin to ultraviolet light, and may last for up to 6 months. Hypopigmentation may persist for up to 2 years. Hematologic NLE is manifest as autoimmune hemolytic anemia, leukopenia, thrombocytopenia, and hepatosplenomegaly. The most well-known form of SLE is congenital complete heart block (CCHB) caused by endomyocardial fibrosis of the conduction system in the area of the atrioventricular node. The diagnosis is usually made in the second trimester when a fixed bradycardia, in the range of 60 to 80 beats per minute, is detected during a routine prenatal visit. Fetal echocardiography confirms complete atrioventricular dissociation with a structurally normal heart. There is no known treatment for prenatally diagnosed CCHB though glucocorticoids, plasmapheresis, intravenous immune globulin, digoxin, or some combination thereof, have been tried. Maternally administered glucocorticoids appear to reduce the risk of recurrence of CCHB in another pregnancy. The prognosis for fetuses with CCHB varies but hydrops fetalis may develop in the most severe cases. Because the endomyocardial damage is permanent, a pacemaker may be necessary for neonatal survival. The manifestations of NLE are probably caused by maternal autoantibodies that cross the placenta and bind to fetal tissue. Anti–Ro/SSA antibodies are found in 75% to 95% mothers who deliver babies with NLE. A smaller percentage of mothers have anti–La/SSB, and some have both. About 15% of infants born to mothers with anti–Ro/SSA antibodies have dermatologic SLE; the incidence of CCHB is much smaller. However, with a previously affected infant, the risk of recurrence increases two- to three-fold. Occasionally, women with no history of SLE give birth to babies with NLE. More than half eventually develop lupus.

Obstetric Management for Women with Lupus

Immunosuppressive Medications

Glucocorticoids Glucocorticoid preparations are the group of drugs most commonly given to pregnant women with SLE, both as maintenance therapy and in “bursts” to treat suspected SLE flares. Dosing regimens in pregnant women are the same as those in nonpregnant patients. Prophylactic treatment with glucocorticoids is not necessary or prudent in women with inactive disease. Maternal side effects of chronic glucocorticoid therapy include weight gain, striae, acne, hirsutism, immunosuppression, osteonecrosis, and gastrointestinal ulceration. Pregnant women are also at risk for preeclampsia, uteroplacental insufficiency, and glucose intolerance. Prednisolone or methylprednisolone should be used as maintenance therapy because of their conversion to relatively inactive forms in the human placenta. Glucocorticoids with fluorine at the 9a position (dexamethasone, betamethasone) are considerably less well metabolized by the placenta and chronic use may lead to undesirable fetal effects.
Antimalarials An accumulating body of evidence suggests that antimalarial drugs may be used safely for the treatment of SLE during pregnancy. Past concerns about teratogenicity including ototoxicity and eye damage appear to be unfounded. In randomized controlled trials, hydroxychloroquine appears to be more efficacious than glucocorticoids for prevention of flare during pregnancy.
Cytotoxic Agents Azathioprine, methotrexate, and cyclophosphamide are used to treat only the most severely affected patients with SLE. Azathioprine, a derivative of 6-mercaptopurine, is not a human teratogen but has been associated with fetal growth impairment and impaired neonatal immunity. Cyclophosphamide is a known teratogen and should be avoided during the first trimester. Thereafter, its use should be limited to women with severe, progressive proliferative glomerulonephritis or SLE-related central nervous system (CNS) disease. Methotrexate is well known to kill chorionic villi and cause fetal death and its use should be scrupulously avoided.
Nonsteroidal Medications The most common types of analgesics used by women with SLE are NSAIDs. Unfortunately, they readily cross the placenta and should be avoided after the first trimester. Although short-term tocolytic therapy with indomethacin appears to be safe, long-term use of any NSAID has been associated with decreased fetal urinary output and oligohydramnios as well as neonatal renal insufficiency.
Other Treatments Several new treatment regimens including cyclosporine, high-dose IVIG, mycophenolate mofetil, and thalidomide have been studied in the treatment of nonpregnant patients with SLE. Only IVIG has been used during pregnancy without reports of adverse fetal effects. Obviously, thalidomide is absolutely contraindicated during pregnancy.
Detection of SLE Exacerbation (Flare) Thorough and frequent clinical assessment remains essential for the timely and accurate detection of SLE flare. The most common presenting symptom in both flare and new-onset disease is extreme fatigue (see Table 18.6). In pregnancy, skin rashes are more frequent than musculoskeletal manifestations. Patients with LN exhibit worsening proteinuria along with pyuria, hematuria, and urinary casts, which can sometimes be confused with the onset of preeclampsia. Laboratory evaluation of SLE activity should be used to confirm flare in confusing cases. Serial evaluation of complement levels has been suggested as a method of predicting SLE flare during pregnancy. However, the predictive value of complement activation has been inconsistent and never been proven to be superior to thorough and frequent clinical assessment. The most specific laboratory test for disease activity is an elevation in the anti–double-stranded DNA (anti–dsDNA) titer that precedes lupus flare in more than 80% of patients and has been shown to correlate with the need for preterm delivery. In combination with anticardiolipin (aCL) antibodies, elevated levels of anti–dsDNA have been shown to predict fetal loss.
Treatment of SLE Flare during Pregnancy Mild to moderate symptomatic exacerbations of SLE without CNS or renal involvement may be treated with initiation or increased dose of glucocorticoids. Relatively small doses of prednisone (e.g., 15–30 mg/d) result in improvement in most cases. For severe exacerbations without CNS or renal involvement, 1.0 to 1.5 mg per kg per day of prednisone in divided doses should be used, and a good clinical response can be expected in 5 to 10 days. Thereafter, glucocorticoids may be tapered by several different approaches (Table 18.7).

1. Consolidate to a single morning dose of prednisone. Reduce the daily dose by 10%/wk, as tolerated. When a dose of 20 to 30 mg/d is reached, reduce by 2.5-mg increments/wk. If the patient remains asymptomatic at a dose of 15 mg/d, reduce the dose by 1-mg increments/wk to a dose of 5 to 10 mg/day.
2. Consolidate to a single morning dose of prednisone. Taper to 50 to 60 mg/d by reducing the dose 10%/wk. Thereafter eliminate the alternate-day dose by tapering it 10%/wk, as tolerated. Thereafter, taper the remaining every other day dose by 10%/wk, as tolerated.

TABLE 18.7. *Suggested methods for tapering prednisone*

Severe exacerbations, especially those involving the CNS or kidneys, are treated more aggressively. Intravenous-pulse glucocorticoid therapy should be given, usually in a dose of methylprednisolone at 10 to 30 mg per kg (about 500–1,000 mg) for 3 to 6 days. Thereafter, the patient is treated with 1.0 to 1.5 mg per kg per day of prednisone in divided doses and rapidly tapered over the course of 1 month. One can expect that 75% of patients will respond favorably to this approach. This regimen may be repeated every 1 to 3 months in severe cases as an alternative to cytotoxic drugs. The use of cytotoxic agents, plasmapheresis, and IVIG should be reserved for severe SLE exacerbations that do not respond to glucocorticoid therapy. Severe proliferative lupus nephritis is often responsive only to cyclophosphamide.
Obstetric Care for Women with Systemic Lupus Erythematosus Clinical precautions in pregnancies associated with SLE are similar to those required for other high-risk pregnancies. Recommended laboratory studies in addition to routine prenatal tests are listed in Table 18.8. The gestational age should be firmly established early in pregnancy. Serial sonography should be performed to assess fetal growth. Antenatal surveillance (e.g., nonstress tests, biophysical profiles, etc.) should be initiated in the third trimester to confirm fetal well-being. Lupus per se is not an indication for cesarean delivery. Instead, the route of delivery should be based on appropriate obstetric indications.

TABLE 18.8. *Management of systemic lupus erythematosus during pregnancy*

ANTIPHOSPHOLIPID SYNDROME IN PREGNANCY

The diagnosis of APS is based on the presence of one or more characteristic thrombotic or obstetric features of the condition in combination with positive serologic testing for antiphospholipid antibodies (aPL). Patients with bona fide APS must manifest at least one of two clinical criteria (vascular thrombosis or pregnancy morbidity) and at least one of two laboratory criteria (positive lupus anticoagulant [LA] or medium to high titers of ß2-glycoprotein I-dependent IgG or IgM isotype aCL antibodies, confirmed on two separate occasions at least 6 weeks apart (Table 18.9). APS may exist as an isolated immunologic derangement (primary APS) or in combination with other autoimmune diseases (secondary APS), most commonly SLE.

Clinical criteria for diagnosis of APS
Pregnancy loss
Recurrent pregnancy loss
Fetal death (>10 wks)
Preterm birth (<34 wks) because of severe preeclampsia or uteroplacental insufficiency
Thromboembolism
Venous
Arterial, including stroke
Clinical features not considered adequate criteria for the diagnosis of APS
Autoimmune thrombocytopenia
Other
Coombs-positive hemolytic anemia
Livedo reticularis
Laboratory criteria for the diagnosis of APS
Lupus anticoagulant
Anticardiolipin antibodies
Immune globulin G, medium- or high-positive
Immune globulin M, medium- or high-positive and lupus anticoagulant

[a] Wilson WA, Gharavi AE, Koike T. International consensus statement on preliminary classification criteria for definite antiphospholiped syndrome: report of an international workshop. *Arthritis Rheum* 1999;42:1309–1311.

TABLE 18.9. *Clinical and laboratory criteria for antiphospholipid syndrome (APS)* [a]

Clinical Features of Antiphospholipid Syndrome during Pregnancy

In the original description of APS, the sole obstetric criterion for diagnosis was fetal loss (>10 menstrual weeks of gestation). At least 40% of pregnancy losses reported by women with LA or medium to high positive IgG aCL occur in the fetal period. More recently, APS-related pregnancy loss has been extended to include women with early recurrent pregnancy loss (RPL) including those occurring in the preembryonic (<6 menstrual weeks of gestation) and embryonic periods (6–9 menstrual weeks of gestation). In addition, APS is associated with other pregnancy complications including gestational hypertension or preeclampsia and uteroplacental insufficiency as manifested by fetal growth restriction, oligohydramnios, and non-reassuring fetal surveillance. Obstetric complications other than pregnancy loss appear to persist in spite of treatment. There have been some attempts to link infertility and failure of in vitro fertilization (IVF) to the presence of aPL antibodies. However, there is no evidence to support such a relationship. Indeed, multiple studies have refuted any association between aPL antibodies and infertility and failed IVF.

Treatment of Antiphospholipid Syndrome during Pregnancy

The goals of APS treatment during pregnancy are two-fold:

1. Improve maternal and fetal–neonatal outcome by preventing pregnancy loss.
2. Reduce or eliminate risk of thromboembolism.

Initial attempts at treating women with APS during pregnancy involved immunosuppression with a glucocorticoid preparation, usually prednisone. Early enthusiasm for treatment of APS with glucocorticoids waned after publication of a small, randomized trial found maternally administered heparin to be as effective as prednisone, without all of the risks associated with chronic glucocorticoid use during pregnancy. At present, maternally administered heparin is considered the treatment of choice, usually initiated in the early first trimester after ultrasonographic demonstration of a live embryo. Daily low-dose aspirin is usually included as well. Live-birth rates among women with APS are generally greater than 70% with regimens including both heparin and aspirin (see Fig. 18.9). However, rates of other obstetric complications associated with APS are not improved, regardless of therapy.

The safe and effective dose of heparin for pregnant women with APS is debated but should probably depend on individual patient history. Women with APS and a history of thromboembolism should receive adjusted-dose anticoagulation with unfractionated heparin or low–molecular-weight heparin during pregnancy (Table 18.10). For women with APS *without* a history of thromboembolic disease, the choice of anticoagulation is less clear. Low-dose heparin prophylaxis may be sufficient for women with recurrent first trimester loss and no history of fetal loss. However, women with a history of fetal death (>10 weeks gestation) may be at higher risk for thromboembolism during pregnancy and should probably receive higher doses of heparin prophylaxis. We treat such women with generous thromboprophylaxis (e.g., 15,000 to 20,000 units of standard heparin or 60 mg of enoxaparin in daily divided doses). Recommendations for postpartum therapy vary but most authorities recommend at least 6 weeks of some regimen of anticoagulation with unfractionated heparin, low–molecular-weight heparin, or warfarin.

Unfractionated Heparin
Low-dose prophylaxis
1. 5,000–7,500 U every 12 h during the first trimester 7,500–10,000 U every 12 h during the second trimester 10,000 U every 12 h during the third trimester unless the aPTT is elevated. The aPTT may be checked near term and the heparin dose reduced if prolonged. or
2. 5,000–10,000 U every 12 h throughout the pregnancy
Adjusted-dose prophylaxis:
≥10,000 U twice a day to three times a day to achieve an aPTT of 1.5–2.5 control
Low–Molecular-Weight Heparin
Low-dose prophylaxis
Dalteparin, 5,000 U once or twice daily, or enoxaparin, 40 mg once or twice daily
Adjusted-dose prophylaxis
Dalteparin, 5,000–10,000 U every 12 h, or enoxaparin, 30–60 mg every 12 h

aPTT, activated partial thromboplastin time.

TABLE 18.10. *Regimens for anticoagulation during pregnancy*

Healthy women with recurrent embryonic and preembryonic loss who have low or negative aPL titers do not require anticoagulation.

Women with APS should be counseled about the potential risks of heparin therapy during pregnancy including heparin-induced osteoporosis (1%–2%) and heparin-induced thrombocytopenia (HIT). Women treated with heparin should be encouraged to take daily supplemental calcium and vitamin D (e.g., prenatal vitamins) and perform daily axial skeleton weight-bearing exercise (e.g., walking). Immune-mediated HIT is much less common but potentially more serious. Most cases have their onset 3 to 21 days after heparin initiation and are relatively mild in nature. A more severe form of HIT paradoxically involves venous and arterial thromboses resulting in limb schemia, cerebrovascular accidents, and myocardial infarctions, as well as venous thromboses. We obtain serial platelet counts for 2 weeks and discontinue heparin if a significant decrease in platelet count occurs.

Postpartum and Catastrophic Antiphospholipid Syndrome

Catastrophic APS is a rare but devastating syndrome characterized by multiple simultaneous vascular occlusions throughout the body, often resulting in death. The diagnosis should be suspected if at least three organ systems are affected and confirmed if there is histopathologic evidence of acute thrombotic microangiopathy affecting small vessels. Renal involvement occurs in 78% of patients. Most patients have hypertension and 25% eventually require dialysis. Other common manifestations include adult respiratory distress syndrome (66%), cerebral microthrombi and microinfarctions (56%), myocardial microthrombi (50%), dermatologic abnormalities (50%), and disseminated intravascular coagulation (25%). Death from multiorgan failure occurs in 50% of patients. The pathophysiology of catastrophic APS is poorly understood. However, the onset may be presaged by several factors including infection, surgical procedures, discontinuation of anticoagulant therapy, and the use of drugs such as oral contraceptives.

Early and aggressive treatment of catastrophic APS is necessary to avoid death. Patients should be transferred to an intensive care unit where supportive care can be provided. Hypertension should be aggressively treated with appropriate antihypertensive medication. While no one treatment has been shown to be superior to another, a combination of anticoagulants (usually heparin) and steroids plus either plasmapheresis or IVIG has been successful in some patients. Streptokinase and urokinase have also been used to treat acute vascular thrombosis. Women suspected of catastrophic APS during pregnancy should probably be delivered.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is a chronic inflammatory process that primarily involves synovial-lined joints resulting in swelling and pain. The following criteria must be met to establish the diagnosis of RA (i.e., seven criteria for classic RA, five criteria for definite RA, three criteria for probable RA, two criteria for possible RA):

- morning stiffness
- pain and tenderness in at least one joint
- swelling of at least one joint
- swelling of at least one other joint
- symmetric joint swelling
- subcutaneous nodules
- x-ray changes typical of RA
- positive test result for rheumatoid factor
- poor mucin precipitate of synovial fluid
- characteristic histologic changes of synovium
- characteristic histologic changes of nodules.

Most cases are mild and require little or no medical treatment. In others, the disease is characterized by intermittent exacerbations with ultimate progression over many years to typical joint deformities.

Pregnancy is associated with clinical improvement in at least 50% of patients, a phenomenon that may be related to elevated blood levels of free cortisol or to enhanced phagocytosis of immune complexes. The rheumatoid factors (i.e., IgM antibodies against autologous IgG) do not cross the placenta, and there is no fetal or neonatal involvement.

Management of RA during pregnancy should include an appropriate balance of medication, rest and exercise, heat, and physical therapy. The basic reliance on large doses of salicylates, NSAIDs, and analgesics must be modified during pregnancy. Low-dose steroids (e.g., prednisone, 5 mg/d) and low-dose aspirin are recommended. Though gold compounds cross the placenta, no fetal adverse effects or teratogenicity have been reported. Gold therapy can be continued in selected pregnant patients with RA who are unresponsive to glucocorticoids. Other NSAIDs and penicillamine are not recommended because of potential detrimental fetal effects. As in SLE, antimalarials (hydroxychloroquine) appear to be another safe option during pregnancy.

Specialized antenatal surveillance is unnecessary for women with RA. Serial ultrasounds and antenatal surveillance should be reserved for the usual obstetric indications. Joint deformities rarely preclude vaginal delivery but mechanical obstacles may occur in women with hip deformities. Cesarean delivery can usually be reserved for standard obstetric indications. The type of anesthesia (regional vs. general) chosen depends on the presence of skeletal deformities or special problems such as atlantoaxial subluxation.

Other Rheumatic (Collagen Vascular) Diseases

Most disorders of undetermined origin, which are characterized by inflammation of various tissues, have been termed systemic rheumatic or collagen vascular diseases. More recently, many have been classified as autoimmune disorders because of their association with the production of autoantibodies and other immunologic aberrations. This group includes:

- mixed connective tissue disorder
- Sjögren syndrome
- polyarteritis nodosa
- dermatomyositis
- scleroderma.

The risk of both maternal and perinatal death is particularly high in patients with polyarteritis nodosa, mixed connective tissue disorder, and scleroderma complicated by renal disease or cardiopulmonary disease. Scleroderma worsens in at least 10% of women during pregnancy. At least 5% have life-threatening complications, usually related to renal or cardiopulmonary disease.

MYASTHENIA GRAVIS

Myasthenia gravis (MG) is a chronic neuromuscular autoimmune disease characterized by fatigue and weakness, usually involving the extraocular, facial, pharyngeal, and respiratory muscles. It is worsened by exertion and relieved by rest and anticholinesterase drugs. Antibodies to human acetylcholine receptors (AChR) are detectable in up to 90% of patients with MG. The anti–AChR antibodies are involved in complement-dependent destruction of the postsynaptic membrane of the myoneural junction, resulting in decreased nerve impulse transmission. Thymoma, thymic hyperplasia, and other autoimmune diseases often accompany MG. The functional abnormalities associated with the disease are similar to those induced by curare. The course during pregnancy is variable, although there is a tendency for

relapse during the puerperium.

The cholinesterase inhibitors and their equivalent doses most commonly used to alleviate symptoms are 0.5 mg of intravenous neostigmine, 1.5 mg of subcutaneous neostigmine, 15 mg of oral neostigmine, 60 mg of oral pyridostigmine, and 5 mg of oral ambenonium. Drugs are adjusted to the dose at which the patient's muscle strength is optimal with a minimum of cholinergic adverse effects. Oral pyridostigmine, or a sustained-release preparation of pyridostigmine, is the most commonly used medication for MG. Overmedication results in unpleasant effects such as abdominal cramps, flatulence, diarrhea, nausea, vomiting, and excessive secretion of saliva and tears. Toxic levels of pyridostigmine lead to a myasthenic crisis-like syndrome involving profound muscle weakness and eventually respiratory failure. Treatment with high-dose glucocorticosteroids has also been used successfully in some patients. Regular rest periods with limited physical activity should be prescribed for the pregnant patient with MG. Infections should be treated aggressively because of their propensity to exacerbate MG.

Careful plans should be made for drug therapy during pregnancy, labor, delivery, and the postpartum period. Some antibiotics such as the aminoglycosides may produce a myasthenic crisis and should be avoided. Other medications may also be harmful in women with MG (Table 18.11). Many patients with MG are sensitive to sedatives, analgesics, tranquilizers, and especially narcotics. Muscle relaxants should be avoided. Local or regional anesthetics are preferable. Magnesium sulfate is contraindicated because the drug diminishes the acetylcholine effect and has been known to induce a myasthenic crisis.

Magnesium salts
Aminoglycosides
Halothane
Propranolol
Tetracycline
Barbiturates
Lithium salts
Trichloroethylene
Colistin
Polymyxin B
Quinine
Lincomycin
Procainamide
Ether
Penicillamine

TABLE 18.11. *Medications that may exacerbate or cause muscle weakness in patients with myasthenia gravis*

Labor typically progresses normally and sometimes more rapidly than usual because smooth muscle is unaffected. Cesarean delivery should be reserved for obstetric reasons. Assisted ventilation should be available in the event of respiratory difficulty. During labor, the patient's oral dose of anticholinesterase should be discontinued and replaced with an intramuscular equivalent.

About 12% to 20% of infants born to women with MG exhibit neonatal MG, which lasts from a few hours to several days. The manifestations are caused by the transplacental transfer of acetylcholine-blocking factor. Interestingly, neonatal MG does not occur in all infants born to mothers with MG. The classic features of neonatal MG differ from those seen in adults. The symptoms usually do not develop until day 1 or 2 of life, probably because of some protection to the infant from the maternal blood levels of anticholinesterase agents. A high index of suspicion is necessary to recognize this phenomenon because an infant who appears healthy at birth may later develop respiratory failure with asphyxia. The involved infant shows generalized muscle weakness and hypotonic limbs and is limp and motionless. The Moro reflex often is weak or absent, and there may be a feeble cry, inability to suck, and associated difficulty in swallowing and breathing. Arthrogryposis (i.e., joint contractures), which may develop as a result of reduced intrauterine movement, has been reported in several infants born to mothers with MG.

SUMMARY POINTS

ERYTHROBLASTOSIS FETALIS

- Rh immunoglobulin should be given to Rh–negative, unsensitized women at 28 weeks gestation, within 72 hours after delivery, and in the event of antenatal procedures and complications associated with fetomaternal hemorrhage.
- Rh–alloimmunized women with anti–D titers 1:16 or greater should be referred for measurements of amniotic fluid bilirubin.
- Serial measurements of amniotic fluid bilirubin are used to identify fetuses at risk for significant fetal anemia.
- Intravascular intrauterine transfusion is most efficacious for the treatment of severely anemic fetuses with hydrops.

PLATELET ALLOIMMUNIZATION

- Platelet alloimmunization results in severe fetal and neonatal thrombocytopenia, which may be ameliorated with maternal administration of intravenous immunoglobulin.

MATERNAL THROMBOCYTOPENIA

- Gestational thrombocytopenia is a benign disorder characterized by mild thrombocytopenia (>70,000/mL), no history of excessive bleeding, no history of thrombocytopenia, resolution of thrombocytopenia 1 to 2 weeks after delivery, and no serious risk to mother or fetus.
- Autoimmune thrombocytopenia is characterized by thrombocytopenia before and after pregnancy, megathrombocytes on peripheral smears, bone marrow aspirate with normal or increased numbers of megakaryocytes, history of excessive bleeding, and absence of splenomegaly.
- Antiplatelet antibodies are not useful in differentiating between gestational thrombocytopenia and autoimmune thrombocytopenia.
- Autoimmune thrombocytopenia is not associated with a significant risk of fetal thrombocytopenia leading to intracranial hemorrhage.

SYSTEMIC LUPUS ERYTHEMATOSUS

- The diagnosis of lupus is based on specific clinical criteria.
- A positive antinuclear antibody (ANA) test is confirmatory in 98% of patients but elevated levels of antibodies to double-stranded DNA are most specific for disease activity.
- Most lupus flares during pregnancy are easily treated with glucocorticoids.
- Prophylaxis with glucocorticoid medication is not indicated to prevent flare during pregnancy.
- Lupus flare during pregnancy is best detected by frequent and thorough clinical assessment.
- Congenital cardiac heart block associated with neonatal lupus is characterized by fetal bradycardia diagnosed in the second trimester in a fetus with a structurally normal heart.

ANTIPHOSPHOLIPID SYNDROME

- The diagnosis of antiphospholipid syndrome (APS) should be based on the presence of thromboembolism or pregnancy loss in combination with medium to high titers of anticardiolipin antibodies or the lupus anticoagulant.
- A regimen of heparin and low-dose aspirin reduces the risk of thromboembolism and pregnancy loss in women with APS.

RHEUMATOID ARTHRITIS

- Pregnancy is associated with clinical improvement in at least 50% of patients with rheumatoid arthritis.

MYASTHENIA GRAVIS

- Myasthenia gravis (MG) is a chronic neuromuscular autoimmune disease characterized by fatigue and weakness, usually involving the extraocular, facial, pharyngeal, and respiratory muscles.
- Women with MG should avoid magnesium sulfate and aminoglycoside preparations, narcotics, and muscle relaxants.
- Neonatal MG occurs in 12% to 20% of infants born to mothers affected with MG.

Human Immunodeficiency Virus

Introduction

In this chapter, we will discuss four important perinatal infections—human immunodeficiency virus (HIV), toxoplasmosis, cytomegalovirus (CMV), and herpes—and two common bacterial infections—intraamniotic infection (IAI) and postpartum endometritis.

It has been more than 20 years since an article appearing in the Morbidity and Mortality Weekly Report drew the nation's attention to a previously unrecognized illness. That report described five gay males who had been diagnosed with *Pneumocystis carinii* pneumonia, an illness theretofore seen only among debilitated hosts. An accompanying editorial noted, “the fact that these patients were all homosexuals suggests an association between some aspect of a homosexual lifestyle or disease acquired through sexual contact and *Pneumocystis* pneumonia in this population” and “all the above observations suggest the possibility of a cellular–immune dysfunction related to a common exposure that predisposes individuals to opportunistic infections such as pneumocystosis and candidiasis.” Although that editorial showed remarkable insight, almost no one at that time perceived that report to be the harbinger of an epidemic that would devastate large swaths of the globe, become a leading cause of infant mortality, and change the practice of medicine and obstetrics around the world.

The ensuing years have been marked by dramatic progress that resulted from the harnessed energies of the nation's scientific community. In rapid sequence an etiologic agent was discovered, diagnostic tests were developed, public health interventions were instituted, and highly active pharmaceutical agents were developed. For those fortunate enough to be able to afford these interventions, the transformation of the epidemic could not have been more remarkable. No longer did a diagnosis ensure a short painful life and a certain death and for pregnant women mean a 25% chance of birthing an HIV-infected child. With access to state-of-the-art treatment there began to be concrete reasons for hope. Although the diagnosis still signals the beginning of a difficult, life-long struggle against the virus, there are effective, although toxic, therapies and the prevention of perinatal transmission can be ensured in almost 99% of cases. In this section of the chapter, developments in the field will be summarized in a fashion that should allow their integration into the practice of obstetrics and, thereby, ensure HIV-infected women the best possible prognosis for themselves and for their children. The focus of practice must be on two components of care, ensuring the health of women and minimizing the risks of transmission.

Microbiology

Retroviruses constitute a large and diverse family of enveloped RNA viruses that use as a replication strategy the transcription of virion RNA into linear double-stranded DNA, with subsequent integration into the host genome. The characteristic enzyme used for this process, an RNA-dependent DNA polymerase that reverses the flow of genetic information, is known as reverse transcriptase. The unique lifestyle of the retrovirus involves two forms, a DNA provirus and an RNA-containing infectious virion. Infection is initiated by the binding of a protein on the surface of the virus (gp120 Env protein) to the CD4 molecule found on some T cells, macrophages, and microglial cells. CD4 was first shown to be a viral receptor in a number of studies showing the susceptibility of CD4-bearing cells to infection and the ability to block infection with anti-CD4 monoclonal antibodies in culture.

HIV is composed of core (p18, p24, and p27) and surface (gp120 and gp 41) proteins, genomic RNA, and the reverse transcriptase enzyme surrounded by a lipid bilayer envelope. The virion contains three structural genes *(gag, pol*, and *env)* and a complex set of regulatory genes, including *tat, vif, nef, vpu*, and *ref* that control the rate of virion production. As noted, it preferentially infects cells with the CD4 antigen, particularly helper lymphocytes, but also macrophages, cells of the central

nervous system and, according to some evidence, cells of the placenta. At least two other cell surface molecules help HIV enter cells. These co-receptors for HIV, called CXCR4 and CCR5, are receptors for chemokines. Individuals who are homozygous for a deletion at the *CCR5* gene appear less likely to acquire HIV, while deletion heterozygotes progress less rapidly if infected.

Epidemiology

Approximately 25% of the 800,000 to 900,000 Americans living with HIV disease are women. Not coincidentally, the vast majority of cases of pediatric acquired immunodeficiency syndrome (AIDS) are secondary to vertical transmission of HIV from mother to fetus. Although AIDS rates are lower in women than men (9.3 per 100,000 women versus 32.4 per 100,000 men in 1999), the cumulative percentage of AIDS cases in women almost tripled from 6.7% in 1986 to 18% in 1999. Women of color constitute an increasing majority of AIDS cases in women. In 1999, African American women accounted for 63% of newly reported AIDS cases, and the case rate for Latinas (14.9 per 100,000) was more than 6 times the rate for white women. By 1998, HIV was the third leading cause of death among African American women ages 25 to 44.

The mode of acquisition of HIV in American women has evolved over time. Early in the epidemic, the majority of female AIDS cases were due to injection drug use (IDU). However, by 1995, the proportion of women infected through the heterosexual route surpassed that of IDU. As of 1999, the proportion of women who had sex with a known HIV-infected partner or an individual at high risk had increased to approximately 40%, while only 30% acknowledged using injection drugs. The proportion of women with no known risk increased to slightly greater than 30% in that same survey. Studies suggest that at least 50% of the latter individuals may have acquired HIV through heterosexual means. A report by the Centers for Disease Control and Prevention (CDC) estimates that 81% of those reporting no ascertained risk were infected via heterosexual means. Although noninjected drugs are not a direct vehicle for infection, cohort studies have revealed that much of the heterosexual risk of HIV is associated with use of drugs, such as alcohol and cocaine, which may mediate risk-taking behaviors.

Other important trends characterize the epidemic in women. For example, an increasing proportion of AIDS cases are occurring in women in the South, perhaps reflecting the dramatic increase in other sexually transmitted diseases (STDs) first seen in that region a decade ago. Poverty status might also vary with gender, with women substantially more likely to be covered by Medicaid and less likely to be privately insured. Poverty, in turn, is associated with risk behaviors (e.g., drug use) that are linked to HIV acquisition. These data demonstrate, yet again, that poverty, drug use, and STDs continue to fuel the HIV epidemic among women in the United States.

Pathophysiology

HIV infection leads to a progressive debilitation of the immune system, rendering infected individuals susceptible to opportunistic infections (e.g., *P. carinii* pneumonia and central nervous system toxoplasmosis) and neoplasias (e.g., Kaposi sarcoma) that rarely afflict patients with intact immune systems. An HIV-infected patient with one of several specific opportunistic infections, neoplasia, dementia encephalopathy, or wasting syndrome, is diagnosed as having AIDS. The diagnosis of AIDS also can be made in the absence of laboratory evidence of infection if the patient has no other known cause of immune deficiency and has the definitive diagnosis of one of a number of indicator diseases. In 1993 the CDC changed the case definition to include all individuals with HIV infection whose CD4 cell counts drop below 200 per cubic millimeter, as well as HIV-infected individuals with advanced cervical cancer, pulmonary tuberculosis, and recurrent pneumonia.

At the time of initial infection, an individual may be asymptomatic or may develop an acute mononucleosis-like syndrome that can be accompanied by aseptic meningitis. There is then an immediate viremia of substantive proportions (up to ten billion viral particles turned over per day) and an equally impressive immune responsive with similar levels of T-cell turnover. Antibodies can be detected in almost all individuals 6 to 12 weeks after exposure but, in rare circumstances, this latent period (the so-called *window phase*) can be longer. After seroconversion has occurred, an asymptomatic period of variable length usually follows. The median clinical latency in the absence of effective therapy was estimated at approximately 11 years. Very few infected persons (<5%) develop AIDS within 3 years. Evidence of immune dysfunction may be followed by clinical conditions ranging from fever, weight loss, malaise, lymphadenopathy, and central nervous system dysfunction to infections such as herpes simplex virus or oral candidiasis. These nonspecific conditions are usually progressive and are a prelude to an opportunistic infection that is diagnostic of AIDS. Studies of infected individuals have noted that 5 years after infection was confirmed, up to 35% had progressed to AIDS. A study of subjects with hemophilia demonstrated that the incidence rate of AIDS after seroconversion was 2.67 per 100 person-years and was related directly to age younger individuals developed AIDS at a slower rate). It should be noted that all these statistics antedate the use of new, more powerful antiretroviral agents, which have a significant effect on both clinical outcomes and surrogate markers of disease progression. The level of virus in the plasma can provide an estimate of the probability that an individual will develop AIDS within 5 years.

Once AIDS is diagnosed, the short-term prognosis is improving (e.g., surviving an initial episode of *P. carinii* pneumonia). The effect that the newest antiretroviral agents, including protease inhibitors (PIs), will have on survival cannot yet be clearly gauged, but they do provide reason for cautious optimism. Conversely, the long-term morbidity related to medications that have been linked to lipodystrophy, among other problems, also remains to be determined. Viral load and CD4 cell counts can be used to predict the likelihood that an individual will develop AIDS during a given follow-up period. Appropriately controlled studies reveal no convincing evidence that the natural history of HIV infection is influenced by gender or pregnancy (Fig. 19.1).

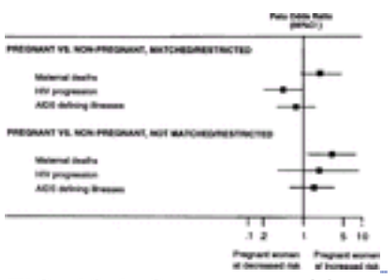

FIG. 19.1. Summary odds ratio of studies which attempted to control for confounding by matching or restriction techniques compared with those which had not used matching or restriction. (From French R, Brocklehurst P. The effect of pregnancy on survival in women infected with HIV: a systemic review of the literature and meta-analysis. Br J Obstet Gynecol 1998;105:827–835, with permission.)

Management

Monitoring The guiding principle in the care of HIV-infected pregnant women continues to be strict adherence to the standards of care that apply to all other HIV-infected individuals. The first step in that care is the monitoring of the woman's immune status with CD4 cell counts and viral load measurements. Monitoring of resistance is becoming a frequent addendum to monitoring regimes (vide infra). Viral loads can be checked every 3 months. Once a decision to initiate therapy is made, viral load monitoring should occur monthly until virus is no longer detectable and then can be cut back to every 2 or 3 months. With appropriate therapy, one can anticipate a drop of 1.5 to 2.0 logs within 1 month of initiation of treatment. The recommended timing of initiation of therapy (vís a vís CD4 cell counts and viral loads) has undergone several revisions over the last few years. Despite the clear benefits of therapy, well-recognized toxicities may make it difficult to maintain strict adherence. Some data suggest that no harm befalls patients who delay therapy until viral loads rise and CD4 cell counts drop further than had previously been recommended. Guidelines are to start therapy in nonpregnant women when the viral load is over 30,000 by HIV RNA (55,000 by polymerase chain reaction [PCR]) or when the CD4 cell count drops below 350 per cubic millimeter. In the nonpregnant state, when those thresholds are passed, highly active antiretroviral therapy (HAART) should be initiated. Initiation during pregnancy is discussed below. Resistance testing has become a staple of care for the HIV-infected woman. Most randomized trials of resistance testing have demonstrated that those assigned to study arms with access to resistance test results had a greater reduction in viral load after the initiation of salvage therapy, although follow-up generally has been short. These tests are recommended for individuals who have just seroconverted or who have failed therapy. *Treatment failure* is defined as the failure to attain an undetectable level of virus or the persistent presence of virus after it had become undetectable. Transient low-level viremia may not be the same as a drug failure, and sustained response to treatment can occur even with occasional low-level viremia. Blood for testing should be obtained before a failing regimen is discontinued lest wild-type virus overgrow before the test is performed. In that circumstance, an individual with no apparent resistance would still fail therapy when reexposed to drugs that favor the growth of the resistant virus over the wild-type strain. In essence, resistance testing is more useful for ruling out, than for ruling in, therapies to be used in a given patient. That is because, as noted, the absence of resistance may merely reflect the reemergence of a wild-type strain after an antiretroviral agent has been withdrawn. In that circumstance, the assays will not detect a low volume of a minority mutant strain. However, if the patient is reexposed to the offending agent, the resistant strain may again attain dominance. It is not possible to perform resistance studies if there are fewer than 1,000 copies of virus detectable. Two types of testing are available, genotypic and phenotypic, each with distinct advantages and disadvantages. Phenotypic testing compares the ability of the virus to replicate in various concentrations of an antiretroviral drug with its replication in the absence of the drug. In general, if the amount of drug required to inhibit viral production by 50% is four-fold or greater for the patient's virus than the control strain, then the patient's strain is considered resistant. Specific cutoffs for resistance for each drug are being developed based on clinical correlation and the serum levels usually attainable for a given drug. Measurement of drug levels per se has not yet been shown to be a useful addendum to standard monitoring. Genotypic testing is directed at detecting mutations in the genes that encode reverse transcriptase and protease formation by the virus. Point mutations in the virus result in the substitution of

amino acids in the proteins produced, namely reverse transcriptase or protease. The significance of these point mutations has to be determined by correlating specific mutations with phenotypic resistance, as measured by viral susceptibility assays and correlation with clinical response to therapy. Genotypic changes leading to resistance are believed to result from the combination of the rapid turnover of HIV (10^7–10^8 rounds of replication per day) and the high error rate of reverse transcriptase when replicating the nearly 10,000 nucleotides present in the HIV genome. Genetic mutants with resistance to antiretroviral agents are then selected by evolutionary pressure when incompletely suppressive drug regimens are used. The rate at which resistance develops will depend on the number of mutations necessary for a significant change in susceptibility to occur. The genetic basis for resistance must be understood before the impact of a specific mutation can be predicted. In addition, mutational interactions may make prediction of phenotype (i.e., susceptibility) difficult when multiple mutations are present. Prediction of cross-resistance to other drugs within a class such as protease inhibitors can be difficult to predict based only on genotype. In clinical practice, most clinicians will rely upon algorithms developed by panels of experts or found in on-line databases. Obstetricians should interpret and act upon these results in consultation with an expert in the field. It has been suggested that HIV-infected pregnant women will benefit routinely from resistance testing, but a few caveats are necessary in that regard. The goal in all cases of HIV infection in pregnancy is to maintain a viral load under 1,000, because that would both allow a vaginal delivery and minimize the mother-to-child transmission rate. However, if a regimen were successful in dropping the load to or below that level, it would be impossible to perform resistance testing. If the regimen is unsuccessful, then resistance testing is warranted, regardless of the patent's pregnancy status. That said, there are considerations that are unique to pregnancy and they relate to the fitness of resistance virus for mother-to-child transmission of HIV. In general, resistance to zidovudine (ZDV, also commonly known as AZT) and other resistance mutations have not been associated with an increased risk of perinatal transmission in most perinatal transmission studies. In one study, detection of ZDV resistance was associated with transmission when adjustment was made for duration of ruptured membranes and total lymphocyte count. Factors associated with resistance at delivery included ZDV use prior to pregnancy, higher log HIV RNA, and fewer $CD4^+$ lymphocytes present. Although perinatal transmission of resistant virus has been reported, it appears to be unusual, and it is not clear that the presence of mutations increases the risk of transmission. In a multisite study of HIV-infected pregnant women (WITS), it was reported that when a transmitting mother had a mixed viral population of wild-type and low-level resistant virus, only the wild-type virus was found in the infant, suggesting that virus with low-level ZDV resistance may be less transmissible.

Pharmaceutical Therapy Although the number of HAART regimens that have been shown to achieve persistently low viral loads continues to increase, they generally fall into one of a few broad categories. The original regimens described in 1996 included dual nucleoside therapy accompanied by a protease inhibitor. There are seven nucleoside reverse transcriptase inhibitors (NRTIs), three nonnucleoside reverse transcriptase inhibitors (NNRTIs), and six PIs approved for therapy, with many others in the pharmaceutical “pipeline,” so theoretically a large number of choices within these categories exists. However, certain medications should not be used in combination. For example, ZDV and D4T have overlapping toxicities, ddI and ddC should not be used in combination, and ddI and d4T have been linked to several fatal cases of mitochondrial toxicity in pregnancy. Because the number of new drugs continues to multiply, as does information about their benefits and toxicities, it has become increasingly difficult for busy clinicians to stay abreast. To assist in that endeavor, the U.S. Department of Health and Human Services has established a Web site (http://www.aidsinfo.nih.gov/) that is regularly updated. The expert panel that authors those update guidelines “strongly recommends” regimens that include either one or more PI(s) (indinavir, nelfinavir, ritonavir + saquinavir, ritonavir + indinavir, ritonavir + lopinavir) or an NNRTI (efavirenz in the nonpregnant patient) in combination with one of several two-NRTI combinations. There is a great deal of clinical outcome data that support the use of a PI in combination with two NRTIs. Some of the PIs, such as ritonavir, are not usually chosen as first-line therapy, because patients often have difficulty tolerating standard dosages and because of the drug's many interactions. Other PIs, such as saquinavir-SGC, create difficulties for many patients because of the large pill burden associated with their use; however, if a woman can maintain the dosage and it is working well, then there is no reason to change drugs. A critical factor to recognize is that poor results often occur with antiretroviral regimens used in a patient who has experienced virologic failure with a previous regimen. That suggests that the first regimen affords the best opportunity for long-term control of viral replication. Because the genetic barrier to resistance is greatest with PIs, many would consider a PI + two NRTIs to be the preferred initial regimen. However, efavirenz (NNRTI) + two NRTIs appears to be at least as effective as a PI + two NRTIs in suppressing plasma viremia and increasing $CD4^+$ T-cell counts, and many would prefer such a regimen initially because it may spare the toxicities of PIs for a considerable time. However, concerns about teratogenicity that have been demonstrated in animal models, as well as a case report of a myelomeningocele after in utero exposure in a human, make this a poor choice for use in early pregnancy. Thus, although the demonstrated ability of efavirenz in combination with two NRTIs to suppress viral replication and increase $CD4^+$ T-cell counts to a similar degree as a PI with two NRTIs supports a preference for efavirenz over the other available NNRTIs, in pregnancy the choice of a different NNRTI may be preferable. Abacavir, a new NRTI + two other NRTIs (i.e., a triple NRTI regimen), has been used with some success, as well. Such a regimen, however, may have short-lived efficacy when the baseline viral load is more than 100,000 copies per milliliter, and has recently been shown to be less effective than efavirenz. Using two NRTIs alone does not achieve the goal of suppressing viremia to below detectable levels as consistently as do the other regimens discussed above and should be used only if more potent treatment is not possible. Use of antiretroviral agents as monotherapy is contraindicated, except when there are no other options, or in pregnancy to reduce perinatal transmission as noted below. When initiating antiretroviral therapy, all drugs should be started simultaneously at full dosage with the following three exceptions: dosage escalation regimens are recommended for ritonavir, nevirapine and, in some cases, ritonavir plus saquinavir.

Considerations Related to HAART Therapy for Pregnant Women Although therapeutic recommendations should not be modified a priori because of pregnancy, a few comments deserve particular mention. First, in regard to the dosage of ZDV, a drug that has been a cornerstone of therapy in pregnancy since 1994, it should be remembered that the antenatal dosing regimen used in the PACTG 076 trial (100 mg administered orally 5 times daily) was selected on the basis of standard ZDV dosage for adults at the time of the study. However, administration of ZDV 3 times daily will maintain intracellular ZDV triphosphate at levels comparable with those observed with more frequent dosing. Comparable clinical response also has been observed in some clinical trials among persons receiving ZDV twice daily. Thus, the standard dosing for ZDV, whether used as a part of a HAART regimen or as single-drug therapy for transmission prevention (discussed below), is 200 mg 3 times daily, or 300 mg twice daily. Although it is possible that these dosing regimens may not have efficacy equivalent to that observed in PACTG 076, a regimen of 2- or 3-times daily is likely to enhance maternal adherence. NRTIs were the first class of drug used for treatment of HIV, and there is a greater experience with their use in pregnancy than with other classes of drug. Most information is available for ZDV, the first agent to be used widely in pregnancy. Most data regarding the safety of ZDV have been reassuring. Almost 1,000 children have been tracked for 4 years with no increase in incidence of neurodevelopmental delay or carcinogenesis. Some concern had been raised, however, as a result of mouse data reported from the National Cancer Institute. That report suggested that mice exposed to high dose rates of ZDV in the third trimester birthed pups that were subsequently found to have high rates of liver, lung, skin, and genitourinary tumors in midlife. Although other investigators have not reported similar findings, the National Cancer Institute data should chasten those who would dismiss all concerns regarding these therapies and reinforce the need for thorough counseling and long-term follow-up. In regard to monitoring of the mother on ZDV, it is necessary to measure the blood count and liver functions only on a monthly basis. The only abnormality that occurs with any frequency is anemia. Other NRTIs have been well tolerated generally and have not been demonstrated to be teratogenic in humans. However, concerns have been raised about potential adverse effects on both mothers and infants related to the avidity of these drugs for mitochondria. By binding to mitochondrial ?-DNA polymerase and interfering with replication, these drugs can induce mitochondrial dysfunction. The greatest inhibition of mitochondrial ?-DNA polymerase is demonstrated by ddC, followed in order by ddI, d4T, 3TC, ZDV, and abacavir. Clinical disorders associated with mitochondrial toxicity include neuropathy, myopathy, cardiomyopathy, pancreatitis, hepatic steatosis, and lactic acidosis. In regard to potential maternal toxicity, several cases of lactic acidosis, three of which were fatal and two of which were accompanied by pancreatitis, have been reported among pregnant or recently delivered women who had been on ddI and d4T therapy along with a variety of third agents since before conception. Two cases of fatal liver failure in pregnant women on ZDV, lamivudine, and nelfinavir also have been reported. These cases developed in late pregnancy, and in several cases the clinical picture was similar to that seen with acute fatty liver of pregnancy, a condition that has been linked to mitochondrial fatty oxidation disorders in the fetus (homozygotic) and mother (heterozygotic). This has led to speculation that the metabolic changes of late pregnancy may enhance susceptibility to complications of nucleoside agents, especially those with greater inhibition of mitochondrial ?-DNA polymerase. That susceptibility is suggested both by the syndrome of acute fatty liver of pregnancy and animal data that demonstrate reduced mitochondrial fatty acid oxidation in late pregnancy and in animals treated with exogenous estradiol and progesterone to mimic pregnancy levels. However, many cases of death outside of pregnancy have been reported related to these medications as well. In any event, although these serious morbidities appear to be rare, providers caring for HIV-infected women receiving nucleoside analog agents should be cognizant of the risk and monitor accordingly. One approach would be to monitor hepatic enzyme levels during the last trimester and to investigate aggressively all new symptoms. Women with substantial elevations in transaminase levels above baseline or other new abnormalities, in the absence of other explanations such as preeclampsia, should have their nucleoside agents discontinued, either with substitution of agents from another class of antiretroviral drugs or discontinuation of all antiretroviral medications. In view of the reports of maternal deaths and toxicity associated with prolonged use of d4T and ddI in pregnancy, this combination should be used in pregnancy with caution and only if other nucleoside agents cannot be used because of resistance or toxicity. In regard to infants, concern about mitochondrial toxicity was raised initially by a French group that reported eight cases of HIV-uninfected infants (among 1,754 exposed fetuses) with abnormalities potentially related to mitochondrial dysfunction, which developed after exposure to prophylactic nucleoside therapy. Two infants had progressive neurologic symptoms and died several months after completing in utero and neonatal courses of ZDV/3TC. Three other infants had mild to moderate symptoms, and three had asymptomatic laboratory abnormalities. Mitochondrial abnormalities were not proven to be the cause of the abnormalities, and the relationship between these findings and in utero and neonatal nucleoside exposure has not been established. In response to these concerns, investigators from several large cohort studies in the United States reviewed all 353 deaths among more than 20,000 children born to HIV-infected women and found no deaths similar to those in the French cohort, although only 6% of the children had been exposed to the combination of ZDV/3TC. Review of data on living children from these cohorts for diagnoses or conditions suggestive of mitochondrial dysfunction is ongoing. Combination therapy also has been linked to increased rates of prematurity in a few European studies, but these have not been confirmed in larger American series. Reports also have warned of an increased rate of neonatal febrile seizures in infants who had been exposed to antiretroviral therapy. Finally, as noted above, efavirenz should not be recommended because of reported teratogenic effects in monkey models. In regard to prophylaxis for opportunistic infections, if the count drops below 200 cubic millimeters, *P. carinii* pneumonia prophylaxis should be instituted, and below 50 cubic millimeters, *Mycobacterium avium* complex prophylaxis should be given and an ophthalmology consult obtained. The specific details of management of the myriad infections to which these women are prone are beyond the scope of this chapter. If HAART therapy is successful in returning CD4 cell counts to levels above the threshold for prophylaxis of opportunistic infections and those levels are maintained for 6 months, then the prophylaxis can be discontinued.

Preventing Perinatal Transmission It has been almost a decade since the results of PACTG Protocol 076 were released. Those results demonstrated that a regimen of ZDV given during pregnancy, labor, and to the newborn for 6 weeks was able to reduce remarkably the risk of perinatal HIV transmission; an almost 70% reduction in transmission risk was observed, from 25% in the placebo group to 8% in the ZDV group. Subsequently, ACTG 185 demonstrated that similar results could be seen, even among women who had previous exposure to ZDV or who had CD4 cell counts below 200 cubic millimeters. ZDV has now been integrated successfully into clinical practice in the United States and Europe, and its widespread use has been accompanied by dramatic declines in perinatal transmission rates in these countries. The regimen consists of ZDV 200 mg 3 times a day in the antepartum period (beginning after 14 weeks). In the intrapartum period, a loading dose of 2 milligrams per kilogram over the first hour is followed by a maintenance dose of 1 milligram per kilogram per hour thereafter. During the neonatal period the infant receives ZDV syrup

for 6 weeks at a dosage of 2 milligrams per kilogram every 6 hours. There are insufficient data to justify the substitution of any agent for ZDV in most circumstances, save perhaps for times when women have not received therapy prior to labor (vide infra). Even if there is evidence of ZDV resistance, which might make ZDV therapy for the prevention of mother-to-child transmission seem futile, ZDV might still have a role. The demonstration of transmission of escape mutants from mother to child suggests that an individual ZDV-susceptible virus might be transmitted, even if the predominant strain(s) in the mother is (are) not susceptible. If the mother is intolerant of ZDV, it may be reasonable to consider using an alternative agent, which potentially could reduce viral load during the antepartum period, and then adding ZDV for the intrapartum (depending on the type of toxicity experienced by the mother) and neonatal periods. Thus, if the therapeutic regimen being used to treat a woman's HIV disease does not include ZDV, it would seem judicious to incorporate it if she becomes pregnant. The recommendation to use ZDV, as opposed to other antiretroviral agents, for the prevention of mother-to-child transmission of HIV is based on two considerations. First, there are empiric data that strongly support its use in that regard. No other agent has been studied similarly. Second, pharmacokinetic studies demonstrate that high levels of drug are available in the fetal compartment. Similar information is unavailable for most other agents. The importance of placental passage of drug is not certain. If viral load thresholds truly are central to transmission risk, than viral dynamics on the maternal side of the placenta might be as important as placental passage of drug. Several publications (Fig. 19.2) suggest that a correlation exists between maternal viral load and rates of mother-to-child HIV transmission and, further, hint at the existence of a clinically relevant threshold. Although other researchers disagree, most data support the thesis that dropping viral loads as low as possible in pregnancy is a useful strategy. There is clear evidence that, even if the viral load is low, those women on antiretroviral therapy will fare better than women with similar viral loads who are not on therapy, and data suggest that combination therapy is even more effective than ZDV alone in reducing rates of transmission. A French team reported that adding 3TC to ZDV reduced transmission rates to 1.6%. A longitudinal study in the United States found that 20% of women with no antiretroviral therapy transmitted HIV to their infant as compared with 10.4% who received ZDV alone, 3.8% who received combination therapy without a PI, and 1.2% who received a combination that included a PI.

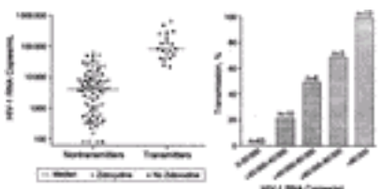

FIG. 19.2. Left: Maternal human immunodeficiency virus–type 1 (HIV-1) RNA levels at delivery in infected nontransmitting and transmitting mothers. Mothers who received zidovudine during gestation or labor and delivery are indicated by the *open circles;* mothers who did not receive zidovudine during gestation, labor, or delivery are indicated by the *darkened circles. Horizontal bars* indicate the median for each of the measured variables. **Right:** Perinatal transmission rate according to HIV-1 RNA levels at delivery. (From Dickover RE, Garratty EM, Herman SA, et al. Identification of levels of maternal HIV-1 RNA associated with risk of perinatal transmission. JAMA 1996;275:599–605, with permission.)

The vast majority of perinatal HIV-1 infection occurs in the developing world. Unfortunately the PACTG 076 ZDV regimen is too costly and logistically complex for many nonindustrialized countries to implement on a widespread scale, and its efficacy in a breast-feeding population (where postpartum transmission remains a real concern) is unknown. An ideal preventive intervention would be cheap, nontoxic to mother and fetus, easy to administer, only need to be given once or for a limited period, and have utility in preventing postpartum transmission. The results of PACTG 076 have spurred the worldwide evaluation of multiple other modalities to reduce transmission. Many of the regimens designed for countries with fewer resources have attempted to achieve reduced numbers of infected children with shortened courses of antepartum and neonatal therapy. These regimens have included a Thai regimen of 4 weeks of antepartum ZDV combined with oral ZDV therapy during labor that reduced transmission to 9% compared with 19% in a placebo arm. Similar findings have been reported from the use of an abbreviated course of ZDV and 3TC in an African trial. An even more dramatic finding emerged from the HIVNET 012 trial which revealed that a single does of nevirapine during labor and again to the neonate could reduce transmission at 6 weeks from the 21% seen in those receiving a short course of ZDV to only 12%. Unfortunately, the benefits of all these regimens are attenuated in populations that breast-feed after the regimens have been completed. Perhaps of greater relevance to American populations are data that demonstrate that even patients whose serologic status is unknown until the peripartum period may benefit from pharmaceutical interventions. In a review of the New York state experience, Wade and colleagues found that the transmission rate from mothers who received no therapy was lowered significantly with ZDV even when therapy was delayed until the first 24 hours postpartum. It was lowered to an even greater extent when therapy was begun during the intrapartum period. Other efforts to prevent transmission have focused on attempts to reduce peripartum and postpartum exposure to the virus. Reduction of intrapartum exposure could include attempts to minimize the duration of ruptured membranes, which has been related to the rate of mother-to-child transmission of HIV (Fig. 19.3). Cesarean delivery is the one strategy that can guarantee that the infant will not be exposed to the risks associated with ruptured membranes during parturition. Evidence has accumulated that cesarean section may be a beneficial addendum to pharmaceutical therapy. Read and her colleagues published a meta-analysis performed on primary data from 15 prospective cohort studies, including more than 7,800 mother-child pairs. In that meta-analysis, the rate of perinatal HIV-1 transmission in women undergoing elective cesarean delivery was 8.2% and 2.0% in those receiving no antiretroviral agents and in those receiving ZDV, respectively. Both rates were significantly lower than those seen among women delivered by either nonelective cesarean or vaginal delivery.

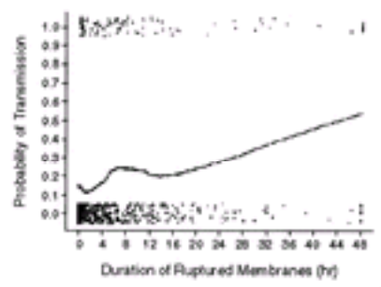

FIG. 19.3. Probability of HIV-1 transmission in relation to the duration of ruptured membranes. The *dots* at the top represent women who transmitted HIV-1 to their infants and those at the bottom, women who did not transmit. (From Landesman S, Kalish L, Burns D, et al. The relationship of obstetrical factors to the mother-to-child transmission of HIV-1. N Engl J Med 1996;334:1617–1623, with permission.)

Subsequently, the results of a European randomized trial of cesarean section were reported (Table 19.1). The results were remarkably consistent with those that had been found by Read. In the European study, HIV-infected women between 34 and 36 weeks of gestation were randomly assigned elective cesarean delivery at 38 weeks or vaginal delivery. Three (1.8%) of 170 babies born to women assigned cesarean delivery were infected compared with 21 (10.5%) of 200 born to women assigned to vaginal delivery ($P < .001$). Seven (3.5%) of 203 infants of women who gave birth by cesarean section were infected compared with 17 (10.2%) of 167 born vaginally ($P = .009$). Unfortunately, the number of participants was too small to allow a separate analysis of the benefit of cesarean section for a patient receiving antiretroviral therapy, and HAART use was not reported from the cohort. There were few postpartum complications, and no serious morbidity was noted in either group. Despite the shortcomings of the trial, it does suggest that among women who were not optimally treated with HAART, cesarean section could have an important effect on reducing rates of mother-to-child transmission of HIV.

TABLE 19.1. *HIV-1 infection status of children according to allocated and actual mode of delivery*

In sum, the above-cited studies indicate that compared with other types of delivery, cesarean delivery performed prior to the onset of labor and prior to rupture of membranes (elective, or scheduled, cesarean) significantly reduces the rate of perinatal HIV-1 transmission by odds ratios of 0.2 to 0.4. On the basis of the data, the American College of Obstetricians and Gynecologists published a committee opinion that concluded that HIV-infected women should be offered scheduled cesarean section in order to reduce the rate of transmission beyond that which could be achieved with ZDV alone. They also pointed out that data are insufficient to demonstrate a benefit for women with viral loads less than 1,000 copies per milliliter of plasma. They suggested that scheduled cesarean sections should be performed at 38 weeks of gestation and that amniocentesis should not be performed in order to avoid contamination of the amniotic cavity with viral antigen from maternal blood. They also suggested that prophylactic antibiotics be employed because of concerns of heightened risks of postoperative infectious morbidity. The data supporting a heightened risk for postoperative morbidity among HIV-infected women are not robust; however, the evidence that all women undergoing an operative delivery face a greater risk of infectious morbidity is overwhelming. The liberal use of antibiotics in the setting of cesarean section and HIV infection would, therefore, seem reasonable. Although not as compelling as the data just cited, there is some evidence that cesarean section could be beneficial even when viral loads are under 1,000 copies. That data come from a meta-analysis of studies that focused exclusively on women who had viral loads lower than 1,000 copies. In those women, antiretroviral therapy still played a major role in reducing transmission, dropping rates from approximately 10% to approximately 1%. Cesarean section apparently dropped the rate from 6% to 1.5%, but there was no control in that analysis for the use of antiretroviral therapy. In sum, there is no strong evidence that cesarean section will provide additional benefit to the HIV-infected woman on therapy who has an undetectable viral load.

TOXOPLASMA

Introduction

Primary maternal toxoplasmosis occurs in approximately 1 of every 900 pregnancies in the United States. This estimate is based on a prospective study of sera from 23,000 pregnant women done in early and late gestation. That study, which was conducted by the National Institutes of Health, also showed that 38% of the women tested had antibodies to *Toxoplasma gondii*, indicating previous infection with the organism. More recent data suggest that the seroprevalence may now be somewhat lower (15% among women of childbearing age). In the earlier data, the presence of antibodies correlated with increasing patient age and was twice as frequent among blacks as among whites. None of the mothers tested had evidence of significant clinical disease. It has been estimated that between 400 and 4,000 babies are born with congenital *T. gondii* infections each year. Some data suggest that congenital infections occur in approximately 1 in 10,000 births.

Microbiology: Transmission

Cats The cat is the definitive host for *T. gondii*, a protozoan parasite. About one half of the cats tested in the United States have antibodies to *T. gondii.* It is thought that cats acquire infection by eating infected wild rodents and birds. A week after infection, the cat begins to shed oocysts in its feces. Shedding of the oocysts persists for about 2 weeks before the cat recovers spontaneously. These animals are susceptible to reinfection and may also shed toxoplasma oocysts when infected with other organisms. Although the cats excrete unsporulated (i.e., noninfectious) oocysts in their feces, within days to weeks these oocysts sporulate and become extremely infectious. The fecal oocysts are an important source of infection to humans through inadvertent ingestion. Because sporulation of the organism occurs after days to weeks in the litter, it may be prevented by having a nonpregnant person change the litter daily. Care must be taken in disposing of cat litter, because the oocysts can remain infectious for long periods in favorable climates.
Meat In Europe, where the use of refrigeration is more limited and meat usually is not frozen, ingestion of infected meat is an important cause of toxoplasmosis. In contrast, in the United States, much of the meat is frozen at some point during storage or transport. Freezing is probably one of the factors responsible for the difference in incidence of toxoplasmosis here and in Europe. Worldwide, about 1% of cattle, 20% of hogs, and 30% of sheep have toxoplasmosis, according to estimates based on isolation of the organism from animal muscle tissue. To avoid contagion from meat, it should be cooked thoroughly at adequate temperatures.

Epidemiology

T. gondii has a worldwide distribution and has been reported from wherever cats are found. It is somewhat more common in tropical and coastal regions and is less common in regions that are either cold, warm and arid, or at high elevation. The infection rate in the United States is significantly lower than that in France. Within the United States, seroprevalence rates are lower in the west central and mountain states, and higher in east Atlantic and east central states.

Pathophysiology

T. gondii exists in three forms: trophozoites or proliferative form (Fig. 19.4), tissue cysts, and the oocytes. The organism undergoes a substantial portion of its life cycle in the cat where, after between 5 and 8 days of infection, there is peak oocyte production. As many as ten million oocysts per day can be shed in feces for periods varying between 7 and 20 days. These oocytes sporulate within 1 to 3 days and can remain infectious for several months in moist soil. At that point they may be carried from point of deposition by other animals (e.g., flies) and deposited in food. It has also been suggested that they can also become airborne from a dried out litter box and lead to human infection. Eating undercooked or raw meat that contains tissue cysts causes approximately one half of infections in most humans. In the human, the trophozoite form of *T. gondii* is seen in the acute phase of the infection, and it is during this phase that host cells are invaded. Thereafter, the organism multiplies every 4 to 6 hours until the cytoplasm becomes so filled with trophozoites that the cells rupture, releasing organisms to invade other cells.

FIG. 19.4. *T. gondii* in trophozoites or proliferative form. (From Jones JL, Lopez A, Wilson M, et al. Congenital toxoplasmosis: a review. Obstet Gynecol Surv 2001;50:296–305, with permission.)

In Utero Transmission Newborns with congenital toxoplasmosis become infected in utero by transplacental passage of the parasite when the mother has acute infection. Chronic infections (onset precedes pregnancy) do not lead to congenital infection except in the rare circumstance of an immunocompromised host (e.g., patient with systemic lupus erythematosus taking steroids, HIV disease). In general, the likelihood of fetal infection increases with each trimester of pregnancy, being approximately 15%, 25%, and 60% in the first, second, and third trimester, respectively. The severity of damage associated with congenital toxoplasmosis also is related to the timing of maternal infection, but in this situation, the risks decrease toward term. Severe fetal disease or fetal death occurs in about 10% of cases when infection occurs during the first trimester and is extremely rare with infection during the third trimester. Mild damage is more frequent in the second and third trimesters (about 5%). Subclinical infections increase from about 2% with first-trimester infections to 50% with third-trimester infections. The results of a case-control study of women with poor pregnancy outcomes and controls suggested that acute infection could be associated with preterm delivery and stillbirth but not with spontaneous abortion. Chronic infections were not associated with any untoward outcomes.

Diagnosis in Pregnancy

Mother Maternal infection with *T. gondii* is usually asymptomatic, although 10% to 20% of infected mothers have lymphadenopathy. Posterior cervical lymphadenopathy is the most frequent finding associated with acute maternal toxoplasmosis. The infection also can result in a mononucleosis-like syndrome with fatigue and lassitude and, rarely, can cause encephalitis. Acute toxoplasmosis should be considered in any pregnant woman who has lymphadenopathy, particularly involving the posterior cervical chain, or mononucleosis-like symptoms. The vast majority, however, of those acutely infected with *T. gondii* are asymptomatic. The clinical picture can be much more severe in immunocompromised adults. In the absence of symptoms, clinicians are forced to rely on serologic tools for the diagnosis of toxoplasmosis in pregnancy. The diagnosis of primary infection with *T. gondii* during pregnancy requires either (a) the demonstration of a seroconversion to this organism, (b) a significant rise in antibody titer obtained from maternal sera taken at two different times, or (c) the detection of toxoplasma-specific immunoglobulin M (IgM) antibody. Adults with primary infection develop immunoglobulin G (IgG) and IgM antibody to toxoplasma rapidly. Toxoplasma-specific IgG antibody develops within 2 weeks after infection, peaks in 6 to 8 weeks, drops down over the subsequent several months, and then persists for life. Toxoplasma-specific IgM develops within 10 days after infection and remains elevated for 6 months to more than 6 years. Some researchers have suggested that the presence of high-avidity IgG antibodies exclude acute infection within the previous 3 months, thereby making it a useful test for first-trimester infection. Because IgM antibody remains elevated for many months, this test may not provide useful information to document recent primary infection in pregnant women. The enzyme-linked immunosorbent assay (ELISA) test for IgM frequently shows the development of high titers of antibody that can persist for many years. Indirect immunofluorescence antibody (IFA) tests for toxoplasma-specific IgM usually show high titers for only about 6 months after infection, following which the titer rapidly drops. The IFA test, then, frequently is more useful than ELISA in differentiating remote from recent primary infection of a pregnant woman. In any case, the presence of IgG and the absence of IgM suggest an infection that is probably at least a year old. Because of difficulties with the reliability of some commercially available tests for IgM, it has been recommended that all positive test results be confirmed in a reference laboratory. Approximately 50% of placentas of congenitally infected infants will show *T. gondii* cysts on histologic slides, and their presence supports the diagnosis of acute infection in the mother during pregnancy. Additional cases can be detected by the presence of parasites in the cord blood. The organism also has been isolated from placental tissue of acutely infected mothers in 2% to 25% of cases. Recovery was more frequent when infection occurred later in pregnancy. Isolation of organisms from tissue specimens, buffy coat heparinized blood, and body fluids can be used, also, for diagnosis. These specimens produce the organism after inoculation into the intraperitoneal cavities of mice or into tissue culture.
Prenatal Diagnosis Antenatal diagnosis of fetal toxoplasmosis used to rely on culture of amniotic fluid (15–20 cc) or fetal blood (1.5–3.0 cc) obtained at the time of diagnostic amniocentesis or cordocentesis, respectively. The specimen was cultured commonly in mice or fibroblast cells. The main difficulties with culture techniques have been that some assays may take up to several weeks to get complete results, and very few laboratories are able to perform the assay. Toxoplasma-specific IgM, when present in fetal blood from cordocentesis, has also been used to diagnose fetal infection prenatally. Unfortunately, fetal-specific IgM antibody frequently does not develop until after 21 to 24 weeks gestation and is positive in only about 50% of infected cases. Additionally, cordocentesis is a procedure that entails some risk. More recently, the PCR has been used to detect *T. gondii* in amniotic fluid and has been shown to be useful in the detection of fetal infections in utero. In one large series, PCR performed better than conventional tests (sensitivity 97.4% versus 89.5%; negative predictive value 99.7% versus 98.7%). PCR of amniotic fluid has, to a large extent, rendered cordocentesis obsolete for the purpose of diagnosing toxoplasma infections.
Child Most congenitally infected newborns are asymptomatic at birth. Literature has shown that detection of toxoplasma-specific immunoglobulin A (IgA) may be a reliable method for the diagnosis of toxoplasmosis in the newborn. A number of these asymptomatic, untreated infants will go on to have delayed and potentially serious manifestations. The 20% with clinically obvious symptoms at birth will exhibit multiple findings. The most frequent clinical findings are chorioretinitis, jaundice, fever, and hepatosplenomegaly. Hydrocephaly or microcephaly and cerebral calcifications can be seen in severe cases. Demonstration of toxoplasma-specific IgM infection may be diagnostic, although in newborns, approximately 20% of infections are not detectable by toxoplasma-specific IgM at birth.

Treatment and Prevention

Treatment of acute toxoplasmosis is primarily supportive. The prognosis, in general, following acute infection is good, except in cases of profound immunosuppression.

The treatment in pregnancy is a bit more complex. In Europe, where the seroprevalence and, hence, the clinical experience is greater, spiramycin is the first-line agent used. However, that agent generally does not cross the placenta, and if fetal infection is detected, women are also treated with a combination of pyrimethamine, folinic acid, and a sulfonamide. Although not definitive, treatment with these regimens may prevent maternal-to-fetal transmission of the infection or improve the outcome among infected fetuses. In one study from France, 163 mothers diagnosed with toxoplasmosis prior to 28 weeks were treated with spiramycin (23 also received pyrithiamine and sulfadiazine). Three fetuses died in utero and 27 were diagnosed with congenital toxoplasmosis. All 27 were free from symptoms and had normal neurologic development at 15 to 71 months. Most studies that control for gestational age at the time of infection suggest that transmission rates are not altered markedly by therapy, but the degree of fetal sequelae may be.

The standard dosage is 25 mg of pyrimethamine by mouth given daily and 1 g of sulfadiazine by mouth 4 times daily for 1 year. Pyrimethamine is a folic acid antagonist and, therefore, may have teratogenic effects when given in the first trimester. Whenever possible, treatment with pyrimethamine in the first trimester should be weighed against potential risk of drug teratogenicity to the infant. Folinic acid, 6 milligrams given intramuscularly or by mouth every other day, should be used to correct the depletion of folic acid induced by pyrimethamine.

Spiramycin can be obtained in the United States through the CDC. It is used more commonly in Europe and, hence, there are no good controlled studies of its efficacy in this country. It has not been found to be teratogenic in humans or animals.

Case-control studies in France, where women routinely receive serial assessments to detect seroconversion, have revealed that risk factors for acquisition of infection include poor hand washing, eating undercooked beef or lamb, and owning a pet cat. Based on these sorts of data, the CDC has recommended that sero-susceptible pregnant women should be counseled to avoid eating raw or undercooked meats that may contain the *T. gondii* cysts. This can be accomplished by using a food thermometer to ensure that the meat is cooked all the way through. Fruits and vegetables should be peeled and washed before eating. Gloves should be used for gardening and during any contact with soil or sand, because cat waste might be found there. Pregnant women should avoid close contact with cat feces, such as changing cat litter. CDC also highlighted the need for obstetricians to educate their pregnant patients about these important preventive steps.

In countries such as France, with extremely high seroprevalence rates, routine serologic screening programs have proven successful in diagnosing recent seroconverters, allowing for prenatal diagnosis of fetal status and either termination of pregnancy or prenatal therapy. There is no consensus for routine screening in the United States. Because of the low prevalence of the disease and the possibility of false-positive results, the American College of Obstetricians and Gynecologists does not recommend routine screening.

Most recently, programs have been undertaken that focus on screening of newborns and the institution of treatment during the neonatal period to minimize the morbidity that would otherwise accrue to congenitally infected children. Many infections in children, that otherwise would be missed on routine clinical examination, can be detected with IgM assays. Treatment of these infected infants has been associated with very low rates of subsequent neurologic or retinal disease.

CYTOMEGALOVIRUS

Introduction

CMV, a member of the herpes virus family, is the largest virus to infect humans. It can code for over 200 proteins, through which it can lead to substantial down-regulation of the immune system and many diseases, such as infectious mononucleosis in young adults. It also causes the most common congenital viral infection, affecting approximately 1% of all live births, about 35,000 infants annually in this country. Congenital CMV infection is acquired by the fetus in utero when the mother develops primary CMV infection while pregnant or with reactivation of a prior maternal infection. Although reactivated disease in the pregnant woman accounts for more than one half of the congenital infections, primary maternal CMV infection is much more likely to result in a severely affected and symptomatic infant. Passive in utero transfer of maternally derived CMV-specific IgG antibody appears to provide some protection to the fetus when CMV is reactivated during pregnancy.

The great majority of infants with congenital CMV are asymptomatic (90%), but some have evidence of disease during the newborn period (10%). About 10% of the symptomatic group have full-blown cytomegalic inclusion disease. An additional 10% of infected infants who are asymptomatic at birth later develop symptoms related to CMV infection. The most common late-onset symptoms in these cases are mental retardation and deafness. These infants usually shed high titers of virus in the urine and saliva for a number of months.

CMV infections can be acquired by the child during the postpartum period through (a) exposure of the infant to infectious maternal body fluids such as cervical secretions, urine, saliva, and breast milk, (b) following blood transfusion or tissue transplantation from an infected donor, or (c) most frequently, through contact with infected individuals, such as in the newborn nursery, day care centers, or from other family members in the household. These cases are called acquired CMV infections, in contrast to congenital infections.

Microbiology

Cytomegaloviruses are members of the herpes virus group. The virus has a diameter of about 180 nanomeres and is encapsulated by an icosahedral capsid containing 162 capsomeres. Within the capsid is double-stranded DNA of about 230 kilobases that is enclosed by a lipid bilayer envelope. The diagnosis of CMV requires laboratory confirmation and cannot be made on clinical grounds alone. Seroconversion, monoclonal antibody, and PCR are among the tools available for diagnosis.

Antibody response (whether maternal or fetal) may play a less important role in transmission and, subsequently, in the development of symptomatic disease than other viral factors, such as the amount of maternal viremia or the timing in pregnancy during which infection and subsequent maternal-to-fetal transmission occurs.

Epidemiology

Seroprevalence of CMV among adult populations shows significant geographic variability. Rates range from 40% to 100% depending on the region surveyed, with most infections being detected solely by serologic screening (i.e., asymptomatic). Countries or regions with low socioeconomic status usually demonstrate very high seroprevalence rates. The risk of seroconversion during pregnancy for a seronegative woman is approximately 2%. However, because congenital infections can follow either primary disease (maternal seroconversion) or reactivation of disease, congenital infections may occur in a much higher percentage of cases. There are two periods in life when infection rates are particularly high-perinatal (related to mother-to-child transmission, breast-feeding, and child-to-child) and reproductive age (putatively related to sexual transmission).

Pregnant women acquire CMV infection either through exposure to infected children (the infected children shed virus in urine, saliva, and nasopharyngeal secretions and are infectious for a prolonged period) or through sexual contact. About 1% to 2% of American women shed CMV from their cervix at any given time, although that number is higher in women with multiple sexual partners.

Pathophysiology

Following primary infection, the virus goes into a latent phase. Intermittent periods of reactivation frequently occur, and virus is again excreted in the nasopharynx, cervix, urine, saliva, and breast milk. Maternal viral shedding increases throughout pregnancy, and neonatal infection becomes increasingly likely as cervical shedding rates increase toward term.

Acquisition of disease by neonates at the time of birth is much more common than congenital infection, but much less devastating. The former types of infection come from CMV carried in the cervix during the late stages of pregnancy and from CMV in breast milk. After primary infection during the prenatal period, the congenital infection rate has been reported to be as high as 55%. Although the great majority of infants with congenital CMV are asymptomatic, infants with symptomatic infection at birth usually have findings associated primarily with the reticuloendothelial and central nervous systems. The severe cases of congenitally acquired symptomatic infection result from primary rather than recurrent infection in the pregnant woman and from infections occurring early in pregnancy. The most common findings in these cases include hepatosplenomegaly, jaundice, a generalized petechial rash, and microcephaly. Less common findings include chorioretinitis with or without optic atrophy, pneumonitis, cerebral calcifications, microphthalmia, microcephaly, seizures, and cerebral and cerebellar atrophy. The mortality of newborns with symptomatic disease is approximately 30%.

Diagnosis

Mother The great majority of primary maternal infections with CMV are asymptomatic and unrecognized. When symptoms do occur, they may go unrecognized because they appear as a mild, infectious, mononucleosis-like illness, with lymphadenopathy, fatigue, and slight fever. Even though CMV is hepatotropic, elevations in liver enzyme levels rarely are seen in primary or recurrent infections. About one third to two thirds of all pregnant women have IgG antibodies to CMV, indicating previous infection. Detection of CMV-specific IgM during the acute phase of infection is useful for making the diagnosis of CMV infection, but only 80% of women with primary infection demonstrate this antibody. In addition, more than a third of mothers with recurrent CMV from latent infection will be positive for CMV-specific IgM. CMV-specific IgM antibodies may persist from 4 to 9 months, and some test methods may give false-positive results because of cross-reactions with other herpes viruses, antinuclear antibody, or rheumatoid factor. A microneutralization assay may be of some utility. In one study, the antibodies did not appear until 15 weeks after infection and persisted thereafter. Thus its absence, shortly after a presumed infection, can help to rule out infection. Viral culture is the gold standard for the diagnosis of CMV infection. Virus usually is detected in the cervix, nasopharynx, and urine of infected individuals. However, culture results are positive with both primary and recurrent infections. PCR has also proven to be quite useful in the detection of CMV. Quantitative PCR testing has proven particularly useful in the management of AIDS and transplant in patients whose high serum levels augur complications, and it offers an early opportunity for the initiation of antiviral therapy.
Prenatal Sonography may be useful for identifying some abnormalities in the fetus that may be related to CMV infection. Nonspecific sonographic findings of fetal hydrops, intrauterine growth retardation, polyhydramnios, fetal ascites, and specific central nervous system anomalies (e.g., ventriculomegaly, periventricular calcifications) suggest an intrauterine infection, possibly CMV, and should be evaluated further with amniocentesis or cord blood sampling. Lynch and others reported the successful prenatal diagnosis of fetal infection by a combination of amniotic fluid culture and measurement of total and CMV-specific IgM and ?-glutamyl transpeptidase in fetal blood samples. In a study of 189 pregnancies with known outcome, Enders and colleagues reported 89.5% sensitivity with the use of amniotic fluid and fetal blood assessments for virus and anti-CMV IgM. They noted that the correct diagnosis of in utero infection with CMV by amniotic fluid analysis could be expected after 21 weeks of gestation and at least 6 weeks after the diagnosis of infection in the mother. Other authors have reported similar sensitivities and have pointed out that those instances of false-negative results often are associated with infants with minimal stigmata of disease. Further studies are needed on the sensitivity and specificity of these methods in identifying infected infants prior to birth. The definitive diagnosis is best made through the detection of viruria during the first week of life. The presence of IgM antibodies in cord serum is suggestive but not sufficiently specific to make a definitive diagnosis.

Management

Mother Susceptible pregnant women have a 2% risk of seroconverting while pregnant. Because this is a relatively low risk of infection and there is a somewhat low rate of possible damage to the fetus, and because no effective therapy is available to infected infants, routine serologic testing of pregnant women generally is not recommended. Probably the single most important method of preventing primary infection during pregnancy is minimizing exposure in high-risk areas, such as nurseries, day care centers, and other places that have a high concentration of young children. Careful hand-washing techniques, as well as proper handling of potentially infectious body fluids, should be instituted to minimize spread of the infection. There are no protocols for the use of antiviral agents (acyclovir and ganciclovir) during pregnancy to decrease the risk of mother-to-child transmission of CMV. It is hoped that a vaccine ultimately will be developed that will prevent CMV. Some authors have suggested that in order to target both mothers most likely to transmit to infants and those most likely to transmit to pregnant women, that young unmarried mothers and all toddlers and preteen children should be considered for vaccination.
Infant Clinically evident infection in newborns and infants is treated symptomatically. In the most severe cases of neonatal infection, antiviral agents such as acyclovir and ganciclovir have been used to suppress the infection, but discontinuation of the medication results in reappearance of the infection. Foscarnet (phosphonoformic acid) has been used in primary symptomatic neonatal disease and has been effective in reducing viral shedding.

HERPES SIMPLEX VIRUS

Introduction

Herpes simplex virus (HSV) causes an extremely common STD with potentially devastating consequences for the perinatally infected neonate. It also is the cause of more calls to the national STD hotline than any other STD. Management of these infections in pregnancy has undergone substantive evolution over the last decades, reducing reliance on operative delivery.

Microbiology

HSV is an encapsulated double-stranded DNA virus that infects susceptible mucosal surfaces. The DNA-containing core is surrounded by an envelope that contains viral proteins that are important for attachment to host cell receptors, cell penetration, and immune escape mechanisms. There is approximately a 50% homology in the DNA sequences of HSV type 1 (HSV-1) and HSV type 2 (HSV-2), the latter being predominantly genital and the former predominantly oral. Either virus can cause serious illness in the neonate. Immunity to one virus may lead to an attenuated illness if an individual becomes infected with the other.

Epidemiology

Whereas only approximately 5% of the reproductive-age population gives a history of clinical herpes infections, serologic surveys suggest that up to 20% of the sexually active population has had genital herpes. That represents a 30% rise in the age-adjusted risk since the late 1970s. The National Health and Nutrition Evaluation Survey revealed that slightly over 25% of women are seropositive for HSV-2 (Fig. 19.5). A large majority of those individuals who are seropositive will shed virus intermittently for many years after the initial infection. The rate of shedding does not vary significantly between those with and those without a history of genital herpes. The reason that most seropositive women are unaware of their status may be related to the presence of antibody to HSV-1 that offers sufficient protection from HSV-2 to mute any symptoms. However, with proper education a large percentage of women can be trained to recognize recurrences. The infection is transmitted from both symptomatic and asymptomatic individuals, with the latter being the cause of the majority of new infections. Transmission seems to occur with greater facility from men to women. However, condoms seem to be more effective in preventing transmission from men to women than from women to men. There is little evidence to suggest that pregnancy, in itself, increases either the frequency or the severity of genital HSV infections. In one study, in an unselected patient population, HSV shedding occurred in only 0.1% to 0.4% of all deliveries. In other studies of pregnant women with histories of HSV, positive culture results have been found in 0.2% to 7.4% of asymptomatic women. It has been estimated that if PCR is used in lieu of cultures, shedding would be detected about 8 times as frequently. The rate of shedding at term is no higher than at other times in pregnancy. Unfortunately, from the therapeutic perspective, most women who shed viruses are not aware that they are shedding or that they are seropositive for HSV.

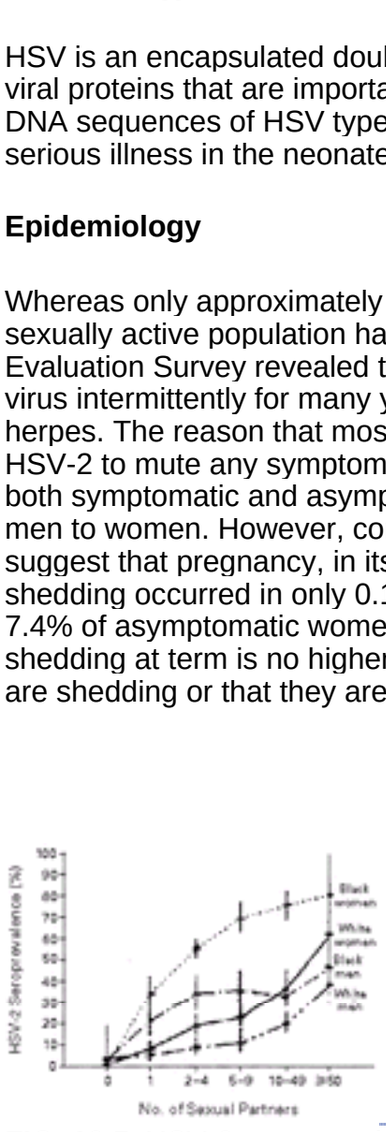

FIG. 19.5. HSV-2 seroprevalence according to the lifetime number of sexual partners, adjusted for age, for black and white men and women in National Health and Nutrition Evaluation Survey (1988–1994). *Bars* indicate 95% confidence intervals. (From Fleming DT, McQuillan GM, Johnson RE, et al. Herpes simplex virus type 2 in the United States, 1976–1994. *N Engl J Med* 1997;337:1105–1111, with permission.)

Pathophysiology

HSV has an incubation period of 2 to 10 days, followed by a primary infection that is characterized by focal vesicle formation and a pronounced cellular immune response. The infection enters a latent phase, with the virus ascending peripheral sensory nerves and coming to rest in nerve root ganglia. Recurrent exacerbations occur intermittently, stimulated by poorly understood mechanisms. Infection may be primary, with a 2- to 3-week course; recurrent, with a 5- to 10-day course; or asymptomatic. Primary infection poses the greatest risk to both mother and infant. Clinically it is extremely difficult to distinguish primary from recurrent disease. Fifty percent of infants born vaginally to mothers with a primary infection will themselves have HSV infection, compared with only 4% of those born to mothers with recurrent infection. Primary infection also may be associated with abortion, low birth weight, preterm birth and, rarely, congenital infection, although less commonly than was once thought. As expected, viral shedding occurs for a significantly longer period with primary infection (1–2 weeks) than with recurrent infection (3–6 days).

Antibodies appear approximately 7 days following the onset of primary infection, reaching a peak in 2 to 3 weeks, and generally remain detectable for life. Titers do not rise significantly with recurrent infections. The significant difference in infection rates in neonates born to mothers with primary infections (50%) versus those born to women with recurrent infections (4%) suggests that maternal antibodies provide some protection. With recurrent infection, the infection rate has been estimated to range from zero to 8% when virus is present at the time of vaginal delivery.

Fortunately, disseminated primary HSV infections in pregnant women are rare. When these infections become disseminated during pregnancy, mortality is high for both the mother and fetus, and systemic antiviral therapy is recommended.

Although HSV shedding occurs in approximately 0.1% to 0.4% of deliveries, the frequency of neonatal infection is actually much lower, occurring in approximately 0.01% to 0.4% of deliveries. The reason for this 10-fold difference in infection between mother and newborn is unknown but probably is related to both a protective benefit of maternal antibodies and to the size of the viral inoculum to which the fetus is exposed during birth. The viral inoculum associated with asymptomatic shedding is several logs less than that associated with primary infection. Because of the inability to mount a timely immune response, maternal seroconversion around the time of delivery may be particularly likely to result in an infected neonate.

Neonatal infection may result from either HSV-1 or HSV-2. The majority of cases of neonatal HSV infections, however, are caused by HSV-2, with approximately 76% of isolates from infected neonates being HSV-2. It is estimated that approximately 90% of cases of neonatal HSV infections can be traced to a maternal source of infection and are secondary to either ascending infection with ruptured membranes or to colonization during the actual birth process.

As noted, approximately 50% of mothers delivering vaginally with a primary genital HSV infection will give birth to an infant with HSV infection. Of these infected neonates, 60% will die during the neonatal period. Of equal concern is that approximately 50% of the survivors will have significant sequelae, such as microcephaly, mental retardation, seizures, microphthalmia, retinal dysplasia, chorioretinitis, meningitis, encephalitis, hypertonicity, apnea, and coma. Although less common, the neonate may also acquire infection from exposure during the neonatal period from either or both parents or from other family members, from other infected infants, or from infected health care workers.

Although there have been isolated reports of “congenitally infected” fetuses with malformations, other investigators have found no such associations. Congenital infections have been defined by the presence of skin vesicles or scarring, chorioretinitis, hydranencephaly, microphthalmia, microcephaly, or an abnormal CT scan of the brain within the first week of life.

Diagnosis

The diagnosis of primary infection is relatively easy to make from a clinical standpoint. There generally are multiple painful ulcers on an inflamed surface. The lesions progress to ulcers, and there may be accompanying painful adenopathy and fevers. However, recurrent infections may be more difficult to diagnose solely on clinical grounds, and other ulcerative lesions (e.g., syphilis, chancroid) can occur, also. Virus isolation by tissue culture remains the most accurate method of confirming the diagnosis of HSV infection and should be utilized if there is any lack of certainty on clinical grounds. Cultural sensitivity decreases with the duration of the lesion. Cytologic tests, such as Pap smear and Tzanck preparations, tend to be less accurate. Rapid accurate tests for HSV, such as PCR, have been demonstrated to have utility in research settings and undoubtedly will eventually establish a role in clinical medicine.

Management

In the nonpregnant individual there are many treatments now available that will shorten the course or ameliorate symptoms. Even before antiviral therapy is instituted, there are some therapies that can be offered. Application of topical cool compresses with Burow solution for 15 minutes 4 to 6 times daily may be helpful for patients with extensive erosions on the genitalia. For an initial case of genital herpes, several medications are available.

- Acyclovir ointment can be applied every 3 to 6 hours (6 times daily) for 7 days. Severe cases may be treated with intravenous acyclovir 5 milligrams per kilogram, infused at a constant rate over 1 hour, every 8 hours for 7 days in patients with normal renal function) or oral acyclovir 200 milligrams 5 times daily for 7 to 10 days.
- Valacyclovir tablets (1 g b.i.d. for 10 days).

For the woman with a recurrent lesion there are also several choices. One is acyclovir (200 mg p.o. 5 times a day for 5 days, 400 mg p.o. b.i.d. for 5 days, or 800 mg p.o. b.i.d. daily for 5 days), generally started during the prodrome or within 2 days of onset of lesions. Famciclovir also is useful for treatment of recurrent genital herpes (dose is 125 mg q12h for 5 days in patients with normal renal function) started at the first sign of symptoms. Finally, valacyclovir (dose is 500 mg q12h for 5 days in patients with normal renal function) can be used.

In pregnancy there are additional considerations: First, it should be remembered that HSV is an STD, so those individuals diagnosed during pregnancy should be screened for other STDs. In regard to the prevention of mother-to-child transmission of HSV, management has changed greatly over the last decades. It was once recommended that pregnant women suspected of having a genital HSV infection or who had a history of prior HSV infection or sexual partners with HSV infections be monitored closely, with third-trimester cultures, for recurrent infection or for asymptomatic HSV shedding. Those women who had a positive culture result near to term were scheduled for elective cesarean section in order to avoid contact between the neonate and the virus during delivery.

That protocol had little impact on the overall incidence of neonatal HSV infection for several reasons. Most women who delivered infants with neonatal HSV infections had no history of infection and no lesions at the time of delivery, and thus would not have met the criteria for monitoring in the first place. It was calculated that a weekly screening strategy would cost approximately $1.8 million for each case of neonatal HSV infection averted. It is not clear whether the neonatal morbidity and mortality actually prevented by such a protocol outweighed the maternal mortality that would result from complications of cesarean delivery. Moreover, cesarean delivery, even with intact membranes, will not prevent all cases of neonatal herpes infections secondary to maternal genital HSV infection. There are many reported cases of neonatal HSV infections in infants that were delivered by cesarean with intact membranes.

Recommendations for pregnant women with HSV infections include the following:

- Cultures should be performed to confirm the diagnosis when a woman has active HSV lesions during pregnancy. If there are no visible lesions at the onset of labor, vaginal delivery is acceptable.
- Weekly surveillance cultures of pregnant women with a history of HSV infection, but no visible lesions, are not necessary and vaginal delivery is acceptable.
- Amniocentesis in an attempt to rule out intrauterine infection is not recommended for mothers with HSV infection at any stage of gestation.
- Cesarean section should be performed if lesions are present at the onset of labor.

It has been suggested that oral acyclovir prophylaxis might have a role in the prevention of recurrence and, thereby, could reduce the need for cesarean section. Several studies have pointed to lowered shedding and cesarean section rates when women with outbreaks during pregnancy are started on acyclovir in later stages of pregnancy. Cost savings with that strategy have been suggested, based upon decision analysis. Although acyclovir is a nucleoside that incorporates into DNA, registries have not revealed an untoward rate of adverse outcomes among exposed infants. Preliminary trials with acyclovir in pregnancy have reported that the need for cesarean section was reduced, with no increase in morbidity for exposed neonates.

Intrapartum It is recommended that term patients who have visible lesions, are in labor, and have ruptured membranes should undergo cesarean delivery. There has been a suggestion that the policy of cesarean section in such circumstances for women with recurrent lesions should be rethought. The presence of antibody in such women may make the mother-to-child HSV transmission rate so low as make the risks of routine cesarean section unjustified. However, most clinicians still opt for cesarean section with visible lesions regardless of the mother's history. Although it has been classically taught that cesarean delivery of women with visible lesions should be performed only if membranes have been ruptured for less than 4 to 6 hours, not all neonates born to mothers with HSV infections become infected, even with membranes ruptured for more than 24 hours. In contrast, neonates born by cesarean delivery within 2 hours of rupture of membranes have developed HSV infection. For patients with active HSV infections and premature rupture of membranes remote from term, there are not enough data to recommend a management protocol that would apply in all clinical situations. The risk of extreme immaturity must be weighed against the risk of neonatal HSV infection. There have been several case reports of infants born without sequelae after prolonged periods of conservative management. Although the use of scalp electrodes has been implicated as a rare etiology of neonatal infection, monitoring by fetal scalp electrode is not contraindicated if needed to adequately assess fetal condition in women with history of HSV infection but without lesions or symptoms. It has been suggested that cultures be obtained at delivery in women with a history of HSV infection to aid the pediatrician in assessing the need for therapy in the newborn.

Treatment

There is no known cure for HSV infection. The purine analogue acyclovir has been used to treat both primary HSV infections and to prevent recurrent HSV infections in nonpregnant women.

Prevention

Although it is not necessary to isolate the infant from the infected mother, the infected parturient should be counseled regarding hand washing and good hygiene to prevent infection of the infant. Every effort should be made to avoid direct contract of the newborn with herpetic lesions.

INTRAAMNIOTIC INFECTION

Introduction

Clinicians continue to apply a number of terms to this entity, including chorioamnionitis, amnionitis, intrapartum infection, amniotic fluid infection, and IAI. We use the last designation to distinguish this clinical syndrome from bacterial colonization of amniotic fluid and from histologic inflammation of the cord or placenta. Prospective studies published in the last few years report rates of 4% to 10% among non-privately insured and privately insured patients, respectively.

Pathogenesis

The ascending route is the most common pathway for development of IAI. A hematogenous or transplacental route of infection occurs with *Listeria monocytogenes.* Other virulent organisms, such as group B streptococci, may lead to a similar blood-borne infection. IAI may occur infrequently as a complication of invasive diagnostic procedures, such as amniocentesis or intrauterine transfusion.

In large investigations using logistic regression analysis, risk factors for IAI were identified as follows: low parity, prolonged duration of membrane rupture, prolonged duration of labor, larger number of vaginal examinations, and duration of internal fetal monitoring. In regard to the use of internal fetal monitoring, we feel that this technique should be used if it enables the practitioner to diagnose and treat labor abnormalities more efficiently.

Once IAI develops, the fetus may swallow and aspirate the infected fluid and is prone to develop pneumonia, enteritis, meningitis, and sepsis. Indeed, a clinical diagnosis of IAI is one of the most important risk factors for neonatal sepsis.

Microbiology

IAI is a polymicrobial infection, involving both aerobic and anaerobic bacteria. Table 19.2 shows the most common isolates in the amniotic fluid of over 400 cases of IAI.

Organism[a]	Number (%)
Group B streptococci	59 (14.6)
Escherichia coli	33 (8.2)
Enterococci	22 (5.4)
Gardnerella vaginalis	99 (24.5)
Peptostreptococci	38 (9.4)
Bacteroides bivius	119 (29.4)
Bacteroides fragilis	14 (3.4)
Fusobacterium spp.	22 (5.4)
Mycoplasma hominis	123 (30.4)
Ureaplasma urealyticum	190 (47.0)

[a]For bacteria, all isolates shown were found in concentrations of $\geq 10^5$ cfu/mL. Genital mycoplasmas were cultured qualitatively.

TABLE 19.2. *Amniotic fluid isolates in 404 cases of intraamniotic infection*

Diagnosis

The most common clinical criteria are fever, leukocytosis, and ruptured membranes; fetal and maternal tachycardia are noted in variable percentages of cases. Foul-smelling amniotic fluid and uterine tenderness, although more specific signs, occur in a minority of cases. In cases of clinical IAI, maternal fever was present in 85% to 99%, fetal tachycardia in 37% to 82%, maternal tachycardia in 19% to 37%, uterine tenderness in 13% to 16%, and foul-smelling amniotic fluid in 9% to 22%. The determination of amniotic fluid glucose concentration is a practical test for diagnosing clinical IAI. With an amniotic glucose concentration less than 5 milligrams per deciliter, the likelihood of amniotic fluid culture results being positive is approximately 90%. On the other hand, when the amniotic fluid glucose concentration is greater than 20 milligrams per deciliter, then the likelihood of a positive culture result is approximately 2%. At intermediate values (for example 14 and 15 mg/dL), the likelihood of a positive amniotic culture result is 30% to 50%.

Management

When IAI is diagnosed, there is a need for delivery of the fetus and for antibiotics. With regard to timing of delivery, there has been excellent maternal–neonatal outcome without use of arbitrary time limits. Cesarean delivery has been performed for standard obstetric indications, not for IAI alone. In nearly all cases, delivery occurred within 8 hours after diagnosis of IAI, and the mean time was between 3 and 5 hours. No critical interval from diagnosis of amnionitis to delivery could be identified. Cesarean section rates are higher among patients with IAI, running 2 to 3 times greater than in the general population. The reason for the increase most likely results from two things. First, IAI commonly develops in the patients with dystocia as an underlying problem. Second, the uterus with IAI is less sensitive to oxytocin.

The benefits of intrapartum treatment have been well established. Intrapartum initiation of antibiotic treatment improves maternal outcome, decreases neonatal bacteremia, and does not result in delayed sepsis (Table 19.3).

TABLE 19.3. *Outcome by maternal treatment group in cases of intraamniotic infection: results of a randomized study*

As noted above, the traditional antibiotic approach to treatment has been with combination therapy, primarily broad-spectrum penicillin with an aminoglycoside, plus clindamycin in some cases (such as cesarean delivery or apparent sepsis). Because of the expense and complexity of such therapy, there has been recent interest in single-drug treatment of IAI. In view of the well-described microbes involved, there would be several reasonable choices of single-agent therapy, but there have not been sufficient comparative trials to recommend alternative single-agent therapy. Studies have addressed the issue of duration of antibiotic therapy after delivery in the treatment of IAI. In one study, all patients received ampicillin plus gentamicin intrapartum, and those patients delivering vaginally where randomized to receive cefotetan 2 gram intravenously as a single dose or as multiple doses every 12 hours for 48 hours. Patients randomized to single-dose therapy also left the hospital more quickly (33 versus 57 hours, $P = .001$). Patients who received single-dose therapy also had a higher rate of “failed therapy” (11% versus 3.7%, $P = .27$). Although this difference did not achieve statistical significance, a three-fold increase in failed therapy raises concern about the limitation of single-dose therapy.

In a study of antibiotic therapy after cesarean delivery for IAI, all patients received ampicillin during labor and clindamycin and gentamicin, one dose each, preoperatively. Patients were then randomized to receive no scheduled postoperative antibiotics versus clindamycin and gentamicin until they were afebrile (for a minimum of at least 24 hours). No patients in either group developed an abscess or readmission for endometritis. Although there was no significant difference in endometritis (14.8% in those with no routine antibiotic versus 21.8% in those treated with clindamycin and gentamicin), there was a nonsignificant, but still 2.5-fold, increase in wound infection rate in patients randomized to no routine antibiotics (5% versus 1.8% with those randomized to clindamycin and gentamicin postpartum).

Based upon the limited observations of these two trials, the nagging concerns about failed therapy in the first study, and the wound infection rates in the second study, it would appear premature to conclude that therapy, after either vaginal delivery or cesarean delivery, in the presence of IAI, is unnecessary.

Outcome

Short-term Outcomes From descriptive studies largely from the early 1980s, several strong consistent observations may be made. Maternal outcome was excellent, with bacteremia occurring in only 2% to 6%. Maternal outcome was more complicated in patients having cesarean delivery. No critical diagnosis to delivery interval was demonstrable. Specifically, neither prenatal mortality nor maternal complications correlated with more prolonged intervals from diagnoses of IAI to delivery. Yet all patients delivered within 4 to 12 hours, and nearly all patients received intrapartum antibiotics. Although prenatal mortality was relatively high, little of this was directly attributable to infection, because most of the prenatal mortality was due to accompanying prematurity. Prior to term pregnancy, neonates have a higher frequency of complications if they are delivered of mothers with IAI. The group with IAI had a significantly higher number with respiratory distress syndrome and any diagnosis of infection. Thus, IAI has a significant adverse effect upon the mother and neonate. Short-term outcome is dependent largely on the organisms in the amniotic fluid (with *Escherichia coli* and group B streptococci more likely to result in maternal or neonatal bacteremia), low birth weight (with low-birth-weight infants faring more poorly), and timing of antibiotic therapy (with intrapartum administration improving outcome).
Long-term Outcomes Traditional complications of IAI have been maternal and neonatal sepsis, neonatal pneumonia and meningitis, and neonatal death. Studies indicate that complications of IAI should be expanded to include periventricular leukomalacia, cerebral palsy, respiratory distress syndrome and, perhaps, other neonatal complications. The hypothesized mechanism is that ascending infection leads to placental and congenital infection. This leads to an overly exuberant production of inflammatory cytokines which, in turn, leads to cell damage. Evidence for these expanded neonatal complications after IAI are as follows:

1. Intrauterine exposure to maternal or placental infection is associated epidemiologically with an increased risk of cerebral palsy.
2. Levels of inflammatory cytokines are increased in the amniotic of infants with brain white matter lesions or respiratory distress syndrome.
3. Experimental intrauterine infection has led to brain white matter lesions in rabbits.

Prevention

Within in the last few years, several intervention strategies for preventing clinical IAI have been evaluated. These are summarized in Table 19.4.

1. Identify dystocia promptly and treat hypotonic dysfunctional labor promptly with oxytocin.
2. In patients with premature rupture of the membranes at term, induce labor with either oxytocin or prostaglandin preparations.
3. In patients with preterm premature rupture of membranes and without contractions, give broad spectrum antibiotics such as ampicillin or amoxicillin plus erythromycin for 7 d.
4. Follow Centers for Disease Control and Prevention and American College of Obstetricians and Gynecologists guidelines for prevention of perinatal group B streptococcal infection.

For patients with preterm labor but without rupture of membranes, perinatal Group B Streptococcal Guidelines should be followed, but broad-spectrum antibiotics for the purpose of preventing chorioamnionitis have not been effective.

TABLE 19.4. *Clinical measures to prevent IAI*

POSTPARTUM ENDOMETRITIS

Introduction

Seven decades into the antibiotic era, genital tract infections continue to pose a common and occasionally severe threat to women after childbirth. Although substantial progress has been made in the control of puerperal sepsis, infection still ranks as the fourth most common cause of maternal death.

The most common cause of puerperal fever is uterine infection, occurring in approximately 1% to 3% of women after vaginal delivery and up to 27% after cesarean delivery, even when prophylactic antibiotics are used. The infection is variously called endometritis, endoparametritis, or simply metritis. Criteria for endomyometritis include fever, uterine tenderness, and purulent or foul lochia, peripheral leukocytosis, and exclusion of another infected site. Nonspecific signs and symptoms such as malaise, abdominal pain, chills, and tachycardia may be present. In the vast majority of cases of uterine infection, initial signs and symptoms develop within the first 5 days after delivery.

Pathophysiology

The major risk factors are summarized in Table 19.5. Cesarean section is the most important predisposing clinical factor for pelvic infection. The severity of infection also is increased in abdominal delivery. Those patients with electively scheduled operations (with no labor and no rupture of membranes) have lower infection rates than those with emergency or nonelective procedures. This observation has been made nearly universally in a large number of studies.

Duration of labor
Cesarean delivery, especially nonelective
Nonelective cesarean delivery, without prophylactic antibiotics
Duration of rupture of membranes
Failure to progress in labor
Number of vaginal examinations
Duration of internal fetal monitoring
Low socioeconomic status
Diabetes

TABLE 19.5. *Major risk factors for postpartum infection*

Risk factors of labor, rupture of membranes, vaginal examinations, and internal fetal monitoring are intricately interrelated, and even sophisticated statistical techniques may not be able to discern which of these factors is an independent variable. Whether amniotomy increases postpartum infection has been the subject of many reports. Amniotomy, as part of a plan of active labor management, probably does not increase the risk. Regardless of race, indigent patients have higher puerperal infection rates than do middle-class patients. The cause is unclear, but differences in flora, hygiene, and nutrition have all been postulated as reasons. Diabetes is also a risk factor for endometritis, with diabetic patients having approximately a four-fold increase in risk. Among patients without labor or ruptured membranes, 9.1% (5/55) of diabetics developed endometritis or wound infection versus 1.8% (2/110) of nondiabetics ($P = .042$). Among patients with either labor or rupture of membranes or both, the infection rate for diabetics was 25% (6/24) versus 6.3% (3/48) for nondiabetics ($P = .032$). Endometritis most often is caused by a mixture of aerobic and anaerobic bacteria from the genital tract. Table 19.6 shows the isolates from one carefully done study.

Isolate(s)	No. (%) of isolates
Facultative gram positive	*51 (40)*
Group B streptococci	8 (6)
Enterococci	7 (5)
Staphylococcus epidermidis	9 (7)
Lactobacilli	4 (3)
Diphtheroids	2 (2)
Staphylococcus aureus	1 (1)
Facultative gram negative	*28 (22)*
Gardnerella vaginalis	15 (22)
Escherichia coli	6 (5)
Enterobacterium spp.	2 (2)
Proteus mirabilis	2 (2)
Others	3 (2)
Anaerobes	*49 (38)*
Bacteroides bivius	11 (9)
Other *Bacteroides* spp.	9 (7)
Peptococci-peptostreptococci	22 (17)
Mycoplasmas	
Ureaplasma urealyticum	39 (30)
Mycoplasma hominis	11 (9)
Chlamydia trachomatis	*2 (2)*

TABLE 19.6. *Endometrial isolates (collected by a triple-lumen catheter) from 51 patients with postpartum endometritis*

Diagnosis

The diagnosis of endomyometritis usually is based on symptoms of fever, malaise, abdominal pain, and purulent or foul lochia. Other sources of fever should be excluded. In clinical investigations, various temperature criteria have been used in the definition of endometritis. These include 100°F (37.8°C) and 100.4°F (38°C) on two or more occasions. When there are signs of infection, multiple risk factors for infection, or persistence of low-grade fever in the puerperium, it is reasonable to presume a genital tract infection is present and proceed with the workup and treatment. We believe that appropriate specimens include a complete blood count, blood cultures, and an aerobic uterine culture. Gram staining of the genital specimen may be helpful when hemolytic streptococci, clostridia, or other anaerobes are suspected.

Treatment

With supportive therapy and appropriate antibiotics, the vast majority of patients improve within 1 to 3 days. For patients with endomyometritis after vaginal delivery, the treatment should include good anaerobic coverage, probably using a single agent (such as broad-spectrum penicillin or cephalosporin or a penicillin–ß-lactamase inhibitor combination).

Among patients with endomyometritis after cesarean section, response to antibiotics is poorer. Initial therapy for endometritis after cesarean section should consist of broad-spectrum antibiotics, with activity against anaerobes as well as Gram-positive and Gram-negative aerobes. In many clinical trials, the combination of clindamycin and aminoglycoside has been considered the standard for comparison for treatment in genital tract infections after cesarean section. A large number of new penicillins and cephalosporins have become available to treat postpartum infection. Although no single agent provides activity against the entire bacterial spectrum, most have sufficient aerobic and anaerobic activity to merit use in endometritis. Table 19.7 gives specific regimens.

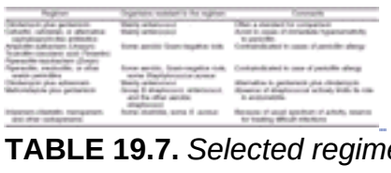

TABLE 19.7. *Selected regimens for initial parenteral therapy of postpartum endometritis*

The new penicillins and cephalosporins usually are tolerated very well and have few side effects. Administration of a single agent requires less time and equipment, but the higher cost of most new agents must also be considered. Metronidazole has excellent anaerobic activity. Because it has little activity against aerobes, its use as single-agent therapy is unwise. Its use in combination with gentamicin still leaves the Gram-positive aerobes (notably group B streptococci and enterococci) uncovered. New antibiotics are being formulated that may replace gentamicin as initial therapy. The monobactams (e.g., aztreonam) have exquisite Gram-negative activity, but they have little activity in the rest of the bacterial spectrum. These agents have the same spectrum as the aminoglycosides and have fewer side effects. Clinical trials of these monobactams in combination with clindamycin have shown excellent results, equivalent to clindamycin plus gentamicin.

For patients who respond promptly to parenteral antibiotics, some questions arise: How long should therapy be continued? Is oral therapy needed as an adjunct? It has been recommended that parenteral therapy should be continued for 24 to 48 hours after the patient becomes afebrile and asymptomatic. Then intravenous antibiotics may be discontinued and the patient discharged without oral antibiotics, unless the patient has had staphylococcal bacteremia. The approach is based upon several descriptive studies plus a randomized trial of oral antibiotic therapy after successful intravenous therapy in women with puerperal endometritis. Patients given placebo had similar subsequent courses to those of patients given oral amoxicillin (after parenteral therapy). Side effects were also similar in both groups (Table 19.8).

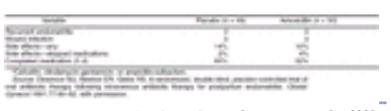

TABLE 19.8. *Oral amoxicillin after intravenous antibiotics for postpartum endometritis*

At the other end of the patient response spectrum, there are patients who do not respond within 48 to 72 hours of appropriate antibiotic therapy. Diagnostic considerations are: (a) an infected “mass” such as abscess or hematoma of the wound or pelvis, extensive pelvic cellulitis, septic pelvic thrombophlebitis, or retained placenta; (b) a resistant organism such as enterococci in patients treated with cephalosporin-like antibiotics or with clindamycin plus gentamicin; (c) a nongenital source of infection such as pyelonephritis, pneumonia, or intravenous catheter phlebitis; (d) a noninfectious fever such as drug fever or factitial fever; or (e) inadequate dosage or inadequate route of otherwise correct antibiotics (Fig. 19.6). Appropriate bedside examination and review of the chart and cultures often reveal the cause. In general, in patients who are stable and not seriously ill, an appropriate change in antibiotics (such as adding penicillin to clindamycin plus gentamicin to add coverage for enterococci) is effective in about 80% of those who had not responded in the initial 48 hours.

FIG. 19.6. Causes of poor response to antibiotics. (From Sweet RL, Gibbs RS. Postpartum infection. In: Sweet RL, Gibbs RS. Infectious diseases of the female genital tract. Philadelphia: Lippincott Williams & Wilkins, 2002, with permission.)

In about 20% of cases, the initial failure to respond is due to resistant organisms, and in another 30%, no cause for the failure is identified. We believe that 48 to 72 hours is an appropriate point to change therapy unless the patient is unstable, when changes are needed more promptly. In the remaining 40% to 50%, the reason for poor response to initial therapy is an infected mass. If the mass or collection is present in the wound after cesarean section, physical examination usually identifies the

source. In other cases, radiographic studies are helpful in identifying pelvic masses or deep-seated wound infection.

Ultrasonography or a CT study may reveal a mass in the pelvis. In patients with persistent pelvic infection after vaginal delivery, an ultrasonographic examination is helpful, because it may reveal a pelvic mass, retained placental tissue, or septic pelvic thrombophlebitis. Sonography is readily available, is inexpensive, and requires no special preparation. When patients are obese or have an open wound, ultrasonography provides a limited examination, and computed tomography is useful (Fig. 19.7 and Fig. 19.8).

Prevention

Principles for use of antibiotic prophylaxis to prevent endometritis after cesarean delivery are well established. These are summarized in Table 19.9.

TABLE 19.9. *Recommendations for use of prophylactic antibiotics in cesarean section*

SUMMARY POINTS FOR HIV, TOXOPLASMOSIS, CMV, AND HERPES

- All pregnant women should have HIV testing recommended to them.
- HIV-infected pregnant women should have regular monitoring of their CD4 cell count and viral load.
- All HIV-infected women should receive ZDV per the PACTG 076 protocol.
- Standards of care for HIV infection should be upheld during the prenatal period.
- During the intrapartum period, attempts should be made to minimize the duration of ruptured membranes among women with HIV infection.
- All pregnant women should be counseled regarding ways in which to minimize the risk of acquiring infection with *T. gondii.*
- Pregnant women who acquire *T. gondii* infections should have studies performed to ascertain the status of the fetus.
- If congenital infection with *T. gondii* is diagnosed and the patient continues the pregnancy, antiparasitic therapy should be instituted.
- CMV is the most common congenital infection in the United States.
- Although patients with antibodies may have reactivation resulting in infected newborns, these children are less frequently and less severely infected then those whose mothers have primary infections.
- Primary, first episode, genital HSV infection may increase the risk of untoward perinatal events, including preterm birth, low birth weight, and congenital infection.
- Viral shedding in labor should be determined by clinical assessment and should be managed with an operative delivery.
- Nucleoside analogues may be used to reduce the frequency of HSV viral shedding and, thereby, the need for cesarean section.

SUMMARY POINTS FOR INTRAAMNIOTIC INFECTION AND POSTPARTUM ENDOMETRITIS

- Both clinically evident IAI and postpartum endometritis are polymicrobial, upper genital tract infections, involving anaerobes, aerobes, and genital mycoplasmas most commonly.
- The benefits of intrapartum treatment of IAI with broad-spectrum antibiotic therapy are well established.
- In addition to causing maternal and neonatal sepsis, neonatal pneumonia, meningitis, and neonatal death, intraamniotic infection is now strongly associated with long-term neonatal adverse outcomes including cerebral palsy, respiratory distress syndrome, and other complications.
- Several effective measures have been identified to prevent clinical IAI.
- Response of postpartum endometritis is very good to a variety of antibiotic regimens, which have coverage against likely aerobes and anaerobes.
- Oral therapy generally is not needed after successful parenteral therapy for endometritis.
- Antibiotic prophylaxis strategies are well established for cesarean section.

SUMMARY POINTS

REFERENCES

All bleeding during pregnancy should be investigated by examination and by imaging studies. There are many etiologies for bleeding in pregnancy but the most clinically significant are placental previa and placental abruption since these conditions can lead to serious fetal compromise. Other causes of bleeding that should be excluded are cervical lesions such as carcinoma or polyps, vaginal lacerations from trauma or carcinoma, other uterine bleeding such as dehiscence of a prior cesarean section scar, and premature cervical dilation, although these usually do not involve large amounts of blood loss. The presence of either placenta previa or abruption places the patient in a high-risk situation that warrants close monitoring. A definitive diagnosis is extremely important since either placenta previa or abruption, in many cases, commits the patient to a period of prolonged bed rest and hospitalization.

PLACENTA PREVIA

Incidence

Placenta previa is encountered in approximately 0.5% to 1% of all pregnancies but its incidence may be higher now than in the past due to the increased diagnosis by widespread use of ultrasound scanning. It is fatal in 0.03% of cases ([1]). Formerly, the diagnosis of milder degrees of placenta previa without hemorrhage may have gone unnoticed by clinical exam. It is more common in multiparous than nulliparous women, occurring in only one in 1,500 nulliparas and as many as 1 in 20 grand multiparas. The incidence in the United States is declining, probably in part due to the declining number of grand multiparous women.

Definition

The definition of placenta previa has been complicated because the original descriptions referred to the location of the placenta in relation to a dilated cervix (i.e., one in labor) determined by digital exam. In this definition of a complete previa, the placenta extends over and beyond the internal os. A partial previa refers to a placenta with its edge partially over the dilated cervix, meaning that if we were to visualize the cervix with a speculum, we would see placental tissue over some part of the dilated cervical area, but not all. The last type of previa, the marginal previa, refers to a placenta where the edge lies very close to and up to the edge of the os but does not cover any of it. In those original descriptions, the distance between the placental edge and the internal os was never defined in terms of centimeters (Fig. 20.1). However, with the advent of transvaginal ultrasound imaging, the cervix can be routinely imaged, even when not dilated, and the internal os is seen as a point, hence the confusion over the terminology. In today's practice, any suspected low-lying placenta seen by transabdominal scan should be further evaluated by a transvaginal scan to determine the distance between the edge of the placenta and the internal os (Fig. 20.2). Those cases where the placental edge completely covers the cervical os will be labeled as a complete previa. Those with the placental edge at the cervical os should be labeled as partial or marginal (partial/marginal) since it is impossible to determine whether those placentas will remain covering the dilated cervix during labor or whether they will remain at the edge of the dilated cervix. The cases in which the placental edge is located within 1 to 2 cm of the internal os are the most confusing. Studies that have evaluated this report that patients with a placenta edge less than 1 cm from the cervical os tend to have cesarean sections because they are most like placenta previa patients (i.e., with bleeding and these are delivered by cesarean section) ([2]). Patients with the edge between 1 to 2 cm of the internal os, however, remain in the gray zone. These patients will benefit most with either a double setup at the time of labor or with close observation in labor and an attempt for a vaginal delivery if there is no bleeding. Patients with a placental edge greater than 2 cm from the cervical os are considered to have normal placentas and not a previa.

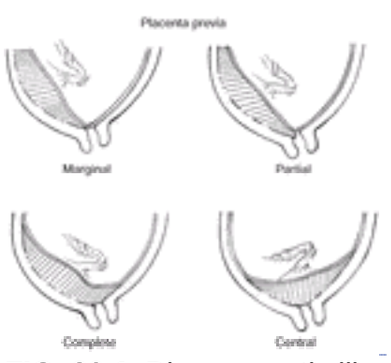

FIG. 20.1. Diagrammatic illustration of the three classic types of previa: Marginal, partial, and complete. These relate to diagnosis by digital or visual examination when the patient is in labor with a partially dilated cervix. The term *central previa* refers to a previa in which the central portion of the placenta lies directly over the cervical os.

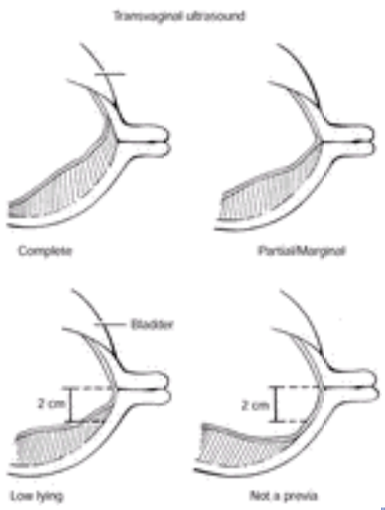

FIG. 20.2. Diagrammatic illustration of the classes of placenta previa diagnosed by transvaginal ultrasound. In the nonlaboring, patient the internal os is seen as a point, and the distance between this and the lower edge of the placenta becomes the more critical reference.

Pathophysiology

Placenta previa is a condition of abnormal implantation (i.e., into the lower uterine segment rather than the corpus or fundal region). The exact pathophysiology is unknown but because it is seen more frequently in patients who tend to be older, multiparous, and had prior cesarean sections or prior uterine curettage, it is thought to result from scarring in the endometrium. This leads to abnormal endometrial tissue, poor vascularization, thinner myometrium, and a less favorable location for implantation. Presumably, the embryo is attracted to healthier tissue which would be the untampered endometrium of the lower uterine segment. Interestingly, it would appear that the anterior uterine segment after cesarean section would be an unfavorable site for implantation but, for uncertain reasons, the uterine trauma from cesarean sections actually increases the risk of previa by as much as six-fold.

Risk Factors

Several risk factors have been found in association with placenta previa (Table 20.1). The most significant is a prior cesarean section (approximately 1 in 200 deliveries; the incidence is higher if a woman has undergone two or more C-sections). Black or minority patients seem to be at higher risk as are women older than 35 years. Other risks include increased gravidity and parity, and cigarette smoking, with a 2.6- to 4.4-fold increase ([3], [4] and [5]). Interestingly, meta-analyses have shown a preponderance of male gender among the fetuses with placenta previa ([6]). The mechanism for this is unknown. Previous abortion has not been consistently shown to be associated with an increase in risk for previa.

Black and minority
Advanced maternal age
High gravidity
High parity
Previous abortion—induced and spontaneous
Prior cesarean section
Cigarette smoking

TABLE 20.1. *Risk factors associated with placenta previa*

Diagnosis

The diagnosis of placenta previa can be made by transabdominal ultrasound. With the advent of the curvilinear probe, the cervical and lower uterine segment is much better imaged and the relationship of the lower placental edge to the internal cervical os can be routinely visualized. However, the most common pitfalls include a full, distended bladder and a lower uterine segment contraction that can lead to misdiagnosis. Of those diagnosed in the second trimester, 90% to 95% resolve by the third trimester due to further development of the lower uterine segment, also referred to as migration of the placenta. However, if the placenta covers the internal os by 20 mm or more, meaning that it crosses the os by 20 mm, there is a 100% sensitivity rate for detection of previa at delivery requiring cesarean section ([2]). Three-dimensional scanning may further increase prenatal detection but remains a new investigational technique for previa at this time. Therefore, it is imperative that follow-up scanning be performed to determine if there is resolution of what appears to be a placenta previa. Marginal and partial placenta previa are significantly less likely to persist into the third trimester (i.e., <5% chance).

Although initially thought to be contraindicated in patients with suspected placenta previa, transvaginal scanning can be safely performed with caution. In many cases, the relationship between the placental edge and the internal os can be difficult to assess and only a close-up view with a transvaginal approach can make a definitive diagnosis (Fig. 20.3). This approach to scanning has been studied carefully and it does not appear to lead to increased vaginal bleeding, in part because it is technically impossible to introduce the probe through the cervix. Another alternative approach is with translabial scanning which has been reported to be 100% sensitive for detection of a previa. However, on occasion, bowel gas can interfere. When a clear diagnosis of placenta previa is made by a transabdominal or translabial scan, there is no need to perform a transvaginal scan. However, when a partial/marginal placenta previa or low-lying placenta is suspected, a transvaginal scan should be performed to confirm the diagnosis and the distance between the internal os and lower placental edge should be determined. Both types of scanning have greatly reduced the false-positive rate by transabdominal scanning alone which is reported to be as high as 25%.

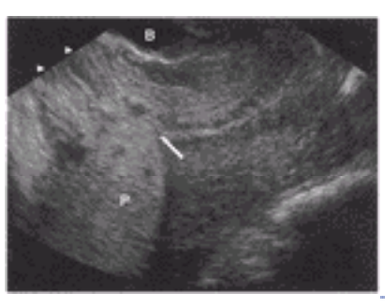

FIG. 20.3. A transvaginal ultrasound image of a complete placenta previa. The *arrow* points to the internal os. *P*, placenta; *B*, bladder.

It is debatable whether transvaginal scanning has made the double setup examination obsolete because the relationship between the placenta and cervix can be identified well by experienced scanners. However, there is probably still a place for this exam, particularly in those patients with a placental edge between 1 to 2 cm from the internal os, and with no bleeding. This type of exam can be used in labor to determine the relationship between the placental edge and the cervix by carefully introducing the examining finger into the cervix with the patient prepped and draped in the operating room so that if placenta is encountered at the internal os, an immediate cesarean section can be performed, particularly in the event of acute hemorrhage. If the cervix is dilated, a finger can be passed through the cervical canal to the internal os and placental tissue can be palpated as gritty, fibrous tissue in contrast to the fetal membranes that are smooth to touch, particularly with amniotic fluid behind them. If placental tissue is palpated to cover the os or is located easily within reach, it is considered to be a previa. In this case, the distance relationship (i.e., whether it is 1 or 2 cm from the os) is insignificant since that is an ultrasound imaging determination. At that point, the patient would be managed by proceeding with a cesarean delivery. However, if the cervix is dilated, the membranes are ruptured to allow the fetal vertex to be better applied to the cervix, tamponading what bleeding may develop and enabling the patient to continue laboring to achieve a vaginal delivery or to augment labor with Pitocin.

Clinical Features

Patients with placenta previa typically remain asymptomatic until they have vaginal bleeding. Many are now detected during second trimester ultrasound screening although they remain asymptomatic. It is becoming increasingly rare to have a patient present late in the third trimester with new diagnosis. There are no means to predict which patients will bleed and when they will bleed. Approximately one-fourth of patients do not bleed prior to 36 weeks ([7]). Usually the first episode of painless

vaginal bleeding occurs without any precipitating event, although intercourse and excessive activity by the patient may be inciting factors. Complete previas are more likely to bleed earlier than partial or marginal previas. The thinning lower uterine segment most likely tears into the intervillous space of the placenta. The blood can bring about uterine irritability and occasionally preterm contractions. The amount of blood in this first bleed tends to be variable, from slight to heavy, although it is usually unlikely to be heavy enough to prompt delivery. However, the amount of subsequent bleeds tends to be increasingly heavier as the cervix and lower uterine segment changes. Blood seen on a patient's feet is usually a good indication of a heavy bleed.

Most patients stop bleeding with bed rest, particularly those in the second trimester. Many patients are placed at bed rest either at home or in the hospital until resolution of bleeding. The bright red blood usually converts to a brownish discharge. In the third trimester, though, the amount of bleeding increases and often, delivery is prompted by one massive bleed after multiple earlier bleeds. The blood is typically of maternal origin and therefore the fetus is usually not in jeopardy. In cases with massive bleeding, the fetal heart rate tracing may show signs of distress, usually with repetitive late decelerations.

Patients with placenta previa are at increased risk for abruptio placentae (rate ratio 13.8), cesarean delivery (rate ratio 3.9), fetal malpresentation (rate ratio 2.8), and postpartum hemorrhage (rate ratio 1.7) ([1]). Although fetal growth restriction was formerly thought to be an outcome of placenta previa, more recent studies do not show an association when comparisons were made between a study group and a well-matched control group and when gestational age at delivery was controlled ([8]). Although it is impossible to predict which patients will bleed and when, one report suggests that patients with elevated maternal serum alpha-fetoprotein (MSAFP) levels greater than 2.0 multiples of the median (MoM) have a 50% chance of requiring hospitalization for bleeding before 30 weeks gestation, to be delivered preterm before 34 weeks, and to be delivered for pregnancy-associated hypertension before 34 weeks ([9]). MSAFP elevations did not predict those with placenta accreta or emergent cesarean hysterectomy. Careful note of the MSAFP levels in the second trimester may help us target those patients who need to be cautioned more specifically about adverse outcomes due to the presence of the previa.

Management

Patients diagnosed in the second trimester should be cautioned about the possibility of bleeding. Intercourse should be avoided unless a follow-up scan reveals further migration of the placenta. Otherwise patients may be allowed their usual activities without excess exertion. A repeat scan approximately every 4 weeks should be performed to determine the persistence or resolution of the previa. If further scans reveal resolution, no further evaluation is necessary. However, if follow-up shows persistent previa into the third trimester, the patient should be further counseled regarding her chances of bleeding. Decreased physical activity would be advisable and travel away from home should be discouraged.

Every patient who bleeds needs to be evaluated. Fetal status should be documented. Depending on the amount of bleeding, intravenous fluids should be started and blood should be cross-matched or, at a minimum, typed and screened. Subsequently, continuous availability of cross-matched blood does not appear to be necessary, as few antepartum patients require emergent transfusion. Rh status should be checked and RhoGam should be administered if patients are Rh-negative and unsensitized. A baseline blood count with hemoglobin and hematocrit should be determined to assess degree of bleeding. These blood counts should be interpreted carefully in the context of normal reserve in these pregnant patients as well as the hemodilution with intravenous hydration. Because pregnant women have such reserve, their vital signs and laboratory values may not directly reflect their vascular compromise until they have had a very large amount of bleeding. Their status may be deceptively stable until they get close to serious decompensation. If signs of hypovolemia are present, such as hypotension and tachycardia, the patient more than likely has had severe hemorrhage—more than might be clinically observed. Since it is rare to develop a coagulopathy with a bleed from a previa, a coagulation profile is not necessary at the onset. A Kleihauer-Betke test for fetal blood is also not necessary since it is rare to find an abnormal test result.

If the fetus is clearly previable, continued monitoring and stabilization of maternal hemodynamics is appropriate. Blood can be transfused as needed to maintain the maternal blood count in a normal range (hematocrit >30) until fetal viability is reached. In patients who decline transfusions, erythropoietin may be a good option. In addition, the use of autologous blood donation in these patients may be a safer therapy in some parts of the world. If bleeding ceases, the patient may be a candidate for continued outpatient bed rest. Outpatient expectant management has been analyzed and the cost–benefit ratio was favorable with no outcome difference between those managed as outpatients versus those managed as inpatients ([10]). Antenatal steroids for fetal lung maturity should be administered between 24 and 34 weeks gestation.

In the third trimester, the threshold for discharging the patient should be higher. A period of prolonged bed rest and observation is warranted and it is not unreasonable to consider hospitalization until delivery. If it appears that immediate delivery is not necessary, patients should be given a course of antenatal steroids, from 24 to 34 weeks with intact membranes. Continuous fetal monitoring should be carried out until the bleeding is stable and then daily fetal assessment is appropriate. Additional episodes of bleeding, despite full bed rest, are not uncommon. Approximately 70% of patients treated expectantly will have a second episode of bleeding and 10% will have a third bleed. Unless acute bleeding mandates preterm delivery, the patient can undergo semi-elective amniocentesis after 36 weeks and delivery if fetal lung maturity can be documented. Approximately 25% to 30% of patients will achieve 36 weeks gestation. If significant bleeding occurs after 34 weeks gestation, a decision to proceed directly to delivery without amniocentesis is justified.

In the event of severe hemorrhage on admission, the medical team should prepare for immediate delivery if the fetus has reached a viable gestation. The anesthesiologist and neonatologist should be notified immediately. Two large-bore intravenous lines should be established and blood should be cross-matched immediately. A Foley catheter should be inserted to monitor urine output. A coagulation panel should also be sent. Continuous fetal monitoring should be performed while preparing for delivery and any decompensation should hasten the delivery process.

In about 20% of the cases with bleeding, the uterus contracts and the additional problem of managing preterm labor needs to be confronted. A transvaginal or translabial ultrasound scan can be performed to assess the cervix if bleeding is not too heavy. If fetal lung maturity is not documented or unlikely, efforts to arrest the labor should be attempted, if only to try to get a course of antenatal steroids on board. However, use of tocolytics is considered controversial and no studies have confirmed their benefit in these patients. The choice of tocolytics should be carefully weighed. Beta-mimetics produce maternal tachycardia and hypotension and are generally contraindicated unless the bleeding appears to be stable. Calcium channel blockers can also cause hypotension. Indomethacin is generally not recommended after 32 weeks because of possible premature closure of the fetal ductus arteriosus. Magnesium sulfate is a popular choice and is the most widely used.

Delivery is by cesarean section for all categories of placenta previa when documented by transvaginal scan with an undilated cervix in the third trimester regardless of whether it is a complete, partial, or marginal previa. However, if the diagnosis cannot be established definitively, such as when vaginal scanning is unavailable, or there is a suspected marginal or partial previa between 1 to 2 cm from the os and without any bleeding, a double setup may be considered when in labor or before labor. If no placenta tissue can be palpated, the membranes should be ruptured and the patient may be allowed to labor. Rupturing the membranes and allowing labor to continue could bring the fetal vertex down, and tamponade any placental bleeding.

In the majority of cases, a low transverse uterine incision can be successfully achieved, particularly with a posterior placenta and with a well-developed lower uterine segment. A transverse incision can still be accomplished in skilled hands even when an anterior placenta is encountered by cutting quickly through the uterus and placenta and delivering the fetus as quickly as possible before there is significant fetal exsanguination. In a good percentage of cases, the placenta previa leads to fetal malpresentation such as transverse lie. In those cases, the best uterine incision would be a vertical, or classical one.

Regional anesthesia may be successfully used for patients with placenta previa. It has been reported that the management of blood pressure for hemorrhage is not a problem and may be the preferred choice due to the lowered amounts of intraoperative blood loss compared to general anesthesia. With heavy bleeding preceding delivery, however, many anesthetists would still opt to use general anesthesia because regional anesthesia in the presence of major hemorrhage may exacerbate hypotension and block the normal sympathetic response to hypovolemia.

Complications

Complications from placenta previa include a longer hospital stay, cesarean delivery (risk ratio [RR] = 3.9), abruptio placenta (RR = 13.8), postpartum hemorrhage (RR = 1.7), fetal malpresentation (RR = 2.8), and maternal death from uterine bleeding (50%) and disseminated intravascular coagulation (DIC) (15.9%) ([1]).

Placenta Accreta One significant complication of placenta previa is placenta accreta, increta, and percreta, particularly with a prior history of a cesarean section. Placenta accreta refers to the placenta being attached to the myometrium but does not invade the muscle; increta is seen with the villi invading the myometrium; and percreta is seen when the villi penetrate through the entire uterine wall and into the bladder or rectum. The presence of placenta previa in a patient with a prior cesarean section is associated with accreta in 10% to 35% of cases. With multiple cesarean sections, the risk may be as high as 60% to 65% ([11]). During antenatal ultrasound scans, the lower uterine segment should be scrutinized for any evidence of a disruption in the demarcation between the placental fibrinoid base known as the Nitabuch layer and the uterine decidua basalis. Color Doppler assessment can be very helpful by demonstrating marked or turbulent blood flow within the placenta and extending into the surrounding tissues, which is also described as lacunar flow. Similar, and perhaps better, scrutiny can be offered by magnetic resonance imaging (MRI) that can demonstrate placental tissue extension through the uterus (Fig. 20.4). MRI diagnosis for placenta percreta may be quite accurate but diagnosis for placenta accreta, a lesser degree of myometrial invasion, is much lower with sensitivity in the 30% to 40% range. The imaging features include a loss of the decreased signal intensity demarcation between myometrium and decidua basalis. However, one report showed a sensitivity of only 38% for the detection of accreta by

MRI. There are some reports of gadolinium-enhanced MRI that can more clearly distinguish a placenta accreta from a percreta. There is not enough data thus far to determine whether MRI is superior to ultrasound for diagnosing placental accreta and percreta.

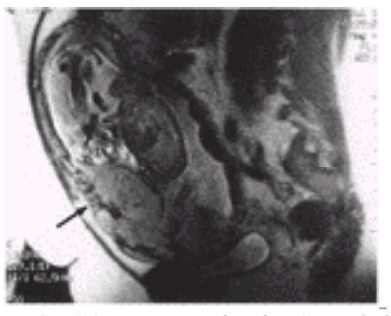

FIG. 20.4. A sagittal T2-weighted magnetic resonance imaged case of placenta percreta. The percreta is low anterior (*arrow*). (Courtesy Dr. Mark Kliewer.)

In the presence of placental accreta, increta, and percreta, the risk of hemorrhage is extremely high. Careful attention should be paid to the lower uterine segment after delivery of the placenta. If bleeding persists despite the usual postpartum uterotonic agents and uterine or hypogastric artery ligation, hysterectomy must be considered. Complications are more likely to arise from delay in making the decision to proceed with hysterectomy. It may be a worthwhile exercise to attempt other methods to control the bleeding before hysterectomy such as oversewing the lower uterine segment, uterine artery ligation, ovarian artery ligation, and uterine packing, but all are associated with mixed results. If definitive hysterectomy is not performed, bilateral arterial embolization of the uterine arteries should be the next option of choice although more experience is needed to determine the success rate of such a procedure for placenta percreta. Precautions to control hemorrhage in general should include intravenous access, blood products, and anesthesiology assistance. If these conditions are suspected by imaging studies prior to delivery, a planned cesarean section after uterine artery catheters are placed for possible embolization may be useful to avoid a hysterectomy. Plans should also be made to deliver in an operating room where there would be access to extra assistance and equipment should a hysterectomy be performed. The interventional radiologists should be notified of the possibility for embolization and the proper equipment should be made available. Other types of management have included methotrexate for placenta accreta tissue left in situ from bladder wall invasion, subendothelial vasopressin to control bleeding, and balloon occlusion in the hypogastric arteries before hysterectomy. Some of these have been reported with mixed results. Ongoing improvements in the management, once hemorrhage is recognized, will decrease overall morbidity to the patient. Other complications in the presence of significant hemorrhage from placenta previa could include complications from hypotension such as acute tubular necrosis and Sheehan syndrome of pituitary infarction. Although maternal mortality is low, less than 1%, and perinatal mortality is less than 5%, there can be significant morbidity for both. Lesser complications include risk for hysterectomy (RR = 33.26), antepartum bleeding (RR = 9.81), intrapartum and postpartum hemorrhages (RR = 1.86), blood transfusion (RR = 10.05), septicemia (RR = 5.55), and thrombophlebitis (RR = 4.85) ([12]). Cases of spontaneous uterine rupture attributable to placenta percreta without prior cesarean delivery have also been reported.

Outcomes

Many reports have suggested a causative effect between placenta previa and low birth weight. The association between placenta previa and fetal growth restriction has been assumed to a large extent. However, more recent studies that have controlled for the gestational age at delivery have found no significant association between previa and growth restriction and the previously seen association is most likely due to preterm birth. Other neonatal outcomes of significance also include an increased risk of congenital anomaly, respiratory distress syndrome, and anemia. The mechanism for the increase in congenital anomalies is not known but the increase in respiratory distress syndrome and anemia can be explained by the increased perinatal bleeding. Mortality, intraventricular hemorrhage, and low Apgar scores are not different, reflecting advances in obstetrics and neonatal treatments.

Recurrence risks for placenta previa are 2% to 3% or six- to eight-fold higher than the normal population. Cigarette smoking further increases these recurrence risks.

Prevention

There are no means to prevent placenta previa. However, some studies have suggested that a cervical cerclage placed between 24 and 30 weeks gestation may decrease the chance of bleeding and blood transfusion while prolonging the pregnancy, increasing the birth weight, and decreasing the hospital stay and costs and admission to the neonatal intensive unit. The mechanism is thought to be due to stabilization of the lower uterine segment. This practice, however, is not established and there have been no large randomized trials to test this intervention ([10]). Other trials found some benefits in a prolongation of pregnancy by 1 week, fewer readmissions for bleeding, fewer hospitalization days, and higher birth weights, although none of these were statistically significant.

VASA PREVIA

A vasa previa occurs in approximately 1 in 1,000 to 1 in 5,000 pregnancies and refers to a condition associated with a very high fetal mortality in the range of 33% to 100%. It is seen when a fetal vessel crosses and covers the internal os (Fig. 20.5). Patients at risk include those with bi-lobed placentas, succenturiate-lobed placentas, low-lying placentas, pregnancies from in vitro fertilization, and multiple pregnancies. These conditions all increase the likelihood that fetal vessels in the membrane will rest over the cervical os. It is technically only possible in two conditions. One is in the presence of a velamentous cord insertion and the other is a placenta with a succenturiate lobe. In both cases, unprotected fetal vessels within the membranes can go undiagnosed and at the time of artificial rupture of the membranes or with advanced labor, these fetal vessels can be ruptured leading to fetal exsanguinations.

FIG. 20.5. A transvaginal color Doppler ultrasound image of a suspected vasa previa. Markers indicate the distance between the internal os and the cord insertion into the membranes away from the placental edge, a distance less than 1 cm. See color figure 20.5.

When fetal blood is suspected, it may be confirmed quickly by doing a test for fetal hemoglobin. Because fetal hemoglobin is resistant to alkaline pH, several alkaline denaturation tests have been developed such as the Apt, Ogita, and Loendersloot tests. These tests differ only in the duration of the test but all are less than 10 minutes. Therefore, they are all suitable for an acute situation prior to grossly obvious fetal deterioration. Fetal distress can be represented by a sinusoidal pattern on the fetal heart monitor.

It is prudent to identify the location of the cord insertion into the placenta and to look for the presence of a secondary placental lobe at the time of a routine second trimester scan to avoid a disastrous outcome. Color Doppler scanning dramatically simplifies this diagnosis and when combined with either transvaginal or translabial scanning, can distinguish a funic presentation (i.e., cord presenting ahead of the vertex) from a vasa previa. Reports have also suggested that three-dimensional ultrasonography and MRI may help in the diagnosis of vasa previa but further experience with these techniques needs to be demonstrated. Transvaginal scanning with color Doppler is currently the most effective means available.

Early recognition has been reported to be associated with decreased fetal mortality. It can assist in planning delivery and preventing iatrogenic harm such as from artificial rupture of the membranes. Elective cesarean delivery decreases the perinatal mortality. In undiagnosed cases, a heightened sense of suspicion and aggressive intrapartum and neonatal management are the only means to achieve successful neonatal outcomes.

PLACENTAl ABRUPTION

Placental abruption is a pathologic condition in which some part of the placenta prematurely separates from the uterus. It is one of the leading causes of fetal and

neonatal mortality.

Incidence

Many factors lead to placental abruption and its incidence seems to be increasing. The incidence is 0.5% to 1.0%. It is a leading cause of perinatal mortality accounting for 10% to 15% of all perinatal deaths, although this rate may be decreasing with improved neonatal care.

Definition

Three types of placental abruption are:

1. Retroplacental—between the placenta and myometrium; severe is 30% to 40% of the surface area, 50% fetal mortality if greater than 60 mL of blood.
2. Marginal, subchorionic—between the placenta and membranes.
3. Preplacental, subamniotic—between the placenta and the amniotic fluid. These are of no clinical significance.

There are several categories of abruptions, some more dangerous than others (Fig. 20.6). The most significant abruption is a retroplacental abruption that can compromise fetal oxygenation and perfusion. These can derive from a marginal abruption, which refers to those located at the edge of the placenta and is seen as a simple lifting of the placental edge away from the uterus. These can be serious when the abruption extends from the margin to the rest of the placenta. A concealed abruption is a retroplacental abruption in which there is no obvious discernible external bleeding.

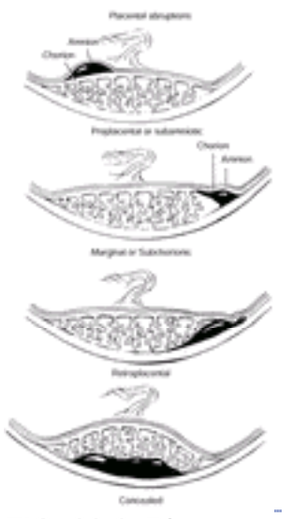

FIG. 20.6. Diagrammatic representation of various degrees of placental abruption: preplacental or subamniotic (between amnion and chorion), marginal or subchorionic (between placenta and membranes), and retroplacental (between placenta and myometrium).

Pathophysiology

The pathophysiology of an abruption depends on the etiology. An abruption is the clinically recognized end result when villi separate from the underlying decidua basalis. In blunt trauma, the cause is clearly a forceful shearing effect. In the majority of other cases, bleeding results from cell death (apoptosis) induced through ischemia and hypoxia. In patients with thrombophilia, the tendency to clotting leads to a thrombotic event in the decidua basalis resulting in ischemia and hypoxia. In patients with chorioamnionitis, lipopolysaccharides and other endotoxins generated from the infectious agents induce the accumulation of cytokines, eicosanoids, and reactive oxygen species such as superoxide. All have cytotoxic potential that promotes ischemia and hypoxia. One of the cytotoxic actions of endotoxin is the induction of nitric oxide synthase (NOS) activity that produces nitric oxide (NO), a potent vasodilator and inhibitor of platelet aggregation. As NO is metabolized, peroxynitrite is generated which is a longer lasting oxidant capable of causing ischemia and hypoxia through actions on vascular endothelial cells. As the beneficial effects of NO are outweighed by the overwhelming inflammation, ischemia and hypoxia result leading to cell death and bleeding. The specific mechanisms involved in this final step are under active investigation ([13]).

Risk Factors

Many risk factors for placental abruptions have been studied extensively ([14]) (Table 20.2). These factors may be categorized. The first is socioeconomic factors with young age, primiparity, single parenthood, and low education being associated with abruption. Also included in this category would be a prior abruption with a recurrence risk ten times higher than those without a prior history. Another category includes physical factors such as blunt abdominal trauma from domestic abuse or a motor vehicle accident. A third category includes uterine defects including myomas and septums. Multiple studies have shown higher incidence of abruptions in patients with a retroplacental myoma, particularly if the myoma volume exceeded 200 cm^3 and was submucosal in location ([15]). The fourth category is the largest and most significant and includes maternal illnesses such as thrombophilias and hypertensive diseases. Finally, a fifth category of iatrogenic causes should be included.

Uterine	
	Myomas
	Uterine septum
	Uterine malformations
Demographic/socioeconomic	
	High parity
	Single parent
	Low education
	Infertility
Medical	
	Unexplained elevated MSAFP and hCG
	Decreased inhibin A
	Antiphospholipid syndrome
	Pregestational diabetes
	Hypertension—chronic and gestational
	Preterm rupture of membranes with chorioamnionitis
Thrombophilias	
	Prothrombin 20210A mutation
	Hyperhomocysteinemia
	Factor V Leiden mutation
	Activated protein C resistance
	Protein C and S deficiency
	MTHFR
	Dysfibrinogenemia
Iatrogenic	
	Sudden decompression of uterus (amniocentesis)
	External cephalic version for breech
	Cigarette smoking
	Cocaine abuse
	Blunt trauma
	Incorrectly applied seat belt
	Cesarean section
	Intrauterine pressure catheter placement
	Heavy physical activity

hCG, human chorionic gonadotropin; MSAFP, maternal serum alpha-fetoprotein; MTHFR, methylenetetrahydrofolate reductase.

TABLE 20.2. *Risk factors associated with placental abruption*

Maternal disease such as hypertension has been associated with increased risks for abruption. In many studies and in a large epidemiologic study of hypertensive women in Nova Scotia, only women with chronic hypertension with superimposed severe preeclampsia were at increased risk for abruption compared to women with chronic hypertension alone, a RR of 3.8 for parous women and 1.6 for nulliparous women. Not surprisingly, the effects of smoking and hypertension appeared to be additive, if not even higher ([16]).

Maternal illness due to premature rupture of the membranes leading to chorioamnionitis has been strongly correlated with the incidence of abruptions from epidemiologic studies, microbiologic, and histopathologic studies of the placentas ([17]). Pathologic evidence to support this includes observations that lipopolysaccharides and bacterial endotoxins are elevated in the amniotic fluid of patients with chorioamnionitis. These agents, in turn, induce the formation of superoxide or free oxygen radicals as evidenced by an increase in the nitrites and nitrates in maternal serum. These are metabolites of NO, an antioxidant that appears to be increased under these infectious conditions. Immunohistochemical studies have demonstrated increased expression of NOS and nitrotyrosine, which are markers for NO metabolism, in placentas from patients with chorioamnionitis and abruptions. Additionally, evidence for apoptotic cell death has been identified in placentas from

both conditions ([13]). This evidence supports a strong link between chorioamnionitis and placental abruption.

Over the past decade, new risk factors have been identified in association with placental abruptions. These factors are encompassed under the umbrella of thrombophilia defects and include anticardiolipin antibodies, presence of the lupus anticoagulant, protein C, S and antithrombin III deficiencies, and the mutations such as factor V Leiden (also know as activated protein C resistance), methylenetetrahydrofolate reductase mutation, and prothrombin *20210A* gene mutation, as well as the more rare congenital dysfibrinogenemia. The autoimmune antibodies, anticardiolipin antibodies, and lupus anticoagulant have been shown for many years to be associated with adverse pregnancy outcomes including placental abruption. Because these are nonspecific antibodies, it is difficult to understand their pathophysiologic role in bleeding. Protein C and protein S deficiency are genetic disorders seen with an increased risk for thrombosis. They have been implicated in preeclampsia and abruption. However, their levels may normally be decreased during pregnancy making it difficult to fully understand their role in the pathophysiology of abruption. More recently, research has focused on specific gene defects that predispose patients to coagulopathy.

Activated protein C resistance (APCR) is the most common genetic factor predisposing to thrombosis and appears to be the most common identifiable cause. This resistance is most often caused by the factor V Leiden mutation and in many cases is used synonymously, although patients can have APCR without the Leiden mutation. In this mutation, there is a nucleotide substitution of adenine for guanine that results in an amino acid substitution of arginine for glutamine. Patients who are heterozygous for this mutation have fewer manifestations of clinical disease than those who are homozygous. Because patients with this mutation have an increased tendency to form clots, they also have a higher risk for abruption due to clotting in the placenta, primarily thought to be in the decidua basalis either early in pregnancy resulting in spontaneous abortions or in the latter half of pregnancy resulting in bleeding and abruption. Furthermore, women with a hypofibrinolytic 4G/4G mutation of the plasminogen activator inhibitor 1 (PAI-1) gene, which is frequently associated with the thrombophilic factor V Leiden mutation, also have a predisposition to thrombosis. A study of women with adverse obstetric complications found that women with placental abruption were more often associated with homozygous and heterozygous factor V Leiden mutation, heterozygous *G20210A* prothrombin gene mutation, homocystinemia, APCR, or anticardiolipin immunoglobulin G (IgG) antibodies. However, other studies have found a weaker link and it is cautioned that these tests should not become standard and routine until larger studies further substantiate their relationship to placental abruption and other pregnancy complications. A concomitant search for therapeutic measures would further justify this type of testing of a beneficial treatment if one can be found ([18]).

One etiologic factor that has been widely studied in association with placental abruption is the condition known as hyperhomocysteinemia. Homocysteine is metabolized from methionine and then remethylated by an enzyme known as methylenetetrahydrofolate reductase (MTHFR) to methionine, with folate and vitamin B_{12} as cofactors. Mutations in the *MTHFR* gene, two known as *C677T* and *A1298C*, prevent this normal remethylation leading to increased levels of homocysteine. These elevated levels of homocysteine can damage vascular endothelium leading to thrombosis formation when they occur in veins or to placental abruption when they cause damage in the spiral arteries supplying flow to the placenta ([19]). Increased levels of homocysteine have been identified in the fasting state in patients with placental abruption and infarction ([20]). Hyperhomocysteinemia was found in 24% of Danish women with a history of placental abruption, intrauterine fetal demise, and fetal growth restriction ([21]). Increasing folate and pyridoxine intake successfully reduced the levels of homocysteine. Pathologic evaluation of the placentas from patients with hyperhomocysteinemia have identified an increase in pathologic features including acute atherosis, infarction, retroplacental hematomas, accelerated villous maturity, and vascular thrombosis ([22]). These abnormalities further support the fact that hyperhomocysteinemia is an etiologic factor in placental abruption. Future randomized trials with folate, vitamin B_6, and vitamin B_{12} supplementation will be informative. For the present, patients with placental abruptions with no obvious etiology should be considered for hyperhomocysteinemia screening.

A final category of risks includes iatrogenic causes. Iatrogenic agents such as nicotine from cigarette smoking and cocaine can both cause vasoconstriction that leads to ischemia and abruption. This alteration in uteroplacental blood flow most likely causes placental lesions (i.e., infarction, oxidative stress, apoptosis, and necrosis) that can bring about disruptions in the placental–uterine interface leading to the abruption. Cigarette smoking was associated with an adjusted odds ratio for abruption ranging from 1.7 in all patients to 3.5 for African Americans, or an approximate two-fold relative risk ([23]). It has also been reported that smoking a pack of cigarettes per day increases the risk by approximately 40% ([24]). In another analysis, approximately 15% to 25% of abruptions can be attributed to smoking ([23]).

Other etiologic factors that are less well studied or less frequent include the iatrogenic risks from cesarean section, extramembranous placement of intrauterine pressure catheters, external version, amniocentesis, incorrect placement of the seat belt, and possibly maternal physical activity. No large case-control study has been performed to settle these associations satisfactorily.

Circumvallate Placenta One final risk for placental abruption is the abnormal placentation known as a circumvallate placenta. It is an abnormality in placental development leading to a thickened placenta with an overall decreased surface area over the uterine wall. In this condition, the membranes of the chorion laéve do not insert at the edge of the placenta but some distance closer toward the center. This leaves a rim of fibrin and blood in various stages of clotting at the membrane and placental junction. The unprotected villi beyond the rim tend to bleed. In addition to hemorrhage, this abnormal placentation can lead to placental abruption, fetal growth restriction, preterm labor, and preterm rupture of the membranes. Typically, a second trimester ultrasound identifies such a placenta by its unusual shape with a raised placental margin that does not lay flat against the uterine wall. However, clinically observed bleeding is usually not seen until the end of the second trimester and beginning of the third trimester. Therefore, when suspicions are raised, the patient will need to be warned of the potential for bleeding and other complications and will need to be followed closely. In summary, many risk factors have now been identified in association with placental abruption. Many are preventable, thus justifying programs that can assess an individual's risk in order to attempt modification of behaviors preconceptually or during pregnancy.

Diagnosis

The diagnosis of a suspected abruption can be made clinically. The symptoms include vaginal bleeding, uterine pain, a tetanic contraction of the uterus, and fetal heart rate abnormalities including a sinusoidal pattern in severe abruption. Bleeding occurs in approximately 80% of cases but the remaining symptoms may be present in less than 20% of cases. A definitive diagnosis can only be made retrospectively after delivery and inspection of the placenta because even ultrasound diagnosis is at best 50% sensitive because hemorrhage can be difficult to visualize. MRI can detect blood through detection of methemoglobin but it is not a practical modality for an acute problem as with an abruption.

Ultrasound diagnosis is usually performed transabdominally but may be supplemented with transvaginal scanning if the bleeding placental edge is low (Fig. 20.7). Careful examination of the retroplacental area is required. False-positive identification of the normal retroplacental complex, the normal vascular complex of uterine vessels, decidua and myometrium, as an abruption has been reported. This complex appears hypoechoic on ultrasound. Acute bleeding may take on a variety of appearances from hypoechoic to isoechoic to hyperechoic and diagnosis of an abruption may be confused by this complex. The hyperechoic retroplacental complex, which is usually no more than 2 cm in thickness, demonstrates very high amounts of blood flow by color Doppler imaging that excludes its likelihood of being a clot that should demonstrate no active flow. Other hypoechoic areas such as a myoma or a uterine contraction can be mistaken for an abruption but again color Doppler can assist in the distinction because contractions demonstrate a large amount of blood flow within them and myomas demonstrate blood flow around most of their periphery and less within them. A repeat scan of a fresh bleed is often helpful since the ultrasound appearance of a clot will change with time, becoming more echogenic at 48 hours and then hypoechogenic within 1 to 2 weeks. Aside from this retroplacental complex, an abruption is also difficult to distinguish from the placenta itself. Acute hemorrhage tends to be difficult to distinguish from the placenta but with time, the clot becomes hypoechoic compared to the placenta.

FIG. 20.7. Transvaginal ultrasound image of a retroplacental abruption. The *markers* indicate the size of the clot, 3.5 × 1.0 cm.

Pulsed-wave Doppler is not a useful tool for abruption diagnosis because the results have been inconsistent. Some studies evaluating the use of umbilical artery Doppler velocimetry have shown no abnormalities despite the presence of large retroplacental clots while others have shown elevated resistive indices and waveforms in both the umbilical and uterine arteries in patients with third trimester hemorrhage. These inconsistent findings probably reflect the heterogeneity of patients who presented with an abruption in the published studies. It also reflects the fact that none of the studies to date have had sufficiently high numbers of patients with isolated abruptions. The majority of these studies have evaluated these markers in a heterogeneous group of patients with a wide number of pregnancy complications in addition to abruptions. Uterine artery Doppler studies between 22 to 24 weeks gestation are better for predicting subsequent preeclampsia and fetal growth restriction.

Therefore, undertaking the use of either of these tests to predict subsequent abruption would not be a valued undertaking at this time. However, use of these tests to detect patients at higher risk for pregnancy outcome complications would be a meaningful exercise.

Other means to diagnose or detect placental abruptions include serum biochemical tests. Two markers that have been studied are MSAFP and maternal serum human chorionic gonadotropin (hCG). Presumably, these proteins leak across the placenta when there is an abnormality in its physiologic and anatomic integrity. These markers are elevated in low-risk women with fetal or neonatal death, pregnancy-induced hypertension, placenta previa, preterm delivery, growth restriction, and perinatal complications but who did not have an a priori risk for a neural tube defect or a chromosomal abnormality. The risk of an unexplained elevated MSAFP has been associated with as high as a ten-fold increase of placental abruptions. Among women with third trimester preterm labor, elevated levels of MSAFP at an MoM of 2.0 was observed when an abruption was present with a sensitivity of 67% without bleeding and 100% with bleeding. The negative predictive value can be as high as 94% and 100%, respectively ([25]).

The latest serum marker to be studied in this context is inhibin A, a placental protein that is currently part of a quadruple–serum-marker screen for detection of Down syndrome in which it tends to be increased. Although preliminary, some studies suggest that inhibin A is decreased in patients with systemic lupus erythematosus who also had placental abruptions.

One other marker worth discussion is a test for fetal hemoglobin in maternal blood such as the Kleihauer-Betke test which is a stain for fetal hemoglobin. This test is routinely ordered for Rh-negative patients with a positive blood-screening test to determine how much RhoGam to administer to protect against sensitization. Studies, however, have shown that it is not a useful test to detect suspected placental abruption. This may be explained by the fact that most abruptions consist of maternal blood and most originate in the retroplacental space where there is no overlap of the fetal and maternal blood compartments as would be encountered with an intraplacental bleed where the fetal blood within villous vessels is in close proximity to maternal blood within the intervillous spaces.

Clinical Features

A patient with an abruption will typically present with painless or painful vaginal bleeding. Approximately 20% will have no external bleeding. Typical symptoms include uterine tenderness and irritability. Uterine tone may be increased and may be difficult to distinguish from uterine contractions. Patients with abruptions can have quite significant coagulopathy that develops over a very short time.

Management

The majority of abruptions are marginal abruptions and patients tend to be quite stable. Large retroplacental abruptions are usually quite symptomatic and more easily diagnosed. They also require more acute and aggressive management to prevent disastrous adverse consequences. The chance of a marginal abruption extending to a large retroplacental hematoma is unknown. The decision to hospitalize a patient with any bleeding or with a diagnosed abruption in the latter half of the second trimester or in the third trimester after fetal viability is established is an easy one. On admission, the patient should have blood drawn for a complete blood count and a type and cross or type and screen depending on the amount of bleeding. With large bleeds, 4 units of packed red blood cells should be made available. A coagulation panel consisting of a prothrombin time (PT), partial thromboplastin time (PTT), fibrin degradation product, and fibrinogen level should be drawn if there is a large amount of bleeding. When the fibrinogen level is less than 150 mg per dL, blood in a red top tube may not clot within 6 minutes or forms and lyses within 30 minutes. With mild bleeding, fetal monitoring and observation is appropriate. If significantly previable, intermittent transfusions may be necessary to maintain the hematocrit above 30.

When there is a large amount of bleeding, fetal well-being should be documented by continuous fetal monitoring, a Foley catheter should be inserted to monitor urine output, frequent maternal vital signs should be performed, and a neonatologist and anesthesiologist should be notified of a potential emergent cesarean delivery. An ultrasound should be obtained to ascertain the amount and location of bleeding. Antenatal steroid treatment should be considered if membranes are intact and the fetus is between 24 and 34 weeks gestation. For any patient with bleeding, consideration for treatment with 1 mg folic acid and vitamin B_{12} and B_6 should be undertaken for the possible link between abruptions and hyperhomocysteinemia.

With mild bleeding, the patient will likely resolve her symptoms and should be able to be discharged once an acceptable time interval without any further bleeding has been established, usually 2 to 5 days. However, the decision on when to discharge patients who have had a large bleed is a more difficult one and there are no strict guidelines. Clearly, no decision on discharge should even be considered if the patient is symptomatic either with pain or contractions. Much of the decision will also rest on the patient's home support, whether she will be able to comply with bed rest, and it would not be unreasonable to keep a patient in the hospital until delivery if she is noncompliant or if the home environment will not allow her to undertake bed rest. Whether the patient is an inpatient or an outpatient, some fetal monitoring program should be established.

The issue of tocolytic use in a patient with a known or suspected abruption who has uterine contractions is a debatable one. Although it was formerly taught that no tocolytics should be used in patients with undiagnosed bleeding, it has now become acceptable to consider a short course of tocolytic therapy for patients with bleeding and contractions provided that the patient is stable, the abruption appears to be limited, fetal well-being is established, gestational age is preterm, and there is a controlled environment ([26]). Tocolytics can also be justified if they can prevent labor until a full course of antenatal steroids can be administered and 48 hours posttreatment can be achieved. Because ß-mimetics can mask or blunt the patient's cardiovascular responses to volume depletion, terbutaline and ritodrine should be avoided. Calcium channel blockers may further reduce the blood pressure and nifedipine should be used with caution. The most accepted agent at the present time is magnesium sulfate. As with patients with preterm labor, these agents should be used in the acute setting and efforts should be made to discontinue them when there is a persistent period of quiescence.

Delivery can be by either vaginal delivery or cesarean section depending on the degree of bleeding, the presence or absence of active labor, and the presence or absence of fetal distress. Operative deliveries have been used liberally, in excess of 50% of cases.

When abruption leads to fetal demise, there is a very high rate of DIC. The best marker of severity is the fibrinogen level. Blood products should be administered as needed to correct the coagulopathy and then plans for delivery should be made. Induction of labor and successful vaginal delivery has been reported. Cesarean section may seriously jeopardize the mother's health in the face of a coagulopathy and should be reserved for those cases where there is fetal distress or when it appears that labor and delivery will not be successfully achieved within a reasonable amount of time, between 12 to 18 hours.

Complications

One complication of placental abruption is uteroplacental apoplexy, also known as a Couvelaire uterus. It occurs rarely but is seen with severe placental abruption in which blood extravasates from the clot into the myometrium. The appearance is that of a blue-tinted uterus. This is a very obvious visual diagnosis but biopsies have confirmed the presence of heme throughout the myometrium. This heme can lead to a very hypotonic uterus and on occasion a hysterectomy is needed in order to control the bleeding. Uterine artery embolization is likely not to be effective, although it has not been reported in the literature.

Another complication is disseminated intravascular coagulopathy marked by a fibrinogen level less than 300 mg per dL, a prolonged PT and PTT. If this occurs, large-bore intravenous lines should be placed and crystalloid and blood products should be given as quickly as possible in the form of packed red cells, fresh frozen plasma, cryoprecipitate, and platelets. A Foley catheter should be placed to monitor urine output and a central venous pressure catheter should be considered if urine output drops below 30 mL per minute.

Outcomes

Several significant adverse outcomes have been seen in association with placental abruptions. In a large epidemiologic study of placental abruption in the United States from 1995 and 1996 that incorporated over 7 millions births, the perinatal mortality rate was reported to be 119 per 1,000 births with abruption compared with 8.2 per 1,000 in all other births ([27]). Although there was significant mortality attributed to prematurity and growth restriction, the high perinatal death rate persisted. Term babies of normal size had a 25-fold higher mortality with an abruption than those without abruption. The pathophysiology regulating this outcome remains to be determined. In another similar epidemiologic study, abruption was also found to be associated with a very high risk for stillbirth (8.9-fold), preterm birth (39.6%), and growth restriction (14.3%). These investigators also evaluated outcomes related to the degree of abruption and found that all abruptions had a significant risk for stillbirth (RR of 31.5 for 75% abruption vs. RR of 5.5% for 25% abruption) ([28]).

Patients with an abruption should be counseled that there is a recurrence risk with an adjusted odds ratio of 6.4 and possibly as high as 25%. Efforts should be made to identify risk factors and to modify them. Fetal surveillance in subsequent pregnancies should be monitored starting at least two weeks before the gestational age at which the previous abruption was diagnosed in order to reduce the recurrence risk. Surveillance could consist of serial ultrasound scans for fetal growth restriction and

placental bleeds in combination with fetal biophysical profiles depending on when the gestational age surveillance is initiated.

Other outcome measures such as intraventricular hemorrhage, cystic periventricular leukomalacia, and cerebral palsy have been evaluated. All are seen in higher frequency among infants delivered because of an abruption. However, many of these infants were also growth- restricted, making it difficult to discern whether these adverse outcomes were attributed to the early gestational age, the abruption, or the growth restriction. Many of these studies were also plagued by small numbers of infants studied.

Prevention

There is no established protocol for the prevention of primary or recurrent abruption. Based on the risk factors that have been identified to date, a protocol could be established to educate patients on the signs and symptoms of an abruption, on how to avoid and report domestic abuse, on how to properly use their seat belts, and on the health-related effects of cigarette smoking. A nutritional educational program can focus on how to increase the patient's folic acid and iron intake. A social service contact can be established for those at risk because of a poor home situation and those engaged in hard physical activity. Ultrasound scanning should be used to scrutinize the integrity of the uterine wall in patients with a prior cesarean section and to identify other uterine or placental abnormalities, such as the presence of a myoma or septum and the placental location in relation to it. Finally, patients with medical illnesses such as hypertension should be seen frequently to optimize their medical well-being.

SUMMARY POINTS

- The workup of a patient who presents with third trimester bleeding should be methodical and thorough in order to optimize the neonatal outcome. The two major etiologies, placenta previa and placental abruption, are better diagnosed today by state-of-the art imaging. Best outcomes can be obtained by following a systematic approach. The risk factors for each should be identified in order to prevent similar future events (Fig. 20.8).

FIG. 20.8. Flow diagram summarizing recommended clinical management for bleeding in the third trimester. Individualization is warranted and the entire clinical picture must be factored into the management plan.

- There are two ways to classify a placenta previa: (a) By visual inspection or digital exam—marginal, partial, or complete; and (b) by transvaginal ultrasound—less than 1 cm, between 1 and 2 cm, or greater than 2 cm from the undilated internal cervical os.
- New imaging modalities including color Doppler ultrasound and MRI can improve on making the diagnosis of placenta previa, accreta, and abruption. This has minimized the need for a double setup exam in the case of a previa.
- Arterial embolization is becoming a standard means to decrease the need for a hysterectomy due to postdelivery bleeding from a previa.
- There are many risk factors for placental abruptions and the clinician should know them. When possible, the risks (i.e., cigarette smoking) should be modified to decrease the chance for abruption.
- Placenta previa and placental abruption can both lead to serious bleeding. However, placental abruption is more likely to lead to significant maternal coagulopathy.
- Expectant management is an acceptable plan for placenta previa and abruptions when the gestational age is preterm, there is no fetal distress, and the patient is stable.
- Amniocentesis should be routinely used in patients with placenta previa and abruption to document fetal lung maturity and plan delivery as soon as possible in these potentially unstable situations.

BREECH PRESENTATION

Breech presentation, the most common obstetric malpresentation, complicates approximately 4% of deliveries.

Definitions

Breech presentation is a polar alignment of the fetus in which the fetal buttocks present at the maternal pelvic inlet. Three types are recognized: frank, incomplete, and complete.

In frank breech presentation, the fetal hips are flexed and the knees extended, so that the thighs are apposed to the abdomen and the lower legs to the chest (Fig. 21.1). The buttocks are the most dependent part of the fetus. Frank breech presentation accounts for 60% to 65% of breech presentations; it is more common at term.

FIG. 21.1. Fetal attitude in frank, incomplete, and complete breech presentations.

In the incomplete breech presentation, the fetus has one or both hips incompletely flexed so that some part of the fetal lower extremity, rather than the buttocks, is the most dependent part (hence the terms *single footling* or *double footling*). This presentation accounts for 25% to 35% of breech presentations and is more common among premature fetuses.

Complete breech presentation is the least common type, accounting for about 5% of breech presentations. In this situation, the fetal hips and knees are both flexed so that the thighs are apposed to the abdomen and the legs lie on the thighs. A significant proportion of these fetuses convert to incomplete breech presentations if allowed to labor.

The position of the breech fetus is described with the fetal sacrum as the reference point; thus, it is right sacrum anterior, left sacrum posterior, left sacrum transverse, and so forth.

A spontaneous breech delivery is one in which the entire infant delivers vaginally without manual aid. In the unusual circumstance of a vaginal delivery of a singleton breech the recommended form is the assisted breech delivery, also known as partial breech extraction. In this delivery the fetus is allowed to deliver by the forces of uterine contractions and maternal bearing-down efforts until the fetal umbilicus has passed over the mother's perineum. After this, delivery of the legs, trunk, and arms are assisted manually; the head may be delivered manually or with forceps. A complete breech extraction, in which manual assistance is applied by traction in the groins or on the lower extremities before delivery of the buttocks, is contraindicated in singleton breech presentations.

Incidence

The incidence of breech presentation is closely associated with birth weight. Breech presentation accounts for 4% of births overall but occurs in 15% of deliveries of low–birth-weight (<2,500 g) infants. Furthermore, the smaller the infant, the higher the incidence of breech presentation, which rises to 30% among infants weighing 1,000 g to 1,499 g and to 40% among those weighing less than 1,000 g.

Viewed from another perspective, the association between breech presentation and low birth weight is even more striking. Only 70% of infants who present as breeches weigh more than 2,500 g; 30% weigh less than 2,500 g (compared with 5% to 6% of infants who are in vertex presentation), and 12% are of very low birth weight, weighing less than 1,500 g.

Cause

Factors that predispose to breech presentation are listed in Table 21.1. The importance of fetal anomalies cannot be overemphasized (Table 21.2). Malformations of the central nervous system complicate 1.5% to 2.0% of breech births: the incidence of hydrocephalus is ten-fold greater, and that of anencephaly two-fold to five-fold greater, than it is among infants presenting as vertex. Up to 1% of infants in breech presentation have a significant chromosomal abnormality: One in 200 has Down syndrome, and the incidence of other autosomal trisomies is increased as well. Of those infants presenting as breeches the incidence of major congenital anomalies is 17% among premature infants, 9% among term infants, and 50% among term infants who die in the perinatal period. It is prudent to keep these numbers in mind when deciding on a method of delivery for a fetus in breech presentation.

Fetal anomalies
Head anomalies
Anencephaly
Hydrocephalus
Chromosomal anomalies
Autosomal trisomies

Unicornuate
Uterine overdistension
Polyhydramnios
Multiple gestation
High parity with lax abdominal and uterine musculature
Pelvic obstruction
Placenta previa
Myomata
Other pelvic tumors

TABLE 21.1. *Factors predisposing to breech presentation*

Type of malformation	Incidence (%)
Central nervous system	2.0
Hydrocephalus	0.6
Anencephaly	0.4
Trisomy 21	0.5
Cardiovascular	0.5
Gastrointestinal	0.5
Genitourinary	0.1
Overall among term infants	9.0
Overall among term infants who die	50.0

TABLE 21.2. *Congenital malformations among term Infants in breech presentation*

For many years an association between cerebral palsy and breech presentation (although not vaginal breech delivery) has been assumed. As it becomes apparent that most fetal insults leading to cerebral palsy occur before term, it appears that cerebral palsy is another cause of breech presentation. In fact, among term infants, the risk of cerebral palsy is not related to presentation after correcting for fetal growth restriction.

In more than 50% of cases, no causative factor for breech presentation can be identified.

Diagnosis

On abdominal examination, the first Leopold maneuver demonstrates the fetal head in the fundus. The third maneuver reveals the softer breech over the pelvic inlet. It is useful to remember that the head narrows down to the neck before attaching to the body, whereas there is no such tapering between the buttocks and body. Auscultation of fetal heart tones usually reveals them to be most easily detected in the upper quadrants of the uterus when the fetus is in breech presentation.

The diagnosis is often made by vaginal examination. In frank or complete breech presentation, the anal orifice may be felt, with the bony prominences of the ischial tuberosities directly lateral to it. Face presentation may be difficult to distinguish from frank breech presentation, with the fetal mouth being mistaken for the anus. It is helpful to remember that the mouth is surrounded by bone, whereas the anus is not. In incomplete breech presentations palpation of the feet on vaginal examination is diagnostic. During labor, any presentation that is not clearly vertex by vaginal examination should be confirmed by ultrasound.

Perinatal Mortality

Perinatal mortality is higher in breech presentation than in vertex, being four-fold greater among term infants and two- to three-fold greater among premature infants. Much of this excess mortality is not preventable; 64% of deaths among term infants in breech presentation are due to malformations or infection. Among premature infants, malformations, infection, maternal disease, and intrauterine death before labor account for 56% of perinatal mortality, and complications of prematurity unrelated to the method of delivery account for another 11%. Thus only about one-third of perinatal deaths among breech infants are due to potentially preventable factors. These factors basically fall into two categories: Trauma and asphyxia.

Trauma to the head is a significant risk in both term and premature infants who present in the breech position, regardless of the route of delivery. Unlike the situation in vertex presentation, in which the fetal head is in the maternal pelvis for hours or days during which molding can occur, the aftercoming head of the breech fetus must come through the pelvis as is—there is no time for molding. Thus, minor variations in maternal pelvic architecture, which would be insignificant in vertex presentation, may become major risks. This problem is compounded for the infant at less than 32 weeks of gestation in whom the head is the largest part. In these circumstances the fetal body may deliver through an incompletely dilated cervix, which then entraps the head. Performance of a cesarean does not ensure a traumatic delivery of the aftercoming head. An inadequate incision or suboptimal uterine relaxation may result in head entrapment leading to significant injury to the infant and mother.

Damage to fetal muscles, soft tissue, and viscera may occur with delivery if the fetus is grasped in places other than its bony pelvis. Likewise, delivery may be associated with nerve injury if the arms are not delivered properly, especially if there are nuchal arms. Finally, trauma to the cervical spinal cord may occur with delivery of a breech fetus with hyperextension of the neck.

Asphyxia may be caused by prolapse of the umbilical cord. The incidence of cord prolapse in term fetuses in frank breech presentation is 0.4%. In complete breech presentation, the incidence is 5% to 6%, and with incomplete breech presentation the incidence may be as high as 10%. Cord prolapse in incomplete breech presentation, although an indication for prompt cesarean delivery, is often not the devastating event that it is in vertex or frank breech presentation. Because the cord is prolapsed between the fetal legs, it often is not markedly compressed during subsequent contractions.

Not all of the excess asphyxia among fetuses in breech presentation is caused by overt cord prolapse. Abnormalities of the fetal heart rate pattern during labor are four to eight times more common in fetuses in breech presentation than fetuses in vertex. An unknown percentage of this is undoubtedly due to occult cord prolapse and other forms of cord compression.

Antepartum Management

Breech presentation diagnosed before 32 weeks gestation should be managed expectantly. The fetuses of approximately two-thirds of multiparas and one-third of primigravidas who are diagnosed as being in breech presentation before 32 weeks of gestation will convert to vertex presentation spontaneously before labor. Breech presentation that persists into the late third trimester should be evaluated by an ultrasound examination for congenital anomalies.

When a breech presentation persists beyond 32 weeks of gestation, some obstetricians have recommended attempts at converting the presentation to vertex by external cephalic version (ECV). Ranney reported his experience with 860 patients managed by external version. Attempts were made to turn the fetus to vertex whenever breech presentation was found in the third trimester, and some patients had repeated versions performed. Ranney was able to lower the incidence of breech presentation at term to 0.6%, about one-sixth the expected number, and encountered no fetal trauma or death and no increase in the incidence of placental abruptions.

The results of Kasule and co-workers are less optimistic. All patients with fetuses in breech presentation after 30 weeks of gestation were prospectively randomized to either an external version group (310 patients) or a control group (330 patients). The subjects in the external version group had the procedure performed between 33 and 36 weeks of gestation. If the first attempt failed, or if the fetus reverted to breech presentation, the procedure was repeated up to three times in subsequent weekly visits. No attempts at external version were made after 36 weeks of gestation. Although their immediate success rate was 80%, 46% of fetuses spontaneously reverted

to breech presentation. There were three perinatal deaths attributed to the procedure: two from abruptio placentae and one from premature labor and delivery. Most important, the incidence of breech presentation at delivery was 52% in the external version group and 51% in the control group, with 49% of fetuses in the control group converting to vertex presentation spontaneously before delivery. The authors surmised that many, if not all, of their successful external versions may have been in patients whose fetuses would have converted spontaneously had nothing been done. This hypothesis, coupled with the three perinatal deaths, led them to conclude that “there is no place for external cephalic version before 36 weeks gestation.”

The *Cochrane Database of Systematic Reviews* found three randomized trials of external version prior to 37 weeks of gestation. These studies showed no effect of ECV before term on the rate of breech presentation at delivery (risk ratio [RR] = 1.02; 95% confidence interval [CI] = 0.89–1.17), cesarean section (RR = 1.10; 95% CI = 0.78–1.54), low Apgar scores (RR = 0.81; 95% CI = 0.44–1.49), or perinatal mortality (RR = 1.19; 95% CI = 0.46–3.05). It was concluded that “in view of the lack of evidence of effectiveness, and reports from observational studies of unacceptably high complication rates from ECV before term, there is at present no place for ECV before term in modern obstetrics.”

If external version at term is to be attempted, it should be done in the labor and delivery suite, using monitoring of the fetal position and heart rate by ultrasound. In the past, the consensus was that no anesthesia should be used, pain being considered a reason to discontinue the attempt. As vaginal breech birth has become less of an option, however, a different approach has been proposed. This involves waiting until the pregnancy has progressed at least to 37 completed weeks of gestation, at which time epidural anesthesia is instituted. External version is attempted, and if successful, the patient has an immediate induction of labor; if unsuccessful, the patient is delivered by cesarean. In either case the epidural used for the external version attempt is used for the delivery as well. This approach seems to have merit, provided one is careful not to be overly aggressive with attempts at external version in an anesthetized patient.

Lau and associates reported a prospective case-control study of external version at term. They reported an overall success rate of 57% in nulligravidas and 84% in multiparas. They also found a rate of reversion to breech presentation of 4%. Complications included a 3.3% incidence of transient fetal bradycardia, and a 0.4% rate (one case) of what the authors called placental abruption. This particular patient had a 3-minute episode of fetal bradycardia and some vaginal spotting, although nothing suggesting abruption was found at the time of emergency cesarean. These same investigators have reported another series of 243 women who underwent attempts at external version. Regression analysis identified three independent predictors of failed version: engaged presenting part, difficulty palpating the fetal head, and nulliparity. The chance of success was 0% if all three variables were present, less than 20% if any two were present, 30% to 60% if only one was present, and 94% if none were present. Interestingly, placental location, position of the fetal spine, attitude of the fetal legs, and maternal obesity were not significant variables for predicting successful version, when the other variables were controlled.

Regarding ECV at term, the *Cochrane Database of Systematic Reviews* concludes that “the chance of breech birth and cesarean section may be substantially reduced by attempting ECV at term. The numbers are too small to give an accurate assessment of the risks of ECV. There is sound reason to use ECV at term, with appropriate cautions.”

It should be noted that successful external version does not necessarily reduce the cesarean rate to that found in other vertex presentations. Lau and colleagues reported a 32% cesarean rate in nulliparous patients after successful external version to vertex presentation; the rate in multiparous patients was 11%.

Active labor and ruptured membranes are contraindications to the procedure. Relative contraindications include an engaged presenting part and an estimated fetal weight of 4,000 g or more. Whether a previous cesarean contraindicates attempts at external version is uncertain, but in modern practice, delivery of breech fetus in a woman with a previous cesarean by elective repeat cesarean seems reasonable.

Management of Delivery

Term Breech Presentation Cheng and Hannah (1993) published a critical review of the literature on singleton term breech pregnancies, reviewing all articles in the English language literature between 1966 and 1992. They found that there were only 24 studies that presented results according to the intended mode of delivery, and which presented outcome data in sufficient detail to be analyzed. Of these 24 reports, only two were randomized trials; * eight were prospective cohort studies and 14 were randomized cohort studies. Twenty-two of these studies, including both prospective trials, did not demonstrate a statistically significant difference in corrected perinatal mortality between those patients for whom a vaginal delivery was planned and those for whom a cesarean was planned. Two series did show significantly worse outcome among those for whom vaginal delivery was planned. When the authors combined all of the data, they produced a “typical odds ratio” for perinatal mortality of 3.86 (95% CI = 2.22–6.69) in the planned vaginal delivery group. Their data on low 5-minute Apgar scores, birth trauma, and short- and long-term neonatal morbidity were similar to the data on perinatal mortality, in that the majority of individual studies did not find a difference between those for whom vaginal birth was planned and those for whom cesarean was planned. When the studies were combined, however, the planned vaginal delivery group fared worse in all categories (Table 21.3). The authors of this review carefully pointed out all of the flaws in the papers they reviewed, and concluded that most of these studies were too poorly done to allow definitive conclusions. They conclude their paper by stating “the only way to obtain more definitive information regarding the effectiveness of a policy of elective cesarean versus that of a trial of labor in women with breech presentation at term is to mount an appropriately sized, randomized controlled trial. In the absence of such a trial, a policy of elective cesarean delivery appears to be a reasonable option for the woman with breech presentation at term.”

	Planned cesarean	Planned vaginal delivery
Apgar <7 at 5 min	1.0	3.86 (2.22–6.69)
Birth trauma	1.0	3.96 (2.76–5.67)
Short-term morbidity	1.0	2.54 (1.74–3.71)
Long-term morbidity	1.0	2.88 (1.04–7.97)

CI, confidence interval.

TABLE 21.3. *Neonatal morbidity, planned vaginal delivery vs. cesarean. Typical odds ratio and 95% CI*

In order to answer the question of the optimal route of delivery of the term breech, Hannah and associates organized the Term Breech Trial, a randomized trial of planned cesarean delivery versus planned vaginal birth for term singleton frank and complete breech infants. This trial was carried out between January 1997 and April 2000 in 121 hospitals in 26 countries. Sixteen were industrialized nations with low perinatal mortality rates, and ten were underdeveloped countries with high perinatal mortality rates. The results of this trial were published in 2000, and will be presented here in considerable detail because of the uniqueness and importance of the study. Patients were eligible for the trial if they were at 37 or more weeks of gestation with a singleton frank or complete breech. Women were excluded for clinical or radiographic evidence of pelvic inadequacy (91% of subjects in both groups had only clinical evaluation of the pelvis), if the fetus was estimated to weigh more than 4,000 g either clinically or by ultrasonography (60% of subjects had sonography, 40% had clinical evaluations of fetal weight), if hyperextension of the fetal neck was felt to be present by clinical exam (31% of subjects) or ultrasonography (69% of subjects), if there was a contraindication to labor or vaginal delivery, or if there were fetal malformations incompatible with life or predisposing to mechanical problems with vaginal delivery. The labor protocol permitted induction and augmentation of labor for usual indications, and called for either continuous electronic fetal monitoring or intermittent auscultation every 15 minutes in the first stage of labor and every 5 minutes in the second. Adequate labor progress was defined as a rate of cervical dilation of =0.5 cm per hour in the active phase, descent of the breech to the pelvic floor within 2 hours of the second stage, and imminent delivery within 1 hour of active pushing. The method of vaginal delivery was spontaneous or assisted; total breech extraction was not permitted. Most importantly, all vaginal deliveries were to be attended by a clinician experienced with vaginal breech delivery (self-defined with confirmation by the individual's department head). The primary outcomes measured were perinatal/neonatal morality and serious neonatal morbidity. The secondary outcomes measured were maternal mortality and serious maternal morbidity (Table 21.4). Power analysis prior to the study calculated a required randomization of 2,800 subjects. An interim analysis of the first 1,600 births revealed a clear advantage for planned cesarean, and therefore recruitment was stopped at 2,088 women (488 additional women had been enrolled while the interim analysis of the first 1,600 was in progress). In the final analysis, the rate of perinatal mortality and morbidity was 1.6% in the planned cesarean group and 5.0% in the planned vaginal delivery group (RR = 0.33; 95% CI = 0.19–0.56; $P < .0001$). Considering perinatal mortality alone, the respective rates for cesarean and vaginal delivery were 0.3% and 1.3% (RR = 0.23; 95% CI = 0.07–0.81; $P < .01$). Similar data for neonatal morbidity alone were 1.4% and 3.8% (RR = 0.36; 95% CI = 0.19–0.65; $P < .0003$). For every subcategory of neonatal morbidity, infants in the planned cesarean group fared significantly better than those in the planned vaginal delivery group. Most interestingly, the improvement in neonatal outcome with planned cesarean was better in the countries with already low perinatal mortality rates. The authors determined that in industrialized nations, one case of neonatal mortality or serious morbidity could be avoided for every seven additional cesareans, whereas in underdeveloped countries, as many as 39 additional cesareans might be needed to avoid one dead or compromised baby. For the entire population studied, the number of additional cesareans needed to avoid one dead or seriously injured baby was 14. The authors' finding of a significant advantage for planned cesarean birth was maintained even after excluding labors which were prolonged, induced, or augmented and after correcting for whether or not epidural anesthesia was used. Finally, and of equal importance, the authors found no differences between the groups in terms of maternal mortality or serious morbidity; there were no differences in maternal morbidity whether the various morbid conditions were totaled or considered separately.

Serious Neonatal Morbidity	
Birth trauma	
subdural, intracerebral or intraventricular hemorrhage	
spinal cord injury	
skull fracture	
peripheral nerve injury	
Seizures at <24 h of age	
Apgar score <4 at 5 min	
Cord blood base deficit ≥15	
Hypotonia for ≥2 h	
Stupor or coma	
Intubation and ventilation for ≥24 h	
Tube feeding for ≥4 d	
Neonatal intensive care unit admission >4 d	
Serious Maternal Morbidity	
Postpartum hemorrhage >1500 mL	
Need for blood transfusion	
D&C for bleeding or retained placenta	
Hysterectomy	
Cervical laceration extending into lower uterine segment	
Vertical uterine incision	
Vulvar/perineal hematoma	
Deep venous thrombosis/pulmonary embolism	
Pneumonia	
Wound infection/breakdown	
Bladder, ureter, or bowel injury	
Genital tract fistula	
Bowel obstruction	
Febrile morbidity (standard definition)	

Source: Hannah ME, et al. Planned caesarean section versus planned vaginal birth for breech presentation at term: a randomized multicentre trial. *Lancet* 2000;356:1375–1383.

TABLE 21.4. *Primary and secondary outcomes in the Term Breech Trial*

The *Cochrane Database of Systematic Reviews* includes a systematic review of the three randomized, controlled trials of planned cesarean versus planned vaginal delivery for breech presentation (Collea and colleagues, 1980; Gimovsky and colleagues, 1983; Hannah and colleagues, 2000) and concludes “policy of planned cesarean section for term breech presentation is associated with a large decrease in perinatal/neonatal mortality, and neonatal morbidity, and a modest increase in maternal morbidity (RR = 1.29; 95% CI = 1.03–1.61). Overall the results clearly favor a policy of planned cesarean section.” Based on this information the American College of Obstetricians and Gynecologists' Committee on Obstetric Practice issued Committee Opinion #265 in December 2001, concluding, “patients with a persistent breech presentation at term in a singleton gestation should undergo a planned cesarean delivery.” It is important to point out that they further stated “a planned cesarean delivery does not apply to patients presenting in advanced labor with a fetus in breech presentation in which delivery is likely to be imminent, or to patients whose second twin is in a nonvertex presentation” (see Chapter 14). There are many points on which one can criticize the Term Breech Trial. It is not a perfect study, but it is a good study. It brings real evidence to bear on the question of breech delivery, and given today's medicolegal and social climate, it may be the best evidence we are ever going to have. Two other points are pertinent. First, almost no obstetrician completing residency in the past 10 years has the training or experience to be skillful at vaginal breech delivery, and the cadre of obstetricians capable of imparting these skills is retiring or giving up obstetrics. Second, the argument that vaginal delivery is significantly safer than cesarean for the mother is becoming more and more difficult to prove. A growing number of studies, including the Term Breech Trial, have shown that maternal morbidity and mortality is as good or better with planned cesarean delivery as with vaginal birth. On the other hand, emergency cesarean or cesarean after a trial of labor is clearly more morbid than either elective cesarean or vaginal delivery. In nearly all recent series, including those in the Cochrane Database, 40% to 45% of women given a trial of labor for breech presentation eventually were delivered by cesarean, which greatly increases the overall risk of morbidity and mortality in the total group for whom vaginal breech delivery is planned. Two fairly large retrospective studies of term breech delivery from Sweden confirm the findings of the Term Breech Trial. Herbst and Thorngren-Jerneck published a series of 1,050 term singleton breeches delivered at a single institution between 1988 and 2000. A planned vaginal delivery group of 699 women was compared to a planned cesarean group of 327. Acidemia at birth, low 5-minute Apgar scores, neonatal intensive care unit admissions, and the rate of neonatal neurologic morbidity were all significantly greater among infants in the planned vaginal delivery group. Roman and associates studied 15,818 term singleton breeches delivered in Sweden between 1987 and 1993. A summary of their neonatal data is shown in Table 21.5 and demonstrates a clear advantage for cesarean delivery. Of significant importance, the authors found the same rates of maternal morbidity for elective cesarean (1.7%) and vaginal delivery (1.8%). The maternal morbidity rate for emergency cesarean was 2.8%.

TABLE 21.5. *Neonatal outcome, cesarean vs. vaginal breech delivery (OR and 95% CI)*

Given the data from these studies I believe it is time to consider the matter settled. Unless and until another large, randomized, controlled trial reveals different findings from what is known from these studies, the route of delivery for the term singleton breech should be cesarean.

Premature Breech Presentation Almost no randomized prospective data are published regarding delivery of the premature infant in breech presentation. Penn and co-workers attempted a multicenter, randomized, controlled trial in 26 hospitals in England, in an effort to determine the optimal mode of delivery for breech infants at gestational ages between 26 and 32 weeks. After 17 months of attempting to enroll patients the study was abandoned because only 13 women from 6 hospitals had been recruited. The authors stated, “The low accrual rate was due to clinicians' reluctance to randomize eligible women.” Eller and VanDorsten polled the Maternal-Fetal Medicine Units network and found 7 of 11 centers willing to do a randomized controlled trial comparing cesarean to vaginal birth for breech infants between 24 to 28 weeks of gestation; because of small numbers they calculated this study would require at least 10 years. No center in the network was even willing to study breech birth in pregnancies greater than 28 weeks of gestation. Therefore, management decisions regarding the premature breech must be made based on retrospective data, which suffer from serious shortcomings. These data, however, all indicate that cesarean delivery is preferable for the premature breech.

The Effect of Parity To separate primigravidas whose fetuses are in breech presentation as a group needing cesarean delivery is fallacious for two reasons: First, there are no data to suggest that primigravidas are at more risk than parous women for fetal injury, cord prolapse, difficult vaginal delivery, or perinatal death. Second, this philosophy implies that a parous woman in labor with a fetus in breech presentation is not at very high risk. The parous woman is at no less risk than the multiparous woman because a subsequent fetus may be larger than previous infants delivered, and because the pelvis may be adequate for vertex presentation but not for the unmolded head of a breech fetus.

Extension of the Fetal Neck Ballas and Toaff demonstrated that when the fetal neck is hyperextended to an angle of greater than 90 degrees (Fig. 21.2), vaginal delivery is associated with a 70% incidence of fetal spinal cord transections. This complication is avoided by cesarean delivery if generous abdominal and uterine incisions are employed, and the head is delivered slowly while attempts are made to flex the neck.

FIG. 21.2. Hyperextension of the fetal neck.

Management of Vaginal Delivery Occasionally a patient will arrive at the hospital in the process of delivering a breech infant. In such circumstances, a vaginal delivery is probably less traumatic to both infant and mother than a rushed cesarean under suboptimal emergency conditions. The Cochrane Review anticipates this problem without providing a solution, stating “one problem with a policy of routine cesarean section for breech presentation at term is that in time the skills of breech delivery will be lost, placing women who deliver before cesarean section can be carried out at increased risk.” To prepare as much as possible for such circumstances, given the paucity of actual experience with vaginal breech delivery, all obstetricians should frequently review the principles of vaginal breech delivery. Vaginal delivery of a fetus in breech presentation requires the attendance of at least an obstetrician and an anesthesiologist. It is preferable to have a pediatrician in attendance as well. The fetal monitor should be taken to the delivery room, and monitoring should be continued until one is committed to a vaginal delivery. Such a commitment occurs when the fetal umbilicus passes over the mother's perineum, at which time the fetal head is in the maternal pelvis. Traction on the fetus before that point constitutes a total breech extraction and should be avoided. Once the fetal umbilicus passes over the maternal perineum, a loop of cord 4 to 6 inches in length should be brought down to prevent subsequent excessive traction on the cord. The legs may then be delivered by flexing the knees and sweeping the legs out from in front of the fetus. A towel is placed around the fetal pelvis, which is then grasped, and downward traction is applied until the fetal scapulae pass under the maternal symphysis. Then the fetal body is rotated so that the shoulders are in an anteroposterior position, and the anterior arm is flexed and swept out under the symphysis. The fetus is then rotated 180 degrees in the direction that will keep the fetal back toward the maternal symphysis, and the other arm is swept out in a similar manner. It is important during delivery of a breech that the fetus not be allowed to assume a position with the fetal face or abdomen toward the maternal symphysis. If the breech infant is delivering so rapidly that cesarean birth is not feasible, the aftercoming head usually delivers spontaneously. Should this not occur, delivery of the fetal head with Piper forceps will be necessary. An assistant must support the fetal body during application of these forceps (Fig. 21.3). The temptation to elevate the fetal body to provide better visualization must be resisted, because this maneuver hyperextends the neck. Rather, the fetal body should be supported parallel to the floor, and the operator should

drop to the knee for application of the forceps. The application is pelvic rather than cephalic, with the forceps being applied to the lateral aspects of the maternal pelvis, not wandered around from the posterior using landmarks on the fetal head, as one would do in vertex presentation. Controlled delivery of the fetal head is then accomplished, with suctioning of the fetal airway as soon as the mouth passes over the perineum.

FIG. 21.3. Breech delivery with Piper forceps to the aftercoming head. Note that the infant's body is being supported parallel to the floor.

A generous episiotomy is necessary for any vaginal breech birth. For the term-sized infant, a mediolateral episiotomy is appropriate.
Management of Cesarean Delivery Abdominal delivery does not guarantee a traumatic birth of the fetus in breech presentation. Just as in vaginal delivery, it is important to grasp the fetal bony pelvis rather than soft tissue during extraction. The most serious complication is head entrapment by the uterus contracting down around the neck after delivery of the body. Some physicians have advocated a vertical uterine incision so that it may be extended should this occur. This may be the best choice for the premature fetus accompanied by a poorly developed lower uterine segment. Because such an incision compromises future childbearing, the obstetrician should perform a low transverse cervical incision for the term fetus or the premature fetus when labor has resulted in a well-developed lower segment. Such an incision can be extended in a J-shaped (rather than a T-shaped) manner, if necessary. A technique that may obviate the need for this in the face of head entrapment is general anesthesia with an agent that rapidly relaxes the uterus. The anesthesiologist should be alerted that this might become necessary even if the cesarean is begun under regional anesthesia.

FACE PRESENTATION

In face presentation, the fetal neck is hyperextended so that the occiput touches the back. The presenting part is that part of the fetal face between the orbital ridges and the chin (Fig. 21.4). The incidence is approximately one in 550 births.

FIG. 21.4. Face presentation.

Cause

Proposed causative factors include anencephaly, high parity, contracted pelvis, large infant, small infant, and nuchal cord. It is interesting to note that, in the majority of studies, one of the larger categories is that in which no causative factor can be identified; this varies from 2% to 97%, with an average frequency of 38%.

Anencephalic fetuses frequently present by the face if the fetal presentation is cephalic. However, because the course and mechanism of labor, management of delivery, and perinatal outcome are entirely different in this situation, these cases should be excluded from consideration of face presentation. The association between face presentation and anencephaly is important to remember, however, because when face presentation is suspected clinically, ultrasound studies are indicated to rule out this anomaly.

Most series demonstrate an association between high parity and face presentation; whether this relation is causal is not clear. The average reported incidence of contracted pelves in series of face presentations is 15%. In reality, the incidence is probably much lower, because in most series only those patients with arrested labor were studied radiographically. Contracted pelvis or cephalopelvic disproportion is probably diagnosed clinically with excessive frequency in face presentation, because the extended head feels larger on abdominal palpation and because the head is often floating at the onset of labor. However, if large series of radiographically diagnosed pelvic contraction are examined, it is rare to find a case of face presentation, none being reported in three series of radiographically diagnosed pelvic contraction totaling more than 700 patients. The weight of evidence seems to indicate that pelvic contraction is not of causative significance in face presentation.

Some authors associate face presentation with large infants, on the assumption that cephalopelvic disproportion may result from excessive fetal size in spite of a normal pelvis. The argument that large infants cause cephalopelvic disproportion, and thus face presentation, is weakened by the high proportion of vaginal deliveries in most series of face presentations. Furthermore, the average incidence of large infants (variously defined) in series of face presentations is 12%, not significantly different from that in the general obstetric population.

Many series have demonstrated an increased proportion of low-birth-weight infants among face presentations and ascribed causative significance to prematurity, although other studies have found no excess of low–birth-weight infants. Part of the discrepancy results from the inclusion of anencephalic fetuses in many series—fetuses that usually are small for gestational age. The average incidence of low birth weight is 11% in those series of face presentation in which it is possible to exclude anencephalics; this is not significantly different from the incidence of low birth weight in the general population. Thus it is difficult to conclude that low birth weight or prematurity are causative factors in face presentation.

Nuchal cord occurs in approximately 25% of cephalic deliveries. The average incidence of nuchal cord in face presentation is 10%. Nuchal cord is not a cause of face presentation.

Of all the proposed causative factors in face presentation, there is no unanimity of opinion regarding their significance, and as reported by Cruikshank and Cruikshank, none can withstand careful scrutiny. There does seem to be an association between face presentation and high parity, but 34% of face presentations occur in primigravidas. All of the postulated causes presume that face presentation develops after the onset of labor. Cases of face presentation that occur before labor are called primary and are thought to be due to increased tone in the extensor muscles of the fetal neck. The usual attitude of the fetal neck is flexion caused by greater tone in the flexor muscles, but occasionally infants are seen in whom the extensors predominate. In addition to face presentation, hyperextension of the neck occurs in transverse lie (i.e., “flying fetus”) and in breech presentation; in fact, up to 5% of breech fetuses have hyperextended necks.

To ascertain the true incidence of primary face presentation, it is necessary to examine large series of x-ray films obtained before labor. In three such series, seven primary face presentations were found among 1,762 patients, an incidence of one face presentation in 251 cases, which is more than twice the reported incidence of face presentation at delivery. These data, coupled with the uncertainties surrounding the proposed causative factors, make it most likely that all face presentations are primary and intrinsic to the fetus and that there are no significant causative factors. The preponderance of multiparas in series of face presentation is compatible with this theory. Increased extensor muscle tone cannot cause extension of the neck if the head is fixed in the pelvis; thus, face presentation is less likely to occur during the last 1 to 2 weeks of pregnancy in a primigravida with an engaged presenting part than in a multipara in whom the head often is not engaged until after the onset of labor.

Diagnosis

The diagnosis usually is made by vaginal examination during labor followed by ultrasound studies. Face presentation is rarely diagnosed prior to the onset of labor, with 35% of cases being diagnosed in the first stage, 27% in the second stage, and 35% at the time of delivery. At the time of diagnosis, 60% of face presentations are mentum (chin) anterior (MA), 15% are mentum transverse (MT), and 25% are mentum posterior (MP).

Mechanism and Course of Labor

In face presentation, the presenting diameter is the tracheloparietal (trachelobregmatic), which is 0.7 cm longer than the presenting diameter in vertex presentation (the suboccipitobregmatic). Internal rotation in face presentation occurs between the ischial spines and the ischial tuberosities, lower than in vertex presentation. After internal rotation to MA has placed the fetal chin under the maternal symphysis, delivery occurs by flexion of the fetal neck. It is important to remember that in face presentation, the distance from the leading edge to the largest presenting diameter is greater than that in vertex presentation. Thus, engagement of the presenting part probably has not occurred until the face is at a +2 station.

Safe vaginal delivery of a term-sized, persistent MP is impossible for two reasons: the short fetal neck cannot span the full length of the maternal sacrum so the fetal head and shoulders must enter the maternal pelvis at the same time, and even if this should occur, the persistent MP would have to deliver under the symphysis by extension, but the neck is already maximally extended. Many MPs will spontaneously rotate and convert to MA; the average reported rate being 35%. This may be an artificially low value because, as pointed out earlier, rotation does not occur until the head is well down in the pelvis. Surgical intervention before that point would make the incidence of spontaneous rotation seem lower. In fact, some series report spontaneous rotation rates of 50% to 65%. When the face is MT at the time of diagnosis during labor, spontaneous rotation to MA usually occurs.

Most patients with face presentations have durations of the first stage of labor similar to those of patients with vertex presentations, although there may be some prolongation in MP presentations. Likewise, the length of the second stage is similar to, or only slightly longer than, that in vertex presentation.

Management

The average reported incidence of spontaneous or elective low forceps delivery in face presentation is 72% (range, 40% to 90%). The average rate of cesarean delivery is 15%, and in only two series was it greater than 29%. In older series, up to 12% of face presentations were delivered by various operative vaginal procedures, including midforceps rotation, version and extraction, and manual conversion of face to vertex (Thorn maneuver). These procedures are associated with high perinatal mortality and maternal morbidity, and there is no place for them in the modern management of face presentation.

Face presentation alone is not a contraindication to oxytocin stimulation of labor, and it can be done for the same reasons and with the same precautions as in vertex presentation. Likewise, outlet forceps delivery in MA presentation can be accomplished using the same criteria one would use in vertex presentation, but midforceps delivery in face presentation should be abandoned. Because of the altered diameters of the presenting part, if the face is not bulging the perineum, any forceps delivery is probably a midforceps operation and should not be attempted.

The old adage “if a face is progressing, leave it alone” is still valid. This applies to MT and MP presentations as well as to MA, because of the likelihood that these presentations will convert to MA. Rotation may not occur, however, until the presenting part is on the pelvic floor. In any face presentation, as in vertex presentation, if progress in dilation and descent ceases despite adequate contractions, delivery should be accomplished by cesarean. Conversely, as long as dilation and descent continue, management should be expectant.

The only series using fetal monitoring extensively in the management of face presentation reported variable decelerations in 59% of 29 infants, severe variables in 29%, and late decelerations in 24%. Only 14% of patients in the study (4 of 29) had no fetal heart rate abnormality. It seems plausible that the increased incidence of fetal heart rate abnormalities is due in part to abnormal pressure on the extended head, neck, or eyes, similar to the mechanism of heart rate abnormalities described in occiput posterior presentations. Therefore, face presentation is an indication for electronic fetal monitoring.

BROW PRESENTATION

In brow presentation, the fetal neck is midway between flexion and hyperextension, and the presenting part is that portion of the head between the orbital ridges and the anterior fontanelle. Brow presentation is less common than face; the reported incidence is approximately one in 1,400 births.

Cause

As in face presentation, numerous factors have been proposed as causative in brow presentation. Most series report a few cases of brow presentation associated with placenta previa, polyhydramnios, uterine anomalies, and fetal malformations, but these are no longer seriously proposed as causes of brow presentation. Likewise, the reported incidence of nuchal cord in brow presentation is lower than that in the general obstetric population, and nuchal cord seems to be related to brow presentation only by coincidence. The average incidence of low birth weight among brow presentations is 13%; this does not seem to be etiologically significant. Most data suggest however that cephalopelvic disproportion is more commonly associated with brow presentation than with face presentation.

Many authors believe that brow presentation, like face presentation, is nearly always primary (i.e., caused solely by factors intrinsic to the fetus). Others believe that brow is an unstable or transitional presentation, representing a head in the process of converting from vertex to face presentation or vice versa. If this is true, and if, as proposed, all face presentations are primary, then all brow presentations must likewise be primary. If so, how can the apparent association between brow presentation and cephalopelvic disproportion be explained? Two factors seem relevant:

1. “Relative” cephalopelvic disproportion is more likely to occur in brow presentation because the presenting diameters of the fetal head are greater than in face or vertex presentation (see “ Mechanism and Course of Labor” below).
2. Persistent brow presentation probably selects for patients with smaller pelves, because in patients with larger pelves, the brow may convert to face or to vertex before being recognized.

Diagnosis

The diagnosis is nearly always made by vaginal examination or sonographic studies, or both. Most cases are diagnosed in labor, with approximately one-half diagnosed during the second stage. If labor is progressing, the diagnosis is often missed until late in the second stage of labor.

Mechanism and Course of Labor

When the fetal head engages as a brow presentation, there are three possible mechanisms of labor, depending on whether the brow converts to a face, converts to a vertex, or persists as a brow. Spontaneous conversion to face or vertex occurs in approximately 50% of cases, with 30% converting to face and 20% to vertex. However, in those series in which the brow presentation was diagnosed early in labor, spontaneous conversion rates of 67% to 75% are reported. In fact, many occiput posterior presentations probably enter the pelvis as brows but are never diagnosed as such.

Regardless of the eventual outcome, the brow usually engages transversely at the pelvic brim. The engaging diameter is the mentoparietal, which is about 1.5 cm longer than the engaging diameter in vertex presentation and 0.8 cm longer than that in face presentation.

Most would agree that there is no mechanism of labor for a term-sized, persistent brow under most circumstances, and therefore vaginal delivery is impossible. Vaginal delivery however can occur if the fetus is quite small or the pelvis very large.

Most series report a definite prolongation of labor with brow presentation, but the duration of labor in those patients who eventually convert to face or vertex is no different from the duration of labor with vertex presentation. It would seem that those cases destined to convert to face or vertex and deliver spontaneously have normal to slightly prolonged labor, whereas those destined to persist as brows often have very prolonged labors unless timely intervention is undertaken.

Management

The best recommendation for management of brow presentations is the same as that for face presentations. If dilation and descent are progressing normally, expectant management is best. If progress ceases, delivery should be by cesarean. The association of cephalopelvic disproportion with brow presentation may contraindicate the use of oxytocin to stimulate labor. Forceps deliveries are acceptable if the brow converts to MA face or vertex. Persistent brow presentations, once progress in labor has ceased, require delivery by cesarean, and all forceps operations are contraindicated.

In assessing whether progress in labor has stopped, it is important to remember that if the fetus becomes arrested at the pelvic brim, tremendous caput succedaneum

may form over the brow, giving a false impression of descent of the head.

SHOULDER PRESENTATION (TRANSVERSE LIE)

When the long axis of the fetus lies perpendicular to that of the mother, the condition is termed a *shoulder presentation* or *transverse lie*. This malpresentation complicates one in 300 births.

Definitions

In transverse lie, the fetal head lies in one maternal iliac fossa and the buttocks in the other. A better term for this would be *transverse presentation*, but this term is avoided because it is often confused with transverse position of vertex presentation. Because the fetal shoulder usually lies over the pelvic inlet, the formal term is shoulder presentation, which should be considered synonymous with transverse lie. The fetal position is described with the fetal acromion used as a reference point and is termed *left or right acromion*, according to which side of the mother the fetal shoulder is directed. Because the fetal back may be directed anteriorly, posteriorly, superiorly, or inferiorly, the additional qualifying terms *dorsum superior, dorsum anterior*, and so on are used as well. Thus, a fetus with its head on the mother's left and its back toward the mother's head would be described as left acromion dorsum superior.

If one fetal pole lies in a maternal iliac fossa and the other pole lies in the opposite upper quadrant of the uterus, the lie is said to be oblique or unstable.

Cause

The most common causative factors are high parity with lax abdominal wall and uterine musculature, and conditions in which the fetus is small in relation to the volume of the uterus (i.e., prematurity and polyhydramnios). Shoulder presentation may also be caused by anything that prevents descent of a fetal pole into the maternal pelvis, such as pelvic contraction, placenta previa, lower uterine segment myoma, or an ovarian tumor in the cul-de-sac. These conditions should be kept in mind for any patient who presents with a transverse lie, but especially in the patient of low parity who has this malpresentation at or near term.

Diagnosis

The diagnosis usually can be made by physical examination of the maternal abdomen, with the fetal head and buttocks palpable in the iliac fossae and no fetal pole at the pelvic inlet. A very high or unreachable presenting part on vaginal examination suggests transverse lie. All such findings should be confirmed by ultrasound.

Mechanism of Labor

The tiny fetus in transverse lie may deliver by the mechanism of conduplicato corpore, in which the fetal body doubles up on itself and the fetal head and buttocks enter the maternal pelvis simultaneously. This is often associated with rupture of fetal abdominal viscera.

If the fetal weight is greater than about 800 g, there is no mechanism of labor. Uterine contractions will wedge the fetal shoulder into the maternal pelvis, and eventually the membranes will rupture and the fetal arm will prolapse into the vagina. Such a condition is termed a *neglected transverse lie.* If labor is permitted to continue, there will be progressive thinning of the lower uterine segment, a Bandl retraction ring will form, the uterus will rupture, and eventually both the fetus and the mother will die.

Management

Shoulder presentations diagnosed before term should be managed expectantly, because most will convert to polar presentations before labor. If the patient is not at term but the cervix is significantly dilated (> 3 cm), hospitalization and bed rest should be considered as the incidence of cord prolapse in such a patient is 10% to 15% should rupture of membranes occur.

If the patient is at term (37 or more completed weeks gestation), external version may be attempted with the same techniques and precautions as described for breech presentation. Induction of labor may be undertaken immediately if the version is successful and the cervix favorable. External version may also be attempted in early labor; provided the membranes are intact and no fetal part has entered the pelvis. Before any version attempt, ultrasound should be used to rule out placenta previa and pelvic masses.

If the patient is in active labor or has ruptured membranes, and the fetus is of a gestational age to be considered viable, delivery must be by cesarean. Because of exceedingly high morbidity and mortality for both mother and fetus, there is no role for internal version and extraction in the management of transverse lie in singleton gestation. Because the lower uterine segment may be poorly developed, vertical uterine incisions are often necessary. If, however, the fetus can be manipulated to a polar presentation after opening the abdomen but before entering the uterus, a low transverse incision may be performed. This usually is possible only if the membranes are still intact.

The patient with a neglected transverse lie is an obstetric emergency. Usually she is septic, and often the fetus is dead. If the uterus is still intact, it is exceedingly thin. Some patients will be completely dilated on arrival at the hospital, but the temptation to try vaginal maneuvers such as internal version must be resisted as this will often result in uterine rupture and may lead to maternal death. Such patients should have basic laboratory studies, coagulation indices, and blood cultures obtained. Rapid intravenous hydration and antibiotic therapy should be instituted, type-specific blood should be available, and the patient should be taken promptly to the operating room for cesarean delivery. Cesarean hysterectomy is often the best procedure for such patients, especially if the uterus has ruptured or is grossly infected. In the past, various vaginal fetal destructive procedures were described for treating the neglected transverse lie with a dead fetus. Given that obstetricians today have almost no training in such procedures, they should be abandoned in favor of cesarean delivery, even in the face of a dead fetus.

COMPOUND PRESENTATION

A compound presentation occurs whenever some part of a fetal extremity is prolapsed alongside the presenting part. By far the most common type is vertex/hand or vertex/arm, in which some part of the upper extremity is alongside the head. Much less common types are breech/arm and vertex/foot. The reported incidences range between one in 400 and one in 1200 births.

Cause

Situations in which the presenting part fills the pelvis poorly predispose to compound presentation. The most obvious of these is prematurity, which is associated with most compound presentations. In fact, the incidence of this complication among infants who weigh more than 1,500 g is only one in 1,600 births.

Diagnosis

The diagnosis almost invariably is made by vaginal examination and generally is made late in labor. At least 50% of these malpresentations are diagnosed in the second stage of labor. Whenever a fetal hand or arm is palpated on vaginal examination, the examiner must be certain that the fetal head is in the pelvis as well, before concluding that the presentation is compound. If the head is not easily palpated in the pelvis in such circumstances, most likely the diagnosis is shoulder presentation with a prolapsed arm, a much more serious and urgent obstetric condition.

Management

Management of vertex/arm and vertex/hand presentations should be expectant. One of three outcomes will occur:

- the prolapsed part will withdraw back up into the uterus as labor progresses
- the baby will deliver with the arm or hand alongside the head
- progress in labor will cease, in which case cesarean delivery is indicated.

The reported incidence of cord prolapse in compound presentation is 10% to 20%, but many of these are related to attempts to replace the prolapsed arm into the uterus, which often necessitates upward displacement of the fetal head. For this reason, attempts at replacement of the prolapsed part in compound presentation

should be avoided.

Because of the increased incidence of cord prolapse, electronic fetal monitoring should be used in these situations. Vertex/arm and vertex/hand presentations are not indications for cesarean delivery in and of themselves. Indications for cesarean delivery in such circumstances include failure to progress in labor, cord prolapse, and fetal distress.

Cases of breech/arm presentation should be managed as any other breech presentation would be managed. Cases of vertex/foot presentation are rare, but those few reported cases have a perinatal mortality two to three times that of other compound presentations, and are best managed by cesarean delivery. In essence, these are variants of shoulder presentation.

There is no role for internal version and extraction in the modern management of compound presentation, although this was commonly done in the past.

UMBILICAL CORD COMPLICATIONS

The mean length of the umbilical cord at term is 55 to 60 cm, and the normal range (5th to 95th percentile) is 35 to 80 cm. The longest umbilical cord reported measured 129 cm. The length of the cord is related to fetal activity in the first two trimesters; there is little change in the length of the cord after 28 weeks of gestation. At term, mean cord length is slightly (1.6 cm) but significantly longer in male fetuses compared with females, and is 4.5 cm greater in vertex infants compared with breech. There is no correlation between cord length and either fetal or placental weight.

Cord Prolapse

The reported incidence of prolapse of the umbilical cord varies between 0.2% and 0.6% of births. Cord prolapse almost never occurs with cords shorter than 35 cm; the incidence is 0.4% with normal-length cords (35–80 cm) and 4% to 6% with cords longer than 80 cm. Besides excessive cord length, other causative factors include malpresentation in approximately 50% of cases, low birth weight (<2,500 g) in 30% to 50% of cases, grand multiparity (more than five pregnancies) in 10% of cases, multiple gestation in 10% and obstetric manipulation, including artificial rupture of membranes, in 10% to 15%. Table 21.6 shows the association between cord prolapse and malpresentation, especially with nonfrank breech, compound, and shoulder presentations. Nearly 50% of cord prolapses occur during the second stage of labor.

Presentation	Incidence (%)
Vertex	0.14
Breech	2.5–3.0
Frank	0.4
Complete	5.0
Incomplete	10.0
Shoulder (transverse lie)	5.0–10.0
Compound	10.0–20.0
Face-brow	Rare

TABLE 21.6. *Incidence of cord prolapse*

The diagnosis of cord prolapse should be suspected in any patient who develops fetal heart rate abnormalities after rupture of the membranes, either spontaneous or artificial. The heart rate abnormalities usually observed are sustained bradycardia and, less frequently, profound variable decelerations (Fig. 21.5). All such patients should be promptly examined or reexamined and the diagnosis confirmed by palpation of the cord alongside the presenting part or in the cervix or vagina.

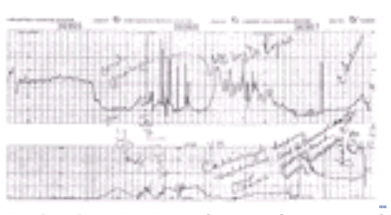

FIG. 21.5. Fetal monitor tracing associated with umbilical cord prolapse.

When cord prolapse is diagnosed, every effort should be made to prevent compression of the cord by the presenting part. The patient should be placed in steep Trendelenburg or the knee–chest position, and the presenting part should be manually elevated as far out of the pelvis as possible and held there until delivery is accomplished. Once the diagnosis is made, further palpation of the cord must be avoided, because this causes spasm of the umbilical arteries and may further compromise the fetus. Confirmation of fetal cardiac activity should be by ultrasound rather than by cord palpation. In fact, ultrasound is the only certain way to confirm fetal viability. There are at least two reported cases in which nonpulsatile cords were palpated and no fetal heart tones were heard with Doppler or stethoscope but ultrasound revealed fetal heart rates of 50 to 80 beats per minute. In both cases, prompt delivery resulted in surviving infants.

Cesarean delivery is the treatment of choice in almost all cases if there is fetal cardiac activity. Even at complete dilation, the perinatal outcome is better with cesarean delivery than with such maneuvers as breech extraction or high forceps. If the fetus is dead with no fetal cardiac activity present by ultrasound, and the fetal lie is polar, the mother usually is better served by allowing continued labor and vaginal delivery.

In most series of cord prolapse, perinatal mortality is approximately 15%. Among term infants and among all infants delivered by cesarean within 10 minutes of cord prolapse, mortality is less than 5%. Murphy and Mackenzie reported a retrospective study of 132 consecutive cases of cord prolapse in a single hospital. The overall perinatal mortality was 9% (12 of 132 infants). However, all but one death was due to either extreme prematurity or congenital malformations; the perinatal mortality rate attributable to asphyxia was 0.8% (one case). Of the 120 survivors they reported, only one infant had a major neurologic handicap.

True Knots

The reported incidence of true knots in the cord is 0.3% to 2.1% of births, the mean being about 1.0%. As is true of all cord accidents, true knots are more common if the cord is abnormally long. Ten percent of true knots occur in cords greater than 80 cm in length, and 3% of cords longer than 80 cm have true knots. However, many true knots must form early in pregnancy, for the incidence in aborted fetuses is 0.9%. True knots can be diagnosed only after delivery in the vast majority of cases, because unless the knot is pulled tight, there is no reduction of flow or increase in perfusion pressure, and thus no abnormality of the fetal heart rate or Doppler velocimetry. The patient with a tight knot will demonstrate a typical cord pattern of variable decelerations (Fig. 21.6) and will, of necessity, be managed like any other patient with fetal heart rate abnormalities.

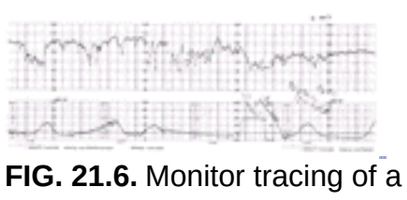

FIG. 21.6. Monitor tracing of a fetus with a tight true knot in the umbilical cord.

The Collaborative Study of Cerebral Palsy found no difference in 5-minute Apgar scores or neurologic abnormalities at 1 year of age between controls and infants born with true knots in the cord. There is an association however between true knots and antepartum stillbirths. About 4% to 5% of stillborns have true knots in the cord, compared with 1% of live-born infants.

Nuchal Cord

The incidence of loops of umbilical cord around the fetal neck is 25% of live-born infants, with 21% having one loop around the neck and 4% having two or more. In fact, 0.1% of fetuses have four or more loops of nuchal cord; the maximum reported number is nine. The incidence is 14% with short cords (<35 cm), 23% with normal length cords, and 53% with cords longer than 80 cm. There is no evidence that nuchal cords cause fetal death or significant degrees of fetal distress. The Collaborative Study of Cerebral Palsy found no increase in the incidence of depressed 5-minute Apgar scores, perinatal mortality, or abnormal neonatal development among infants with nuchal cords. It did demonstrate reduced 1-minute Apgar scores in these infants, however. Although nuchal cords are at times diagnosed by ultrasound, the excellent outcome of these infants demonstrates that no alteration in management is indicated unless the fetus develops bona fide distress during labor.

Body Coils of Cord

The incidence of coils of umbilical cord around various parts of the fetal body other than the neck is 0.5% to 2.0%, and is more frequent with long cords. As with nuchal cords, body coils are not associated with any increase in low Apgar scores, perinatal mortality, or neonatal morbidity.

SUMMARY POINTS

- The singleton breech fetus at term should be delivered by cesarean. This is a level A recommendation based on type I evidence.
- The preterm singleton breech at 28 weeks of gestation and beyond should be delivered by cesarean. This is a level A recommendation based on type II-2 evidence. There is no real evidence about the optimal mode of delivery of the singleton breech at 24 to 27 weeks of gestation.
- In the absence of contraindications, external cephalic version (ECV) should be attempted at term in singleton breech fetuses. At present there is no role for ECV before term.
- Fetal anomalies and chromosome abnormalities are important causes of breech presentation. Likewise, fetuses that have sustained neurologic insults leading to cerebral palsy often present as breeches.
- Nearly all cases of face presentation and compound presentation should be managed expectantly and vaginal delivery anticipated. Persistent mentum posterior (MP) face, persistent brow, and essentially all cases of shoulder presentation should be delivered by cesarean.

From 1970 to 1990, the cesarean delivery rate in the United States increased from 5% to 25%. The four primary indications for cesarean delivery include dystocia, elective repeat cesarean delivery, fetal distress, and abnormal fetal presentation. *Dystocia*, translated, means “difficult birth” and includes all abnormalities that may occur in women during labor. Although the incidence of cesarean delivery in the United States has recently equilibrated at between 20% and 25%, it is generally accepted that this number of abdominal deliveries remains excessively high. Perhaps one reason for the continued high rate of cesarean delivery is a poor understanding of the labor process and the lack of an organized approach to the management of labor. This fundamental lack of understanding often leads to unnecessary induction of labor, which has an a priori risk of cesarean delivery of at least 25%, or to inadequate augmentation of abnormal labor. With fewer inductions of labor and better augmentation of labor, one can expect a decline in the cesarean delivery rate.

Efforts at reducing the cesarean delivery rate have more recently focused on the categories of dystocia and repeat cesarean section. Obviously, the best method to decrease the incidence of repeat cesarean deliveries is not to do one initially. Hence, new efforts are being directed at the diagnosis and management of labor abnormalities in term pregnancies. The purpose of this chapter is to review these labor abnormalities and management options.

KEYS TO THE MANAGEMENT OF NORMAL LABOR

A thorough examination of the management of labor and delivery is available in a comprehensive text edited by Creasy, and the normal labor process is reviewed in Chapter 2 of this text. There are several key points in the management of labor (Table 22.1). The first is that normal labor progresses in a predictable fashion after the diagnosis of labor is made. However, diagnosing labor is more difficult than one might believe. If the diagnosis of labor is made in error, all subsequent actions are incorrect, as one is essentially performing an induction of labor and different management is required. Labor in its simplest terms is defined as cervical change effected by regular, painful uterine contractions. In nulliparous women in their first labor, cervical change is usually manifest by cervical effacement, or thinning, followed by cervical dilation (Fig. 22.1). Conversely, in multiparous women, the initial stage of labor is often characterized by cervical dilation followed by effacement.

Labor progress is predictable
Diagnosis of labor is critical
Labor in nulliparas is different from labor in multiparas
Labor progress should be graphically followed
Cardinal movements of labor should occur
Prompt intervention is needed if labor does not progress appropriately
Medical therapy with oxytocin is effective
Clinical judgment must be made regarding the role of cesarean delivery

TABLE 22.1. *Keys to the management of labor*

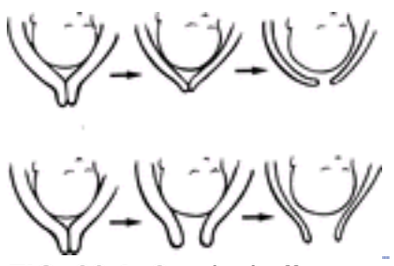

FIG. 22.1. Cervical effacement and dilation: nulliparas versus multiparas. The upper portion of the figure depicts the cervical changes in early labor of the nulliparous woman. Note that cervical effacement precedes significant dilation. The lower portion depicts the cervical changes of the multiparous woman in early labor. Significant cervical dilation may precede achievement of complete cervical effacement.

The normal labor curve as defined by Friedman is shown in Figure 22.2. This curve was developed by Emanuel Friedman based on the observation of several thousand laboring women. The first stage of labor is divided into the acceleration phase, active phase, and deceleration phase. The acceleration phase occurs when the active phase of labor starts. The cervix is usually effaced and dilated less than 4 cm. In the active phase, one can anticipate a minimum of 1 cm of dilation per hour (Table 22.2). The deceleration phase likely is an aberration of the mathematic analysis of Friedman's original data, and as such is likely not a physiologic event. In the second stage of labor, from complete dilation until delivery, one can again anticipate the laboring woman gaining a minimum of 1 cm of station of the fetal head in relation to the maternal pelvis per hour. Cervical examinations should be performed periodically to confirm that progress is being made. Experienced obstetricians often will perform examinations every 2 to 3 hours, depending on the presentation of the patient. After each examination, the progress of labor should be documented

graphically on some form of a labor curve, and a plan formulated with regard to future examinations and potential interventions.

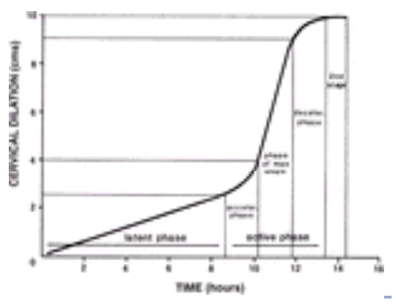

FIG. 22.2. The Friedman labor curve. This figure depicts the normal labor curve developed by Emanuel Friedman. Note the different phases of the first stage of labor, including the latent phase, acceleration phase, active phase, and deceleration phase. (Adapted from Friedman EA. *Labor: clinical evaluation and management*, second ed. New York: Appleton, 1978.)

TABLE 22.2. *Expected length of different phases of labor* [a]

Nulliparous women and multiparous women experience fundamental differences in labor. Figure 22.3 is an example of a labor curve showing the difference in labor patterns expected between nulliparas and multiparas. Labor is the force of uterine contractions overcoming the resistance of the female reproductive tract, including the lower uterine segment, cervix, vagina, and perineum. In nulliparous women, more uterine force is required to overcome resistance in the reproductive tract and the uterus tends to be less effective in maintaining effective uterine contractions. In multiparous women less uterine force is required and the tissues of the reproductive outlet, having been stretched by the previous delivery, have less resistance. As a result, the myometrium of the multipara usually maintains effective contractile activity. Thus, nulliparous women are more likely to develop labor abnormalities that require intervention. Multiparous women usually labor quickly and meet all expected milestones without the need for significant intervention.

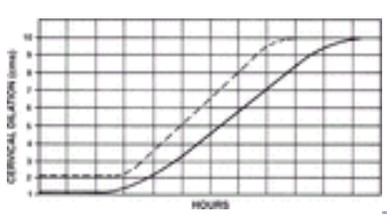

FIG. 22.3. Labor curve of nulliparas versus multiparas. Note that different labor slopes are expected between nulliparous (*solid line*) and multiparous women (*dotted line*).

In addition to graphically depicting labor progress, the practitioner should pay close attention to the *cardinal movements of labor* (Table 22.3). This term refers to the changes that occur in the flexion and position of the fetal head throughout labor. The cardinal movements of labor usually occur in the following sequence: engagement of the fetal head, descent of the fetal head, flexion of the fetal head, internal rotation (assumption of an occiput anterior position), extension (as the fetal head progresses through the birth canal and crowns at the perineum), external rotation (or restitution to the transverse position), and then shoulder rotation after the head has delivered. Abnormalities in the cardinal movements of labor may be reflected by abnormal fetal head position and other specific abnormalities discussed subsequently.

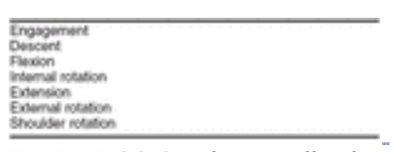

TABLE 22.3. *The cardinal movements of labor*

If labor is progressing appropriately a noninterventional approach is indicated, providing for maternal comfort and encouragement. However, if these landmarks are not achieved by the woman in labor, then timely intervention is recommended. Thus, the next important key in the management of labor is prompt intervention when labor progress is inadequate. Ineffective uterine contractions lead to increased tissue acid content in the myometrium, which further contributes to poor contractility. The longer labor continues in a dysfunctional pattern, the less likely the underlying problem can be corrected with medical therapy. Prompt medical therapy for desultory labor is another important key to success in the management of labor.

A schematic employing these key components of labor management is shown in Figure 22.4. Normal labor is characterized by coordinated uterine contractions, cervical dilation, gain in station of the fetal head, and normal progress in the cardinal movements of labor. With careful attention to achieving these milestones of normal labor, a successful vaginal delivery is likely. However, should the parturient not achieve these milestones, prompt intervention is more likely to increase the chances for vaginal delivery. Although an aggressive approach with regard to diagnosing labor abnormalities may enhance maternal and fetal outcome, the last important key to the successful management of labor is to use clinical judgment on when to abandon medical therapy in favor of surgical management. If the judgment is made that continuing medical therapy may compromise either mother or fetus, then prompt surgical delivery (cesarean or operative vaginal delivery) should be considered.

FIG. 22.4. Keys to the management of labor. This schematic depicts how the keys to the management of labor can be used to help ensure good maternal and fetal

outcomes.

EPIDEMIOLOGY OF DYSTOCIA

The precise incidence of dystocia is difficult to determine and varies with different populations and different labor and delivery units based on local practice patterns. According to the National Center for Health Statistics, 28% of women who delivered in the United States in 2000 were diagnosed with labor abnormalities, with a primary cesarean delivery rate of 16.1%. Dystocia is more common in nulliparous women than in multiparous women and is more common in the first stage of labor than in the second stage of labor. Labor abnormalities occur in approximately 25% to 30% of nulliparous women and 10% to 15% of multiparous women. Dystocia occurs in the second stage of labor in about 5% to 10% of nulliparous women and is relatively rare in multiparas (<2%).

Abnormal labor is a common indication for cesarean delivery. In the United States in 2000, 22.9% of pregnancies were delivered by cesarean (National Center of Health Statistics), down from the highest incidence of 25% in 1988, but slightly higher than the 20.6% rate in 1996. In 1990, the overall rate was 23.7%, with 7.1% for the indication of “failure to progress” or dystocia and 8.5% for a repeat procedure. Other indications included abnormal presentation (2.6%), fetal distress (2.3%), and other problems (3.2%). Improved management of labor with a decrease in the number of cesarean deliveries for dystocia (and then having less need for repeat procedures) should be the goal of every labor and delivery unit in the United States. While there have been many proposed targets for the overall rate of cesarean delivery, none of these figures are based on scientific evidence.

The American College of Obstetricians and Gynecologists (ACOG) published a monograph focusing on cesarean delivery in the United States. This work was developed by a special ACOG task force to address cesarean delivery rates and published in 2000. The primary conclusions of this report were that efforts to reduce the cesarean delivery rate in the United States should focus on two benchmarks. First, there should be a focus on nulliparous women at term (37 weeks or greater) with singleton fetuses in cephalic presentation. In 1996, the cesarean delivery rate for this group was 17.9%, and the ACOG task force concluded that efforts to achieve a reduction to the 25th percentile, or 15.5%, in this group of women were reasonable and could be accomplished. Second, the task force recommended that efforts be made to reduce the percentage of women attempting vaginal birth after cesarean (VBAC). Of multiparas at 37 weeks gestation or greater with singleton fetuses and vertex presentations with prior low transverse cesarean incisions, 30.3% attempted VBAC in 1996. The task force recommended that a primary goal at the 75th percentile for this year, or 37%, would be reasonable. However, in 2000 the rate of attempted VBAC declined to 20.6%. Clearly, efforts to address the cesarean delivery rate in the United States have been a daunting challenge.

ETIOLOGY OF DYSTOCIA

Traditionally, the causes of abnormal labor have been attributed to the “powers” (uterine contractility), the “passage” (maternal pelvimetry), or the “passenger” (position and size of the fetus). In more scientific terms, these represent a primary dysfunctional labor, cephalopelvic or fetopelvic disproportion, abnormal fetal head position, and asynclitism. This section evaluates each of these potential causes of dystocia. The generic term “failure to progress” is often used as a diagnosis to justify cesarean delivery. This term is more appropriately used as a sign of an underlying problem and does not represent a diagnosis. Hence, the term “failure to progress” is not sufficient to describe the labor problem and should not be used.

Primary Dysfunctional Labor

Primary dysfunctional labor refers to inadequate uterine contractility to maintain appropriate progress in labor. In general, an adequate uterine contraction pattern is one in which there are four concerted synchronous contractions every 10 minutes (Fig. 22.5). However, some women contract less frequently and continue to progress adequately in labor such that no intervention or treatment is required. Unlike the cardiac conduction system, the uterus has no defined nervous system for the conduction of electric signals to stimulate muscle contractions. The readiness of the uterus for labor is heralded by the occurrence and widespread distribution of gap junctions throughout the myometrium. Gap junctions allow for the rapid transmission of calcium fluxes through the uterine musculature and, hence, the occurrence of global uterine contractions. The uterus commonly has focal contractions throughout pregnancy (Braxton Hicks contractions) which are not of sufficient strength or duration to effect cervical change and therefore do not constitute labor.

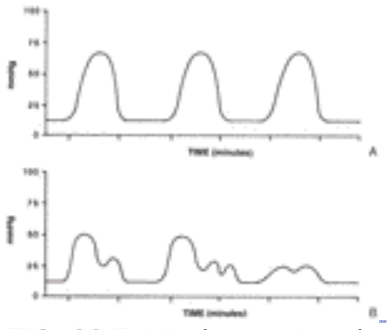

FIG. 22.5. Uterine contraction patterns. Uterine contractions can be depicted using tocodynometry (external monitoring) or direct uterine pressures (using intrauterine pressure catheters). **A:** Contraction pattern of a normal labor. Significant pressure is obtained with contractions every 2 to 3 minutes. **B:** Uterine contraction patterns typical of primary dysfunctional labor. Contractions achieve varying degrees of pressure and are often combined (coupling).

Smooth muscle cells of the uterus are not randomly distributed but are arranged in a specific fashion such that maximal force can be generated to effect vaginal delivery. In women with uterine embryologic abnormalities such as a didelphic uterus or bicornuate uterus, labor is not often successful in achieving vaginal delivery, as global, concerted uterine contractions cannot occur because of the abnormal arrangement of uterine smooth muscle cells. Similar problems may be noted in women exposed to diethylstilbestrol (DES) in utero with uterine anomalies characteristic of this teratogen (e.g., T-shaped uterus).

In the structurally normal uterus, contractions begin to occur less randomly days to weeks before the initiation of labor. Moreover, there is a distinct diurnal variation of uterine contractility such that, in most women, uterine contractions occur more frequently and labor most often commences at night. These rhythmic variations may be the result of hormonal patterns in which specific and predictable changes in different hormones (e.g., corticotropin-releasing hormone, progesterone, estradiol) allow for more frequent and stronger uterine contractions until the final signal for labor. While the precise nature of this signal in women is not known, cortisol appears to play a key role in the initiation of parturition.

As the normal uterus approaches term and labor commences, different foci for the initiation of a uterine contraction may be present (Fig. 22.6). This phenomenon often leads to the clinical scenario in which some contractions are quite hard and lengthy whereas other contractions are mild and of short duration. Women will have mild contractions interspersed with firmer, more painful contractions because of the lack of a dominant “pacemaker” in the uterine musculature. Eventually, as labor progresses, one of these foci of uterine contractility predominates over other foci, resulting in more concerted and painful uterine contractions. As this occurs, true labor commences with effacement and dilation, and this change is reflected in the uterine tocodynometry patterns (see Fig. 22.5). In a primary dysfunctional labor, uterine activity shifts from the concerted global contractions to more focal and less efficient contractions by allowing the reemergence of other pacemaker foci (see Fig. 22.6). Medical therapy with oxytocin is effective at correcting the underlying pathophysiology and restoring the pattern of global and concerted uterine contractions.

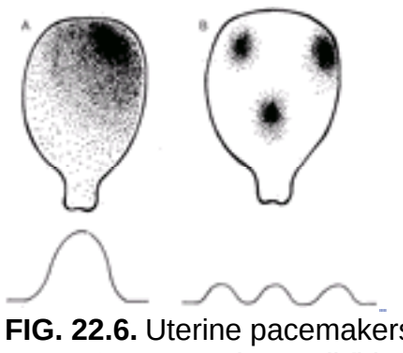

FIG. 22.6. Uterine pacemakers and contractions. **A:** Normal uterine contraction pattern associated with a single dominant pacemaker focus. **B:** A uterus with three separate pacemakers, all firing sequentially. Note that the uterine pressure achieved in this situation is less than that shown with a single dominant pacemaker.

Although usually quite effective, oxytocin therapy may be of little benefit if the woman has intrauterine infection complicating labor. If the parturient has clinical signs of intrauterine infection, then labor progress is often desultory and not remedied with oxytocin augmentation. Clinical signs of intrauterine infection include maternal fever (>38°C), fetal tachycardia (baseline fetal heart rate of >160 beats/min), elevated maternal white cell count, uterine tenderness when the uterus is relaxed, and foul-smelling vaginal discharge. With the diagnosis of intrauterine infection, broad-spectrum antimicrobial agents should be administered and uterine activity stimulated with oxytocin if labor is not progressing adequately.

Cephalopelvic Disproportion

True cephalopelvic disproportion (CPD), or fetopelvic disproportion, is a rare occurrence in the labor and delivery suite. Some authorities believe that CPD occurs in one in 250 pregnancies. CPD occurs when the fetal birth weight or the fetal head is of sufficient size or orientation to preclude entry into the maternal pelvic inlet. This diagnosis if often made in retrospect after the birth weight is known and the positioning of the fetal head has been determined at the time of cesarean delivery. However, in the United States, the term CPD is used to describe almost any unsuccessful attempt at vaginal delivery. Further, the diagnosis of CPD is often used when labor progress is not sufficient and medical therapy is not successful or even not attempted. These cases often reflect inadequate use of oxytocin and are not problems with large fetal size or a small maternal pelvis. CPD is an important diagnosis because it has prognostic information for subsequent pregnancies when VBAC is considered. In women with a prior diagnosis of CPD, success rates of VBAC vary from 50% to 70%. Additionally, they should be managed differently during the VBAC with prompt repeat cesarean if labor does not progress appropriately.

Another important contribution to the fetopelvic relationship is the size of the fetus. Pregnancies with macrosomic fetuses (>4,000 g birth weight) have a greater risk of cesarean delivery for dystocia as a result of true CPD. In a study by Turner and colleagues, fetal macrosomia was associated with longer first and second stages of labor, greater need for oxytocin therapy, and a greater risk for cesarean delivery for CPD refractory to oxytocin. In their patient population, they had an overall incidence of cesarean delivery of 5.2%, but if birth weight was 4,000 to 4,500 g, the incidence of cesarean delivery was 13.8%. Also, forceps delivery was employed in 31.8% of infants with a birth weight of 4,000 to 4,500 g, whereas forceps were used in 13.6% of deliveries overall.

Unfortunately, there are no good predictors of fetal weight to guide management. Sonographic estimates of fetal weight at term are notoriously spurious and can miscalculate birth weight by 500 g or more. The obstetrician employing Leopold maneuvers to estimate fetal weight by palpation of the maternal abdomen can only estimate small, average, or large fetal size. Hence, it is not advisable to induce labor or perform a cesarean delivery for presumed macrosomia unless the obstetrician judges a dangerous situation exists for vaginal delivery (e.g., high risk of shoulder dystocia). Numerous studies of induction of labor for presumed macrosomia consistently show an increase in the cesarean delivery rate with no decrease in neonatal morbidity and poor prediction of macrosomia.

When the diagnosis of a labor abnormality is made, clinical pelvimetry should be performed to assess the dimensions of the maternal pelvis (Fig. 22.7). Only in the rare cases in which the maternal pelvis is markedly small or if there is clear CPD should cesarean delivery be performed without the prior use of oxytocin. For example, labor through a platypelloid pelvis with a normal term-sized fetus is rarely successful because of the markedly shortened anterior–posterior diameter that characterizes this pelvic architecture. After assessment of the pelvic type, approximations of the fetal size should be undertaken. Medical therapy with oxytocin should be instituted unless the fetus appears to be markedly macrosomic (>4,500 g).

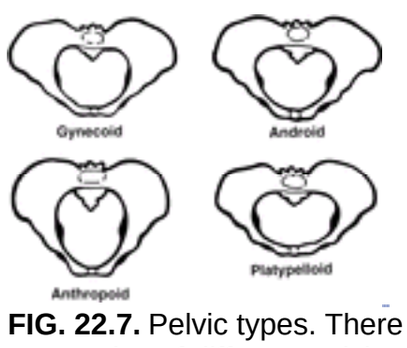

FIG. 22.7. Pelvic types. There are four primary pelvic types: gynecoid, android, anthropoid, and platypelloid. Some women may have a mixed pelvic type with features suggestive of different pelvic types and will not fit conveniently into one of these four categories.

Abnormal Position of the Fetal Head

Abnormal positions of the fetal head include occipital posterior (OP), deep transverse arrest, and deflexion abnormalities such as face and brow presentations and reflect fundamental abnormalities in the cardinal movements of labor. Different positions of the fetal head are depicted in Figure 22.8. An OP position is unfavorable for successful vaginal delivery, particularly if the parturient has an android pelvic structure, as the long diameter of the fetal head negotiates the maternal pelvis at a relatively high station leading to poor descent. Additionally, the fetal heart tracing may have some unusual decelerations that are difficult to interpret, leading to more advanced testing of the fetal acid–base status (e.g., fetal scalp pH determinations). The OP position is a relatively rare cause of dystocia, accounting for about 1 in 250 cesarean deliveries, but it can be corrected with oxytocin therapy. Operative vaginal delivery, either through a Scanzoni maneuver or through a straight OP application with traction, is another option for delivery. A Scanzoni maneuver involves rotating the OP fetus to an occipital anterior (OA) position with forceps and then completing the delivery with forceps from the OA position. A Scanzoni maneuver is associated with a higher incidence of maternal trauma (third- and fourth-degree lacerations of the perineum and sulcus tears of the vagina) and fetal trauma (spinal cord transection). Hence, such deliveries should be performed only by obstetricians skilled in these techniques. Moreover, delivery of the OP fetus with forceps should probably be attempted only if the fetal head has attained at least at +1 to +2 station. At higher stations, cesarean delivery may be the safest alternative. The prudent obstetrician will realize that assigning station in a labor characterized by an OP position is more difficult than in an OA position and often leads to the impression of a lower station than is actually present. Care should be taken to accurately assess the biparietal diameter in relation to the maternal ischial spines.

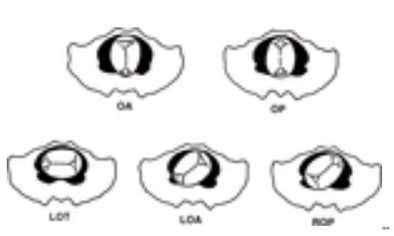

FIG. 22.8. Position of the fetal head. The sutures of the fetal head should be palpated, and the fetal head position should be recorded to ensure that the normal cardinal movements of labor are being followed. The fetal occiput with the maternal position constitute the reference points. Hence, *OA* refers to the occiput anterior position; *OP*, occiput posterior; *LOT*, left occiput transverse; *LOA*, left occiput anterior; *ROP*, right occiput posterior. Any fetal position can occur and should be noted on the labor curve.

A deep transverse arrest occurs in the second stage of labor where the fetus maintains an occipital transverse (OT) position at a low pelvic station. Deep transverse arrests are often associated with abnormal maternal pelvic architecture and may not be easily delivered via forceps. Keilland forceps were designed to address the problem of the deep transverse arrest. Vacuum delivery should probably be avoided in this circumstance, as excessive traction of the fetus with a deep transverse arrest can result in birth trauma. Cesarean delivery is the prudent option if the fetal station is not sufficiently low for operative vaginal delivery or if excessive traction is required to effect delivery. Operative vaginal delivery for a deep transverse arrest should be performed only by obstetricians skilled in the use of forceps for this problem.

Deflexion abnormalities also cause dystocia. The classic forms of deflexion abnormalities include brow and face presentations. Typically, a brow presentation is characterized by the long axis of the fetal head negotiating the short axis of the midpelvis, precluding vaginal delivery. A fetus in the brow presentation may spontaneously convert to a vertex or face presentation. Whereas fetuses with a brow presentation that do not convert rarely deliver vaginally (except in women with generously sized midpelvic dimensions with a small fetus), face presentations will often deliver vaginally if the mentum, or chin, is positioned anteriorly (mentum anterior). Although these extreme flexion abnormalities are usually easily diagnosed and are relatively rare, other mild flexion abnormalities may not be so readily evident. Flexion abnormalities may be suspected in a prolonged or protracted labor unresponsive to oxytocin. Unfortunately, there are no safe and accepted means to

correct flexion abnormalities of the fetal head.

Often, abnormal fetal position may occur as the result of the maternal pelvic type (see Fig. 22.7). For example, android pelvic types often lead to deep transverse arrest or OP position because of the progressive narrowing of the pelvis. Women with an anthropoid pelvis tend to have fetal positions persistently OA or OP, thus interfering with the normal cardinal movements of labor. Finally, women with a true platypelloid pelvis have transverse arrests, assuming the fetal head negotiates the shortened pelvic inlet. Because many women have mixed pelvic types, careful clinical pelvimetry may provide valuable information in the management of dystocia.

Asynclitism

When asynclitism of the fetal head occurs, the sagittal suture of the head is either deviated posteriorly or anteriorly in relation to the maternal outlet (Fig. 22.9). As with other situations involving abnormal positioning of the fetal head, a larger diameter of the fetal head is expected to negotiate the bony pelvis of the mother. In these situations, the second stage of labor is often prolonged and arrest of descent is common, leading to an increased need for operative vaginal delivery. An important aspect of performing operative vaginal delivery involves correction of the asynclitism of the fetal head. This correction can often be accomplished with forceps that have a sliding lock or through vacuum extraction of the fetus, where the precise attitude and positioning of the fetus is of less importance.

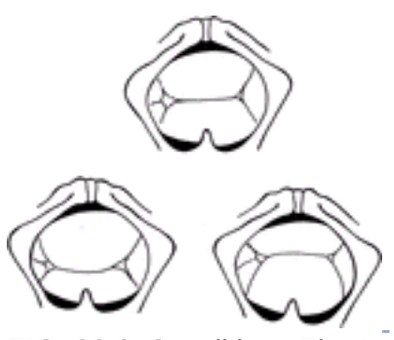

FIG. 22.9. Synclitism. The term *synclitism* refers to the relative orientation of the fetal sagittal suture with the maternal bony pelvis. **Top:** Normal synclitism of a fetus in left occiput transverse position, with the sagittal suture equidistant between the anterior and posterior segments of the maternal pelvis. **Lower Left:** Posterior asynclitism, where the sagittal suture is closer to the posterior bony pelvis, and more of the right parietal bone is palpated. **Lower Right:** Anterior asynclitism in which the sagittal suture is more anteriorly located, and the left parietal bone is more readily evident.

Fetal Abnormalities

Specific fetal abnormalities may contribute to the etiology of dystocia. Fetuses with neuromuscular disease, and particularly those that have suffered an in utero demise, may have flexion abnormalities. Also, fetal conditions such as hydrocephalus, hydrops fetalis, and tumors of the head or sacrum can lead to mechanical obstruction of the birth canal and hence cause dystocia, which is usually not remedied except by cesarean delivery.

SPECIFIC LABOR ABNORMALITIES

Only if the progress of labor is closely monitored can labor abnormalities be diagnosed. Moreover, the timely diagnosis of these labor abnormalities, with prompt medical therapy, should improve the chances of achieving a vaginal delivery. These labor abnormalities can be classified as either arrest disorders (Fig. 22.10) or protraction disorders (Fig. 22.11). Table 22.2 provides parameters for abnormal labor.

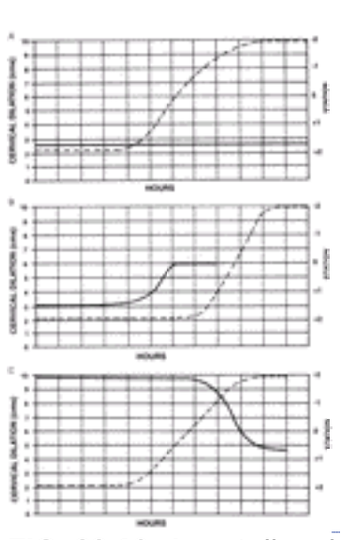

FIG. 22.10. Arrest disorders. These figures depict examples of different arrest disorders. **A:** Prolonged latent phase. Although one might say that a prolonged latent phase is not strictly an arrest disorder, it reflects an abnormality in the normal progress of labor in which the change into the active phase is arrested. **B:** Arrest of dilation, in which the cervix achieves 6 cm of dilation but then does not change for 2 hours. **C:** Example of an arrest of descent. The fetal head moves from a -2 station to a 0 to -1 station but then makes no further progress.

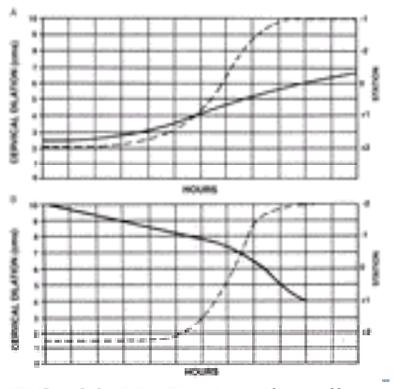

FIG. 22.11. Protraction disorders. These examples of protraction disorders are exaggerated to depict each abnormality. In each case, these abnormalities should be detected early, and appropriate therapy instituted. **A:** Protracted active phase. Note that the average slope is much less than 1.5 cm per hour. **B:** Prolonged and neglected second stage. Intervention should occur sooner than indicated on this partogram.

Prolonged Latent Phase

A prolonged latent phase (see Fig. 22.10A) occurs when regular painful uterine contractions are present for an extended period of time without entering the active phase of labor. Although a prolonged latent phase is not generally classified as an arrest disorder, some authorities believe that the latent phase is an example of a primary dysfunctional labor. In nulliparous women, the definition of a prolonged latent phase is a period of uterine activity without cervical change for more than 20 hours; in multiparas this time period is 14 hours. The cervix may be dilated up to 4 cm and completely effaced. The precise etiology is not clear but likely reflects ineffective uterine contractions without a dominant myometrial pacemaker. The management of a prolonged latent phase is controversial, and in general there are two possible approaches. Some obstetricians believe that a prolonged latent phase reflects an underlying labor abnormality that should be managed aggressively with

amniotomy and oxytocin. The other approach is to provide supportive measures including intravenous hydration and narcotic pain relief. Studies comparing these approaches have not shown either to be a clearly superior choice, so either treatment plan is acceptable as long as the patient understands the plan and risks. The more aggressive approach in some cases may be an induction of labor with the attendant higher risk of cesarean delivery, whereas the more conservative approach runs the risk of prolonging a potentially dysfunctional labor. Either option is acceptable. Deciding which course to take requires obstetric judgment and a motivated, informed patient.

Arrest of Dilation

An arrest of dilation occurs when there is no cervical change after 2 hours in the active phase of labor despite uterine activity (see Fig. 22.10B). In most cases, arrest of dilation occurs as a result of ineffective uterine contractions. Uterine contractions may become dysfunctional and lose their synchronous, rhythmic nature. Figure 22.5 shows an example of the loss of a dominant myometrial pacemaker with the expression of two pacemakers firing independently and without coordinated uterine contractions. In any case, prompt medical therapy with oxytocin usually corrects the underlying problem. In those rare cases where CPD is evident on evaluation of the patient, prompt cesarean delivery is indicated.

Arrest of Descent

After complete dilation is achieved, the primary goal of the second stage of labor is to gain station of the fetal head through the maternal pelvis with eventual delivery. If the patient does not gain station of 1 cm after an hour of adequate pushing efforts, an arrest of descent is diagnosed (see Fig. 22.10C). The cause of this arrest disorder may be one or a combination of several underlying abnormalities, including inadequate uterine contractions, CPD, abnormal fetal position, and asynclitism. If an arrest of descent is diagnosed, the obstetrician has several options, including the use of oxytocin, operative vaginal delivery, or cesarean delivery. The choices for therapy should be guided by the fetal status, station of the fetal head, maternal status, and operator experience.

Protracted Active Phase

When cervical change continues with adequate uterine contractions in the active phase of labor, but over a longer time period than anticipated, then a prolonged active phase is the diagnosis (see Fig. 22.11A). In nulliparous patients, cervical change is less than 1.2 cm per hour, whereas in multiparous patients cervical change is occurring at less than 1.5 cm per hour. A prolonged active phase may be the result of inadequate uterine contractility, but often both the timing and strength of uterine contractions appear to be normal and cervix dilation occurs slowly despite oxytocin therapy. The underlying problem may be true CPD or an undiagnosed flexion abnormality. Oxytocin therapy often is not successful in accelerating labor, and an arrest of dilation or descent may be inevitable regardless of the therapies employed. Should a protracted active phase lead to an arrest of labor despite oxytocin therapy, cesarean delivery is the best therapeutic course.

Prolonged Second Stage

An exaggerated example of a prolonged second stage is shown in Fig. 22.11B. A prolonged second stage is diagnosed when the fetal head descends less than 1 cm per hour. A second stage lasting longer than 2 hours has traditionally been considered abnormal and is an indication for operative vaginal delivery or cesarean delivery. However, more contemporary management allows for more flexibility in the management of the second stage of labor. If the fetus is tolerating the stresses of the second stage well and some gain in station is being made, then there is no indication for terminating the second stage solely on the basis of time in the second stage. Because epidural analgesia may increase the length of the second stage, there is no reason for intervention on the obstetrician's part if the fetal heart rate tracing is acceptable and the mother is comfortable. However, maternal exhaustion will often occur and result in the need for operative intervention. As with the other labor abnormalities, an attentive obstetrician with a plan of management for any contingency should improve both maternal and fetal outcome in abnormal second stages of labor.

In summary, several specific labor abnormalities may occur and can easily be diagnosed. With a rational plan of management, the need for cesarean delivery can be avoided and salutary maternal and fetal outcomes accomplished. The term “failure to progress” thus is not sufficient for a diagnosis. For example, a woman may have “arrest of dilation” followed by treatment with oxytocin. Should this be unsuccessful, then she may require cesarean delivery for “arrest of dilation refractory to oxytocin therapy.” Addressing labor abnormalities in more specific terms enables more rational treatment strategies to be used in the current and future pregnancies, regardless of the outcome.

EPIDURAL ANALGESIA AND LABOR PROGRESS

The impact of epidural analgesia on the occurrence of dystocia and the cesarean delivery rate has been controversial. Epidural analgesia is an excellent form of pain relief for the laboring woman, and in some labor and delivery units, the majority of laboring women opt for this therapy (see Chapter 3). Epidural analgesia is a vital part of the obstetrician's and anesthesiologist's armament to provide pain relief during labor, and both the ACOG and the American Society of Anesthesiologists endorse the use of epidural analgesia for pain management in labor.

However, epidural analgesia may have contributed significantly to the cesarean delivery epidemic of the past two decades. A meta-analysis by Morton and colleagues in 1994 of epidural use in the laboring woman cites an increased risk of 10% for cesarean delivery. Studies have supported this finding. Traynor and associates in 2000 reported that epidural analgesia was associated with a four-fold increased risk for cesarean delivery (12.2% in women with epidural vs. 3.3% in women without epidural), and that the risk for cesarean delivery increased progressively with higher station, less dilation, and less effacement at the time of catheter placement. Similarly, in 2000, Sizer and Nirmal found that epidural analgesia was associated with an increased incidence of OP presentation, leading to a three-fold increase in the risk for cesarean delivery (13.7% for OA presentation, 41.7% for OP presentation) and for operative vaginal delivery (24.4% for OA presentation, 43.7% for OP presentation).

Conversely, other studies contradict these reports and note that epidural use was not associated with an increase in the incidence of OP presentations. Clark and colleagues published a prospective randomized trial in 1998 comparing epidural analgesia with intravenous opioids for pain relief. The cesarean delivery rates were no different in the two groups (13.6% in the opioid group, 9.6% in the epidural group). Imprey and co-workers, in a retrospective review of 1,000 nulliparas, found that an increase in the epidural use from 10% to 57% over the course of 7 years did not result in an increase in the cesarean delivery rate of 3.8% to 5%. Zhang and colleagues, in a summary of studies regarding the use of epidural analgesia and labor outcome, concluded that clinical trials of epidural use of low-dose bupivacaine did not increase the risk of cesarean delivery. Notably, however, observational studies do indicate an increase risk for cesarean and instrumental deliveries, suggesting that selection bias may skew these results. These data depict the exceptional difficulty of studying this clinical issue, given the complexity of the labor process and the multitude of factors that may impact on labor outcomes.

The key to the rational use of epidural analgesia is the approximation of fetal station and cervical dilation. In a 1999 study, Holt and colleagues reported that the strongest risk factor for needing cesarean delivery with epidural analgesia was station at the time of epidural placement. The higher the station at the time of epidural, particularly if -1 or higher, the greater the risk for cesarean delivery. Based on these studies, it seems prudent to recommend that epidural placement be delayed until fetal station has reached the midpelvis. Importantly, women in labor should not be denied epidural analgesia when clinically reasonable and safe.

OPTIONS FOR THE MANAGEMENT OF DYSTOCIA

Once dystocia is diagnosed and a specific abnormality identified, the obstetrician has a number of therapeutic options that can lead to vaginal delivery rather than immediate cesarean delivery. Oxytocin should be administered first unless there is a clear contraindication to this medication, as this is an effective and safe therapy in experienced hands and can correct most labor abnormalities. A schematic depicting an example of one method to manage abnormal labor is shown in Figure 22.12.

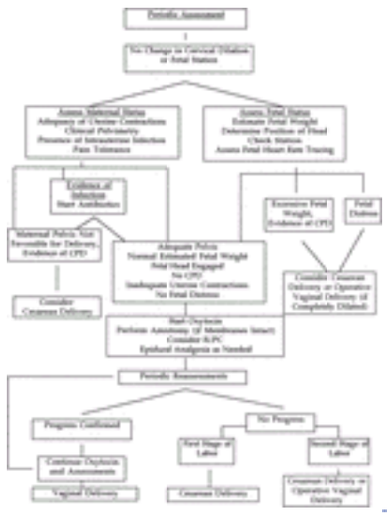

FIG. 22.12. Therapeutic options in the management of dystocia. This schematic provides one algorithm for the management of dystocia. The primary goal is to effect vaginal delivery with good maternal and neonatal outcomes.

Mapping the Progress of Labor

A key adjunct to the management of labor is the use of some form of a labor curve. Several different labor curves have been developed, and no one is better than any other. Several reports have shown that the graphic analysis of labor progress improves maternal and fetal outcomes while lowering cesarean delivery rates, including sites in underdeveloped countries. Many labor and delivery units use the concept of “alert” and “action” lines (Fig. 22.13). In this type of partogram (or labor curve), crossing an alert line merely means that labor progress is slowing, while crossing the action line indicates that a specific action must be taken. Mapping labor progress allows for the timely diagnosis of dysfunctional labor and the prompt institution of medical therapy. Therefore, most contemporary labor and delivery suites have incorporated the use of labor curves into the routine management of laboring women.

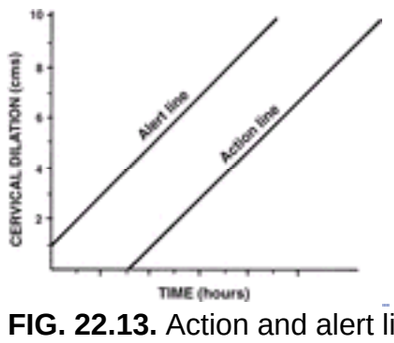

FIG. 22.13. Action and alert lines in the management of labor. This figure depicts the alert and action lines graphically. This type of labor curve has been used successfully to manage labor in many different settings. With this curve, slowing of the labor curve is first marked by an alert that labor is not progressing normally. Then, with further lack of progress, the action line is crossed, mandating that some form of action (medical or surgical therapy) be instituted. (Adapted from Philpott RH, Castle WM. Cervicographs in the management of labor in primigravidae: II. The action line and treatment of abnormal labor. *J Obstet Gynecol Br Commonw* 1972;79:599–602, with permission.)

Amniotomy

Artificial rupture of membranes has been used in the management of slow or desultory labor for decades. This intervention has been deplored by some obstetricians as needless intervention and recommended by others as a useful adjunct. Retrospective studies with relatively small sample sizes suggest that amniotomy could speed normal labor and stimulate abnormal labor to again meet normal milestones. However, large-scale prospective randomized studies do not support the routine use of amniotomy in the management of dystocia (Fig. 22.14). Although normal labor is accelerated modestly, particularly in multiparous women, women in whom amniotomy was routinely used did not have lower rates of cesarean delivery. Additionally, there is a modest increase in the rate of intrauterine infection in women who underwent amniotomy early in the course of labor (e.g., <4 cm dilation). Rupture of the membranes is also associated with variable decelerations of the fetal heart rate as a result of umbilical cord constriction. This problem can, in some cases, be remedied with amnioinfusion of warm saline into the uterine cavity through an intrauterine pressure catheter (IUPC). In such situations, the obstetrician uses one measure to improve outcome (amniotomy) which unfortunately leads to further interventions that otherwise could have been avoided.

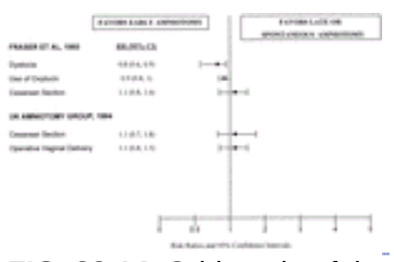

FIG. 22.14. Odds ratio of the effect of amniotomy on labor dystocia. Amniotomy has little effect on the course of labor, the incidence of dystocia, or the incidence of cesarean delivery.

Conversely, there are reasonable indications for amniotomy. Amniotomy is an excellent method for labor induction if the cervix is favorable and the fetal head well applied to the cervix. The judicious use of amniotomy after 5 cm does accelerate labor in the multiparous woman, but less so in the nullipara. Also, oxytocin tends to work more efficiently if the membranes have been ruptured. Disruption of the membranes is required for internal monitoring of the fetal heart rate tracing or of uterine activity. Rupturing of the membranes will detect meconium staining of the amniotic fluid and alert the obstetrician and pediatrician to be prepared for a potentially high-risk circumstance regarding care of the newborn and the prevention of meconium aspiration.

Thus, amniotomy can be a useful adjunct in the management of labor, but only if used wisely and in appropriate circumstances. As long as the parturient is making adequate progress in labor and the fetal heart rate tracing is normal, there is no indication for amniotomy. Spontaneous rupture of the membranes usually occurs at between 7 and 9 cm dilation. Cervical examinations should be minimized after the membranes have been ruptured to decrease the chance of infection because the number of cervical examinations correlates well with the risk of intrauterine infection.

Intrauterine Pressure Catheters

An IUPC is often introduced into the amniotic cavity to help determine the strength of uterine contractions. Application of the catheter requires that the fetal membranes are ruptured, either through spontaneous or artificial rupture of the membranes. Some IUPC require a pressure transducer at the bedside which requires calibration to obtain reliable pressure measurements. More recent devices have the pressure transducer in the tip of the catheter, presumably yielding more reliable pressure measurements. Unfortunately, these pressure readings may be spurious, but more importantly there is a wide range of variation in the duration, strength, and frequency of contractions in normal labor. Thus, quantification of labor using IUPC and applying one standard to all women in labor seems unlikely to lead to favorable maternal outcomes.

Many different quantitative approaches to uterine contractility have been proposed using IUPC technology. For example, the Montevideo unit is the average intensity of the uterine contractions multiplied by the number of contractions over a 10-minute period (expressed as mm Hg/10 min). A total of 200 Montevideo units indicates that there is adequate uterine contractility to effect labor progress. Past studies have suggested that if this level of uterine activity was achieved and no labor progress resulted, then one could state that an adequate trial of labor had been completed and justify cesarean delivery. Other studies ave found that IUPCs increase the rate of

intrauterine infection with no definable benefit. No study to date has shown that the use of IUPC technology improves maternal or perinatal outcome. Therefore, there is no compelling reason to use IUPC in the management of labor. Perhaps the best application for IUPCs is in assisting nursing personnel with the use of oxytocin so that the precise timing of uterine contractions can be determined.

Oxytocin

Oxytocin is a nine–amino-acid peptide (Fig. 22.15) normally produced in the hypothalamus and secreted by the posterior pituitary in a spurting or pulsatile fashion. During normal pregnancy, serum oxytocin concentrations remain essentially unchanged throughout gestation, and there is only modest increase in total serum concentrations before labor. However, with labor, plasma levels increase and then peak in the second stage. Oxytocin receptor expression increases in the decidua in the weeks preceding the onset of labor, and increases sharply just before labor. Oxytocin receptors are expressed primarily in decidua, myometrium, and breast tissue. Myometrial sensitivity to oxytocin parallels expression of oxytocin receptors such that responsiveness begins at about 20 weeks of gestation and then dramatically increases at about 30 weeks of gestation. Oxytocin is cleared from peripheral blood by the liver and kidney and is also significantly metabolized by oxytocinase, an enzyme produced in abundant quantities by the placenta and gestational tissues.

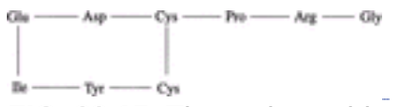

FIG. 22.15. The amino acid structure of oxytocin. Oxytocin is a nine–amino-acid peptide with two disulfide bonds.

Oxytocin may be administered intravenously, subcutaneously, intramuscularly, and buccally. With intravenous administration, there is a concentration-dependent increase in its serum levels but with wide individual variation in responsiveness to the drug. Intravenous administration of oxytocin has effects only on tissues expressing receptors and thus has an excellent therapeutic index. Oxytocin administration results in an increase in the frequency, duration, and strength of uterine contractions. The myometrial response to oxytocin is highly variable, and uterine hyperstimulation may occur at any dose of administered oxytocin depending on the individual patient. Uterine hyperstimulation necessitating discontinuation of the drug or a decrease in the dose being used is the most common side effect of the medication. The only known side effects of oxytocin not related to uterine activity include disturbances in water homeostasis and electrolytes. Oxytocin has approximately 1% the antidiuretic effect of vasopressin, and these side effects are usually seen only at high concentrations of oxytocin infusion (e.g., 40–50 total units administered). Also, intravenous boluses of oxytocin can lead to hypotension and tachycardia as a result of a paradoxical relaxation of vascular smooth muscle.

From the first clinically described use of oxytocin in the 1940s, there has been controversy as to the best and most appropriate regimen for oxytocin use. Table 22.4 summarizes some different acceptable oxytocin protocols currently used. Historically, early regimens of oxytocin administration were highly individualized by physician preference, ranging from relatively low doses to extremely high doses. For example, Seitchik and Castillo found that the most important determinant of the maximum oxytocin dose and the frequency of hyperstimulation was dose-incrementation interval. Those patients who received lower dose increments (every 30–40 min) by 1.0 mU per minute had lower oxytocin doses and less hyperstimulation with good outcomes.

TABLE 22.4. *Acceptable oxytocin protocols*

However, more recent studies have shown that low-dose protocols may result in higher cesarean delivery rates when compared to higher-dose oxytocin protocols. Satin and colleagues used two different methods of oxytocin administration. In one 5-month period, they used a low-dose regimen in 1,251 women where the starting dose of 1 mU per minute was increased by 1 mU per minute every 20 minutes until 8 mU per minute was reached, and then the incremental increase was by 2 mU per minute every 20 minutes up to a maximum of 20 mU per minute. For the next 5-month period (1,537 women), they studied the higher-dose regimen advocated by O'Driscoll in which the starting dose of 6 mU per minute was increased by 6 mU per minute every 20 minutes up to a maximum of 42 mU per minute. Among those patients being augmented, the average maximum oxytocin dose was greater in the high-dose protocol (14.7 mU/min vs. 6.6 mU/min), as was the incidence of uterine hyperstimulation (52% vs. 39%). Notably, there was a significant decrease in the cesarean section rate for dystocia (9% vs. 12%), the use of forceps (12% vs. 16%), rates of neonatal sepsis (8% vs. 12%), and a shorter time from admission to delivery (10.1 h vs. 13.4 h).

In a following study, Satin and colleagues compared two incremental dosing intervals of high-dose oxytocin, comparing a 20-minute dosing interval versus a 40-minute dosing interval. In those women receiving oxytocin for labor augmentation, 603 were in the 20-minute interval group and 564 were in the 40-minute interval group. The results of this study showed that the maximum oxytocin dose, the time from admission to delivery, and the incidence of uterine hyperstimulation were similar in each group. However, women receiving incremental increases in oxytocin at 20-minute intervals had a significantly lower cesarean section rate for dystocia (8% vs. 12%).

A randomized study by Xenakis and associates compared the low-dose protocol of Seitchik and Castillo to a higher-dose protocol in which oxytocin was commenced at 4 mU per minute and increased by 4 mU per minute every 15 minutes. They found a significantly greater number of cesarean deliveries in women receiving the lower-dose regimen (25.7% vs. 10.4%). There were no differences in maternal or neonatal outcome or in the incidence of hyperstimulation. The average maximal dose of oxytocin in the high-dose regimen was only 9 mU per minute, suggesting that achieving a more rapid response with higher doses does not require excessive amounts of oxytocin and that prompt correction of the labor abnormality is critical for success.

These studies suggest that a higher dose of oxytocin will stimulate a higher proportion of patients earlier, resulting in more timely correction of dysfunctional labor and in a lower risk for cesarean delivery (Fig. 22.16). There are numerous factors that can account for the wide variation in responsiveness to oxytocin infusions, including differences in oxytocin receptor expression, differences in oxytocin plasma concentrations, and differences in oxytocinase concentrations and activity.

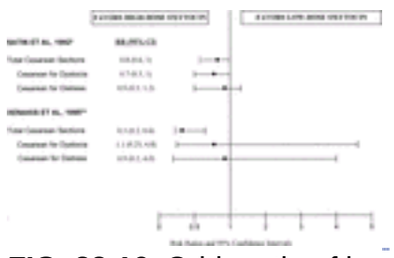

FIG. 22.16. Odds ratio of low-dose oxytocin versus high-dose oxytocin. High-dose oxytocin results in lower overall cesarean delivery rates.

An important unanswered question relates to the safest maximum dose of oxytocin. While some authorities advocate a maximal dose of 42 mU per minute, there are few data upon which to base this recommendation. In a prospective randomized double-masked trial of oxytocin dosage in labor induction and augmentation by Merrill and Zlatnik, two different doses were used. A low- dose regimen of 1.5 mU per minute increasing by 1.5 mU per minute every 30 minutes was compared with a higher-dose regimen of 4.5 mU per minute increasing by 4.5 mU per minute every 30 minutes. Higher-dose oxytocin was associated with a significant shortening of labor, but with no significant differences in cesarean delivery rates. The highest oxytocin dose administered was 117 mU per minute and there were no differences in neonatal outcomes. Hence, no solid recommendations based on data can be made regarding the maximal safe dose of oxytocin.

Regardless of the choice of protocols, clinical judgment should be used when oxytocin therapy is prescribed. There should be no evidence of fetopelvic disproportion based on clinical pelvimetry and estimated fetal weight. If the pelvis is not adequate, or the fetus is large, then the dysfunctional labor may be a sign that vaginal delivery is not safe, and cesarean delivery would be the more appropriate therapy. Additionally, oxytocin should not be used in women with prior classic cesarean section scars because the risk of uterine rupture is high (5%–10%). Care should be taken when women with prior low transverse cesarean sections are being augmented with oxytocin. Although the studies regarding the use of oxytocin and the risk of scar dehiscence are mixed, one should know the total dose given and follow the course of labor carefully. Vaginal birth after cesarean section is addressed more fully in Chapter 24. Oxytocin is an extremely effective drug when used appropriately but can be dangerous for mother and fetus if used inappropriately. Therefore, clinical judgment is required whenever oxytocin is used in the management

of dystocia.

Obstetric Patience

Traditional management of labor has been challenged by some new concepts based on scientific data rather than expert opinion. These new ideas rely on the obstetrician's patience and willingness to allow time for the patient to progress at a somewhat slower rate than has previously been felt to be acceptable. In this regard, these concepts are based on the use of fetal monitoring to ensure that the fetus is tolerating labor well.

Traditionally, an arrest of the active phase of labor with oxytocin augmentation for more than 2 hours was an indication for cesarean delivery. However, studies by Rouse and colleagues question this 2-hour time limit. In their initial study, the Rouse group found that extending the time period of active-phase arrest while on oxytocin from 2 hours to 4 hours was both safe and effective. In their original cohort of 542 normal women presenting with arrest of term labor, 126 demonstrated no labor progress after 2 hours of oxytocin augmentation. However, 101 of these 126 delivered vaginally, decreasing the overall cesarean delivery from 26% (if the 2-hour limit was used) to 8% for the entire study. In those women with presumed adequate labor on the basis of Montevideo units, 32 of 52 delivered vaginally simply by waiting for 4 hours rather than moving to cesarean after 2 hours. These women did have a higher incidence of intrauterine infection, but without increased neonatal morbidity.

In a following study, Rouse and colleagues observed 501 women with a similar protocol. Of these women, 38 had sustained adequate labor for 2 hours based on Montevideo units and no progress in labor. By merely waiting another 2 hours, 23 (or 61%) delivered vaginally and avoided an otherwise indicated cesarean delivery based on traditional criteria. Again, there were no adverse neonatal effects of continuing oxytocin for 4 hours, and there was a higher incidence of intrauterine infection in those women who labored further. Additionally, they found that achievement and maintenance of 200 Montevideo units, the value traditionally noted to represent “adequate” labor, was not predictive of delivery route.

While patient numbers are as yet insufficient to change traditional recommendations on the management of labor arrest, these studies, if confirmed, strongly suggest that allowing more time for oxytocin augmentation is reasonable, effective, and safe. A key issue again is that one management plan should not necessarily apply to all women in labor, as there is considerable individual variation in labor progress and responsiveness to oxytocin.

Two studies have explored different strategies of managing the second stage of labor. These studies have compared two groups of women in the second stage, in which one group of women was encouraged to push promptly with the diagnosis of complete dilation while the other group was encouraged to rest for 1 to 2 hours (or more) before starting pushing efforts. In the study by Fraser and associates, nulliparous women in the delayed pushing group were encouraged to wait at least 2 or more hours prior to pushing. Over 900 women were enrolled in each group. When compared to the early pushing group, women who delayed pushing had a lower incidence of “difficult delivery” (17.8% vs. 22.5%). Difficult delivery was defined as the need for midpelvic delivery, low-pelvic delivery with rotation, any manual rotational delivery, or second stage cesarean delivery. The primary difference was in the incidence of midpelvic delivery (9.3% vs. 13%), while cesarean delivery rates were similar (5.0% vs. 5.7%). Maternal morbidity and neonatal outcomes were similar between the two groups.

The other study of delayed pushing, by Hansen and colleagues, was also a randomized prospective trial comparing immediate versus delayed pushing efforts in over 250 women. In those women randomized to delayed pushing, nulliparas were rested for 120 minutes while multiparas rested for 60 minutes. The investigators found that there were no statistically significant differences in instrumental delivery rate, neonatal outcome, and rates of perineal injury. Women who rested had a longer second stage of labor, but decreased total time pushing, fewer decelerations, and less fatigue. Only three cesarean deliveries were performed, all in the control group. The authors concluded that delayed pushing, up to 4.9 hours, was safe and may be useful in selected patients.

The studies described in this section underscore the value of obstetric patience. While there are average times for the first and second stages of labor, these studies show that traditional and arbitrary time limits may be extended safely in selected patients, with improved maternal outcomes and continued good neonatal outcomes.

Operative Vaginal Delivery

Operative vaginal delivery should only be performed if the following criteria are met: complete cervical dilation, engagement of the fetal head filling the hollow of the sacrum, known position of the fetal head, and sufficient operator experience. Forceps- or vacuum-assisted vaginal delivery should be performed only on behalf of the mother or fetus and not for the convenience of the obstetrician. In the context of dystocia, the primary reason for moving to assisted vaginal delivery is an arrest of descent of the fetal head. This arrest may be due to inadequate uterine contractions, insufficient maternal pushing efforts, abnormal position of the fetal head (OP or deep transverse arrest), or asynclitism of the fetal head. In these situations, the mother often has pushed for 2 hours or more and may be unable to continue with effective pushing efforts because of exhaustion.

Appropriate forceps use or indications for vacuum extraction are dependent on the experience of the obstetrician. Experienced obstetricians skilled in the use of forceps have the judgment to use the appropriate instruments and traction for a successful and safe vaginal delivery. Less experienced providers may find vacuum extraction more successful but vacuum-assisted delivery still requires judgment and skill for a safe delivery. Even with vacuum extraction, prudent use in specific situations will decrease the incidence of maternal and fetal complications. An all too common occurrence is the inappropriate use of operative vaginal delivery with adverse obstetric and neonatal outcomes, usually due to inappropriate application at a higher than expected station. In experienced hands, there are no differences in neonatal outcome in infants delivered by normal vaginal delivery or by outlet forceps.

Cesarean Delivery

If all the previously outlined measures are not successful, then cesarean delivery is likely needed to obtain a good maternal and neonatal outcome. Although one should not move to cesarean delivery before all options are considered, similarly one should not hesitate to operate if a successful vaginal delivery is not possible without potential serious risk or harm to the fetus and neonate. Delay in moving to cesarean delivery when indicated can potentially lead to adverse maternal and neonatal outcomes such as postpartum hemorrhage, uterine rupture, and birth injury. Cesarean section is discussed in detail in Chapter 24.

ACTIVE MANAGEMENT OF LABOR

Since the mid-1960s, an organized approach known as the active management of labor (AMOL) has been developed and advocated by the obstetric staff at the National Maternity Hospital in Dublin, Ireland. Initially conceived by Kieran O'Driscoll, this approach has been modified over the years. The advocates of AMOL cite a continuing low cesarean delivery rate (approximately 10%) with excellent outcomes for mother and infant. The primary goal of AMOL is to prevent prolonged labor. Women are guaranteed that they will either be delivered, or close to delivery, within 12 hours of admission to the labor and delivery unit. The style and content of this labor management have generated much controversy and misunderstanding in the United States. For example, many obstetricians believe that the active part of AMOL is aggressive intervention in the laboring woman or high oxytocin doses, but in fact it refers to the fact that an obstetrician (usually the head of the department) reviews the labor progress of each patient to ensure that optimal outcomes are achieved.

Basic Concepts of AMOL

Table 22.5 lists the primary components of AMOL. Perhaps the hallmark feature of AMOL is that no patients are admitted to the labor and delivery unit unless the diagnosis of labor has been made. Labor is defined as painful, regular uterine contractions with complete cervical effacement, regardless of cervical dilation. The average dilation of the cervix at the time of admission is 2 to 3 cm. AMOL applies only to the nulliparous patient, as multiparous women who have had previous vaginal delivery usually do not have prolonged labor and have a higher risk of uterine rupture with oxytocin administration. After the diagnosis of labor has been made, amniotomy is performed at the time of admission regardless of cervical dilation. The diagnosis of labor is key. If this diagnosis is incorrect, then an induction of labor is being initiated with the attendant increased risk for cesarean delivery.

Comprehensive prenatal education
Admission only after labor is diagnosed
Strict criteria for the diagnosis of labor
Delivery with 12 h of admission
One-on-one nursing care
Immediate amniotomy at admission (if membranes still intact)
Frequent cervical examinations to ensure progress in labor
Prompt intervention if labor progress not confirmed
High-dose oxytocin protocols
Epidural analgesia is available
Midpelvic and rotational forceps not used
Continuous internal audit
“Active” involvement of attending obstetrician

TABLE 22.5. *Key concepts of active management of labor*

On admission, a nurse-midwife or student midwife is assigned to the patient who stays with only this patient throughout her entire labor. There are no provisions for change of nursing shifts. Also, these patients receive detailed instructions on expectations during labor in prenatal birthing classes. One-on-one nursing care, with a clear vision of the ensuing labor, alleviates maternal anxiety and is perhaps the most distinguishing feature of AMOL over other styles of labor management as practiced in the United States.

Cervical examinations to corroborate labor progress are performed by the midwives every 1 to 2 hours. If the patient does not make adequate progress in labor, oxytocin administration is promptly initiated at 6 mU per minute and increased by 6 mU per minute every 15 minutes until 7 to 8 contractions occur every 15 minutes (see Table 22.4). During labor, the patient is never left unattended by the midwife assigned to her care and uterine activity is palpated by the midwife. The midwife assigned to the parturient will then perform the delivery with the head midwife in attendance. The attending obstetrician is asked to intervene only when there is need for an obstetric operation, such as episiotomy, forceps delivery, or cesarean delivery. Midforceps delivery and rotational forceps are not performed.

With AMOL at the National Maternity Hospital, cesarean delivery rates for dystocia are less than 10%. Oxytocin is used in 50% to 60% of nulliparas and only 10% to 15% of multiparas (who are not managed with this program). Delivery occurs in less than 12 hours in 98% of women. Cerebral palsy rates approximate that of the United States, or about 2 per 1,000 births, and birth trauma is rare. Epidural analgesia is allowed and does not impact significantly on the cesarean delivery rate. Clearly, AMOL suits the population served at this hospital well.

Lessons from AMOL

Three prospective randomized trials of AMOL have been conducted in the United States (Table 22.6). Lopez-Zeno and colleagues found a significant decrease in the cesarean delivery rate in nulliparous patients in the AMOL arm of the studies, from 14.1% to 10.5%. Frigoletto and associates randomized over 1,200 to AMOL or traditional management and found no decrease in the cesarean delivery rate but were able to show a modest decrease in the duration of labor in the AMOL arm. In the third study, Rogers and colleagues also found no significant decrease in cesarean delivery rate but confirmed a decrease in the length of labor. These discrepancies may be because AMOL may not significantly reduce the cesarean delivery rate if the baseline rate is 11% or less. In other nonrandomized studies, AMOL has been shown to decrease the primary cesarean delivery rate by 25% to 50%, and a recent meta-analysis by Glantz and McNanley showed that the risk of cesarean delivery for dystocia was decreased on average by 34%. In an analysis of these three randomized trials, AMOL resulted in a lower risk for cesarean delivery (Table 22.6, Fig. 22.17) and a greater incidence of delivery within 12 hours of labor (Fig. 22.18). A prospective randomized study performed at the National Maternity Hospital in New Zealand by Sadler and co-workers found that the cesarean delivery rate was similar in their conventionally managed and actively managed women (9.4% vs. 9.7%), but that women in the AMOL had shorter labors and a lower relative risk for prolonged labor.

TABLE 22.6. *Cesarean delivery incidence in randomized studies of active management of labor*

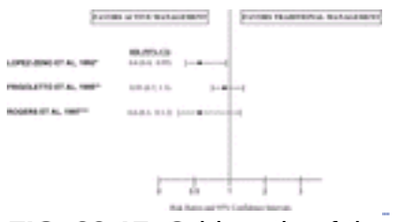

FIG. 22.17. Odds ratio of the effect of active management of labor on cesarean delivery rate. Active management of labor is associated with a lower risk of cesarean delivery in one study but with equivocal results in two studies.

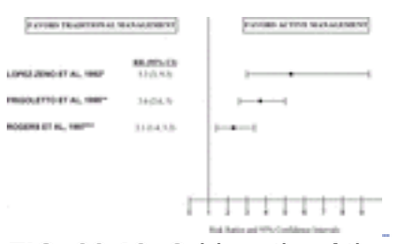

FIG. 22.18. Odds ratio of the effect of active management of labor on delivery within 12 hours. Active management of labor is associated with delivery within 12 hours of presentation to the labor and delivery units in each study depicted.

Many lessons can be derived from the AMOL protocol. First, AMOL is a regimented integrated approach to the management of labor in all nulliparous women admitted to the hospital. In many ways, this philosophy runs counter to the concept of individualizing patient care according to each woman's specific situation. However, application of protocols in some situations, as in clinical practice guidelines, leads to more standardized application of appropriate therapies with concomitant improved outcomes. Whereas much has been made of the use of early amniotomy and the relatively high doses of oxytocin employed in AMOL protocols, a detailed analysis by Thorton and Lilford indicates that the most important component of AMOL in achieving a low cesarean birth rate is one-on-one nursing. And perhaps the most important aspect of nursing care in this setting is the alleviation of maternal anxiety and the prompt diagnosis and treatment of dystocia.

AMOL is an excellent example of how an organized approach to labor management can lead to improved outcomes. Although AMOL cannot be adopted in its entirety in all labor and delivery units in the United States, the principles of AMOL can be adapted in many situations. First, normal women at term with uterine contractions should be admitted only when they are in active labor. Obviously, there are exceptions to this concept, but premature admission with interventions usually implies that an induction of labor is being performed for no clear indication. Second, dysfunctional labor should be promptly diagnosed and treated with appropriate medical therapy. Third, efforts to alleviate maternal anxiety through prenatal education and attentive, sympathetic caregivers should be maximized. Unfortunately, labor and delivery units in the United States would find it impossible to provide one-on-one nursing care throughout labor with the current staffing policies of most units. However, more personal interactions with all caregivers, from nurses to obstetricians, should be encouraged. And last, there is little delay in making the decision to move to cesarean delivery, improving both maternal and neonatal outcomes. Although critics of AMOL cite perceived excessive intervention (based on the use and doses of oxytocin), proponents of AMOL counter that a cesarean delivery rate of 20% to 25% versus less than 10% is the greater intervention.

SUMMARY POINTS

- Dystocia is common, particularly in the nulliparous woman, and is a common indication for cesarean delivery.
- Early amniotomy does not improve labor outcomes. However, amniotomy after 5 cm of dilation can shorten the time of labor but at the expense of a modest increase in infectious morbidity.
- Early application of epidural analgesia can contribute to labor abnormalities, particularly in the second stage, and can lead to an increased need for operative vaginal delivery.
- Active management of labor (AMOL) protocols can decrease the cesarean delivery rate in some populations.
- Oxytocin protocols using higher doses (3–6 mU/min and increasing concentrations every 15–20 min) decrease the need for cesarean delivery for dystocia with adequate safety for mother and fetus.
- All authorities agree that the primary goal in managing women in labor is to obtain healthy babies with minimal maternal morbidity. However, the methods used to achieve these goals elicit a great deal of controversy among obstetricians. Nevertheless, following the principles of labor management as outlined in this chapter should ensure good maternal and fetal outcomes.

SUMMARY POINTS

REFERENCES

The enthusiasm for operative vaginal delivery peaked in the early 20th century when almost 50% of all deliveries were with forceps. Over the last three decades this has changed and worldwide there has been a decrease in the use of operative techniques. This has been accompanied by a relative increase in abdominal delivery. There are various explanations for this trend including the development of more effective anesthesia techniques, the introduction of antibiotics, the effective use of blood products, and the development of improved surgical techniques. Thus, cesarean section has become the most commonly performed surgical procedure of our time and operative vaginal delivery rates have significantly decreased. When operative vaginal delivery is performed now, it is more commonly carried out with a vacuum extractor than with forceps and in some parts of the world (Scandinavia), forceps are hardly ever used. In the United States and increasingly in Europe, medicolegal concerns have reduced enthusiasm for operative delivery and the teaching thereof. This is an unfortunate situation since, for the correct indication, and in well-trained hands, operative vaginal delivery is safe and effective and reduces the incidence of abdominal delivery and its attendant complications. The objectives of this chapter are two-fold: first, to outline the basic knowledge that should be required of those wishing to perform operative vaginal deliveries, and second to discuss selected important topical issues that have recently been highlighted in the literature.

APPLIED MATERNAL PELVIC ANATOMY

The art of ante- and intrapartum clinical assessment of the maternal pelvis is slowly disappearing from many training programs as this aspect of obstetric evaluation continually receives less emphasis. In many instances, the argument that labor is the best test of the cephalopelvic relationship is a reasonable one. The counter argument, however, is that accurate clinical maternal pelvimetry may reveal findings that would prevent an unnecessarily difficult labor in a case of obvious cephalopelvic disproportion.

A knowledge of the female pelvis and its different configurations is important. Figure 23.1 shows the four parent types of maternal pelvis, defines their major characteristics as described in the Caldwell-Moloy classification, and lists the percentage of women with each type of pelvis. Table 23.1 lists some important diameters of the maternal pelvis. Detailed clinical knowledge of the type of pelvis and the relative dimensions of that pelvis and the fetal presenting part attempting passage through that pelvis, should form the foundation of any decision to undertake operative vaginal delivery. To this end, the following sections present applied anatomy of the maternal pelvis and fetal head.

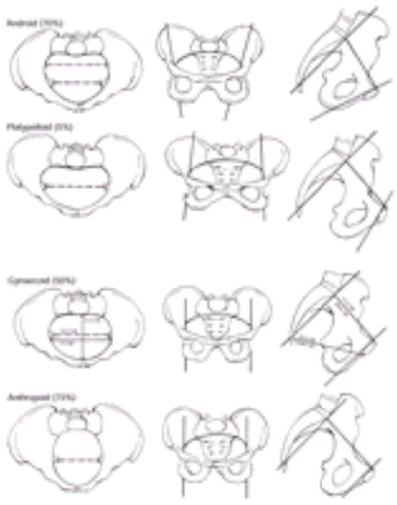

FIG. 23.1. The four major types of female pelvis.

Region of the pelvis	Measurement (cm)
Brim (inlet): AP	11.5 cm
Brim: Transverse	13.0 cm
Midcavity (midpelvis: AP and transverse)	12.0 cm
Cavity: AP and transverse	10.5 cm
Outlet: AP	12.5 cm
Outlet: Transverse	11.0 cm

AP, anteroposterior.

TABLE 23.1. *Diameters of the female pelvis*

PERFORMING CLINICAL PELVIMETRY

The pelvis is usually assessed in terms of the inlet, midcavity, and outlet.

Inlet

The inlet can only be adequately evaluated prior to engagement of the fetal head, since once the head occupies the midcavity the posterior inlet cannot be accessed. The examiner first assesses the anteroposterior (AP) diameter of the inlet by measuring the diagonal conjugate (distance from the undersurface of the symphysis pubis to the sacral promontory). The obstetric conjugate (the narrowest AP diameter of the inlet) is estimated by subtracting 2 cm from the diagonal conjugate. The transverse diameter of the inlet cannot be measured clinically. An idea of the shape and the extent of the circumference of the inlet can be gained by sweeping the examining fingers laterally along the pelvic brim. If more than two thirds of the brim can be easily palpated, and especially if the posterior portions of the brim can be felt, there may be a contracted inlet.

Midcavity (Midpelvis)

The midcavity of the pelvis is evaluated by assessing the shape of the sacrum (curved or straight), the width of the sacrosciatic notch, and the prominence of, and distance between, the ischial spines. A contracted midpelvis characteristically shows a flattened forward projecting sacrum, prominent ischial spines with a narrowed interspinous distance, and a shortened sacrospinous ligament which is less than two fingerbreadths long.

Outlet

Evaluation of the outlet consists of:

- determining the distance between the ischial tuberosities (normally approximately 10 cm)
- palpating the coccyx to determine its orientation and mobility (normally mobile and not protruding into the pelvic cavity)
- evaluating the subpubic angle (>90 degrees) and retropubic angle (flattened in a platypelloid pelvis and sharply angulated in an android pelvis)
- determining the convergence or divergence of the pelvic sidewalls (see Fig. 23.1).

During labor, clinical pelvimetry can be combined with fetal parameters such as head position, molding, caput succedaneum, asynclitism, maternal and fetal soft tissue edema, presence of meconium, descent of the head, and fetal heart rate response, with contractions or pushing. By assimilating the information from repeated examinations an idea of how the fetal head is progressing through the pelvis can be gained. In this way the operator is afforded a more complete estimation of the chances of a successful vaginal delivery using forceps.

The use of the term “adequate pelvis” is to be discouraged since it is very nonspecific. Clinical assessment of the maternal pelvis prior to an operative vaginal delivery is a prerequisite and the findings should be documented in more definite terms with mention being made of the nature of the pelvic inlet, the midpelvis, and the outlet. Since each delivery is a separate event, and applies to a specific fetus, the best time to assess the adequacy of a particular patient's pelvis is during labor and delivery. In this way the relationship between the pelvis and the fetal head can be better evaluated.

Some important definitions of clinical pelvimetry are given in Table 23.2.

Engagement:	The widest diameter of the fetal presenting part (in most cases the bi-parietal diameter of the fetal head) is at or below the plane of the maternal pelvic inlet. The best method of determining this is a combination of abdominal and pelvic examination.
Station:	The relationship between the leading bony part of the fetal presenting part (usually the cranium) and the maternal ischial spines. Usually, but not always, the fetal bi-parietal diameter is engaged when the leading portion of the skull is felt at 0 station. The most common source of error in assessing station is caused by the cephalopelvic disproportion. In circumstances where severe caput succedaneum precludes accurate diagnosis of the station, operative vaginal delivery should not be contemplated.
Attitude:	The relationship of the fetal head to the fetal spine. The head may be flexed, extended, or in a neutral attitude ("military attitude").
Position:	The relationship of the denominator of the fetal presenting part to the maternal pelvis. In a cephalic presentation the denominator is the occiput while in a breech presentation it is the sacrum. The position is always described in relation to the maternal left and right sides of the pelvis.
Presentation:	The relationship between the leading fetal part and the maternal pelvic inlet. The fetus may have a cephalic, breech, or shoulder presentation.
Lie:	The relationship between the fetal and maternal longitudinal axes, which may be longitudinal, oblique, or transverse.
Asynclitism:	The relationship between the anterior and posterior parietal bones and the sagittal suture. When neither of the parietal bones precedes the sagittal suture the head is synclitic. If the anterior parietal bone precedes the sagittal suture there is anterior asynclitism, and when the posterior parietal bone precedes the sagittal suture there is posterior asynclitism.
Molding:	This term describes the phenomenon of abutment or overlapping of the fetal skull bones caused by excessive pressure on the fetal head. In general the occipital and frontal bones slip under the parietal bones when molding occurs.

TABLE 23.2. *Important definitions of clinical pelvimetry*

American College of Obstetricians and Gynecologists' Classification of Station

In 1988 forceps operations were redefined by the American College of Obstetricians and Gynecologists (ACOG). The new classification uses the level of the leading bony point of the fetal head in centimeters at or below the level of the maternal ischial spines (0+ to 5+) to define station instead of the previously used method of describing the birth canal in terms of thirds (0+ to 3+).

APPLIED FETAL CEPHALIC ANATOMY

A knowledge of term fetal skull anatomy is important for anyone performing operative vaginal deliveries since different head positions present different diameters which significantly impact the rate of success in terms of delivery. Figure 23.2 shows important landmarks, and Figure 23.3 presents relevant diameters of the fetal skull. Table 23.3 shows the diameters and circumferences of the fetal head that will need to negotiate the maternal pelvis in specific fetal head positions.

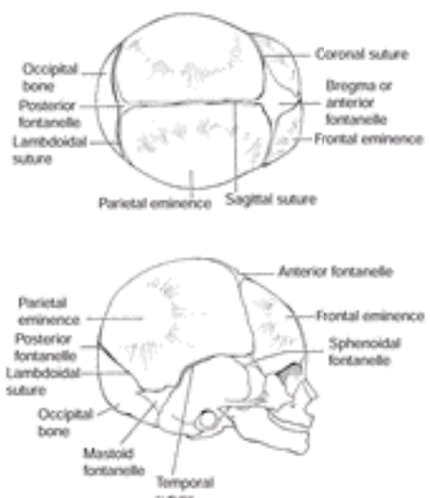

FIG. 23.2. Important landmarks of the fetal skull.

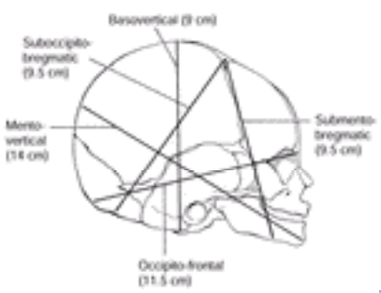

FIG. 23.3. Important diameters of the fetal skull.

Diameter	Measurement (cm)
Suboccipital-Bregmatic Nape of neck to center of bregma	9.5 cm
Submental-Bregmatic Below chin to center of bregma	9.5 cm
Mentum-Vertical Point of chin to above posterior fontanelle	14.0 cm
Basal-Vertical Base of skull to most distant point of vertex	9.0 cm
Occipital-Frontal Root of nose to occipital protuberance	11.5 cm
Bi-parietal Between two parietal eminences	9.5 cm
Bitemporal Greatest distance between the two halves of the coronal suture	8.5 cm

Circumference	Measurement (cm)
Suboccipital-Bregmatic × Bi-parietal Well-flexed vertex	28 cm
Occipital-Frontal × Bi-parietal Deflexed vertex and occipital posterior positions	33 cm
Mentum-Vertical × Bi-parietal Brow presentation (largest possible diameter)	35.5 cm

TABLE 23.3. *Diameters and circumferences of the fetal head that will need to negotiate the pelvis with the head in specific positions*

A number of terms are applied to swellings seen on the neonate's head. Some such as *caput succedaneum* are expected and do not pose a risk to the neonate, and some are pathologic and need immediate attention. Figure 23.4 shows these swellings schematically.

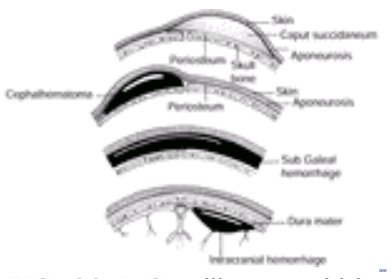

FIG. 23.4. Swellings and bleeds associated with normal and operative vaginal delivery.

Caput Succedaneum

Commonly referred to as caput, caput succedaneum describes edema of the scalp (serous effusion between aponeurosis and periosteum) overlying the leading part of the skull. This is a normal occurrence, the result of pressure from the cervix interrupting venous and lymphatic drainage from the scalp during labor. There are varying degrees of caput and these are described subsequently. Caput usually disappears within hours after birth.

Caput succedaneum should be differentiated from two life-threatening bleeding differential diagnoses: cephalhematoma and subgaleal (subaponeurotic) hemorrhage.

Cephalhematoma A cephalhematoma is a collection of blood between the periosteum and the skull bone. The extent of the bleed is limited by the periosteal attachments at the suture lines but can still be significant. Cephalhematomas usually take hours to develop and weeks to reabsorb.
Subgaleal (Subaponeurotic) Hemorrhage This occurs when emissary veins are damaged and blood accumulates in the potential space between the galea aponeurotica (epicranial aponeurosis) and the periosteum of the skull (pericranium). Since the subaponeurotic space has neither containing membranes nor boundaries, the subgaleal hematoma may extend from the orbital ridges to the nape of the neck. This condition is dangerous because of the large potential space for blood accumulation and the possibility of life-threatening hemorrhage. Subgaleal bleeding presents with diffuse swelling of the head and signs of hypovolemic shock (e.g., pallor, hypotension, tachycardia, and increased respiration rate). The signs may be present at delivery or may not become clinically apparent until several hours or up to a few days following delivery. The swelling is usually diffuse, shifts dependently when the infant's head is repositioned, and indents easily on palpation. However, in some cases the swelling is difficult to distinguish from the edema of the scalp. On occasion, the hypotension and pallor are the dominant signs while the cranial findings are unremarkable.

Molding Molding is an expected deformation of the fetal head that occurs during the delivery process. A small amount of occipitoparietal molding is normal during the second stage of labor but excessive skull bone molding (particularly parieto-parietal molding) is abnormal during the first stage of labor. Molding can be classified in the following way (Fig. 23.5):

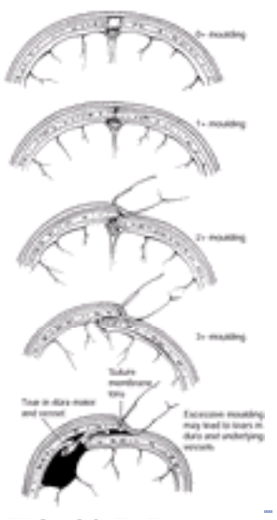

FIG. 23.5. Degrees of molding of the fetal head.

0+ = suture easily felt between the two bones
1+ = no suture felt but the bones can be separated easily with minimal digital pressure
2+ = overlap of bones but they can be separated with digital pressure
3+ = overlap of bones that cannot be separated with digital pressure.

FETAL HEAD POSITION AND ITS DETERMINATION

Knowledge of the position of the fetal head is essential in order to safely perform an operative vaginal delivery. The obstetrician should be able to determine the relationship of the fetal cranial bones and fontanelles to one another, and using this information, plan and execute the procedure. It should be remembered that caput succedaneum, molding, asynclitism, and maternal and fetal soft tissue edema can all combine to mask the true fetal head position. However, an attempt at determining the position of the fetal head should become a reflex action during a vaginal examination in labor. In difficult cases, ultrasound can be used, either translabially or transabdominally. It is axiomatic that until the exact head position is known, forceps should not be applied.

Abdominal Examination as Part of the Routine Assessment Prior to Operative Vaginal Delivery

Examination of the abdomen should be included in the assessment of a patient prior to vaginal examination and any attempt at operative vaginal delivery. This evaluation will help in a number of ways. First, it will confirm the lie and give an idea of where the fetal back is in relation to the uterine midline. If the fetal back is not felt or is palpated laterally, there is a higher likelihood of the baby being in an occipitoposterior or transverse position. Often this knowledge will help the examiner make sense of an otherwise difficult vaginal examination. Second, fetal weight can be assessed and, in experienced hands, this has been shown as to be accurate as intrapartum ultrasound evaluation. Third, and possibly most important, the amount of fetal head palpated above the pelvic brim can be assessed (Fig. 23.6). This is an important observation, and one that is more frequently used in Europe than in the United States. Crichton described a method of assessing the level of the fetal head clinically in terms of “fifths of the fetal head palpable above the maternal pubic symphysis” ([1]) (Fig. 23.7). No more than two-fifths of an unmolded fetal head should be palpated abdominally once the occiput is felt at the ischial spines. If a significant proportion of the fetal head (more than three fifths) is still palpable above the pubic symphysis, regardless of the fact that scalp is felt at the ischial spines, the head should be regarded as unengaged and an operative delivery should be avoided.

FIG. 23.6. Abdominal palpation and the determination of the amount of fetal head still above the pelvic brim.

FIG. 23.7. The rule of three's. See text for complete description.

PREREQUISITES FOR OPERATIVE VAGINAL DELIVERY

Prior to embarking on any operative vaginal delivery it is important to ensure that the procedure will meet with the greatest possible chance for success. To this end a number of prerequisites have been suggested ([2]). Table 23.4 presents a mnemonic that I have found useful in ensuring the best chance of success for an operative vaginal delivery. Some of the most important prerequisites for a non-rotational operative vaginal delivery can be easily remembered with the use of this mnemonic (F-O-R-C-E-P-S).

F	**F**avorable head position (OA/AP ±45 degrees from the AP diameter)—unless intended rotational delivery **F**etal assessment (weight and status)
O	**O**pen Os (completely dilated cervix)
R	**R**ule of three's, **R**uptured membranes
C	**C**ontractions present, **C**onsent (verbal or written)
E	**E**ngaged head, **E**mpty bladder, **E**pidural or other form of adequate anesthesia
P	**P**repared for cesarean section, if needed **P**repared for neonatal resuscitation, if needed **P**elvimetry (clinical) adequate **P**reoperative note written
S	**S**tirrups and lithotomy position with attention paid to pressure points and prevention of hyperflexion at the hips (to avoid femoral nerve apraxia)

AP, anteroposterior; OA, occipital-anterior.

TABLE 23.4. *Prerequisites for an operative vaginal delivery*

PREPARATION OF THE PATIENT

Preparation for a forceps delivery is very important and can influence the delivery outcome significantly. Essential aspects include:

- proper positioning
- adequate anesthesia
- understanding of the process
- recheck that prerequisites have been satisfied
- “ghosting”

Proper Positioning

Proper positioning will usually be in a modified lithotomy position with the patient sitting up in a way that she can view and remain actively involved in the delivery. In special cases (such as cardiac disease) this should be modified with the patient in a Fowler position with her feet on small stools below the level of her hips. The legs should be abducted but not to the point where excessive tension is placed on the perineal body since spontaneous tearing or unanticipated extension of an episiotomy may occur during delivery. In cases where a direct application of the Kielland forceps is being attempted, the patient's buttocks should overhang the edge of the table (Fig. 23.8). This will allow the shank and handle of the anterior branch to be perpendicular to the floor during the initial application of the blade which may be essential to obtain correct positioning (discussed later in this section). Care should be taken not to overflex the hips, although sufficient flexion to approximate a McRoberts position is useful during the delivery itself. Once the delivery is accomplished the patient should be repositioned to prevent pressure on or stretching of the nerves.

FIG. 23.8. Positioning for an operative vaginal delivery.

The most common nerve injuries noted following vaginal delivery with prolonged lithotomy positioning and their putative mechanisms are listed in Table 23.5. The patient's hands should be positioned on handles attached to the table during the delivery to allow her to support herself and maximize maternal pushing efforts during traction.

Femoral nerve (L2, 3, and 4)	Presentation: Quadriceps paralysis and impaired knee extension, loss of patellar reflex, hypoesthesia over the front of the thigh and medial aspect of calf, numbness of the anterolateral area of thigh Etiology: Hyperflexion of the hips with traction or compression injury of the nerve, prolonged lithotomy position with lanking at Poupart ligament, mid-forceps delivery, retractions at CS, epidural anesthesia
Lateral femoral cutaneous nerve (L2 and 3)	Presentation: Numbness over anterolateral thigh Etiology: Compression of the nerve under the inguinal ligament from prolonged or incorrect lithotomy position, retractions at CS
Common peroneal nerve (L4 and 5, S1 and 2)	Presentation: Foot drop, hypoesthesia over anterolateral aspect of lower calf, foot, and toes Etiology: Compression of the nerve at the lateral aspect of the knee where it is very superficial by a lithotomy pole, has also been reported after epidural anesthesia
Lumbosacral trunk (L4 and 5)	Presentation: Paralysis of the dorsiflexors of the ankle with footdrop, hypoesthesia over the lateral aspect of the calf and foot, slight weakness of the quadriceps (L4), slight weakness of the hip adductors (L4, L5) Etiology: Compression of head against sacrum, more common in midcavity operative vaginal delivery, has been reported after epidural anesthesia
Sciatic nerve (L4 and 5, S1, 2, and 3)	Presentation: Inability to flex leg, pain from gluteal region down to the foot Etiology: Traction injury from lithotomy position, metforcaps, incorrect intramuscular injection
Obturator nerve (L2, 3, and 4)	Presentation: Inability to adduct leg, hypoesthesia medial thigh Etiology: Lithotomy position, acute flexion of hip, hematoma, trauma from forceps blades
Saphenous nerve (L2, 3, and 4)	Presentation: Hypoesthesia medial foot and anteromedial lower leg Etiology: Lithotomy position

CS, cesarean section.

TABLE 23.5. *Common nerve injuries, presentation, and etiology*

Adequate Anesthesia

Optimal analgesia for forceps operations is provided by epidural or spinal conduction anesthesia. Frequently, however, the situation does not allow this, and in such cases a pudendal block and perineal infiltration should be instituted if possible. General anesthesia may occasionally be indicated.

Understanding of the Process

Full understanding of the process will help the patient participate and cooperate in the delivery. Explaining each step as it happens, encouraging her, and communicating one-on-one with her as the operation is performed will allay the patient's anxiety and allow her to feel part of the delivery. This is important since patients often feel quite apprehensive about the procedure.

Recheck that Prerequisites Have Been Satisfied

One of the most important prerequisites to recheck just before placing the forceps is the fetal head station and position. This may change during the preparation of the patient and in some cases forceps may no longer be required.

“Ghosting”

Assembling the forceps or vacuum extractor prior to use will enable the operator to check that, in the case of the forceps the two branches are from the same set and that they articulate well, and that in the case of a vacuum extractor all parts fit together and function. The instrument can then be held in a way that simulates the intended application.

THE VACUUM EXTRACTOR

The vacuum extractor is a device made up of a vacuum cup (of various shapes and designs), a method of developing a vacuum within the cup, and a handle used to apply traction to the cup (and via the cup to the fetal head) (Fig. 23.9). It is beyond the scope of this chapter to describe all of these devices in detail but some description of the more commonly seen vacuum extractors is appropriate.

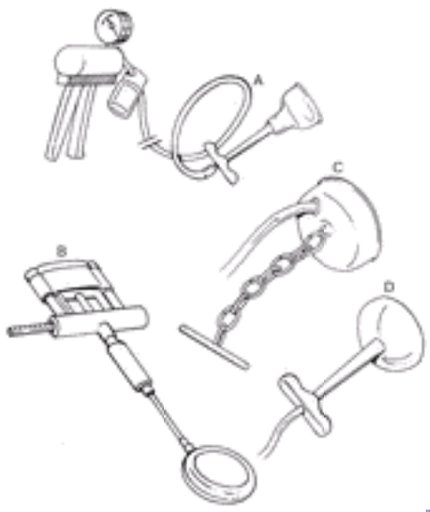

FIG. 23.9. Vacuum extractor cup designs.

Malstrom designed the stainless steel vacuum cup in the 1950s and this revolutionized the practice of operative vaginal delivery. The device works on the principle of creating an artificial caput (chignon) within the suction cup that enables the cup to hold firmly onto the fetal scalp allowing traction thereon. In the U.S. the stainless steel cups have almost completely been replaced by plastic and Silastic soft cup extractors (Kiwi extractor, Silastic cup, Mityvac M-cup, and plastic versions of the original Malstrom design, see Fig. 23.9). Suction is developed using either an electrical pump system or a handheld device.

There have been arguments about the relative success rates and trauma incidence of the different vacuum extractor models. Johanson and Menon reviewed nine trials involving 1,375 women for the Cochrane Database ([3]). They report that soft cups are significantly more likely to fail to achieve vaginal delivery (odds ratio [OR] 1.65, 95% confidence interval [CI] 1.19–2.29). However, the soft cups were associated with less scalp injury (OR = 0.45, 95% CI = 0.15–0.60). There was no difference between the two groups in terms of maternal injury. The authors concluded that metal cups appear to be more suitable for “occipitoposterior,” transverse, and difficult “occipitoanterior” position deliveries. The soft cups seem to be more appropriate for straightforward deliveries. There are some design issues that may be important in the choice of device for specific situations. The relatively rigid rod connecting the handle and cup in most plastic extractor designs precludes accurate placement of the instrument on deflexed or posteriorly positioned heads; this contributes to failure. However, high success rates with a rigid but plastic “M” (mushroom) cup (similar to the original Malmstrom stainless steel cup) have been reported in operations involving these common cranial malpresentations.

CHOICE OF INSTRUMENT FOR CEPHALIC PRESENTATIONS

Outlet Operations/Low-pelvic Operations (Rotation 45 Degrees)

With adequate analgesia, the vacuum extractor and forceps are equivalent instruments. If a vacuum extractor is chosen, any of the previously mentioned instruments can successfully be applied.

Low-pelvic Operations with Rotation More Than 45 Degrees and Midpelvic Operations

Procedures that do not involve significant cranial asynclitism are equally well managed by any of the vacuum instruments discussed. For cases in which there is an asynclitic head in a transverse position, the appropriate cup choices include an occipitoposterior (OP) metal cup (e.g., Bird design, O'Neil design) and a plastic OP design (e.g., Kiwi, Mityvac “M”).

If vacuum extraction is performed using a direct OP cup, appropriate choices include an OP metal cup (e.g., Bird design, O'Neil design) or a plastic OP design (e.g., Kiwi, Mityvac “M”) (see Fig. 23.9). Rotational delivery with a vacuum extractor, or delivery of the fetal head in an OP position, can prove difficult and there is a significant risk of maternal soft tissue injury. These types of procedure should be restricted to the experienced surgeon only.

It should always be remembered that high-pressure vacuum generates large amounts of force and that inexpert use will result in poor outcome regardless of the instrument used.

INDICATIONS AND CONTRAINDICATIONS FOR VACUUM EXTRACTION

Maternal and fetal indications for vacuum-assisted delivery are listed in Table 23.6. Relative contraindications for vacuum extraction are given in Table 23.7. The precise gestational age at which a fetus is considered too premature for vacuum extraction delivery is controversial. Bofill and colleagues ([4]) use a gestational age of 34 weeks as the cutoff point. Morales and colleagues, however, found no significant difference in neonatal morbidity rates following vacuum extraction of preterm infants (birth weights of 1,500 to 2,499 g [3 lbs, 4 oz to 5 lbs, 6 oz]) and full-term infants.

Maternal indications
Need to avoid voluntary maternal expulsive effort (e.g., the mother has cardiac or cerebrovascular disease)
Inadequate maternal expulsive efforts
Maternal exhaustion or lack of cooperation
Fetal indications
Nonreassuring fetal heart tracing
Prolonged second state of labor
Failure to progress in second stage of labor

TABLE 23.6. *Indications for vacuum-assisted delivery*

Operator inexperience
Fetal prematurity (<34 wks of gestation)
Fetal scalp trauma
Unengaged head
Incomplete cervical dilation
Uncertain fetal head position
Active bleeding or suspected fetal coagulation defects
Suspected macrosomia
Inability to achieve proper application
Prior failed forceps delivery
Nonvertex presentation or other malpresentation
Cephalopelvic disproportion
Delivery requiring rotation or excessive traction
Inadequate anesthesia

TABLE 23.7. *Relative contraindications for vacuum extraction*

Placement of the Soft-Cup Vacuum Extractor

A proper vacuum extraction depends upon (a) the accuracy of cup application, (b) the traction technique, (c) the fetal cranial position and station at the time of

application, (d) the cup design, and (e) the fetopelvic relationship.

Prior to use of the vacuum extractor, the prerequisites for any operative vaginal delivery should be satisfied (see Table 23.4).

Cup Application Correct cup placement is paramount and determines the likelihood of success to great extent. The patient is usually placed in the dorsal lithotomy position and adequate anesthesia can usually be provided with an epidural, spinal, or pudendal block. Prior to cup placement the fetal presentation, amount of fetal head palpable above the symphysis pubis, fetal head position, and station should again be confirmed. In cases where fetal head position is difficult to determine, transabdominal or transperineal ultrasound can be of benefit. The soft cup is introduced by spreading the patient's labia, compressing the cup, and inserting it gently by pressing inward and downward with the inferior edge over the posterior fourchette. Some operators use surgical soap or lubricant to moisten the edge of the cup to help form an effective seal. When correctly applied, the vacuum cup is positioned centrally over the point of cranial flexion, or the pivot point (Fig. 23.10). When the vector of traction force is directed through this pivot point, the fetal head is flexed and not twisted obliquely or extended as the extraction proceeds. Anatomically, the pivot point is an imaginary spot over the sagittal suture of the fetal skull, located approximately 6 cm posterior to the center of the anterior fontanelle or 1 to 2 cm anterior to the posterior fontanelle. When a standard 60-mm cup is used this translates into a position where its edge is approximately 3 cm or 2 fingerbreadths behind the center of the anterior fontanelle in the midline over the sagittal suture. Thus, in vacuum extraction operations, the anterior fontanelle becomes the reference point for checking the instrument application because access to the posterior fontanelle is partially blocked once the extractor cup is in place, rendering this familiar landmark unusable. The farther the cup is placed from the midsagittal position on the fetal head over the cranial pivot or flexion point, the greater the failure rate. Oblique applications result in cranial deflexion or asymmetry as traction is applied. This increases the work of extraction by presenting a larger cranial diameter to the birth canal than would occur had the application been correct.

FIG. 23.10. Optimum placement of the vacuum extractor cup on the fetal head.

Correct cup placement maintains flexion of the fetal head and avoids traction over the anterior fontanelle (which aggravates fetal neck extension). After positioning the cup, but before inducing the vacuum, the edge of the cup should be palpated circumferentially to detect any entrapment of maternal soft tissue between the cup and the fetal head. Apart from causing significant vaginal or cervical tears with resultant maternal hemorrhage, entrapment of maternal tissue will cause “pop-off” and a failed procedure. Once the surgeon is convinced of an appropriate placement, full vacuum is applied (i.e., 550–600 mm Hg) and traction follows. The degree of vacuum determines the traction forces (see Fig. 23.3). Effective traction usually requires a pressure of at least 0.6 kg per cm^2 (440 mm Hg). Although more negative pressures reduce the risk of cup detachment, lowering the pressure beyond 0.8 kg per cm^2 (588 mm Hg) increases the risk of fetal scalp and cerebrocranial trauma. During traction, the operator places the nondominant hand within the vagina, positioning the thumb on the extractor cup and one or more fingers on the fetal scalp. The dominant hand is used to grasp the handle of the instrument. When positioned like this, the surgeon follows the descent of the presenting part and can better judge the appropriate angle for traction while gauging the relative position of the cup edge to the scalp. This helps to detect cup separation while preventing rocking motions or torque (which should be avoided). Once vacuum is applied, the cup should not be twisted. Twisting the cup may lead to “cookie-cutter” or semi-circumferential laceration of the fetal scalp, although this is less likely to occur with the soft cup than with the metal cup. Traction should be in line with the pelvic axis and coordinated with maternal expulsive efforts. In some situations the vacuum extractor can be used to aid rotation of the fetal head during traction efforts (discussed subsequently). Descent must begin with the initial traction effort; failure to achieve a change in station mandates prompt reassessment of the procedure. Two common vacuum extraction traction techniques exist: continuous vacuum with maintained traction efforts throughout the procedure versus intermittent vacuum with the vacuum and the traction efforts released between contractions. These techniques have been studied in a randomized controlled trial. No differences were detected between the two groups with regard to the rapidity of delivery, rate of instrument failure, or maternal or fetal outcomes. Thus, the use of either technique is acceptable. Some authors suggest that continued moderate traction may aid in maintaining the progress made in descent of the fetal vertex. If the cup is dislodged, it is reapplied only after careful inspection of the fetal scalp for injury. Traction is continued until the head is crowned. As the head clears the pubic symphysis, the vertex is pulled upward at an approximate angle of 45 degrees to the floor. Once the head is delivered, suction is released, and the cup is removed. Delivery then proceeds as usual. Although no “standard of care” currently exists regarding the duration of a vacuum extraction attempt, the number of traction attempts permitted, or the number of “pop-offs” that should be tolerated, common sense decrees certain limits. *Most experts suggest that vacuum extraction should not be attempted for more than 20 to 30 minutes, that traction attempts should be limited to four to five, and that the procedure should be abandoned after three cup detachments.* Approximately 85% of births requiring vacuum extraction are delivered with four or fewer than four pulls. Thus, if a prolonged extraction with any instrument occurs, the obstetrician must carefully consider if progress truly is taking place. Procedures leading to multiple cup pop-offs or procedures requiring a large number of traction efforts are best abandoned because it is believed that this practice risks injury as the obstetrician strains to overcome disproportion. Finally, the procedure should also be abandoned if there is any evidence of fetal scalp trauma. No data exist dealing with how long one should persist in the face of fetal bradycardia. I would advise that unless delivery is assured and imminent, operative vaginal procedures should not be performed or should be abandoned in favor of a cesarean section when there is persistent bradycardia. It is very reasonable to attempt an operative vaginal delivery while preparations are being made for cesarean section if it seems highly likely that the procedure will be successful. Detailed documentation of the operative delivery in the medical record is very important and is discussed in the following section.

Advisory Letter

On May 21, 1998 the U.S. Food and Drug Administration (FDA) released an advisory letter to alert individuals who use vacuum extractors and inform them that these devices may cause serious or fatal complications such as subgaleal (subaponeurotic) hematoma and intracranial hemorrhage. This letter was in response to an increased incidence of reported vacuum-related fetal injuries. The FDA also wanted to ensure that those responsible for the care of neonates are alerted when a vacuum-assisted device is used so that they may adequately monitor for the signs and symptoms of device-related injuries ([5]). The letter made the following points as to technique:

The vacuum extractor should only be used when a specific indication exists.
The operator should be versed in its use and aware of indications, contraindications, and precautions.
The operator should follow manufacturers' recommendations regarding cup placement, vacuum strength, cumulative duration of applications, and number of extraction attempts.
Rocking movements or torque should not be applied to the device and only steady traction in the line of the birth canal should be used.
Neonatal care providers should be alerted that a vacuum has been used.
Neonatal staff should be educated about the specific complications associated with vacuum devices.
Adverse events and complications associated with vacuum-assisted devices should be reported to the FDA under the auspices of the Safe Medical Devices Act of 1990.

Following publication of the advisory there was significant discussion at both the organizational and lay level. In some instances draconian restrictions were placed on the use of the vacuum extractor and, in response, ACOG published a committee opinion expressing specific concerns that (a) the advisory letter was based on a very low risk of adverse events, and that (b) reaction to the advisory may result in a higher cesarean section rate, or alternatively in the increased use of forceps by those not trained to use them. The ACOG committee strongly recommended that there be continued use of vacuum-assisted delivery devices in appropriate clinical settings ([6]).

Subsequent to the ACOG committee opinion, Ross and colleagues studied the effect of the FDA advisory letter on the reporting of vacuum-related injuries ([7]). They noted a 22-fold increase in reported events within the first 6 months after publication, when compared with the rate prior to the advisory letter—5 per year before versus 110 per year after the advisory letter. There were 10 neonatal deaths, 30 life-threatening events, 12 non–life-threatening events, and 3 equipment failure reports. Of note is that the increased number of reports was due to a significant increase in reports from vacuum device manufacturers (8%–43%). There was a decrease in the number of “voluntary” reports (56%–20%). The authors believe that the sudden increase in reports represents better compliance with reporting, increased awareness of the dangers, and a continued increase in the use of the vacuum extractor. They suggest that that the device may not be as innocuous as was once thought and that many adverse events were going unreported prior to the advisory letter.

In support of this contention is a retrospective chart review from the University of Miami conducted on patients delivered between 1995 and 1999. There were 355 patients in each group who were matched for age, ethnicity, parity, estimated gestational age, and birth weight. Vacuum extraction was 600% more likely to have occurred when the patient had an epidural anesthetic (OR = 6.6 [range, 2.6–16.6]). Following delivery with a vacuum extractor neonates were almost four times more likely to go to a neonatal intensive care unit (OR = 3.7 [range, 1.3–9.6]). There were no differences in the rates of maternal lacerations or meconium-stained fluid.

Whether or not the babies were admitted for observation or whether the increased rate of admission truly represented increased risk of injury is unclear.

OBSTETRIC FORCEPS

Anatomy of Forceps

Forceps are a paired instrument made up of two branches that are usually attached to each other in some way by a locking mechanism. In general, the branches are side-specific and the left branch is applied to the left side of the maternal pelvis using the left hand. The right branch is applied to the right side of the maternal pelvis using the right hand. One exception to this rule is the Salinas forceps which has branches that may be applied without concern to side specificity. Application techniques are described subsequently.

Classic forceps have branches that are made up of a handle, shank, lock, and blade (Fig. 23.11). The tip of the blade is referred to as the toe, the base of the handle is referred to as the heel, and the portion where the shank runs into the blade is termed the shoulder. In some cases an additional part is included to aid in traction and this is termed a traction bar (De Lee forceps) (Fig. 23.11).

FIG. 23.11. Common types of obstetric forceps.

Handle Most forceps in current usage have some form of handle that incorporates finger grips or lateral flanges. In some cases, the handle may be very small (Laufe divergent forceps and Wrigley forceps, see Fig. 23.11) or rather bulky as in the Salinas forceps. Classic Elliot forceps have a screw and wheel built into the heel of the instrument that allows adjustment of the distance between the heels in order to limit head compression during use.
Shank The shank connects the blade to the handle and usually incorporates the locking mechanism. The shanks may be parallel, overlapping, or divergent, and vary in length from very short (Laufe) to rather elongated (Piper, Kielland, Bailey-Williamson forceps). They may also be straight or have varying degrees of curvature (Piper forceps).
Lock The lock (Fig. 23.12) is usually built into the left-sided shank (or at the junction of the shank and handle) except in the case of the Salinas forceps where the lock forms part of the handle itself. The lock may be:

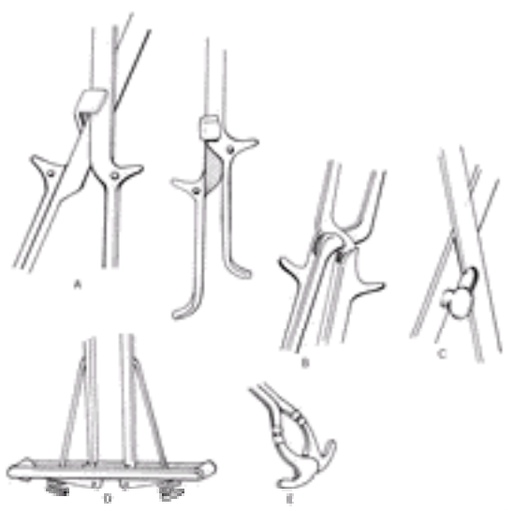

FIG. 23.12. Types of locks: Sliding, English, French, handle.

- sliding (only found on the left shank and allows sliding of the shanks while locked—Kielland forceps)
- English (which is formed by the mating of a tongue and slot mechanism—Simpson, Elliot, Neville-Barnes, Anderson forceps)
- French (which has a nut that is tightened to fix the lock)
- pivot (forms part of the finger grip and tends to force the blades apart as traction is applied—Laufe forceps)
- handle (Salinas forceps).

Blade The blade is the portion of the forceps that grasps the fetal head. Blades may be fenestrated (Simpson, Elliot, Neville-Barnes), pseudo-fenestrated (Luikart-Simpson), or solid (Tucker-McLane, Salinas). Fenestrated blades are purported to cause more maternal tissue damage during rotation. Solid blades are thought to reduce maternal injury by reducing friction but they are associated with increased fetal head slippage. Most forceps have a rigid blade that does not deform; the Salinas forceps however does allow some deformation of its shape because of its minimal thickness. Most forceps have two curvatures: A pelvic curvature which is usually concave upward to approximate the maternal pelvic curve of Carus, with the tip of the blade usually about 3 inches above the level of the handles; and a cephalic curvature designed to fit snugly around the fetal head with a diameter of no less than 7.5 cm at its widest portion. Blades best suited to a molded fetal head tend to be those that are elongated and have a more shallow cephalic curvature (Simpson, De Lee forceps). In cases where the fetal head is less molded a shorter blade with a more rounded cephalic curvature may be more suitable, although either type of forceps may be safely used under both circumstances. Kielland and other rotational forceps, including the Salinas forceps, have almost no pelvic curvature, and this allows safe placement and rotation of the blades in transverse head positions. Rotation of a fetal head using a forceps with a pelvic curvature mandates use of the Scanzoni maneuver (whereby the heel follows the circumference of a large circle during the rotation in order to negate the pelvic curvature of the blade). Some forceps have a reverse pelvic curvature (Piper and Hawkes-Dennen forceps) in order to allow use during vaginal breech delivery.
Traction Bar Some forceps (Hawkes-Dennen) have a built-in device to allow the handles to rotate as the head descends through the birth canal. The idea is to optimize the outward and downward vectors so that the head follows the curve of Carus with the least soft and hard tissue friction. This principle of axis–traction can also be obtained using a traction bar (see Fig. 23.11) which fits onto the handle flange of some forceps.

Mechanical Aspects of Obstetric Forceps

From a mechanical point of view, forceps have four potential actions:

1. Correction of deflexion, asynclitism, or positional abnormalities of the fetal head that impedes or retards descent, rotation, and accommodation within the pelvis.
2. Extraction, which includes augmenting or replacing the expulsive force generated by uterine contractions and voluntary pushing.
3. Reduction of the friction between the fetal head and the birth canal.
4. Transient, artificial enlargement of the soft tissue of the birth canal which reduces the resistance of the outlet.

An understanding of the mechanical forces and principles involved in a forceps delivery is important since it allows the operator to better judge the chances of success in each individual case.

Type of Forceps Delivery

Two main parameters determine the successful outcome and associated morbidity of operative vaginal delivery. These are (a) the station at which the procedure is

performed, and (b) the degree of rotation required. Based on the new definition of station, the types of forceps delivery were reclassified by ACOG in 1988 (Table 23.8). This new classification has been validated in a comparative study of 357 forceps deliveries classified using both systems. Allowing for up to 45 degrees of rotation in an outlet forceps delivery, and classifying any delivery from 0 to 2+ station as midforceps, regardless of rotation, did not increase morbidity.

Outlet forceps:
1. Scalp is visible at the introitus without separating labia
2. Fetal skull has reached pelvic floor
3. Sagittal suture is in AP diameter or right or left OA or OP position
4. Fetal head is at or on perineum
5. Rotation does not exceed 45 degrees
Low forceps:
Leading point of fetal skull is at station + or ≥2 cm and not on the pelvic floor
a. Rotation = or <45 degrees (left or right OA to OA, or left or right OP to OP)
b. Rotation >45 degrees
Midforceps:
Station above +2 cm but head engaged

AP, anteroposterior; OA, occipital-anterior; OP, occipital-posterior.

TABLE 23.8. *Classification of forceps deliveries*

Indications As the specialty has evolved, so have the uses and indications for forceps. We no longer accept stimulation of contractions, artificial molding of the fetal head, forceful dilation of the cervix, or delivery from a high station as indications for forceps. The indications for operative vaginal delivery may be divided into standard and special indications (Table 23.9). It must be understood that regional and international practice differences wilS apply and that no indication for operative vaginal delivery is absolute.

Standard indications: apply to the patient in whom the fetal head is engaged and the cervix is fully dilated
1. Delayed second stage
a. This is defined in the ACOG technical bulletin (No. 196, August 1994) and is different for nulliparous and multiparous women.
i. Nulliparous—lack of continuing progress for 3 h with regional anesthesia, or 2 h without regional anesthesia.
ii. Multiparous—lack of continuing progress for 2 h with regional anesthesia, or 1 h without regional anesthesia.
2. Suspicion of immediate or potential fetal compromise.
3. Elective shortening of the second state for maternal and fetal benefit
a. Need to avoid maternal expulsive effort (as in certain maternal cardiac pulmonary, ocular, and cerebrovascular conditions).
b. Need to augment maternal expulsive effort (as in certain maternal neuromuscular diseases, maternal exhaustion, and lack of cooperation or excessive sedation/analgesia).
c. Selective shortening of the second stage when the head is on the perineum and oriented within 45 degrees of the AP diameter.
d. Selective shortening of second stage to avoid potential fetal and maternal complications resulting from persistent pushing efforts when there is a malposition of the fetal head.
Special indications:
1. Delayed second stage due to malposition or asynclitism of the fetal head where there may be correctable borderline disproportion due to the abnormal head position.
2. Prolapse of the umbilical cord at complete dilation.
3. Nonobstetric indications, which include the extraction of vaginal and rectal foreign bodies, including drugs. (refs)
It is generally understood that a higher level of judgment and skill are necessary when operative vaginal delivery is carried out for special indications. A good understanding of the indication(s), and documentation of this prior to the procedure, will help the obstetrician plan the delivery. In addition, it will help ancillary personnel understand the urgency or need for the procedure and allow them to orchestrate their involvement (anesthesiologist, neonatologists, nursing, and OR personnel).

ACOG, American College of Obstetricians and Gynecologists; AP, anteroposterior; OR, operating room.

TABLE 23.9. *Indications for operative vaginal delivery*

Contraindications

Under certain circumstances operative vaginal delivery should be avoided, or at least carefully considered in terms of relative maternal and fetal risk. The specific reason for the procedure should be carefully documented. Accepted contraindications to forceps delivery are listed in Table 23.10.

1. A noncooperative patient, or one who refuses operative vaginal delivery
2. A fetus with a known bone demineralization condition (e.g., osteogenesis imperfecta) or bleeding diathesis (e.g., alloimmune thrombocytopenia, hemophilia)
a. An unengaged fetal head
b. An unknown position of the fetal head
3. A prior failed operative vaginal delivery attempt (unless there is an obvious reason for the failure unrelated to cephalopelvic disproportion which is unlikely to occur again, and there is justification for a second attempt)
a. A known fetal weight in excess of 4,500 g

TABLE 23.10. *Contraindication to forceps delivery*

Choice of Instrument

There are approximately 700 different types of forceps described. Most authors subscribe to a classification system that divides forceps into classic and specialized subtypes.

The classic subtype includes such forceps as the Simpson, Elliot, Neville-Barnes, Anderson, Tucker-McLane, and Naegle. These forceps would be suitable for most general prophylactic indications (outlet forceps).

The specialized subtype, which includes the Kielland (see Fig. 23.3), Barton (see Fig. 23.4), and Piper (see Fig. 23.5) forceps, is employed for specific tasks such as rotational deliveries (Kielland and Barton), correction of asynclitism (Kielland), and delivery of the aftercoming head in a breech delivery (Piper).

A novel type of forceps has been introduced into the U.S. from Mexico. The Salinas forceps has two identically shaped, nonfenestrated blades with minimal pelvic curvature which can be used interchangeably (see Fig. 23.11). The Salinas forceps also has a lock at the heel of the forceps and the blades are convergent. The blades are kept in place by maternal tissue and no compressive force is generated by the forceps. The operator holds the locked base of the forceps in both hands and applies gentle traction to effect delivery. The blades will slip off if excessive force is applied. The Salinas forceps can also be used for rotation of the fetal head.

The choice of one instrument over another depends on the indication, the training of the obstetrician, the instruments available, and the situation at hand. A comparison of the perceived advantages/disadvantages of forceps versus vacuum extraction is shown in Table 23.11. There are some who choose their forceps based on the condition of the maternal soft tissue (nonfenestrated blade when there is a lot of edema and potential for tearing; overlapping rather than parallel shanks for a patient with a narrow introitus), fetal head molding (Simpson forceps for a molded head and an Elliot-type forceps for a nonmolded head to allow a better fit of the forceps blade to the fetal head shape), or fetal presentation (Piper forceps for the aftercoming head). The need for a rotation or correction of asynclitism also may dictate the type of forceps used (i.e., Kielland, Luikart-Simpson, Barton, or Salinas forceps). Delivery of the aftercoming head in a breech delivery using Piper or Laufe-Piper forceps will permit flexion of the head without excess traction on the fetal spine and reduce the incidence of spinal cord injuries. Face presentation is another unique situation and, in general, mentum-anterior presentations can be delivered using Kielland or Simpson forceps. Rotation of the mentum- posterior/mentum-transverse face presentation to a mentum-anterior presentation has been described but few choose to perform these maneuvers.

Vacuum extractors:
Easier to learn
Quicker delivery
Less maternal genital trauma
Less maternal discomfort
Fewer neonatal craniofacial injuries
Less anesthesia required
Forceps:
Fewer neonatal injuries, including cephalohematoma, retinal hemorrhage, and transient lateral rectus palsy
Higher rate of successful vaginal delivery

TABLE 23.11. *Comparative advantages of vacuum extractors and forceps*

Application of Forceps Correct insertion of the forceps into the vaginal canal and application to the fetal head is paramount to a successful procedure. The forceps

should be placed between contractions. In almost all cases one of two methods will allow good application of the forceps: direct and wandering. Application of the forceps blades should be a gentle and smooth process requiring minimal force. In most cases, if the blade is correctly inserted and positioned, gravity should be sufficient to allow the forceps blade to fall into place. During training it is a good idea to learn to apply the forceps using only the index finger, middle finger and thumb to grasp the shank (Fig. 23.13). The blade should be positioned using the index and middle fingers placed under or on the edges depending on the method employed. No force should be required and if there is resistance the blade should be removed and reapplied. In this way maternal and fetal injury will be minimized. A lubricant such as K-Y jelly placed on the blade may reduce friction and facilitate placement.

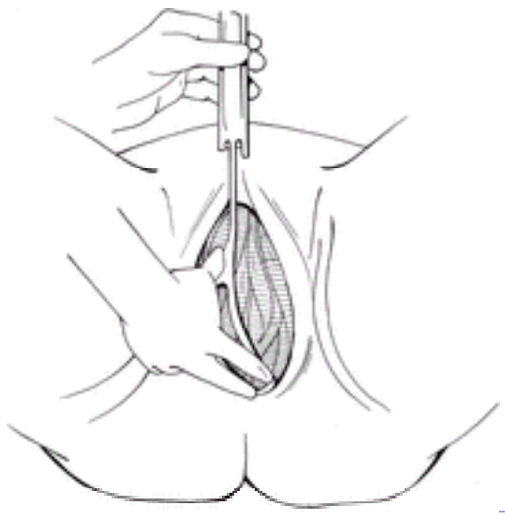

FIG. 23.13. Grasp of forceps.

Direct Placement With this method, the left blade (i.e., the blade that lies on the maternal left) is conventionally placed first. The operator holds the shank at the level of the lock, and the blade is placed into the vagina in the approximate position that it will ultimately lie. The right middle finger is used to support the edge of the blade at the introitus and the right index finger is used to gently apply the upper border of the blade onto the fetal head. The fingers or hand are not placed deep into the vagina. The practice of placing a hand into the vagina to “protect” the vaginal wall is probably not beneficial since this reduces the available space and increases the force required to place the blade. Once the left blade is correctly positioned, minimal force with the left hand will be required to slide it further into the birth canal and into its correct final position. The index and middle fingers of the right hand “walk” along the upper and lower borders of the blade as it enters the birth canal gently pushing it in and adjusting its position. When correctly placed the branch should be firmly held by the fetal head and maternal tissue (not immovable) and the shank and handle should be in the position expected from the “ghosting.” If the position is different from that anticipated the branch should be gently removed by reversing the movements required to initially place it, and the fetal head position should be checked (if necessary, by a more experienced operator). If the anticipated shank and handle angle are incorrect, attempting to place the right hand branch and forcing the two together is absolutely contraindicated. This will only result in maternal and fetal injury. Once the left branch is placed, an assistant can be asked to hold the branch in position or it can be briefly left unattended while the right branch is placed. Holding the right branch with the right index finger, middle finger and thumb, the right branch is placed into the vagina in the approximate position that it will ultimately lie. The right branch should be above the left in order to ensure correct locking. The left middle finger is used to support the edge of the blade at the introitus and the left index finger is used to apply slight pressure onto the fetal head. Once the right blade is correctly positioned, minimal force with the right hand will be required to slide it further into the birth canal and into its correct final position. The index and middle fingers of the left hand “walk” along the upper and lower borders of the blade as it enters the birth canal gently pushing it in and adjusting its position to complement that of the left branch. No force should be used to lock the instrument and the final shank and handle position should be the same as that expected from the “ghosting”. Once both branches are placed, the fetal head position and the application of the forceps should be checked prior to any traction efforts.

Wandering Placement With this method the left branch is also placed first. The operator holds the shank at the level of the lock, and the blade is placed into the vagina with the toe of the blade at the posterior fourchette and the branch held straight upward. The right index and middle fingers are used to support the edge of the blade (Fig. 23.14) at the introitus and to apply slight pressure onto the fetal head. The fingers or hand are not placed deep into the vagina. Once the left blade is correctly positioned, minimal force with the left hand will be required to begin sliding it further into the birth canal. Usually gravity and the weight of the branch is all that is required. As the blade moves into the birth canal the right index and middle fingers (which are held on the maternal left and right edges of the blade, respectively) gently push the blade laterally (maternal left) and “wander” it into position using successive small finger movements and without placing the fingers deep into the vagina. The handle will move in an arc from an initial vertical position to a horizontal position. Once learned, this is a smooth and seamless process. The position is checked as previously described. Once the left branch is placed, an assistant can be asked to hold the branch in position or it can be briefly left unattended while the right branch is placed. Holding the right branch with the right index, middle finger and thumb, the right branch is placed into the vagina in the same way as was the left branch. Once correctly positioned, minimal force with the right hand will cause the blade to move into the birth canal. The left index and middle fingers (which are held on the maternal right and left edges of the blade, respectively) gently push the blade laterally (maternal right) and “wander” it into position in the same way as was done with the left blade. The right branch should be kept above the left during this process to enable correct locking. No force should be used to lock the instrument and the final shank and handle position should be the same as that expected from the “ghosting”.

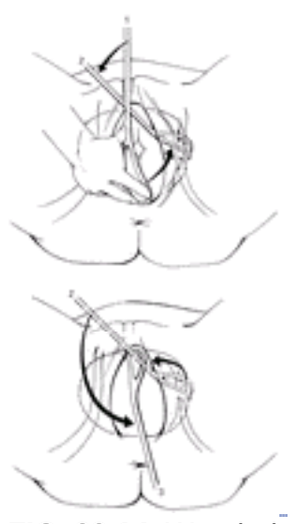

FIG. 23.14. Wandering placement of forceps.

Once the blades are placed, their positioning should be checked. The blades are correctly placed when they are situated against the sides of the fetal head in the spaces between the orbits and the ears (Fig. 23.15). The toe of the blade should reach slightly beyond the malar eminences in order to allow even pressure distribution and to concentrate traction and compression forces on one of the less vulnerable regions of the fetal head. Prior to applying rotational or traction forces the operator should check the following:

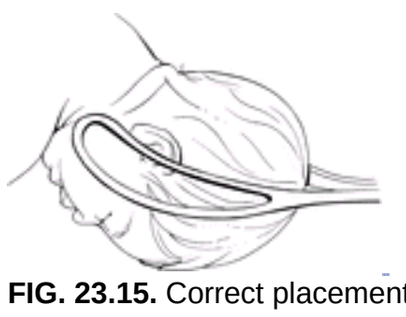

FIG. 23.15. Correct placement of the forceps blades on the fetal head.

The forceps have not accidentally penetrated the side wall of the vagina (any sudden vaginal bleeding after forceps placement should prompt immediate assessment).
The sagittal suture should be palpated symmetrically and perpendicularly between the two blades.
The posterior fontanelle should be palpable close to (about 2 cm) the plane of the shanks but not within the borders of the blade.
The handles, which should not require any more than minimal pressure to close completely, should be pointing straight out and not to either side.
No significant part of the fenestration of either blade should be palpable in front of the fetal head.

Occipitoanterior Positions

Placement of the forceps in a direct occipitoanterior (OA) position can be accomplished as described above. Minor modifications are required when the head is in a left or right OA position. The exact location of the sagittal suture and posterior fontanelle should be known and the final arrangement of the forceps branches should be “ghosted” prior to insertion.

In left occipitoanterior (LOA) positions the left blade should be placed first using either a direct or a wandering approach. Once the left blade is correctly aligned, the right blade can also be placed using either approach. Under most circumstances the wandering approach will work well. The operator must remember that the blade will need to be maneuvered around the sinciput. Careful digital manipulation with the left index and middle fingers will be required to avoid injury to maternal and fetal soft tissue. If the handles do not lock easily the application is incorrect and should be checked. When this occurs the most common cause is that the blade has not been wandered far enough to clear the fetal brow, or has not advanced enough to lie flat against the fetal cheek. Gentle manipulation with index and middle fingers can be tried after unlocking the blades, but frequently the best action is to remove the blade and reintroduce it.

In an upright occipitoanterior (ROA) position, either blade can be placed first using the direct or wandering approach. If the right blade is placed first, once the left blade is positioned the handles will need to be separated and crossed over in order to lock the branches. If the left blade is placed first, the operator will need to manipulate it to a greater extent than in an LOA placement. In either case, care should be taken to prevent soft tissue injury. Rotation from ROA or LOA to direct OA is usually automatic as traction is gently applied and no deliberate elevation of the fetal head is needed.

Traction

Once the forceps have been applied and the position of the blades checked, traction is usually initiated with maternal contractions. The birth canal has a definite curve and this should be kept in mind when applying traction during a forceps delivery. In order to minimize friction, the traction forces on the fetal head should be maintained perpendicular to the axis of the pelvis. This necessitates following of the curve of Carus. The higher the forceps are applied, the greater the initial downward pull required to negotiate the pelvic curve. As the head descends in the birth canal the angle of traction moves forward (in the supine patient), ultimately turning upward at the outlet.

In order to optimize traction efforts the operator should stand slightly to the side of the patient. It is recommended that a right-handed individual stand to the maternal right with the right hand facing upward and the shanks of the closed forceps between the index and middle fingers (Fig. 23.16). The index and middle fingers are curved around the flange of the handle loosely in a forceps with crossed shanks or a sliding lock. In a Simpson-type instrument the middle finger can be placed in the space between the shanks with the index and ring fingers being placed on the handle flange. This hand will apply the outward traction force. Because the traction occurs at the level of the lock (as opposed to the end of the handles) compression of the fetal head will be limited. By angling the body sideways the major muscle group involved is the deltoid. This acts as a natural limited to the amount of traction that is applied. If the operator was standing directly in front of the patient the much more powerful biceps group would be supplying the majority of the traction force. By only using two fingers the operator will further limit the amount of force applied.

FIG. 23.16. Methods of hand placement and stance.

The left hand is placed palm down on the shanks of the forceps and exerts a downward force. This is known as the Pajot maneuver. The combined outward and downward forces can be adjusted to produce a vector that follows the curve of Carus (axis–traction). Similar axis–traction can be applied using the Saxtorph maneuver (see Fig. 23.16) in which the operator is seated and uses the fingers of the left hand to pull the locked shanks downward. Simply pulling in the direction of the handles with a classic-type forceps (Simpson or Elliott) will cause the fetal head to be pulled up under the symphysis pubis. This is because the pelvic curvature of the forceps results in the handles being in a plane that is anterior to the plane of the pelvis in which the fetal head is present. When using an instrument with no pelvic curvature, or a reverse pelvic curvature, it is important not to elevate the handles more than 45 degrees above the horizontal in order to reduce the potential for sulcus tears from the toe of the blade.

A large amount of research has gone into determining what forces constitute safe levels for traction and compression. It has been calculated that during normal spontaneous delivery of the fetal head, second stage expulsive forces range between 8.6 kg and 15 kg. During forceps operations traction forces have been estimated to range from 16 kg to 23 kg. The traction forces are reduced by 25% and 50% by the use of forceps with crossed shanks.

Delivery of the fetal head in an OP position has been associated with increased traction and compression forces probably due to the larger presenting diameters of the fetal head.

Traction should be released between contractions in order to reduce the intracranial pressure differential to which the fetus is exposed. In addition, by releasing the pressure between contractions the vagally induced bradycardia that often accompanies traction efforts will be somewhat alleviated. Because of the potential for fetal heart rate abnormalities during delivery, the fetal heart rate should be continuously monitored during forceps deliveries.

Once the head crowns the handles of the classic-type forceps they can be elevated until they are almost perpendicular to the floor. The hand on top of the shanks will now be pulling almost directly outward. At this point the delivery can be completed with the forceps, or the branches can be disarticulated and the delivery can be completed using a modified Ritgen maneuver.

Occipitotransverse Positions

Occipitotransverse (OT) head position frequently results in a deep transverse arrest and resultant cephalopelvic disproportion. In most cases, this requires rotation of the fetal head to OA or OP to allow vaginal delivery, but occasionally, patients with a platypelloid pelvis will spontaneously deliver a baby with a transverse head position. The options open to the modern obstetrician faced with a deep transverse arrest in an OT position include:

- digital or manual rotation
- rotation with traction using a vacuum extractor (see Chapter XX)
- rotation with forceps
- cesarean section

Unless the operator has had sufficient training and experience with rotational delivery using forceps, cesarean section is frequently the most prudent choice.

DIGITAL OR MANUAL ROTATION

In some cases, particularly if the operator has a small hand, digital or manual rotation can be successfully used to rotate the fetal head from an OT position to an OA position. The digital method entails placing the tips of the index and middle fingers onto the edge of that part of the anterior parietal bone that overlaps the occipital bone in the area of the posterior fontanelle. Pressure is then exerted with the tips of the fingers in an attempt to rotate the posterior fontanelle upward and toward the symphysis pubis (see Fig. 23.6). In a manual rotation the whole hand is introduced into the birth canal and the fingers are placed under the posterior parietal bone. The

thumb is positioned on the anterior parietal bone and the head is rotated (Fig. 23.17). Care should be taken not to completely disengage the fetal head. These maneuvers are difficult for people with large hands; instrumental rotation may be preferred in these circumstances.

FIG. 23.17. Digital and manual rotation.

If digital or manual rotation is successful, the patient should be encouraged to push in order to increase descent of the fetal head and to stabilize the fetal head position. If the delivery is to be completed using forceps, the fingers should be kept on the fetal head while the forceps are placed (see Fig. 3.17).

ROTATION WITH TRACTION DURING VACUUM EXTRACTION

The vacuum extractor has been promulgated as an instrument with which to effect rotation of the fetal head. While this is true to some extent, it must be remembered that such rotation should only be accomplished by traction in the axis of the pelvis and not by twisting or rotational motions with the vacuum cup. By applying traction in the correct plane, the head is forced to rotate by virtue of the architecture of the soft tissue and bones of the pelvis. The operator should assess the position of the fetal head and take into account the malposition and the attitude and asynclitism of the presenting part. By applying the traction force in an appropriate direction to correct the flexion and asynclitism of the head, rotation will occur automatically as the head descends. The use of a twisting motion is contraindicated because of the risk of cephalhematoma and scalp laceration imposed by the significant shearing force that can be delivered to the soft tissue of the head. This effect is more pronounced when using the metal cup systems than with the Silastic cup. In most situations where rotation is required, choice of an appropriate forceps method will be more likely to result in successful rotation than use of the vacuum extractor.

ROTATION WITH FORCEPS

Rotation of the fetal head from a transverse position to an OA position is one of the most demanding (and satisfying) obstetric operative procedures. It is also one of the most technically demanding. Forceps rotation can be accomplished using classic forceps (i.e., Elliott, Tucker-McLean, Neville-Barnes), specific rotational forceps (Kielland, Barton), or Salinas forceps. The blades may be applied using the classic method, the wandering method, or the direct method.

When using a forceps with no, or minimal, pelvic curvature (Kielland, Salinas), I prefer using the direct method to apply the blades to a head in a deep transverse arrest (Fig. 23.18). In my experience this method involves the least manipulation. If performed correctly, the blades will be correctly positioned with the minimum potential for fetal and maternal injury. The wandering method is a better choice when using a classic-type forceps. I do not believe that a forceps with a pronounced pelvic curvature should be applied using the classic method and I therefore only describe the classic method using a Kielland forceps. When performing a rotational delivery my preference is to use a forceps designed for rotation rather than a classic-type forceps.

FIG. 23.18. Direct application of Kielland forceps for rotation.

Occipitoposterior Positions

An occipitoposterior position may be managed by delivery as a direct OP, by digital or manual rotation, by instrumental rotation, or by a combination of these methods. In general, a well-flexed head in an OP position can be delivered as a direct OP. If the head is extended or only minimally flexed then attempting a direct OP delivery may result in an increased risk of maternal and fetal trauma. This is because of the greater traction required to deliver the head due to the larger diameter presented. There is also the chance that traction on a deflexed head will exaggerate the extension and worsen the situation. Under these circumstances I prefer to rotate the head to an OA position, and this will usually help flex the head as well.

Digital or Manual Rotation

This is performed similarly to that described previously for OT positions except that the arc of rotation is greater.

Instrumental Rotation

Forceps or vacuum extraction can be useful for rotating an OP to an OA position. Either classic-type forceps or an instrument designed for rotation (Kielland or Salinas forceps) can be employed.

If a classic-type forceps is used the blades are placed in the same way as for an OA position (described previously). If the head is in a right OP position the forceps are applied as for a left OA and vice versa. Once the branches are locked the posterior fontanelle should be felt approximately 2 cm below the shanks, with the sagittal suture midway, and perpendicular, between the two blades. The head is then rotated into an OA position with the direction of rotation toward the side of the fetal back. As described earlier, the handles of the forceps should describe a wide arc in order to limit the arc of the toes of the blades. Once the rotation is complete, the now upside-down forceps branches should be removed and replaced in the correct orientation. The easiest way to do this is to have two sets of forceps available for use. As the upside-down forceps branch is removed it can be replaced with the appropriate blade from the other set of forceps. The remaining upside-down blade keeps the head in the OA position during the changeover. Once the replacement branch is correctly positioned the remaining upside-down branch can be removed and replaced with the second branch of the replacement set of forceps. The delivery is then completed as previously described.

If Kielland forceps is used, the blades are applied as for an OA (or LOA/ROA) position using the technique described earlier. The buttons on the handles should face the fetal occiput. The rotation is carried out as already described except that the head is rotated through 180 degrees rather than 90 degrees. The handles should

rotate on their axis since there is no pelvic curvature to contend with. It may be necessary to elevate the head during the rotation and if this is the case the operator may need to lower the handles toward the floor in order to better the forceps with the birth canal. The same slow, controlled maneuvers and precautions should be used as described previously. There is no need to reverse the blades after the rotation and once the head is OA, traction can be applied for delivery. Alternatively, there are some who place the forceps with the buttons facing the sinciput (upside-down application) for the rotation and then remove and replace the forceps for the delivery (either with the Kielland or with a classic-type forceps).

POST-DELIVERY MANAGEMENT

Following operative vaginal delivery the flexion of the patient's hips should be relieved in order to minimize the risk of nerve injury from prolonged pressure or stretching. The episiotomy repair should be performed as expeditiously as possible to limit blood loss and tissue exposure. The birth canal and cervix should be inspected for lacerations and tissue damage. I prefer not to repair minor lacerations that are not bleeding since they will usually heal very quickly. Even cervical tears that are not bleeding are best left alone under close observation. Care should be taken to inspect the periurethral and perianal/rectal areas after any repairs to exclude perforating sutures. Any complaint of anal pain after a forceps delivery should prompt a careful inspection for a vaginal or vulval hematoma. Any sudden drop in hematocrit should indicate a search for continued bleeding either obvious (vaginal or vulval) or occult (retroperitoneal hemorrhage).

Complications of Operative Vaginal Delivery

Complications arise in two main areas:

1. Inappropriate evaluation and underestimation of dystocia.
2. Misuse of an instrument.

It is important to point out that almost all of the complications seen with operative vaginal delivery have also been reported with spontaneous, uninstrumented vaginal deliveries. This should be kept in mind before attempting to link a particular injury directly to an instrumental delivery.

The risks can be divided into maternal and fetal/neonatal.

Maternal Complications Associated with Operative Vaginal Delivery

Lacerations The reported incidence of severe laceration (i.e., third-degree and fourth-degree laceration) during vacuum extraction procedures ranges from 10% to 30%. Operative vaginal delivery with forceps is responsible for a higher incidence of third- and fourth-degree perineal lacerations (closer to 50%) than with spontaneous delivery or vacuum extraction. Meta-analysis of available studies has shown that forceps operations are more likely to specifically result in anal sphincter trauma than vacuum extraction. In pooled data from 8 randomized trials studying maternal delivery trauma, a 6% decrease (95% CI = -.10 to -.02) in anal sphincter trauma occurred if a vacuum extractor, and not forceps, was employed.

Stress Urinary and Anal Incontinence Delivery trauma is suspected to predispose the patient to subsequent pelvic floor dysfunction; however, data indicate that the long-term effects of operative vaginal delivery on rectal or urinary incontinence are more complex than originally believed. Interpretation of all the available data is not straightforward. There is a suggestion that vaginal delivery is a major contributor to, but not the sole culprit of, long-term perineal dysfunction. It is believed that the greater the degree of perineal trauma, the greater the likelihood that there will be residual sphincter abnormalities. Arya and colleagues ([8]) retrospectively studied the incidence of new-onset urinary incontinence after forceps and vacuum delivery compared with spontaneous vaginal delivery. They enrolled primiparous women delivered by forceps (n = 90), vacuum (n = 75), or spontaneous vaginal delivery (n = 150). They then followed these women at 2 weeks, 3 months, and 1 year after delivery and showed that incontinence was similar in the 3 groups at 2 weeks after delivery. The proportion of women developing new-onset urinary incontinence decreased significantly over time in the spontaneous vaginal (*P* = .003) and vacuum delivery groups (*P* = .009) but not in the forceps group (*P* = .2). There was no relationship between urinary incontinence and a history of vaginal lacerations, epidural anesthesia, length of second stage of labor, or infant birth weight. These authors concluded that in primiparous women, urinary incontinence after forceps delivery is more likely to persist compared with spontaneous vaginal or vacuum delivery. A Swedish study of three large databases involving 1,559 patients who presented for incontinence surgery later in life (20–40 years after delivery) linked the need for surgery to some independent variables. The study included 189 women who had experienced an operative vaginal delivery (almost all were vacuum deliveries). There were positive associations between diabetes, body mass index, parity, birth weight, epidural, and age at first delivery. Interestingly, in this study, operative vaginal delivery, cesarean section, and episiotomy were shown to be protective against incontinence surgery in later life. Farrell and co-workers (level II-2) studied 690 Canadian primiparas who filled out a questionnaire about urinary incontinence during, and 6 months after, their first pregnancy ([9]). Twenty-five percent delivered by cesarean section, 19% had an operative vaginal delivery, and 56% had a spontaneous vaginal delivery. The median birth weight was 3,489 g. The rate of urinary incontinence at 6 months was 26%. Vaginal delivery was associated with a higher rate of urinary incontinence than cesarean section. Ten percent of women who had a cesarean section and 22% of those who had a spontaneous vaginal delivery reported postpartum urinary incontinence (OR = 2.1 [range, 1.1–-3.7]). Thirty-three percent of those who had a forceps delivery reported postpartum incontinence (forceps [33%] vs. spontaneous vaginal delivery [22%]; OR = 1.5 [range, 1.0–2.3]) and forceps (33%) vs. cesarean section (10%) (OR = 3.1 [range, 1.7–5.9]). Vacuum extraction showed no higher incidence when compared with spontaneous vaginal delivery, but when compared with cesarean section there was a significantly higher rate of postpartum incontinence (vacuum extraction vs. spontaneous vaginal delivery, no significant difference; vacuum extraction vs. cesarean section (OR = 3.5 [range, 1.3–9.1]). The authors concluded that cesarean section performed before or during labor reduces postpartum urinary incontinence. Meyer and co-workers studied 107 Swiss primiparas during their pregnancy and at 10 weeks and 10 months after delivery ([10]). The methods used for collecting data included questionnaire, clinical examination, assessment of bladder neck behavior, urethral sphincter function, and intravaginal/intraanal pressures during pelvic floor contractions. The results did not show any significant differences between the women who had forceps delivery and those who delivered spontaneously in terms of urinary incontinence (20% vs. 15% at 10 months), fecal incontinence (4% vs. 5% at 10 months), and diminished sexual response (12% vs. 18% at 10 months). More women in the forceps group however were shown on objective testing to have a weak pelvic floor (20% vs. 6%; *P* = .05) and low intraanal pressure (*P* = .04). The authors concluded that forceps delivery is not responsible for a higher incidence of pelvic floor complaints, or a greater change in bladder neck behavior or urethral sphincter function. However, they do believe that patients who have had a forceps delivery have a significantly greater decrease in intraanal pressure and a greater incidence of a weak pelvic floor. In terms of fecal incontinence, McArthur and colleagues questioned over 5,000 postpartum women and showed that forceps deliveries are associated with higher risk than vacuum extraction (OR = 1.94; 95% CI = 1.30–2.89) while cesarean section may offer some protection (OR = 0.58; 95% CI = 0.35–0.97). This area of obstetrics remains under-researched and the value of anal manometry and the current methods used in the diagnosis and ascertainment of postpartum anal injury/dysfunction have been questioned. Long-term follow-up studies controlling for prepartum pelvic support status (e.g., preexisting rectal dysfunction or urinary incontinence, length of labor, anesthesia, clinically observed perineal trauma, and delivery method) are required before changes in current practice can be recommended. Patients should be counseled that significant vaginal trauma may be related to long-term sphincter dysfunction, but that a relatively atraumatic operative vaginal delivery (i.e., one that does not cause rectal or sphincter rupture) is not known to cause a higher rate of dysfunction than that which follows spontaneous vaginal delivery.

Nerve Injuries Following Operative Vaginal Delivery An uncommon but distressing complication of vaginal delivery (be it spontaneous or operative) is a nerve injury which is usually the result of incorrect positioning and undue compression or traction on a nerve. Fortunately most of these injuries are apraxias, which recover, but occasionally a neuronotmesis or axonotmesis occurs with long-term disability. The most common cause of these injuries is excessive flexion of the maternal hips at the time of delivery (forced McRoberts position with attendants applying significant pressure to flex the patient's hips) and episiotomy repair (prolonged hyperflexion of the hips). Because the repair of lacerations and the episiotomy may be lengthy, it is advisable that the operator adjust the patient's position after delivery so that there is minimal flexion of the hips. Care should also be directed to pressure points on the patient's legs to avoid nerve compression injuries, and adequate padding and positioning is essential. The common injuries and their causes and presentations are shown in Table 23.5.

Neonatal Injury and Operative Vaginal Delivery

Neonatal Injuries Associated with the Vacuum Extractor

Scalp Bruising/Lacerations Ecchymoses and, uncommonly, scalp slough or lacerations can follow vacuum extraction. Most of these injuries occur when the recommended limits to total cup applications are exceeded. *Subgaleal hemorrhage* is a serious neonatal complication of vacuum extraction. This complication occurred in 1.0% to 3.8% of vacuum extractions in one series but has been much less common in some more recent studies. Approximately half of all subgaleal hemorrhages are related to vacuum extraction. The remainder are associated with forceps operations; less commonly, they occur following spontaneous delivery. This complication has not been reported in recent vacuum extraction meta-analyses, attesting to the rarity of severe scalp injuries, while emphasizing the importance of following strict technical guidelines when performing vacuum extractions/operations. Despite the low incidence of subgaleal bleeding, notification of pediatric personnel whenever an extraction is performed is mandatory, regardless of the immediate condition of the baby because subgaleal hemorrhage may not be clinically apparent until some hours postpartum. Infants with subgaleal hemorrhage present with a boggy scalp, swelling crossing the suture lines, and an expanding head circumference. They may also have signs of hypovolemia, pallor, tachycardia, and a falling hematocrit. Cephalhematoma is another fetal complication of vacuum extraction. This complication is more common with vacuum extraction (14%–16%) than with forceps delivery (2%). Intracranial hemorrhage has been found to occur in one of every 860 vacuum-assisted deliveries compared with one of every 1,900 spontaneous deliveries (a statistically significant difference). Yet, the comparative rate of intracranial hemorrhage is not statistically different when vacuum extraction, forceps delivery, and cesarean section during labor are compared. It is possible that the abnormal labor that necessitated the assisted delivery may be an underlying cause for a portion of the morbidity attributed to operative deliveries. Retinal hemorrhages may be more common in vacuum-assisted deliveries than with forceps (38% vs. 17%) but are most often associated with duration of labor. Because these hemorrhages resolve within several weeks, they are unlikely to be associated with long-term morbidity. Transient neonatal lateral rectus paralysis has been found to occur more frequently in vacuum-assisted deliveries (3.2%) than in forceps deliveries (2.4%), normal spontaneous vaginal deliveries (0.1%), and cesarean sections (0%). Because the paralysis

resolves spontaneously, it is unlikely to be of clinical importance. Vacuum extraction is associated with a higher rate of neonatal jaundice than is spontaneous delivery or forceps procedures, and this is possibly related to the higher rate of cephalhematoma.
Long-term Neonatal Outcomes The few available studies evaluating long-term neurologic sequelae of instrumental delivery have found no differences among children delivered spontaneously and children delivered by either vacuum extraction or forceps. Vacuum extraction has not been found to result in significant intellectual or neurologic disability.
Neonatal Injuries Associated with Forceps (Fig. 23.19)

FIG. 23.19. Forceps-associated injury. (Courtesy of Dr. Gerardo Cabrera Meza.)

Exactly how much neonatal injury can be attributed to a forceps delivery is difficult to assign since it is well known that a protracted spontaneous labor can result in a poor neonatal outcome. The most commonly described neonatal injuries include those described in the following paragraphs.
Superficial Scalp and Facial Markings These will invariably be present and only occasionally are of significance. Obviously correct placement of the forceps blades will prevent tissue damage to sensitive regions such as the eyelids and face. Inappropriate forceps application (sometimes referred to as the fetal grip) can be easily noted by the bruising on the baby's face in the neonatal period. In general, if the parents are prepared for the markings that they see, and it has been explained to them that these are temporary, their acceptance is good. Abrasions and lacerations are not expected or acceptable, and a careful assessment of one's technique should follow any such occurrence. Excessive pressure on the fetal face can result in vesicle formation, lipoid necrosis, and massive face and head trauma. Pressure localized over the mastoid region can result in facial erve injury. Most superficial injuries are short-lived and recovery is uncomplicated.
Facial Nerve Injury Injury to the facial nerve has been reported and is usually the result of compression of the nerve against the rigid cervical spine from a forceps blade at the point where the nerve is superficially placed in the mastoid region. This is usually a transient event, but may result in permanent injury.
Cephalhematoma Cephalhematoma occasionally occurs with forceps delivery (2%) but is more commonly seen after vacuum extraction (14%–16%). Skull fracture, subgaleal hematoma, and intracranial hemorrhage have all been reported after complicated or difficult forceps deliveries. It is difficult to assess the risk, however, since these problems have also been noted after complicated spontaneous deliveries. In addition, no data are available addressing the incidence of these complications in normal vaginal or abdominal deliveries. If a difficult delivery occurs, the neonatal personnel should be advised and the infant should then be appropriately observed and investigated.
Retinal Hemorrhage This complication occurs with forceps deliveries (17%) but is more frequently seen after vacuum extraction (38%; $P < .05$).
Corneal Abrasions/External Ocular Trauma Forceps delivery is associated with an increased rate of eyelid edema (39%) and minor external ocular trauma (17%) when compared with babies born by spontaneous vaginal delivery (eyelid edema = 10%, and external ocular trauma = 6%). Corneal abrasion is possible and corneal edema has been reported. Long-term sequelae are extremely rare and ophthalmologic screening should be reserved for specific cases.
Intracranial Bleeds It is the intracranial hemorrhages and infarcts seen following a difficult operative vaginal delivery that are of great concern. Whether or not a specific neonate suffers cerebrovascular injury due to the underlying condition that precipitated the fetal distress that resulted in delivery with the forceps, or whether the damage was caused directly by the forceps at the time of the delivery, is frequently difficult to discern. The decision to attempt a forceps delivery in the face of fetal distress can often be a difficult one. If the operator is experienced and confident that delivery can be achieved with an uncomplicated procedure, appropriate use of forceps in an emergency situation (while preparations for cesarean section are underway) can significantly reduce the time to delivery and reduce potential fetal injury. In most cases with a bad outcome there is no guarantee that cesarean section would have resulted in any different outcome from an appropriately performed operative vaginal delivery. Abdominal delivery in these situations certainly does not remove the threat of litigation. Therefore it is advised that cesarean section be performed for obstetric reasons and not out of fear of litigation.

FAILED OPERATIVE VAGINAL DELIVERY AND SEQUENTIAL USE OF INSTRUMENTS

A failed forceps/vacuum delivery attempt was, until recently, not thought to significantly worsen the neonatal course or increase morbidity or mortality of the neonate. This impression was based on small series. More recent, large, population-based studies have revealed that a failed operative delivery, or the sequential use of different instruments, does significantly increase morbidity and mortality. Towner and colleagues performed a population study of 583,340 live-born, singleton babies delivered from nulliparous women in California between 1992 and 1994 ([11]). They restricted the study to babies with birth weight between 2.5 and 4.0 kg and breech deliveries were excluded.

Approximately 30% of the deliveries were by operative techniques.

The authors studied the relationship between mode of delivery and the morbidity/mortality of the babies. The study showed that, when compared with spontaneous vaginal delivery, vacuum extraction (OR = 2.7 [range, 1.9 - 3.9]), forceps delivery (OR = 3.4 [range, 1.9 - 5.9]), and cesarean section after abnormal labor (OR = 2.5 [range, 1.8 - 3.4]) resulted in an increased incidence of subdural and cerebral bleeds. Intracranial bleeding occurred with the following frequencies:

- 1:334 failed vacuum extraction or forceps followed by cesarean section
- 1:860 after vacuum extraction
- 1:664 after forceps
- 1:907 after cesarean section during labor
- 1:2,750 after cesarean section without labor
- 1:1,900 normal spontaneous vaginal delivery.

Differences in the rate of intracranial hemorrhage were reported after the use of vacuum extraction or forceps delivery (OR = 1.2 [range, 0.7–2.2]).

One of the surprising findings in this study was that the common risk factor for intracranial bleeding was abnormal labor, rather than simply the mode of delivery.

When compared with successful forceps or vacuum extraction alone, the rate of intracranial bleeding was two to three times higher in babies born after a sequential operative vaginal delivery, or after a failed forceps/vacuum procedure that was followed by a cesarean section. These findings were confirmed by a similar study by Gardella and colleagues who used Washington state birth certificate data linked to hospital discharge records and compared 3,741 vaginal deliveries by both vacuum and forceps, 3,741 vacuum deliveries, and 3,741 forceps deliveries to 11,223 spontaneous vaginal deliveries ([12]). They showed that compared with spontaneous vaginal deliveries, the sequential use of vacuum and forceps had significantly higher rates of intracranial hemorrhage (RR = 3.9 [range, 1.5–10.1]), brachial plexus (RR = 3.2 [range, 1.6–6.4]), facial nerve injury (RR = 13.3 [range, 4.7–37.7]), seizure (RR = 13.7 [range, 2.1–88]), depressed 5-minute Apgar score (RR = 3.0 [range, 2.2–4.0]), assisted ventilation (RR = 4.8 [range, 2.1–11]), fourth-degree (RR = 11.4 [range, 6.4–20.1] among multiparous women) and other lacerations, hematoma (RR = 6.2 [range, 2.1–18.1] among multiparous women), and postpartum hemorrhage (RR = 1.6 [range, 1.3–2.0]). The relative risk of sequential vacuum and forceps use was greater than the sum of the individual relative risks of each instrument for intracranial hemorrhage, facial nerve injury, seizure, hematoma, and perineal and vaginal lacerations.

Based on these two studies, there is now no question that the sequential use of vacuum and forceps is associated with an increased risk of both neonatal and maternal injury. Unless there is a reasonable likelihood of atraumatic vaginal delivery, a “trial of operative vaginal delivery” is something that should be undertaken with caution. The use of the term “failed forceps” should fall out of use as careful preoperative assessment of mother and baby are applied. A failed forceps suggests that a forceps delivery was attempted and that obvious, repetitive, but futile efforts were made to deliver the baby with at least one genuine attempt at rotation or traction that was without success. When the term “failed forceps” is used it implies that the underlying expectation of the operator was to complete the delivery with the chosen instrument.

In a situation where the correct indications and prerequisites apply, and an appropriate, albeit unsuccessful attempt is made, a better term to use when documenting is “abandoned trial of forceps.” This shows that the attempt was justifiable but stopped when the operator recognized a complication such as an inability to properly apply the instrument, inability to correctly rotate the head, or a lack of descent despite a correct application of the instrument. In this case it is clear to anyone reviewing the chart, that the operator sensed a problem and did not persist.

STRATEGIES TO REDUCE INJURY

One of the most important clues as to the potential for successful operative vaginal delivery can be found in the details of the labor course. Use of labor monitoring graphics such as the Friedman curve or the Philpott and Castle “alert and action lines” will lead to early identification of those patients most likely to have dystocia. The combination of the “history” (labor course) and physical examination will usually allow an accurate assessment of the potential for vaginal delivery. The wise obstetrician will very carefully evaluate a patient who is a candidate for a forceps delivery but who has had a protracted labor. Frequently a slow course, or a second

stage arrest, will be associated with an unusually large baby, an unsuitable pelvis, or an unrecognized malposition. These complications may well contraindicate any attempt at instrumental delivery. The fact that a patient can get to complete dilation with a baby whose head appears to be engaged does necessarily mean that the safest route of delivery is vaginal.

Once the decision to proceed with a forceps delivery has been made, the selection of the appropriate instrument, correct positioning of the patient, and satisfaction of the aforementioned prerequisites are important.

The willingness to reassess the decision after application of the forceps blades is also important. Merely applying the blades, or attempting to apply the blades will not cause maternal or fetal damage unless excessive force has been used. At this point, if the application is incorrect or inappropriate, the procedure should be abandoned and the blades gently removed. Whether or not to attempt a second application will again be a judgment call. It is recommended that if this is to occur there should be a careful reevaluation of fetal and maternal condition. If both mother and baby are in good condition, the most experienced individual should be the one to reassess the situation and reapply forceps, if appropriate.

Knowing when to abandon a forceps operation is just as critical as knowing when to attempt one, and reflects the maturity and experience of the operator. This should be an infrequent occurrence since abandoning a procedure almost always indicates incorrect assessment in the first place. However, there will be cases where application of the forceps changes the head position, or results in asynclitism that was not there in the initial evaluation. If, at the traction attempt, there is no descent of the fetal head it is fruitless to continue applying more traction as this is the cause of most fetal injury. The safety of the mother and baby should always be first in the mind of the operator and there should never be a need to complete the operation at all costs. There are no good data addressing the important questions of how many traction attempts are reasonable, or how long the forceps procedure should take. These aspects of obstetrics can only be acquired by clinical training, and are dependent on the experience, skill, and integrity of the operator.

Does Fetal Distress Preclude Operative Vaginal Delivery?

Vintzileos and colleagues demonstrated that in cases where the vacuum extractor was used to deliver babies with suspected fetal distress there were no differences in blood gas parameters when compared with normal spontaneous deliveries. The authors concluded that the use of vacuum extraction is not contraindicated in cases of fetal distress ([13]).

Documentation and Safety Issues

The application and use of forceps is associated with a definite risk profile that should be explained to the patient prior to their use. If the situation allows, it is my practice to write a short preoperative note detailing the following:

1. Indication for the procedure along with the time and date of the note.
2. The amount of head palpable above the pelvic brim.
3. The position and station of the fetal head.
4. The degree of molding of the parietal bones.
5. The amount of caput succedaneum palpable.
6. The estimated fetal weight.
7. A clinical assessment of the maternal pelvis.
8. A statement regarding the fetal heart rate and character.
9. A statement about the maternal contractions.
10. A statement about maternal condition and type of anesthesia to be used.
11. A statement that the mother understands the reason for the procedure and accepts the risks.

After the delivery an operative note should be written or dictated and should contain as much of the following information as possible:

1. Preoperative and postoperative diagnoses along with the time and date of the note.
2. Reiteration of the physical findings (outlined previously) at the time of the procedure, especially if these were different from those detailed in the preoperative note.
3. Number of applications of the forceps, ease of application, and any complications with the application. If possible have a nurse or assistant document the exact times of application and traction.
4. Duration and force of each traction attempt, as well as the number of traction attempts.
5. Complete explanation of a failed or abandoned procedure with reasons.
6. Detailed description of any maternal or neonatal injuries.
7. Cord blood gases if the 5-minute Apgar is less than 7.

Informed Consent for Forceps Operations?

Although not frequently done, I believe that unless there is an emergency situation, a forceps delivery should be discussed with the patient as one would discuss any operative procedure. In this way informed consent can be obtained and the patient can be prepared for what to expect. The risks and benefits of operative vaginal delivery should be explained (and compared with those of cesarean section) and the patient should be aware of her options. I recommend that this be detailed in the patient's chart prior to the delivery. Most lawsuits are generated as a result of lack of communication between the doctor and the patient. Dissatisfaction with an outcome will always be heightened if the patient feels uninvolved with the decision and perceives that she has been misinformed about the risks. The best time to educate the patient is during her prenatal course or on admission to the hospital. When the patient signs her consent forms during the admission process I believe that a consent form for operative vaginal delivery should be included. The information provided should include a description of what forceps look like and that, despite their shape and size, they are specially designed to protect the mother and baby by gently grasping the fetal head and assisting the infant to negotiate the last portions of the birthing canal. The fact that a timely operative delivery will the time and energy required during the birthing process should be explained. The fact that correct forceps use can be lifesaving should be stressed. The patient should, however, also understand that bad outcomes will still occur due to unforeseen problems, and the obstetrician should be prepared to explain the maternal and fetal/neonatal risks specific to forceps operations. The possibility of facial bruising and possible facial nerve or eye injury should be mentioned before the delivery because of the emotional impact of these injuries after the delivery has occurred, especially when the patient or her family makes accusations that these risks were never mentioned. The detractors of informed consent complain that after being informed of the potential risks of operative vaginal delivery most women will elect to proceed with cesarean section and will forgo vaginal delivery. The argument against this point of view is that since cesarean section is a viable option that will allow minimization of fetal injury (and one that is not associated with a prohibitively high incidence of maternal or neonatal injury) patients have the right to choose to avoid potential trauma to their baby. Many authorities fear that by providing more detailed written informed consent the medicolegal risk increases since it is not possible to cover every eventuality and thus the informed consent will be regarded as incomplete or misleading. This is obviously a controversial matter but at this time there is no standard of care in the United States that demands a written informed consent prior to operative vaginal delivery.

Post-Delivery Responsibilities

It is very important that neonatal caregivers be informed of a vacuum or forceps delivery, and that they monitor the infant for signs of any complications.

CONCLUSIONS

Operative vaginal delivery has been an important part of obstetric practice for nearly 400 years. We must make every effort to retain these skills, to modify and improve them in every possible way, and then to pass them on to those who will follow us. It is in this way that women and children of future generations will benefit from the many years of experience that have gone before them.

SUMMARY POINTS

- Adequate assessment of the “pelvis and passenger” is essential prior to attempting an operative vaginal delivery. Careful assessment of the maternal abdomen prior to attempting operative vaginal delivery forms an important part of this assessment. If the fetal head is not felt to be completely engaged and there is excessive molding of the fetal head, the procedure should be avoided. There are important prerequisites, which if satisfied, will reduce the chances of failed operative vaginal delivery procedures.
- Failed operative vaginal delivery and sequential operative vaginal delivery attempts with different instruments significantly increase the risk of neonatal intracranial complications.
- Both forceps and the vacuum extractor are acceptable and safe instruments for operative vaginal delivery. Operator experience should determine which instrument should be used in a particular situation. The vacuum extractor is associated with an increased incidence of neonatal cephalhematomata, retinal hemorrhages, and jaundice when compared with forceps and the neonatal care provider should be made aware of the mode of delivery in order to exclude these complications.
- Large fetal size and prolonged labor are associated with an increased risk of shoulder dystocia and careful consideration should be given to performing operative vaginal delivery under these circumstances.
- Forceps delivery may be preferable to vacuum extraction in small-for-gestational-age babies since it is associated with a lower incidence of intraocular bleeding.
- Operators should attempt to reduce the time between vacuum application and delivery of the baby since cephalhematoma is more likely if the interval exceeds 5 minutes.
- Midforceps operations, if performed under the correct circumstances by an adequately trained individual, should still be considered an appropriate procedure to be used and taught.
- Efforts should be made to train resident obstetricians in the use of operative vaginal delivery techniques since appropriate and safe employment of forceps and vacuum-assisted delivery still is an important part of modern-day obstetrics.

SUMMARY POINTS

SUGGESTED READINGS

Cesarean section is a term commonly used in obstetrics to describe the delivery of a viable fetus through an incision in the abdominal wall (laparotomy) and the uterus (hysterotomy). However, the words cesarean and section used together are redundant, because both imply incision. Cesarean birth and cesarean delivery are preferable terms and are used interchangeably in this chapter.

Cesarean delivery has played a major role in lowering both maternal and perinatal morbidity and mortality rates during the past century. The initial purpose of the surgery was to preserve the life of the mother with obstructed labor, but indications have expanded over the years to include delivery for a variety of more subtle dangers to the mother or the fetus. Contributing to its more frequent use is its increased safety, which is largely a result of better surgical technique, improved anesthesia, effective antibiotics, and availability of blood transfusions. Nevertheless, there has been increasing concern over what is considered by many to be an excessive cesarean rate in contemporary obstetrics.

The percentage of babies in the United States delivered by cesarean dramatically increased from less than 5% in 1965 to 25% in 1990. The reasons for this striking increase are multiple. During the 1970s and 1980s, it was assumed that cesarean delivery would be the solution to numerous obstetric problems. Facing increasing medical-legal pressures, obstetricians gradually abandoned most vaginal breech and forceps deliveries, broadened the definition of intrapartum fetal distress, and liberalized the diagnosis of dystocia. Also, a greater number of older women and older primigravidae, whose primary cesarean rates are higher, were having children. Finally, the escalation in primary cesareans increased the overall cesarean rate, because in most subsequent pregnancies, babies were delivered by repeat cesarean.

Although perinatal outcome in the United States improved during the period when the cesarean rate increased, it also improved in other countries where cesarean rates remained low. Moreover, the incidence of cerebral palsy has not declined during the past 20 years because perinatal morbidity and mortality are more often a function of antepartum events, abnormal fetal growth, congenital anomalies, and premature birth. Delivery by cesarean usually is associated with an increased cost for the health care system and the patient when compared with vaginal birth. These factors have led to efforts to reduce the rate of cesarean delivery. Most emphasis has been placed on decreasing the number of repeat cesareans by encouraging vaginal birth after cesarean (VBAC). Accordingly, the percentage of women attempting VBAC increased from less than 10% in 1988 to about 30% in 1996. During this same period, the percentage undergoing cesarean declined to about 20%. Unfortunately, initial enthusiasm for VBAC has been dampened by the results from several studies showing adverse maternal and perinatal outcomes in some women who attempted it. In turn, this has led to a steady decline in the number of women attempting VBAC and an increase in the overall cesarean rate to about 24%.

INDICATIONS

Cesarean birth is necessary whenever labor is unsafe for either mother or fetus, when labor cannot be induced, when dystocia or fetal problems present significant risks with vaginal delivery, and when an emergency mandates immediate delivery. It is not practical to list all potential indications for cesarean delivery or to discuss the numerous changes in obstetric management hat have influenced these over the years (Table 24.1). Many indications are well accepted, a number are subjective or selectively applied in individual patients, and others are more controversial. The majority of cesareans are performed for fetal indications, a few are solely for maternal reasons, and some benefit both fetus and mother. Repeat cesarean accounts for approximately 30% of cesarean deliveries in the United States, dystocia is the indication for up to 30%, and fetal distress, breech, and other conditions are responsible for the remaining cases.

Accepted
Failed induction
Cephalopelvic disproportion
Failure to progress in labor
Proven fetal distress
Placental abruption
Placenta previa
Umbilical cord prolapse
Obstructive benign and malignant tumors
Active genital herpes infection
Abdominal cerclage
Conjoined twins
Controversial (or selective)
Breech presentation
Repeat cesarean
Congenital fetal anomalies, major
Cervical carcinoma
Prior vaginal colporrhaphy
Large vulvar condylomata
HIV infection

HIV, human immunodeficiency virus.

TABLE 24.1. *Common indications for cesarean delivery*

Labor Contraindicated

Uterine contractions can be hazardous to the mother under certain circumstances. These include central placenta previa, previous classic uterine incision, myomectomy transecting the uterine wall, or uterine reconstruction. In these situations, labor and vaginal delivery may result in uterine rupture and hemorrhage, endangering the life or future health of the mother. Conditions in which labor is dangerous to the fetus include placenta previa, velamentous insertion of the cord or other forms of vasa previa, and cord presentation. More recent indications include treatable fetal anomalies such as meningomyelocele and certain degrees of hydrocephaly.

Failed Induction

Conditions such as alloimmunization, diabetes mellitus, intrauterine growth retardation, and hypertensive disorders constitute a threat to the mother or fetus and often

require delivery when the cervix is unfavorable for induction. If attempts to induce labor are inappropriate or unsuccessful, cesarean birth is the only alternative. This is especially true in nulliparous women. More effective methods of softening the cervix before inducing labor preterm may reduce the need for cesarean.

Dystocia

Mechanical problems of the uterus, fetus, or birth canal or ineffective uterine contractions that result in unsuccessful progress of labor and vaginal delivery are referred to collectively as *dystocia.* This term encompasses a variety of commonly used clinical terms, such as failure to progress, cephalopelvic disproportion (CPD), and dysfunctional labor. However, CPD is a relative term. Although fetal macrosomia sometimes causes CPD, most cesarean births for abnormal labor involve a normal-sized infant. Dystocia occasionally is also caused by soft tissue tumors and abnormal fetal presentations.

Intrapartum Fetal Heart Rate Abnormalities

Electronic fetal monitoring improves the chance of detecting fetal compromise, but its inaccuracy (false-positive rate) has also contributed to the increased number of cesarean births. Nonreassuring fetal heart rate patterns and the diagnosis of fetal distress are discussed elsewhere. Many clinicians have replaced vaginal breech deliveries with cesarean delivery to avoid the risk of intrapartum asphyxia or delivery-related trauma from head entrapment and umbilical cord prolapse. An increase in adverse perinatal outcome with singleton vaginal breech delivery was confirmed in one large randomized controlled trial.

Maternal or Fetal Emergency

Certain maternal or fetal conditions require immediate delivery of the baby because vaginal delivery is either impossible or inappropriate. Such circumstances include severe placental abruption, hemorrhage from placenta previa, prolapse of the umbilical cord, active genital herpes, and impending maternal death.

COMPLICATIONS

A variety of postpartum complications—including unexplained fever, endometritis, wound infection, hemorrhage, aspiration, atelectasis, urinary tract infection, and venous thromboembolism—occur in up to 25% of women who undergo cesarean delivery. The frequency of cesarean-related maternal death varies with the institution and with the condition necessitating the procedure. However, rates are less than 1 per 1,000 operations, and many deaths are related to an underlying maternal illness or anesthetic complications.

Late maternal complications of cesarean delivery include intestinal obstruction from adhesions, dehiscence of the uterine incision in subsequent pregnancies, and abnormal myometrial invasion of the placenta (accreta, increta, percreta) in subsequent pregnancies. Both intestinal obstruction and scar dehiscence are more common with the classic incision than with a lower uterine segment incision. The incidence of abnormal myometrial invasion by the placenta (accreta, increta, percreta) increases with each cesarean and can result in severe and intractable hemorrhage at delivery, often requiring cesarean hysterectomy. This should be suspected in all women with a placenta previa and a history of cesarean.

TYPES OF CESAREAN OPERATIONS

Almost all contemporary cesareans are performed using a transperitoneal approach to reach the uterine wall. An extraperitoneal technique was sometimes used in the past in patients with an infected uterus in an attempt to reduce the chance of peritonitis. More effective antibiotics have now made this approach unnecessary.

The two major types of cesarean operations are classified by the location and direction of the uterine incision. The first are those incisions made in the upper segment of the uterus (Fig. 24.1). The vertical incision usually made in the anterior fundus is referred to as a *classic incision.* It is used primarily when it is difficult to deliver the infant through a low uterine segment incision. The second type is characterized by incisions made in the lower portion of the uterus after the bladder has been displaced downward (Fig. 24.2). The preferred and most frequently used is the low transverse incision. A vertical incision may also be made in this area, but it usually involves the upper uterine segment unless the lower segment is quite elongated by labor.

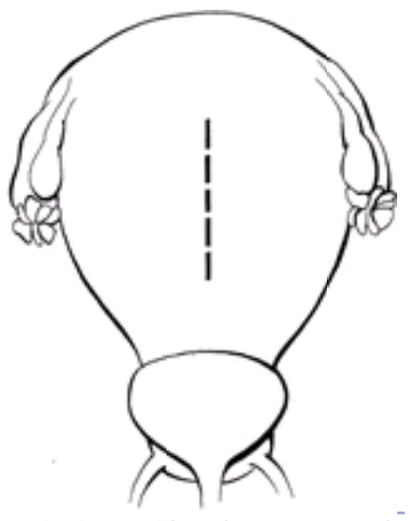

FIG. 24.1. Classic cesarean incision in the upper segment of the uterus.

FIG. 24.2. Incisions in lower uterine segment. **A:** Low transverse incision. **B:** Low vertical incision.

Occasionally, variations are used because of unanticipated difficulty (Fig. 24.3). These incisions are best avoided by careful assessment and planning. A J-shaped incision is made when the obstetrician begins a transverse lower uterine segment incision and finds the lower uterine segment to be too narrow. It often is not realized that the incision is inadequate until delivery is attempted. A vertical extension from one end is necessary to avoid extension into the broad ligament. The T-shaped incision is made for similar reasons.

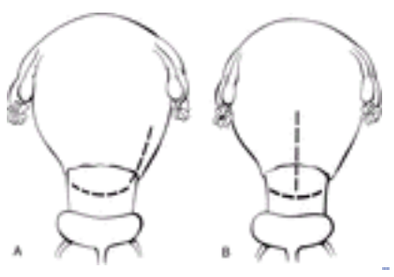

FIG. 24.3. Undesirable variations of uterine incisions. **A:** J-shaped incision. **B:** T-shaped incision.

ANESTHESIA

The choice of anesthetic technique and agents is dictated by a number of factors, as discussed elsewhere in Chapter 3. Most patients requiring immediate delivery because of fetal distress, hemorrhage, or shock are not candidates for spinal or epidural anesthetic techniques. The same is true for women with previous injury or surgery to the spine, skin infections of the lower back, or coagulopathy. Conversely, patients with active pulmonary disease, such as pneumonia or tuberculosis, or in whom intubation is judged difficult, are not good candidates for inhalation anesthesia.

The choice between regional block and inhalation anesthesia should be discussed among the patient, anesthesiologist, and obstetrician and should be based on the urgency of delivery, patient choice, and skill of the anesthesiologist.

Regional anesthesia has the potential to adversely affect maternal and fetal hemodynamics. In the dorsal recumbent position, the gravid uterus compresses the inferior vena cava, resulting in decreased venous return and maternal cardiac output and, eventually, hypotension and reduced uterine perfusion. This is referred to as the *inferior vena cava syndrome.* The weight of the pregnant uterus progressively compresses the aorta as the mean arterial pressure falls, thus also reducing blood flow to the pelvis. Hypotension produced by regional anesthetic techniques compounds this problem. Devices attached to the operating table, inflatable wedges or towels placed under the patient, or tilting the table can be used to displace the uterus to the patient's left in preparation for cesarean delivery. Rapid intravenous infusion of physiologic solution containing sodium immediately before the initiation of regional anesthesia also reduces the incidence of hypotension.

The status of the fetus worsens as the time of exposure to anesthesia lengthens. Progressive fetal depression as induction-to-delivery time is prolonged makes it important to avoid unnecessary delay before and during surgery. The abdomen should be fully prepped, draped, and ready for the incision before general anesthesia is induced. On the other hand, reckless surgical techniques for rapid delivery of the fetus are unwise. An induction-to-delivery time of 5 to 15 minutes is reasonable if maternal oxygenation, blood pressure, and displacement of the uterus are monitored and maintained.

OPERATIVE PROCEDURE

Preparation

Cesarean delivery requires the same preoperative care as any major surgery plus additional consideration for the status of the fetus. A patient who is dehydrated from prolonged labor needs volume correction with intravenous fluids. Because anemia is relatively common in pregnancy, a hemoglobin or hematocrit level should be checked preoperatively. Blood is typed and screened to be available for immediate transfusion. Routine preparation of autologous blood is not cost effective for most cesarean patients, because few are transfused. However, autologous blood can be prepared during the antepartum period if the patient is at high risk for hemorrhage as with placenta previa or accreta. Because the bladder will be in the operative field, it is necessary to place an indwelling catheter before beginning surgery. The patient and her partner should be given an explanation of the details of the operation, the reason it is necessary, and the risks involved. Informed written permission for the procedure, anesthetic, administration of blood, and possible hysterectomy, if necessary, is then signed by the patient.

With elective repeat cesarean delivery, it is the obligation of the physician to obtain evidence of fetal maturity. Documentation by noninvasive techniques is outlined in Table 24.2. If the criteria confirm gestational age assessment on the basis of menstrual dates in a patient with normal menstrual cycles and no immediately antecedent use of oral contraceptives, delivery can be scheduled after 39 weeks by menstrual dates. Ultrasonography is considered confirmatory of menstrual dates if there is gestational age agreement within 1 week by crown-rump measurement obtained at 6 to 11 weeks, or within 10 days by the average of multiple measurements obtained at 12 to 20 weeks. When the fetal gestational age remains uncertain, amniocentesis for amniotic fluid studies should be employed to ensure fetal maturity. Awaiting the onset of spontaneous labor is another option.

Fetal heart tones documented for 20 weeks by nonelectronic fetoscope or for 30 weeks by Doppler
36 weeks since a positive serum or urine human chorionic gonadotropin pregnancy test was performed by a reliable laboratory
An ultrasonographic measurement of the crown-rump length, obtained at 5 to 11 weeks, that supports a gestational age of >39 weeks
Ultrasonography obtained at 12 to 20 weeks that confirms the gestational age of >39 weeks determined by clinical history and physical examination

TABLE 24.2. *Fetal maturity assessment before elective repeat cesarean delivery*

Aspiration of the acidic contents of the stomach, a known risk of general anesthesia in pregnant women, can be avoided by pretreatment with any of several medications. Prophylactic antibiotics are administered to reduce the risk of postpartum infection, which is increased with prolonged labor, prolonged rupture of the membranes, and numerous cervical examinations. A single dose of a broad-spectrum antibiotic, such as 1 g of a cephalosporin, usually is given after the umbilical cord has been clamped. However, if an intrapartum infection is apparent preoperatively, therapeutic antibiotics should be given before surgery and continued postoperatively. Preparation of the abdomen includes scrubbing the skin with soap and an antiseptic agent such as nonorganic iodide. The abdomen is then draped, leaving the area for the incision exposed. Personnel trained in neonatal resuscitation should be available.

Surgical Technique

A lower abdominal midline vertical incision and the transverse Pfannenstiel incision are used most commonly for cesarean deliveries. The vertical incision minimizes blood loss and allows extension above the umbilicus, if necessary. It also allows for rapid access to the abdominal cavity because of diastasis of the rectus muscles, common in late pregnancy. Nevertheless, the transverse Pfannenstiel incision is used more frequently because of the cosmetic result preferred by most women. Entry through this incision is relatively rapid in experienced hands, visualization of the pelvis is adequate, and there may be less risk of subsequent herniation.

The abdomen is opened in layers, and any large bleeding vessels are clamped. Meticulous hemostasis is postponed if it will unduly delay delivery of the fetus. The abdominal cavity is inspected briefly, and the direction and degree of rotation of the uterus are noted. Retractors are placed in the abdominal incision for better visualization. The bladder is dissected carefully away from the serosa of the uterus and a small transverse incision is made in the midline of the uterus, a few centimeters below the peritoneal incision (Fig. 24.4A, Fig. 24.4B, Fig. 24.4C, Fig. 24.4D and Fig. 24.4E). Care should be taken to keep the fetal membranes intact. Under direct vision, the incision is extended laterally with bandage scissors in a gentle upward curve using the operator's fingers as a guide (Fig. 24.4F).

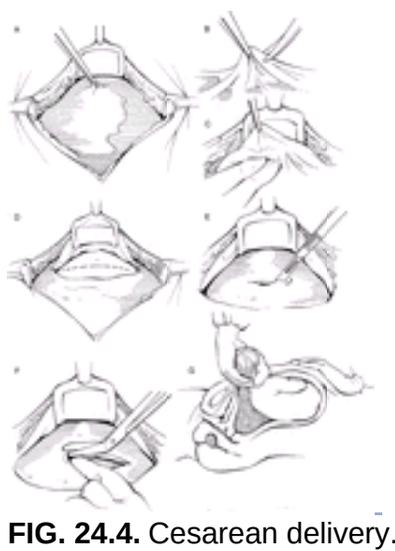

FIG. 24.4. Cesarean delivery. **A:** Reflection of peritoneum from the serosa of the uterus to the bladder is identified. **B:** Peritoneal reflection between the uterus and

bladder is elevated and incised. **C:** The bladder is displaced away from the lower uterine segment. **D:** The bladder is retracted, and the incision is planned to be 2 to 3 cm below the peritoneal incision. **E:** A small incision is made through the uterine wall to the fetal membranes. **F:** A uterine incision is made in a curvilinear shape, using bandage scissors. **G:** The fetal head is elevated through the uterine incision by the operator's hand.

An alternative method of opening the uterus in a woman with an adequately developed lower uterine segment is to make a shallow curvilinear incision through the pubocervical fascia to the fetal membranes. Inserting both index fingers into the opening, the operator pulls laterally, bluntly opening the uterus. The operator ruptures membranes and inserts one hand beneath the lower edge of the uterine incision to feel the presenting fetal part. If vertex, the occiput is identified, and the head is flexed and brought into the uterine incision (Fig. 24.4G). The assistant or operator exerts fundal pressure to deliver the fetal head gently through the incision, after which an assistant suctions the mouth and nares with a bulb syringe while the operator continues to deliver the shoulders gently in a manner similar to that of a vaginal delivery. Specially designed forceps or a vectis also can be used to deliver the head through the uterine incision.

After delivery, the umbilical cord is clamped and divided, and the infant is handed off the operative field. Although spontaneous delivery of the placenta is preferable, it may be removed manually by blunt separation from the uterine wall. The uterine cavity is inspected for any structural abnormality, and retained placental tissue and membranes are removed. Dilation of the endocervical canal from above is usually unnecessary. Following delivery of the placenta, oxytocin should be administered to stimulate uterine contractions and reduce bleeding.

The cut edges of the uterine incision may be grasped with ring forceps or other noncrushing clamps for traction and to control bleeding. The uterine incision may be closed with a one-layer or two-layer technique (Fig. 24.5A and Fig. 24.5B). With the exception of a shorter operating time using the one-layer technique, neither has been found superior to the other. Persistent bleeding in the incision line may be controlled with interrupted figure-of-eight sutures or electrocautery. Inspection of the uterine incision and surrounding organs should be followed by removal of abdominal packs and lavage and suctioning to remove any residual blood, amniotic fluid, or meconium. If desired, surgical sterilization via tubal ligation may be performed at this point. It adds little time or morbidity to cesarean delivery and does not significantly prolong postpartum recovery. The Pomeroy method is the simplest sterilization technique and gives satisfactory results.

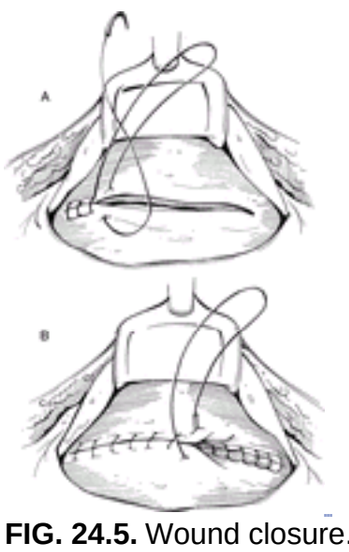

FIG. 24.5. Wound closure. **A:** First layer of closure. **B:** Second layer of closure.

The abdominal incision is closed most commonly with a delayed-absorbable synthetic suture, although a nonabsorbable suture is also acceptable in high-risk groups. A mass-layer closure should be considered for vertical incisions, especially in patients at high risk of disruption.

Postoperative management is similar to that of any patient who has had major surgery, including removal of the urinary catheter on the first postoperative day, oral feedings advanced as tolerated, and early ambulation to avoid thromboembolism. Most women are ready for discharge on the third postoperative day, although hospitalization should be continued if clinically indicated and documented by the physician in the patient's record.

Closure of the Classic Incision

The thickness of the upper uterine wall sometimes requires a three-layer closure to and including the serosa. Continuous suture techniques may be used, but interrupted sutures frequently give a more exact closure. The first layer should include about half the thickness of the wall and can be continuous or figures-of-eight. A second continuous layer is placed to avoid leaving a space between the layers. The third layer should close the serosa in a manner that minimizes exposed raw surfaces using continuous, unlocked absorbable suture. Each bite of the needle should begin on the raw surface of the wound and exit through the serosa a few millimeters from the cut edge. With this technique, sometimes referred to as a baseball stitch, the cut edge is infolded, and the serosa is on the surface.

Techniques for Difficult Cesarean Deliveries

After a prolonged obstructed labor, the fetal head often is impacted in the midpelvis. Manipulation of an impacted fetal head may result in damage to a thinned and elongated lower uterine segment, with extension of the incision into the cervix or broad ligament and laceration of uterine vessels. The vaginally placed hand of an assistant pushing upward can facilitate dislodgement of the fetal head.

Most malpresentations can be delivered safely through a low transverse uterine incision extended widely to deliver the aftercoming head. However, this may impossible with a preterm malpresentation or other circumstances such as placenta previa. If the lower uterine segment is too narrow to accommodate a transverse incision, a vertical incision should be performed, even if it extends into the uterine corpus.

Incision of the uterus through the maternal surface of the placenta can result in considerable hemorrhage. The operator should continue quickly to extend the incision for delivery of the fetus but not cut or fracture the placenta, because disruption of chorionic vessels may result in fetal hemorrhage. Instead, the placenta should be separated from the uterine wall to allow access to the fetal membranes so that rupture may occur and the fetus may be delivered. Occasionally, an internal podalic version and breech extraction are necessary.

POSTMORTEM CESAREAN DELIVERY

Most obstetricians will never be forced to decide whether or not postmortem cesarean is necessary. Nevertheless, all should be familiar with the general principles. First, the certainty of maternal death must be clinically established quickly and preferably confirmed by electrocardiographic or electroencephalographic findings. Documentation of fetal well-being before deciding on delivery may give erroneous information, because the time from apparent fetal death to actual fetal death or serious damage is unknown. Second, the abdomen and uterus should be opened rapidly, ignoring aseptic precautions. Third, the fetus must be delivered quickly, given immediate resuscitation, and transferred to an intensive care nursery. Finally, the placenta should be removed and the uterus and abdomen closed.

The outlook for the infant is improved if delivery occurs before maternal death, and survival continues to be possible if delivery is accomplished within 10 minutes of maternal death. Unfortunately, the degree of damage from cerebral hypoxia is difficult to predict and the prognosis for the fetus is usually ominous. Uncommonly, a mother who opposes fetal intervention dies before giving birth, thereby presenting the obstetrician with an ethical dilemma.

PRIMARY ELECTIVE CESAREAN

Performing a cesarean delivery solely because the patient desires to avoid labor would have seemed unthinkable 20 years ago. However, in recent years a growing number of patients and physicians have supported the notion that women have the right to choose elective cesarean rather than go through the rigors of labor, regardless of any obstetric or medical indication. Proponents reason that women have the right to choose their method of delivery because of the inconveniences of unscheduled labor and the possibility that vaginal delivery may result in pelvic support disorders. The practice of performing primary cesarean delivery for these reasons has gained wide acceptance in some parts of the world among women of higher socioeconomic status.

Although cesarean delivery in modern obstetrics is considered a safe procedure, recovery time and the risk of thromboembolic episodes and infections are still higher with cesarean birth than with vaginal birth. Furthermore, although most elective surgeries are done only once, a primary cesarean often is followed by repeat cesarean deliveries, with morbidity increasing with each birth. The risks of complications such as uterine rupture, placenta previa, and placenta accreta increase proportionately with the number of cesareans performed. All may result in severe hemorrhage, postpartum hysterectomy, urologic and bowel injury, and even maternal death.

The controversy surrounding primary elective cesarean delivery will not be resolved unless adequate controlled studies are performed. Until that time, the decision to perform cesarean delivery on demand should be made only after careful consideration of all of the risks involved.

VAGINAL BIRTH AFTER PREVIOUS CESAREAN

The rising number of women undergoing elective repeat cesarean has been one of the principal reasons for the steady increase in the cesarean delivery rate in the United States during the last 30 years. Not surprisingly, several governmental and professional organizations have advocated a trial of labor (TOL) in all women with a prior cesarean. Based on the results of early studies comparing VBAC with repeat cesarean, VBAC appeared to be successful in 60% to 80% of women undergoing TOL. Uterine rupture, the most serious potential complication of attempted VBAC, appeared to be a rare event with few consequences. However, the results of more recent prospective trials indicate that a decision to undergo a TOL after previous cesarean is not as straightforward as it once seemed.

Safety

Most of the emerging body of literature comparing VBAC with repeat cesarean suggests that a TOL should be offered to thoughtfully selected candidates. Contraindications include a classic scar, a low vertical scar that extends into the upper segment of the uterus, previous uterine rupture, and a T-shaped scar. Other factors that may increase the likelihood of uterine rupture include two or more prior cesarean deliveries, macrosomia, induction of labor, the presence of müllerian anomalies, and postdatism. The patient should be aware that problems could arise during her pregnancy that could necessitate repeat cesarean delivery.

Some minor complications may be more common in women who undergo repeat cesarean. However, the most recent meta-analysis of retrospective and prospective series comparing VBAC with repeat cesarean has showed that most major complications are more likely for women who attempt VBAC (Fig. 24.6). Most complications occur in women with a failed TOL, especially if an emergency cesarean is necessary.

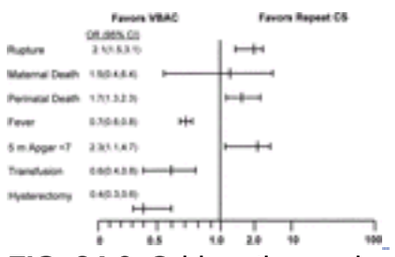

FIG. 24.6. Odds ratio graph comparing morbidity of trial of labor versus elective repeat cesarean delivery.

The degree of perinatal morbidity and mortality after a failed TOL, especially in cases of uterine rupture, has been under-appreciated until recently (see Fig. 24.6). In theory, fetal damage is minimized if delivery can be accomplished expeditiously. However, fetal damage can occur even if delivery occurs less than 18 minutes after uterine rupture. Furthermore, immediate delivery requires around-the-clock in-hospital obstetric and anesthesia coverage, typically available only in large university or tertiary level centers. In one survey, anesthesiologists were available in-hospital on nights and weekends in only 26% of hospitals with 500 to 1,499 births per year, and in only 3% of those with fewer than 500 births per year. Although the absolute risk of perinatal death associated with VBAC is low (12.9 per 10,000), it is significantly greater than with elective cesarean, especially if uterine rupture occurs.

Success of Labor

In most published series, 60% to 80% of women who attempt VBAC have successful vaginal births. However, many of these studies have included only women who meet strict inclusion criteria, excluding those who otherwise would be considered VBAC candidates in clinical practice. Based on the available evidence, the probability of successful VBAC for women whose first cesarean was done for a nonrecurring indication is similar to the probability of vaginal delivery in all laboring patients. Moreover, their probability of success is improved if they also have had a previous vaginal delivery, regardless of whether or not it was before their first cesarean birth or was a successful VBAC. In contrast, successful VBAC is less likely for women whose primary cesareans were performed for labor dystocia (50%–70%).

Vaginal Birth After Cesarean in Obstetric Practice

Counseling Potential Candidates for VBAC Only women who meet specific criteria and who can deliver in appropriate facilities should be offered VBAC (Table 24.3). Initial evaluation includes a search for contraindications to VBAC and review of medical records if the type of previous incision is unknown (Table 24.4). Once this evaluation is complete, thorough, impartial, and factual counseling should be given and reviewed at intervals during pregnancy. Notably, the probability of achieving a successful VBAC and the magnitude of the maternal and perinatal risks associated with a failed TOL should be discussed with each potential candidate and documented in the prenatal record. Support and encouragement should be given regardless of the decision made. Global mandates for TOL after previous cesarean are inappropriate, because individual risk factors are not considered.

1. One or two prior cesarean deliveries
2. Clinically adequate pelvis in relation to fetal size
3. No other uterine scars, anomalies, or previous rupture
4. Patient consent
5. Physician capable of monitoring labor and performing an emergency cesarean delivery immediately available throughout active labor
6. Availability of anesthesia and personnel for emergency cesarean

TABLE 24.3. *Criteria for vaginal birth after cesarean*

1. Prior classic or T-shaped incision or other transmural uterine surgery
2. Contracted pelvis
3. Medical or obstetric complication that precludes vaginal delivery
4. Patient refusal
5. Inability to immediately perform emergency cesarean because of unavailable surgeon or anesthesia personnel, inadequate staff or facility

TABLE 24.4. *Contraindications to vaginal birth after cesarean*

Intrapartum Management A TOL after previous cesarean should be conducted in facilities where anesthesia, obstetric, and blood bank personnel are immediately available. Each hospital should develop a protocol for management of VBAC (Fig. 24.7). One reasonable approach to the initial evaluation of a woman attempting VBAC includes the following measures:

FIG. 24.7. Flow sheet showing one management scheme for vaginal birth after cesarean.

- Intravenous access on admission
- Blood count, type and screen
- Nothing by mouth
- Continuous electronic fetal monitoring
- Alert anesthesia, obstetric, and neonatal personnel

Once labor has begun, women attempting VBAC should be frequently evaluated and monitored. Most authorities recommend continuous electronic fetal heart rate monitoring during labor. Personnel who are familiar with the potential complications of VBAC should be present to watch closely for fetal distress and inadequate progress of labor.
Induction and Augmentation Spontaneous labor is preferable to labor induction and augmentation in any woman who is attempting a TOL after a previous cesarean delivery. Several series have documented increased rates of failure, as well as uterine rupture, in women who have had a previous cesarean and who are undergoing labor induction or augmentation, especially if prostaglandin preparations are employed as cervical ripening agents. The use of misoprostol is of particular concern.
Analgesia There are few contraindications to epidural anesthesia, and adequate pain relief may encourage a greater number of women to choose TOL over repeat cesarean. Epidural analgesia rarely masks the signs and symptoms of uterine rupture, and success rates for VBAC are similar to those experienced by women who receive other types of pain relief.

Uterine Rupture

Uterine rupture, the most serious complication of VBAC, is often life threatening for both mother and baby. Incomplete or partial rupture refers to an opening of the previous scar but not the overlying peritoneum. This includes extrusion of intrauterine contents into the broad ligament. A complete rupture is a separation of the previous scar *and* overlying peritoneum with extrusion of intrauterine contents into the abdominal cavity. Scar dehiscence is defined as an *opening of the previous scar with intact overlying visceral peritoneum and no expulsion of intrauterine contents* (also termed a *window*).

Intrapartum uterine ruptures requiring emergency treatment occur in approximately 0.5% of patients with a transverse low-segment scar. The rupture usually involves the old scar and lower uterine segment but may be stellate and extend intraperitoneally or retroperitoneally. Contributing factors include induction with oxytocin or prostaglandin preparations, dysfunctional labor, more than one prior cesarean delivery, high parity, and even previous perforation of the nonpregnant uterus by curettage, hysteroscopy, metroplasty, and myomectomy.

Diagnosis The signs and symptoms of uterine rupture may be surprisingly subtle. However, the diagnosis soon becomes apparent as the maternal or fetal condition, or both, deteriorate. Fetal heart rate pattern abnormalities are identified with uterine rupture most consistently, although none is specific. A common scenario involves variable decelerations that evolve rapidly into late decelerations, bradycardia, and undetectable fetal heart tones (Fig. 24.8). Hence, all fetal heart rate pattern abnormalities exhibited by women attempting VBAC should be investigated thoroughly.

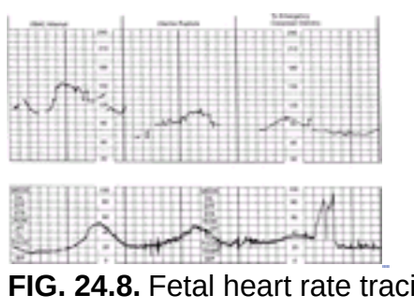

FIG. 24.8. Fetal heart rate tracing shows changes in pattern during uterine rupture.

Other clinical findings of uterine rupture include uterine or abdominal pain, which usually occurs in the area of the previous incision, may range from mild to severe, and sometimes is described as a *tearing* sensation. Uterine contractions often diminish in intensity and frequency, although no rupture-specific pattern has been identified. Vaginal or intraabdominal bleeding is associated with anxiety, restlessness, weakness, dizziness, gross hematuria, shoulder pain, and shock. Loss of station of the presenting part is diagnostic but not essential for the diagnosis.
Management Women who are suspected of having uterine rupture should undergo immediate exploratory laparotomy and cesarean delivery. Perinatal outcome is dependent on the severity of the rupture and its relationship to the placenta and umbilical cord. Damage to the placenta or umbilical cord may lead quickly to hypoxemia, permanent end-organ dysfunction, and fetal death. Fetal extrusion into the abdominal cavity is particularly detrimental. Once delivery has been accomplished, repair of the uterine defect is possible in many cases and may be considered if it appears technically feasible, if the patient wants to retain fertility, or if her condition is not jeopardized by continued hemorrhage. The wound edge should be debrided before reapproximation followed by closure similar to that used for cesarean delivery. Hysterectomy is required if there has been extension into the broad ligament vessels, extensive damage to the uterine myometrium, or in the presence of placenta accreta.
Pregnancies After Uterine Rupture If the site of the ruptured scar is confined to the lower segment, the rate of repeat rupture or dehiscence in labor is 6%. In contrast, if the upper segment is involved, the rate jumps to 32%. Therefore, women with prior uterine rupture are best delivered by repeat cesarean as soon as the fetus is mature or at 36 to 37 weeks of gestation, before the onset of labor.

CESAREAN HYSTERECTOMY

Indications

Occasionally, hysterectomy must be performed immediately after cesarean or vaginal delivery. A useful classification is based on emergency indications (e.g., uterine rupture, uncontrollable uterine hemorrhage, placenta accreta, uterine infection) and nonemergency indications (e.g., for significant uterine pathology such as carcinoma in situ or uterine leiomyomas).

Emergency Indications Uncontrollable uterine hemorrhage may result from uterine rupture, uterine atony, placenta accreta, placental site sinusoids after placenta previa, or a coagulation defect. When surgery is indicated to control hemorrhage of uterine origin, the patient's desire to preserve childbearing capacity and the current danger are assessed. Nonsurgical management is indicated in such circumstances as uterine atony and coagulation defect. Bimanual uterine massage, oxytocin, prostaglandin administration, and blood replacement should be used before surgical intervention is considered. Hemorrhage from lower uterine segment venous sinuses associated with placenta previa sometimes can be controlled with mattress or figure-of-eight 2-0 to 0 absorbable sutures. With uterine atony, surgical interruption of the arterial flow to the uterus may be tried as the first measure of control. The operator may proceed to bilateral ligation of the hypogastric or the uterine arteries. If this is not efficacious, hysterectomy may be necessary. Hysterectomy can also be lifesaving as treatment of severe uterine infection. The patient who has experienced a second-trimester septic abortion with septic shock, peritonitis, or uterine perforation may be saved by prompt hysterectomy. Clostridial infection, dehiscence of a classic incision with uterine infection, or a severe uterine infection unresponsive to antibiotics should also be treated by hysterectomy.
Nonemergency Indications The risks and benefits of hysterectomy for nonemergency indications are much less certain than for emergency conditions. Hysterectomy performed at term is associated with hemorrhage, infection, thromboembolism, and injury to contiguous organs. The declining use of hysterectomy despite an increase in the incidence of cesarean delivery reflects a generally accepted conservative approach in most situations. Tubal ligation is a safer operation at term than is

hysterectomy. When carcinoma in situ must be treated, removal of the cervix at the time of hysterectomy is much more certain and technically less complicated in the nonpregnant state. The decision to perform a nonemergency hysterectomy requires good judgment, which is based on existing skills, facilities, and the needs of the individual patient.

Procedure

The technique for hysterectomy is described elsewhere, but some points are especially pertinent to its performance immediately after cesarean or vaginal delivery. In general, blood is conserved if the uterine wound for cesarean delivery is closed rapidly before beginning the hysterectomy. Normal ovaries should be preserved, and the operator should be aware that the relative shortening of the uteroovarian ligament at term necessitates extra care in the placement of clamps and sutures in this area. The increased vascularity of the pregnant uterus requires considerable care in the correct placement of clamps and sutures.

In the uterus at term, palpation of the portio of the cervix is often difficult, and portions of the cervix may be left behind inadvertently at the time of hysterectomy. This may be avoided by vaginal placement of easily palpated clips or clamps on the cervix prior to surgery. Alternatively, a vertical incision can be made in the lower uterine segment and extended caudad until the limits of the cervix are identified. Drainage of the pelvic cavity may be necessary, depending on the adequacy of hemostasis. In emergent situations or when the patient is unstable, a supracervical hysterectomy is simpler and quicker and may be preferable to total hysterectomy.

SUMMARY POINTS

- Cesarean delivery has played a major role in lowering both maternal and perinatal morbidity and mortality.
- Cesarean birth is necessary whenever labor is unsafe for either mother or fetus, when labor cannot be induced, when dystocia or fetal problems present significant risks with vaginal delivery, and when an emergency mandates immediate delivery.
- A variety of postpartum complications—including unexplained fever, endometritis, wound infection, hemorrhage, aspiration, atelectasis, urinary tract infection, and venous thromboembolism—occur in up to 25% of women who undergo cesarean delivery.
- The risk of late complications of cesarean, including uterine rupture, placenta previa, and placenta accreta, is directly proportional to the number of previous cesarean deliveries.
- The preferred and most frequently used is the low transverse incision.
- The decision to perform cesarean delivery on demand should be made only after careful consideration of all of the risks involved.
- A TOL after cesarean is safest in patients with only previous low transverse incisions.
- A TOL after cesarean preferably is undertaken in facilities where an immediate emergent cesarean can be performed.
- Women whose primary cesarean was performed for a nonrecurring condition have a better chance of success than women whose primary cesarean was performed for labor dystocia.
- Major complications occur more often in women who have a failed TOL after cesarean than in those who have an elective repeat cesarean.
- The most devastating complication of VBAC is uterine rupture, occurring in 0.5% of all women who attempt a TOL after cesarean.
- Uterine rupture during a TOL after cesarean often results in fetal damage or death, even if delivery is accomplished quickly.

SUGGESTED READINGS

The critically ill obstetric patient presents unique challenges to the clinician. Pregnancy alters the function of virtually every organ system; thus, both the baseline state and the patient's response to physiologic aberrations are different in the pregnant patient compared with her nonpregnant counterpart. In addition, fetal considerations often are important in designing a diagnostic and therapeutic approach to the critically ill gravida. Numerous situations may be encountered in which the physiologic demands of mother and fetus may be opposite. Many of the principles that apply to the critically ill nongravid patient apply in pregnancy, as well. This chapter explores a number of conditions in critical care medicine that are unique to pregnancy.

SHOCK IN PREGNANCY

Shock encompasses various pathophysiologic aberrations that lead to inadequate tissue perfusion and impaired cellular metabolism. Although hypotension often is the most obvious clinical sign in shock of any cause, such blood pressure changes are the final common manifestation of a number of distinct pathologic processes. The successful clinical management of patients in shock depends on the proper definition of the underlying pathophysiology, as well as an understanding of the unique effects of pregnancy on such conditions.

Several types of shock have been defined. This chapter focuses on the pathophysiology, diagnosis, and treatment of hypovolemic and septic shock, the types most commonly encountered in the pregnant patient.

In the nonpregnant patient, hypotension generally is defined as a systolic blood pressure less than 90 mm Hg or a mean arterial pressure less than 60 mm Hg. During pregnancy, this definition has less value, because blood pressures as low as 80/50 mm Hg commonly are seen in healthy pregnant women. Further, although a mean arterial pressure of 60 mm Hg may be adequate for perfusion of the adult heart and brain in a nonpregnant adult, the effects of a given blood pressure on uteroplacental perfusion cannot easily be generalized but are related to gestational age and placental condition. Whereas a blood pressure of 80/50 mm Hg may be adequate in one pregnant woman, another woman with pregnancy-induced hypertension and uteroplacental insufficiency may suffer inadequate placental perfusion and fetal distress with a diastolic blood pressure of 90 mm Hg. During pregnancy, shock is more reliably diagnosed on the basis of the overall clinical picture, including heart rate, mental status, urine output, and fetal condition, than on the basis of any absolute arterial pressure.

HYPOVOLEMIC SHOCK

Despite the availability of modern blood banking techniques, hemorrhage remains a major cause of maternal mortality. Pertinent physiologic changes that affect a woman's response to hemorrhage during pregnancy include a 50% increase in plasma volume with slightly lesser increases in circulating red blood cell mass. These changes, as well as an increase in resting heart rate of 10 beats per minute, result in about a 50% increase in resting cardiac output in the term gravida compared with her nonpregnant counterpart. Such changes are accompanied by a decrease in systemic vascular resistance, resulting in a net decrease in mean arterial pressure during the second trimester. At term, an average of 500 milliliters of blood is lost with vaginal delivery, compared with a mean blood loss of 1,000 milliliters with cesarean section. Such losses usually are well tolerated by the pregnant woman because of the physiologic hypervolemia.

Early in the course of massive hemorrhage, there are decreases in mean arterial pressure, cardiac output, central venous pressure, pulmonary capillary wedge pressure (PCWP), stroke volumes, and oxygen consumption and increases in arterial venous oxygen content difference. These changes are accompanied by compensatory increases in heart rate, systemic and pulmonary vascular resistance, and myocardial contractility. In addition, the redistribution of cardiac output and blood volume result in diminished perfusion to the kidneys, gastrointestinal tract, skin, and uterus, with relative maintenance of blood flow to the heart and brain. In the pregnant patient, such redistribution may result in fetal hypoxia and distress, even in the absence of an overt maternal hypotension. To some extent, the fetus acts like a miner's canary: regardless of absolute maternal blood pressure, significant maternal shock is virtually never seen in the presence of a reassuring fetal heart rate pattern. During this initial phase, initial oxygen extraction by the maternal tissues is increased. Further maldistribution of blood flow results in local tissue hypoxia and metabolic acidemia. If not promptly corrected, such shunting of blood from the renal and splanchnic beds may result in acute tubular necrosis and may contribute to pulmonary capillary endothelial damage, resulting in the adult respiratory distress syndrome (ARDS) even if resuscitation eventually is successful. In a similar manner, such tissue hypoxia and damage may give rise to thromboplastin release resulting in disseminated intravascular coagulation (DIC). Hemorrhagic shock also has been demonstrated to suppress bone marrow hematopoiesis. Once such shock has progressed to the point of end-organ failure, secondary consumptive coagulopathy, and depressed hematopoiesis, survival may not be possible even with adequate replacement of volume, red blood cells, and clotting factors.

As the blood volume deficit exceeds 25% to 30%, the compensatory mechanisms begin to become inadequate to maintain cardiac output and blood pressure. At this point, additional losses of blood may result in rapid clinical deterioration that produces a cycle of cellular death and vasoconstriction leading to organ ischemia, loss of capillary membrane integrity, and additional loss of intravascular fluid volume to the extravascular spaces. Thus, time is of the essence in restoring hemodynamic and oxygenation parameters to normal if survival is to be optimized.

The management of the patient in hemorrhagic hypovolemic shock is directed toward two goals: restoring circulating blood volume and eliminating the source of hemorrhage. The management of the most common causes of obstetric hemorrhage (e.g., lacerations, retained placenta, uterine atony) is described in detail elsewhere. The therapeutic restoration of circulating blood volume begins with a rapid infusion of crystalloid solution and packed red blood cells. These maneuvers form the cornerstone of therapy for hemorrhagic shock. Patients with normally functioning hearts may respond better to hypovolemic shock with blood volume replacements that are 500 to 1,000 milliliters in excess of their predicted norm. Such expansion dilates the constricted capillary networks that persist from the initial hypotensive phase and assists in resolving acidosis at the cellular level.

Continued replacement of blood with crystalloid solutions and packed red blood cells alone results in eventual depletion of labile clotting factors and platelets and may result in a dilutional coagulopathy which, itself, may contribute to further bleeding. This is to be distinguished from the consumptive coagulopathy which also may arise secondary to shock and tissue damage. A fibrinogen level below 100 milligrams per deciliter or prolongation of the prothrombin and active partial thromboplastin times in a bleeding patient are indications for fresh frozen plasma infusion. Platelet transfusion should be guided by platelet counts. One unit of platelets raises the platelet count by 8,000 to 10,000 per cubic millimeter and should be considered in a bleeding patient with a platelet count below 30,000 per cubic millimeter.

SEPTIC SHOCK

The incidence of septic shock appears to be increasing. Septic shock accompanies up to 50% of bacteremias caused by Gram-negative organisms and 5% of those caused by Gram-positive organisms. In the overall hospital population, once clinical shock is evident, the mortality rate is 40% to 50%. Although pregnancy classically has been considered a factor that predisposes a patient to septic shock, data to support this are lacking. It seems more likely that such older observations stemmed from delayed diagnosis and treatment in the pregnant patient. In obstetrics, septic abortion, chorioamnionitis, pyelonephritis, and endometritis are the most common conditions associated with septic shock. Postpartum infection with group A streptococcus is increasingly recognized as an uncommon, but potentially lethal, complication of the puerperium, a condition made more serious by the virulent nature of this infection and its rather protean clinical manifestations. Although it may be presumed that with a younger population, the mortality with septic shock is somewhat less than in the overall population, this condition continues to account for a significant percentage of maternal mortality.

Septic shock in obstetrics most commonly is associated with infection caused by endotoxin-releasing Gram-negative aerobic coliform organisms. Endotoxin, a complex cell wall–associated lipopolysaccharide, is released into the circulation at the time of bacterial death, resulting in multiple hemodynamic effects. The subsequent activation of lymphocytic T cells and mast cells results in histamine and kinin activation, as well as the activation of kallikrein and a decrease in kallikreinogen and kallikrein inhibitor. These changes result in the release of bradykinin, a potent arterial dilator. Complement activation and the release of arachidonic acid metabolites, nitric oxide, endorphins, and other endogenous mediators play a major role in the pathophysiology of septic shock. In addition, septic shock results in a marked reduction of vasopressin (antidiuretic hormone) levels, further impairing the body's vasoconstrictive response and capacity for intravascular fluid retention. This generalized inflammatory response, similar to that seen with other conditions such as anaphylaxis, is responsible for much of the pathophysiology seen with these conditions and has been termed the systemic inflammatory response syndrome.

Early septic shock is a classic example of distributive shock, related to a systemic maldistribution of relatively normal, or even increased, cardiac output. Clinical findings include hypotension, fever, and chills. Initial hemodynamic findings include decreased systemic vascular resistance and high-normal or elevated cardiac output. The continued maldistribution of cardiac output leads to local tissue hypoxia and the development of lactic acidosis and end-organ dysfunction. This decrease in systemic vascular resistance is caused by the release of vasoactive substances, as well as by vascular endothelial cell injury, which promotes capillary plugging secondary to complement-induced leukocyte aggregation. These factors lead to increased arteriovenous shunting.

The treatment of septic shock in this early phase involves optimizing preload by restoring relative intravascular volume with crystalloid infusion, as well as aggressively treating the underlying infection. Although some authorities advocate the use of colloid solutions for volume replacement, there is no convincing evidence that the use of such solutions decreases the incidence of pulmonary edema or ARDS. If the offending organism is known, single-agent antibiotic therapy may be used. More commonly in obstetrics, the infection is polymicrobial, and broad-spectrum coverage for Gram-negative and Gram-positive aerobic and anaerobic organisms is most appropriate. If an abscess is involved, prompt surgical drainage after initial resuscitation is mandatory.

If the process continues, the patient may enter a second hemodynamic phase of septic shock. Of primary importance in this late phase is the development and progression of myocardial dysfunction leading to ventricular failure. Although commonly viewed as a late finding, studies assessing stroke work index and ventricular ejection fraction have demonstrated depressed intrinsic ventricular function even in the early stages of septic shock, when increases in heart rate are compensatory and associated with a normal or high cardiac output. This myocardial depression is a direct effect of myocardial depressant substance in the serum of patients with septic shock. When ventricular function has deteriorated to the point in which cardiac index is frankly depressed (i.e., <3–4 L/min per m^2 in pregnancy) in the presence of adequate preload, the prognosis is extremely grave. Pulmonary hypertension, another important hemodynamic alteration often associated with septic shock, may have additional profound hemodynamic consequences.

For most pregnant patients in septic shock, maximal ventricular function is obtained by means of optimizing Starling forces with a PCWP of about 16 mm Hg. Patients who remain hypotensive after such preload manipulation require treatment with pressor agents such as dopamine hydrochloride. This agent, in dosages of less than 5 micrograms per kilogram per minute, improves renal blood flow by way of dopaminergic mesenteric vasodilation; in dosages of 5 to 30 micrograms per kilogram per minute, a positive inotropic effect also is seen. In dosages that exceed 30 micrograms per kilogram per minute, the favorable effect on blood pressure is principally one of a-adrenergic vasoconstriction. Additional inotropic or vasoconstrictive agents may need to be administered in refractory septic shock. Treatment with vasopressin has been effective in improving urine output, decreasing pulmonary vascular resistance, and reducing the need for additional pressor agents. Initial studies suggest the infusion of methylene blue (an inhibitor of nitric oxide synthesis) may prove effective in counteracting myocardial depression, maintaining oxygen transport, and reducing the need for additional adrenergic support. The use of glucocorticoids in septic shock continues to unfold. Original enthusiasm for early, high-dose steroid treatment in patients with septic shock was followed by well-designed studies demonstrating not only a lack of benefit, but potential harm, from such therapy. More recently, the demonstration of an altered hypothalamic–pituitary–adrenal axis in patients with septic shock have led to additional investigations suggesting that lower-dosage replacement therapy with hydrocortisone may be beneficial, by interfering with the physiologic expression of the systemic inflammatory response syndrome.

The hemodynamic manipulation of patients whose hypotension fails to respond rapidly to volume infusion may, at times, be assisted by pulmonary artery catheterization, allowing the clinician to achieve optimal preload before the institution of inotropic or vasoconstrictive therapy.

Patients who recover from the initial hemodynamic instability of septic shock may suffer prolonged morbidity secondary to endotoxin-mediated pulmonary capillary injury and noncardiogenic pulmonary edema (i.e., ARDS). Such lung failure is a major cause of death in patients with septic shock. Similarly, pregnant patients whose hypotension was prolonged may experience acute tubular necrosis. Endotoxin-mediated endothelial cell injury and associated thromboplastin-like activity, as well as prolonged shock from any cause, may also lead to activation of the coagulation cascade and to a clinical picture of DIC. Even in the absence of frank tissue hypoxia, septic stimuli may lead to coagulation abnormalities.

Of special interest to obstetricians is the demonstration that, in patients in septic shock, *adult* heart rate variability is diminished; such observations have been suggested as potentially useful in the diagnosis of adult septic shock.

FETAL RESPONSE TO MATERNAL HEMODYNAMIC INSTABILITY

Fetal well-being depends principally on the maintenance of maternal oxygenation and uterine blood flow. During severe fetal hypoxia, cardiac output decreases and pulmonary vasoconstriction occurs, with redistribution of the fetal circulation favoring blood flow to the brain, heart, and adrenals at the expense of splanchnic and even placental blood flow. Although Starling's law is operative in the fetus, ventricular stroke work varies over a much smaller range of end-diastolic pressures. Changes in cardiac output manifest themselves primarily by changes in fetal heart rate alone. As maternal arterial PO_2 falls, there appears to be no corresponding fall in fetal PO_2 as long as the maternal PO_2 exceeds 60 mm Hg. Because the fetus operates on the steep portion of the oxygen dissociation curve (Fig. 25.1) (i.e., normal fetal PO_2 range, 10–33 mm Hg), further falls in maternal and fetal PO_2 result in dramatic decreases in fetal oxygen saturation and fetal hypoxia. Unfortunately, observations using the fetal pulse oximeter have demonstrated that the administration of oxygen to the mother using most readily available oxygen delivery methods does not result in improvement in fetal oxygen saturation.

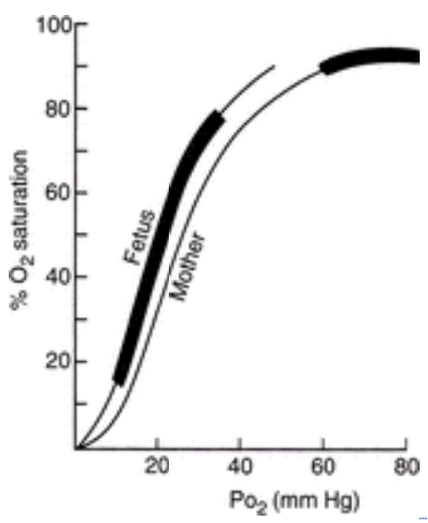

FIG. 25.1. Oxygen dissociation curves for human maternal and fetal blood, indicating the physiologic range of PO_2 and O^2 saturation for mother and fetus. (From Clark SL, Phelan JP. *Critical care obstetrics*, second ed. Boston: Blackwell Scientific, 1990:343, with permission.)

Near term, uterine blood flow approaches 500 milliliters per minute and accounts for about 10% of total maternal cardiac output. The uterine arteries show little capacity for autoregulation; thus, uterine and placental blood flow fall in direct proportion to maternal systemic arterial pressure. In the hypotensive mother, compensatory maternal vasoconstriction aimed at maintaining circulation to the heart and brain decreases uterine blood flow even further. Thus, maternal hypotension, whether caused by supine venacaval compression, conduction anesthetic, or even amniotic fluid embolism (AFE), may be first heralded by fetal bradycardia. Because maternal compensatory mechanisms maintain systemic arterial pressure at the expense of uterine blood flow, such abnormal patterns may be seen even in the absence of overt maternal hypotension. Thus, during the critical course of a gravely ill mother, careful monitoring of fetal well-being is essential. Even in a medical or surgical intensive care setting, continuous electronic fetal heart rate monitoring is often an important part of the care of the critically ill and unstable pregnant patient.

INVASIVE HEMODYNAMIC MONITORING

Since its introduction into clinical medicine in the early 1970s, the pulmonary artery catheter has come to play an important role in the management of critically ill patients with hemodynamic instability. Several prospective trials demonstrate the benefits of this technique in select, critically ill patients, including a reduction in morbidity and mortality in some subsets. On the other hand, the risk–benefit ratio of invasive monitoring in the general population of seriously ill patients has been questioned. When obstetric patients require such monitoring, optimal patient outcome is predicated on the clinician's understanding of the hemodynamic changes associated with pregnancy, as well as a working knowledge of indications for invasive hemodynamic monitoring. Although invasive hemodynamic monitoring rarely is required in the pregnant patient, an understanding of the hemodynamic principles derived from such techniques may assist the obstetrician–gynecologist in the noninvasive management of less critically ill patients.

The pulmonary artery catheter is a multilumen catheter placed most commonly through the internal jugular or subclavian vein (Fig. 25.2). As the catheter is advanced through the great vessels and heart, its location can be determined precisely by observing characteristic pressures and waveforms (Fig. 25.3). When the catheter is placed correctly, the lumens terminate in the pulmonary artery and the superior vena cava or right atrium and allow direct assessment of central venous pressure, PCWP, and pulmonary artery pressure. S_xO_2 and cardiac output can be computed either continuously or intermittently using a fiberoptic thermistor system. These measurements may be combined with mean arterial pressure and body surface area and heart rate to calculate additional important hemodynamic indices, such as systemic vascular resistance and left ventricular stroke work index (Table 25.1). In critically ill obstetric patients, discrepancies often are seen between measurements of PCWP and central venous pressure. In such circumstances, clinical use of the central venous pressure measurement alone would be misleading and possibly deleterious. With rare exceptions, the complications seen with pulmonary artery catheterization are associated with obtaining central venous access and are similar whether a central venous pressure line or pulmonary artery catheter is used. For these reasons, in a modern perinatal intensive care unit, central venous pressure monitoring alone seldom is indicated.

Determinants of Cardiac Output

In addition to heart rate, important determinants of cardiac output are preload, afterload, and an assessment of myocardial contractility.

Preload Preload represents the volume or pressure generated within the ventricles at end diastole. According to Starling's law, ventricular output is directly proportional to ventricular preload. Clinically, right ventricular preload is measured as central venous pressure, and left ventricular preload as PCWP. Because the left side of the heart perfuses the myocardium, brain, and uteroplacental unit, PCWP is the preload measurement of interest in clinical practice. When central venous pressures are used, it is done with the tacit assumption that the preloads of the right and left sides of the heart are equivalent. In a critically ill patient, this often is not the case, thus further limiting the usefulness of central venous pressure in the hemodynamically unstable obstetric patient.
Afterload Afterload describes the resistance to the flow of blood during ventricular systole. It is not measured directly; rather, after the measurement of cardiac output, central venous pressure, and mean arterial pressure, afterload is calculated as systemic vascular resistance. Cardiac output fluctuates inversely with systemic vascular resistance. Septic shock and preeclampsia are examples of frequently encountered conditions in obstetrics that may markedly influence systemic vascular resistance.
Ventricular Stroke Work Index Ventricular stroke work is also a calculated parameter (see Table 25.1). The assessment of ventricular stroke work on a modified Starling curve (Fig. 25.4) allows the clinician to directly assess the intrinsic contractility of the left ventricle and to classify myocardial function as normal, hyperdynamic, or hypodynamic. After preload has been optimized, ventricular function may be further affected by the administration of inotropic agents such as dopamine. The use of such agents may shift the intrinsic contractility of the ventricle from the hypodynamic to the normal range, resulting in improved cardiac performance (Fig. 25.5).

Indications

The indications for pulmonary artery catheterization in pregnancy include many of the conditions common to all critical care medicine. These include severe cardiac disease during labor and delivery, septic shock, and hemodynamic instability in patients with uncertain volume. Select patients with complicated severe preeclampsia form a subset unique to pregnancy. It has been suggested that patients with severe hypertension unresponsive to conventional antihypertensive medication, those with pulmonary edema of unknown cause, and those with persistent oliguria may benefit from invasive hemodynamic monitoring. In contrast, hemodynamic monitoring seldom is indicated in cases of hypovolemia associated with obstetric hemorrhage. Normal values for invasively obtained hemodynamic indices have been described and often are valuable in managing the critically ill obstetric patient (Table 25.2).

DISSEMINATED INTRAVASCULAR COAGULOPATHY (DIC) ASSOCIATED WITH PREGNANCY

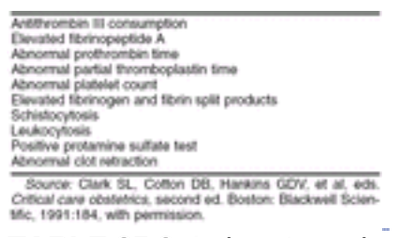
DIC is not a distinct clinical entity; rather, it represents a manifestation of various disease processes that have in common activation of intravascular clotting and fibrinolysis, resulting in excess consumption of soluble coagulation components. In obstetrics, secondary fibrinogenolysis commonly dominates the clotting aberration and results in the circulation of fibrin and fibrinolytic split products, which further accentuate the clinical picture of hemorrhage. In addition, sometimes a dilutional coagulopathy is encountered in pregnancy. This condition occurs when massive hemorrhage is replaced only by red blood cells and crystalloid solution, resulting in a dilutional depletion of platelets and soluble clotting factors. From both a clinical and a laboratory standpoint, dilutional coagulopathy may be confused with a more classic process of intravascular consumption and fibrinolysis. In practice, the hemorrhage associated with dilutional coagulopathy often results in hypotension and shock. The tissue hypoxia that accompanies shock of any cause is well known to potentially activate the coagulation–fibrinolysis cycle associated with DIC. Thus, it is not always possible to draw a clear distinction between dilutional and consumptive coagulopathy.

Pathophysiology

A number of conditions in obstetrics may trigger the intravascular coagulation–fibrinolysis sequence. All have in common some form of endothelial disruption or release of tissue thromboplastins into the central circulation. Thus, clotting may occur by either the intrinsic or the extrinsic coagulation pathways. After activation of the clotting cascade, fibrin monomer polymerizes, forming insoluble fibrin. Serum plasminogen simultaneously begins the degradation of fibrin. The breakdown products of fibrin and fibrinogen (i.e., fibrinolytic split products) then bind the soluble fibrin monomer to prevent further polymerization. In addition, plasmin inactivates factors V, VIII, IX, and XIII and inhibits the platelet-mediated primary phase of coagulation. The fibrin monomer that does polymerize is filtered within the microvasculature, resulting in fibrin plugs. Such plugging reduces blood flow, which causes tissue hypoxia and organ schemia. The subsequent endothelial damage further enhances the clotting cascade. Thrombocytopenia results from both consumption and destruction secondary to fibrinolytic split products in the microvasculature, a process that also results in microangiopathic hemolytic anemia. The release of thromboplastic material from damaged red blood cells and complement activation further propagate the vicious cycle of intravascular coagulation–fibrinolysis (see Fig. 25.5).

Diagnosis

DIC is suggested clinically by excess bleeding from surgical incision sites or the postpartum uterus. In severe cases, spontaneous bleeding from intravenous sites and other mucous membranes also may be seen. Table 25.3 lists some laboratory abnormalities that may be present in DIC. The prothrombin and partial thromboplastin times are relatively insensitive indicators of clotting status, because results are not prolonged until 40% to 50% of the clotting factors have been consumed. Although levels of fibrinolytic split products and paracoagulation tests are thought to be sensitive indicators of DIC, values may be normal in 10% to 15% of patients with acute DIC.



Antithrombin III consumption
Elevated fibrinopeptide A
Abnormal prothrombin time
Abnormal partial thromboplastin time
Abnormal platelet count
Elevated fibrinogen and fibrin split products
Schistocytosis
Leukocytosis
Positive protamine sulfate test
Abnormal clot retraction
