Pharmacological Therapy The pharmacological approach to the acutely psychotic patient is one of the most challenging and difficult in all of psychiatry. There was an era in psychiatry when there was time to observe the patient to determine whether there was a transient condition that would be self-limiting. The economic forces of today's psychiatry do not permit such an observation period and demand vigorous pharmacological intervention. Perhaps the sole remaining condition in which it would be reasonable to wait before vigorous pharmacological intervention is one that elicits a high index of suspicion of chronic amphetamine abuse, with a positive toxicology screening test result. With these patients it is probably better to wait and treat the agitation with benzodiazepines; the psychosis will usually resolve. Even among these patients will be a small but significant group who will continue with what looks like a schizophreniform or schizophrenia-like illness. Whether this group represent a subgroup of patients who were already at risk for schizophrenia or whether chronic amphetamine abuse sensitizes dopamine receptors in some patients is not known.

Given that it is not economically feasible to wait before initiating treatment, selection of the most appropriate medication becomes a critical decision. The choices basically come down to selection of an antipsychotic agent. For many years this decision involved selecting the antipsychotic agent whose side-effect profile fit the needs of the patient best. If the patient was agitated, a more sedating antipsychotic agent (e.g., chlorpromazine [Thorazine], thioridazine [Mellaril]) would be selected. If not, a less sedating, high-potency compound would be used (e.g., haloperidol, fluphenazine [Prolixin]). Both strategies, however, exposed the patient to extrapyramidal adverse effects initially and to tardive dyskinesia if long-term continuation was needed. With the use of anticholinergic medications, some of the extrapyramidal symptoms could be reduced. However, anticholinergic medications themselves have been associated with decrements in memory, executive functioning, and new learning. Therefore they are used much less frequently than previously and certainly not used routinely unless adverse effects are present. There are now other choices with the advent of the novel serotonin-dopamine antagonists. These antipsychotic agents, while considerably more expensive, hold out the advantage of fewer extrapyramidal adverse effects. They may rapidly become the medications of first choice for psychosis, because they are much better tolerated by the patient and are thus more likely to be taken over a period of time, eliminating the potential for relapse from noncompliance. The expense of readmission of a patient more than makes up for the difference in cost.

Dosage of any antipsychotic agent should be at the lowest possible level, both for adverse effect prevention and for cost. There is a tendency for medication dosages to climb in an effort to shorten the length of the psychosis. Originally, the concept of “rapid neuroleptization was a method of treatment in which a patient was given antipsychotic medication every hour until sedated. Thorough evaluation of this strategy revealed no therapeutic advantages and considerably increased risk for acute dystonic reaction. It is now widely accepted that the full resolution of a psychotic episode may take anywhere from 3 to 6 weeks. Pressure to discharge a patient well before this time certainly places considerable psychological pressure on the physician to increase the medication dosage. It is not clear that there is any advantage to doing this, and maintaining a lower dosage keeps the patient considerably less uncomfortable with adverse effects. If agitation is a problem, addition of a medium- to long-acting benzodiazepine will usually produce the desired results. Benzodiazepines are much better at sedation than are antipsychotic agents. Data suggest that use of a benzodiazepine reduces the amount of an antipsychotic agent that must be used.

A small subgroup of patients present with an acute psychotic episode that rapidly resolves. The more rapid the resolution, the more likely it is that they have a self-limited disorder. These patients will probably not meet the DSM-IV diagnosis of schizophreniform disorder with its requirement of 1 month of symptomatology.

For those whose symptoms do last 1 month or longer and who meet the criteria for schizophreniform disorder, there is a question of how long do they need to be on medication. Although no study has directly addressed this question with patients who met DSM-IV criteria for schizophreniform disorder, strategies have been tested on patients with schizophrenia who have been recruited in an acute episode. Patients who were taken off medication in the first 6 months did much worse than those who were maintained at standard dosages or those who had an 80 percent reduction of dosage. Currently, the low-dosage strategy for maintenance should be considered with the standard antipsychotic agents and probably with the serotonin-dopamine antagonists as well.

With the standard antipsychotic agents, a completely resolved psychotic episode, and full return to premorbid functioning, the usual decision point has been 6 months. This time frame was driven by the finding that almost no cases of tardive dyskinesia occur before 6 months of continuous medication. Going beyond 6 months does increase this risk. With the serotonin-dopamine antagonists, tardive dyskinesia is presumed to be a much lower risk if at all, and thus clinical judgment is needed. If a gradual tapering strategy is selected, the dosage should not be lowered more frequently than every 3 to 4 months if the physician wishes to see the effect of one dosage lowering before initiating the next. Unlike antibiotic use, for example, the infection may well return quickly after premature discontinuation of the medication, psychosis does not immediately reappear even if the medication is completely eliminated. Relapse curves from dosage-discontinuation studies are quite compelling in this regard.

BRIEF PSYCHOTIC DISORDER

History Brief psychotic disorder is a new diagnosis in DSM-IV that subsumes the former diagnostic category of brief reactive psychosis, which first appeared in DSM-II. Brief psychotic disorder is one of the least understood and least studied types of functional psychosis; most research has had methodological flaws and unclear diagnostic criteria. Historically, Karl Jaspers described the concept of a reactive psychosis in 1913. Jaspers described the essential features, which include presence of an identifiable traumatic stressor, close temporal relation between stressor and psychosis, and generally benign course of the psychotic episode.

Jaspers also believed that the content of the psychosis was related to the trauma and served some therapeutic purpose.

Comparative Nosology Over the past century myriad terms have been used to describe psychotic episodes precipitated by stressful events, including good-prognosis schizophrenia, but brief reactive psychosis had gained prominence until the DSM-IV. Compared with the DSM-III and DSM-III-R criteria that required a precipitating stressor and confusion or emotional turmoil during the episode, the new diagnosis of brief psychotic disorder is less restrictive. With its broader definition, brief psychotic disorder will presumably reduce the use of the classification “psychotic disorder not otherwise specified.” Because stressors and reactions to stressors are so ubiquitous and ill defined, reactivity to a stressor is no longer necessary for the diagnosis and is used instead as a descriptor. Scandinavian researchers have been integral in delineating this disorder, which has been gradually gaining international recognition. Conceptual generalization of the disorder is both supported and challenged by culture-bound syndromes such as koro and amok, which demonstrate significant differences while still falling under the rubric of

brief psychotic disorder. The ICD-10 classifies these symptoms as “acute and transient psychotic disorders” (see Table 13.3-1). Subtypes include “acute polymorphic psychotic disorder without symptoms of schizophrenia,” which has an overall picture of unstable, highly emotional symptoms with psychotic features that would not justify a diagnosis of schizophrenia. In contrast, the diagnosis acute polymorphic psychotic disorder with symptoms of schizophrenia also describes an unstable clinical picture, but symptoms of schizophrenia are also present for a major part of the time. If the acute picture is marked by delusions, only a diagnosis of “other acute predominately delusional psychotic disorders” can be used. Finally, any unspecified transient psychotic disorder can be designated as other or unspecified acute and transient psychotic disorders.

Epidemiology Relatively uncommon in DSM field trials, brief psychotic disorder has large discrepancies in reported incidence and prevalence rates because of methodological flaws and diagnostic variability in the literature. Its age of onset is most commonly reported to be in the late 20s or early 30s. Although reliable data on sex and sociocultural determinants are limited, preliminary data suggest a higher incidence in women and persons in developing countries. Such epidemiological patterns are sharply distinct from those of schizophrenia.

Etiology Little is known about the etiology of brief psychotic disorder. The existence of one or many events becomes the identified causative agent in psychotic disorder with marked stressor (brief reactive psychosis). Both the magnitude and the multiplicity of such stressors are posited to be important, but no well-controlled studies assessing the causal role of various types of stressors are available. Severe intrapsychic conflict (an internal stressor) may be the etiological agent for brief psychotic disorder without a marked stressor. Preexisting characterological psychopathology of either cluster A or B variety may predispose a person to development of the disorder. Many explanatory models of this increased vulnerability exist, but most are based on immature defenses and ego development as major contributors. Family studies support a genetic vulnerability to brief reactive psychosis but do not support a genetic link between this disorder and schizophrenia.

Diagnostic and Clinical Features The DSM-IV diagnostic criteria are listed in Table 13.1-4. DSM-IV defines brief psychotic disorder as impairment in reality testing lasting at least 1 day but not more than 1 month. An eventual full return to premorbid levels of functioning is required; if the diagnosis is made without waiting for the anticipated recovery, then the qualifier provision must be added. At least one of the following symptoms is present during the circumscribed illness: delusions, hallucinations, disorganized speech, disorganized behavior, or catatonia. Exclusionary criteria include the presence of a mood disorder with psychotic features, schizoaffective disorder, schizophrenia, and any psychotic disorder secondary to the direct physiological effects of a substance or a general medical condition. If symptoms occur in response to one or more events that would be markedly stressful to almost anyone in similar circumstances and within the same cultural context, then the illness bears the specifier *with marked stressor* (formerly referred to as brief psychotic disorder). Conversely, if symptoms are not in response to such an event, the specifier *without marked stressor* is applied. An additional specifier, *with postpartum onset*, indicates the onset of psychotic symptoms within 4 weeks postpartum.

A. Presence of one (or more) of the following symptoms:
(1) delusions
(2) hallucinations
(3) disorganized speech (e.g., frequent derailment or incoherence)
(4) grossly disorganized or catatonic behavior
Note: Do not include a symptom if it is a culturally sanctioned response pattern.
B. Duration of an episode of the disturbance is at least 1 day but less than 1 month, with eventual full return to premorbid level of functioning.
C. The disturbance is not better accounted for by a mood disorder with psychotic features, schizoaffective disorder, or schizophrenia and is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Specify if:
With marked stressor(s) (brief reactive psychosis): if symptoms occur shortly after and apparently in response to events that, singly or together, would be markedly stressful to almost anyone in similar circumstances in the person's culture
Without marked stressor(s): if psychotic symptoms do not occur shortly after, or are not apparently in response to events that, singly or together, would be markedly stressful to almost anyone in similar circumstances in the person's culture
With postpartum onset: if onset within 4 weeks postpartum

Table 13.1-4 DSM-IV Diagnostic Criteria for Brief Psychotic Disorder

Patients with brief psychotic disorder typically have rapid-onset psychotic symptomatology and often demonstrate emotional turmoil, confusion, or both. Prompt recovery with a full return to premorbid level of functioning within a month is dictated by definition. It is imperative to assess the impact of culture on symptom presentation prior to making the diagnosis. In the case of brief reactive psychosis, the precipitant may be one or a series of life stressors, such as the loss of an important relationship, familial disruption, or combat-related trauma. In such cases, environmental adversity combines with cultural expectations and support systems to manifest symptoms distinctly.

R.S. was a 44-year-old Haitian male admitted for observation at the local emergency room. He was agitated and combative, requiring restraints and several intramuscular doses of droperidol and lorazepam. The psychiatrist could not interview him under these acute circumstances. His mother arrived soon after and was able to give corroborative history. According to his mother the patient had just learned that his wife and two children had died in a natural disaster in Haiti. Several hours after his first evaluation, the patient was calmer. He told staff that he was hearing his wife talking to him and he wished to “join her.” He also believed the Haitian secret police were coming to arrest him. He was admitted to the inpatient ward and began a course of an antipsychotic agent. By the third day of his hospitalization there was no evidence of the previous psychosis. He was discharged from the hospital and given a follow-up appointment in 1 month. When he returned the next month he had been medication free for that time. He was grieving the loss of his family but was not psychotic. He was referred to a grief group, which he attended for the next 6 months. In that time he remained sad, but there were no other episodes of paranoia or hallucinations.

Differential Diagnosis Sharing rapid onset of symptoms, brief psychotic disorder must be differentiated from substance-induced psychotic disorders and psychotic disorders due to a general medical condition. A thorough medical evaluation including a physical examination, laboratory studies, and brain imaging will help rule out many of those conditions. With only cross-sectional information, brief psychotic disorder is difficult to differentiate from other types of functional psychosis.

The relationship between brief psychotic disorder and both schizophrenia and affective disorders remains uncertain. As noted above, DSM-IV has made the distinction between brief psychotic disorder and schizophreniform disorder clearer by now requiring a full month of psychotic symptoms for the latter. If psychotic symptoms are present longer than 1 month, the diagnoses of schizophreniform disorder, schizoaffective disorder, schizophrenia, mood disorders with psychotic features, delusional disorder, and psychotic disorder not otherwise specified need to be entertained. If psychotic symptoms of sudden onset are present for less than a month in response to an obvious stressor, the diagnosis of brief psychotic disorder is strongly suggested. Other diagnoses to differentiate include factitious disorder, malingering, and severe personality disorders, with consequent transient psychosis possible.

Course and Prognosis The course of brief psychotic disorder is found in the diagnostic criteria of DSM-IV. It is a psychotic episode that lasts more than 1 day but less than 1 month, with eventual return to premorbid level of functioning. Approximately half of patients diagnosed with brief psychotic disorder retain this diagnosis; the other half will evolve into either schizophrenia or a major affective disorder. There are no apparent distinguishing features between brief psychotic disorder, acute-onset schizophrenia, and mood disorders with psychotic features on initial presentation. Several prognostic features have been proposed to characterize the illness, but they are inconsistent across studies. The good prognostic features are similar to those found in schizophreniform disorder: acute onset of psychotic symptoms, confusion or emotional turmoil at the height of the psychotic episode, good premorbid functioning, the presence of affective symptoms, and short duration of symptoms. There is a relative dearth of information on the recurrence of brief psychotic episodes, however, so the course and prognosis of this disorder have not been well characterized.

Treatment Although no available studies directly address the treatment of brief psychotic disorder, the treatment approach should focus on the acute onset of psychotic symptoms. In particular, patient safety is of paramount importance. Depending on the danger the patient represents to self and others, psychiatric hospitalization is often warranted. A patient demonstrating acute psychotic symptoms who also displays a hostile affect or has a history of violence is particularly likely to require hospitalization. In addition to providing a safe and structured environment, hospitalization permits observational monitoring and a medical examination investigating potential etiological factors.

If medication is necessary, a high-potency antipsychotic agent in low dosage is typically recommended. An antiparkinsonism agent may be added if extrapyramidal adverse effects occur. A benzodiazepine used in combination with an antipsychotic agent can act synergistically, thereby lowering the necessary doses of each and reducing the risk of side effects. Benzodiazepines can also be used as monotherapy to reduce agitation without obscuring the clinical picture. The role of other

psychotropic medications such as mood stabilizers and antidepressants is not yet clear.

After the acute episode has subsided, long-term treatment is required. An individualized treatment strategy based on increasing problem-solving skills while strengthening the ego structure through psychotherapy, appears to be the most efficacious. Involvement of the family in the treatment process is crucial to a successful outcome and is reviewed elsewhere in this chapter. There is no role for maintenance antipsychotic treatment in brief psychotic disorder; if such treatment is required, the diagnostic assumptions must be questioned.

SUGGESTED CROSS-REFERENCES

A more detailed review of schizophrenia is presented in Chapter 12; acute and transient psychotic disorders are presented in Section 13.3. Mood disorders are covered in Chapter 14. Personality disorders are discussed in Chapter 24.

13.2 DELUSIONAL DISORDER AND SHARED PSYCHOTIC DISORDER

THEO C. MANSCHRECK, M.D., M.P.H.

Once viewed as too rare to warrant a separate classification, delusional disorder has emerged in recent years as a focus of clinical research and treatment innovation. Better definition and a growing literature have revitalized the efforts to characterize, understand, and treat these conditions. Limited but growing evidence supports not only its occurrence, but its distinctiveness from schizophrenia and mood disorder as well as its treatability. Delusional disorder refers to a group of disorders, the chief feature of which is the presence of a nonbizarre delusion. It is the delusion and the relative absence of other psychopathology that unifies these disorders in terms of natural history and impact on functioning. Once called *paranoia*, this condition as defined in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) and the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) is easier to recognize and less subject to misdiagnosis.

Despite such advances, clinicians are relatively ill-informed about delusional disorders and many have only seen an occasional example. There are several possible reasons why this is so. Persons with this condition do not regard themselves as mentally ill and actively oppose psychiatric referral. Because they may experience little impairment, they generally remain outside hospital settings, appearing reclusive, eccentric, or odd, rather than ill. If they do have contact with professionals, it is more likely to be with lawyers regarding litigious concerns; with medical specialists regarding health concerns; or with the police regarding complaints of trespass, persecution, or threat, rather than with psychiatric clinicians regarding complaints of emotional disorder. A hallmark of these disorders is that the patient does not believe that he or she is deluded or in need of psychiatric assistance. In the infrequent psychiatric encounter, clinicians tend to diagnose these disorders as other conditions, often as schizophrenia or mood disorders.

Although delusional disorders are uncommon, they are probably not as rare as previously thought. While many individuals with such disorders seek assistance from other medical specialists, judges, or the police, they are increasingly being recognized as psychiatrically ill. The relationship of these disorders to other psychoses remains unclear, and much about them is puzzling. The DSM-IV requirement of excluding other conditions is prudent given the special importance of differential diagnosis. Armed with newer and better criteria, clinical research is ongoing in areas such as natural history, pathogenesis, neuropsychology, neuroimaging, treatment, and even genetics. Although the DSM-IV criteria are not definitive, they have provided a sound basis for clinical and research investigation. Systematic studies based on larger samples of these disorders are needed to anchor classification with sound information; however, such studies may be difficult to conduct because of the large numbers of patients required and their reluctance to participate in research. A biological basis for these disorders is proposed on many grounds, but its definition remains elusive. The study of misidentification syndromes (e.g., the Capgras's syndrome) has led to interesting hypotheses and methods that draw on neuropsychological and clinical insights that may inspire progress in delusional disorders. Treatment remains an obstacle, although recent reports suggest that favorable responses to psychopharmacologic and psychotherapeutic interventions are more common than previously thought.

DEFINITION

Delusional disorder is the current classification for a group of disorders of unknown cause, the chief feature of which is the delusion (Table 13.2-1). Although the specific content of the delusion may vary from one case to the next, it is the occurrence of the delusion, its persistence, its impact on behavior, and its prognosis that unifies these seemingly different disorders. In considerable agreement with Emil Kraepelin's concept of paranoia, the revised third edition of DSM-III-R provides reliable criteria for identifying cases and collecting systematic information about these conditions. This development in classification helped to reestablish the clinical importance of this group of disorders and may have reversed a trend of infrequent diagnosis. The criteria use the term *delusional* to avoid the ambiguity of the term *paranoid* used earlier in the third edition of DSM (DSM-III) classification, *paranoid disorders*, as well as to emphasize that the category includes disorders in which delusions other than those of the persecutory or jealous type are present. Although these changes were initially confusing, especially in terms of comparisons to diagnostic approaches elsewhere, they have gained acceptance and have created a more level playing field for further empirical contributions.

Table 13.2-1 DSM-IV Definition of Delusion and Certain Common Types Associated With Delusional Disorders

In 1994 DSM-IV refined the definition and the boundaries with other disorders, including substance-induced disorders, mental disorders due to general medical conditions, mood disorders, and schizophrenia. No laboratory test exists to assist in diagnosis. The DSM-IV definition, like its predecessors, hinges on the presence of a nonbizarre delusion. DSM-IV acknowledges the difficulty of judging whether a delusion is bizarre, meaning clearly implausible, not understandable, and not derived from ordinary life experiences. In contrast, the nonbizarre delusion involves situations or circumstances that can occur in real life (e.g., being followed, infected, or deceived by a lover). DSM-IV also emphasizes the differential diagnoses of schizophrenia, mood disorders, substance-induced disorders, and mental disorders due to a general medical condition before the diagnosis of delusional disorders can be made. These conceptual refinements and demarcations from other conditions have increased the usefulness of the criteria for delusional disorder.

Delusional Disorder According to DSM-IV, the diagnosis of delusional disorder can be made when a person exhibits nonbizarre delusions of at least 1 month's duration that cannot be attributed to other psychiatric disorders. Definitions of the term *delusion* and types relevant to delusional disorders are presented in Table 13.2-1. *Nonbizarre* means that the delusions must be about situations that can occur in real life, such as being followed, infected, loved at a distance, and so on; that is, they usually have to do with phenomena that, although not real, are nonetheless possible. There are several types of delusions, and the predominant type is specified when the diagnosis is made.

In general, the patient's delusions are well systematized and have been logically developed. The person may experience auditory or visual hallucinations, but these are not prominent features. Tactile or olfactory hallucinations may be present and prominent if they are related to the delusional content or theme, examples are the

sensation of being infested by bugs or parasites, associated with delusions of infestation, and the belief that one's body odor is foul, associated with somatic delusions. The person's behavioral and emotional responses to the delusion appear to be appropriate. Impairment of functioning is not marked and personality deterioration is minimal, if it occurs at all. General behavior is neither obviously odd nor bizarre.

Shared Psychotic Disorder This unusual condition has also been called *folie à deux* and *induced or shared psychotic disorder*. It develops in an individual in the context of a close relationship with another person who has an established delusion that he or she also believes, and requires an absence of psychotic disorder prior to the onset of the induced delusion; it is usually classified with paranoid disorders.

HISTORY

Nineteenth-century psychiatry devoted much attention to the description of paranoid disorders, in which delusions are a cardinal feature. Karl Ludwig Kahlbaum's description of paranoia in 1863 was the first in a series of contributions that culminated in the classification of paranoia, and inspired that of folie à deux, morbid jealousy, the better-known schizophrenias, and mania. His work also led to a recognition that paranoid features are nonspecific characteristics of many medical diseases. Subsequent work has led to refined criteria for paranoid and related disorders and has reestablished awareness of less common paranoid presentations such as delusional disorder.

Many clinicians remember being taught that paranoia is so rare that most would not see a single such patient during an entire career. This widespread belief has compromised interest in paranoid disorders. The fact that most persons with delusional disorder live in the community and do not generally seek psychiatric care has made it difficult to carry out systematic case studies. Indeed, knowledge of these conditions has grown slowly. However, case series such as those of Alistair Munro (for delusional disorder, somatic type) or those of Nils Retterstol have been influential in shaping understanding and awareness. What they reveal is that there are persons with these disorders, that the disorders are complex forms of psychiatric illness, and that much remains to be learned.

A major change in the classification of delusional disorders in DSM-III-R and DSM-IV has been to emphasize the central role of delusions in those disorders and to steer away from the vague label of *paranoid*, which has become synonymous with *suspicious* and has come to apply largely to a personality disorder. Indeed, suspiciousness occurs in only some of these disorders. The history of the concept of paranoia indicates that lack of clarity in its use is not new. The word *paranoia* was coined by the ancient Greeks from roots meaning *beside* and *self*. Hippocrates applied this term to delirium associated with high fever, but other writers used it to describe demented conditions and madness. It sometimes meant thinking amiss, folly, and the like; hence, its meaning was unclear. For centuries the term fell into disuse until a revival of interest in the nineteenth century.

In 1863 Karl Kahlbaum classified paranoia as a separate mental illness: “a form of partial insanity, which throughout the course of the disease, principally affected the sphere of the intellect.” Influenced by the new scientific methods of empirical medicine, Kahlbaum emphasized the importance of natural history in mental illness and restricted the use of the term *paranoia* to a persistent delusional illness that remained largely unchanged throughout its course. He noted that delusions could occur in other medical and psychiatric conditions.

Emil Kraepelin found the paranoid concept troublesome and altered his thinking on it with each edition of his influential textbook. His final view advocated three types of paranoid disorder. Like Kahlbaum, Kraepelin based his conclusions on an analysis of the natural history of mental disorders, particularly on outcome, because etiology was obscure. He restricted the definition of paranoia to an uncommon, insidious, chronic illness (he saw 19 cases) characterized by a fixed delusional system, an absence of hallucinations, and a lack of deterioration of the personality. The types of delusions included persecutory, grandiose, jealous, and possibly hypochondriacal. He considered this illness to derive from defects in judgment, a disorder of personality caused by constitutional factors and environmental stress. Paraphrenia was a second paranoid disorder that developed later than dementia precox and was milder. Hallucinations (auditory in particular) occurred, but there was no mental deterioration (dementia). Finally, there was *dementia paranoides*, an illness that initially resembled paranoia but had an earlier onset and showed a deteriorating course. Because of this latter feature, Kraepelin considered dementia paranoides a form of dementia precox that arose from disorders of thought, cognition, and emotion. Kurt Mayer's follow-up of Kraepelin's 78 paraphrenia cases challenged the validity of this category because the vast majority of patients showed an outcome indistinguishable from that of dementia precox, casting doubt on the separability of this group. Karl Kolle's follow-up of Kraepelin's paranoia cases indicated some overlap with dementia precox. Kraepelin also emphasized that isolated paranoid symptoms occurred in a variety of psychiatric and medical illnesses.

Eugen Bleuler also recognized paranoia; he broadened its definition to include cases with hallucinations—a paranoid form of dementia precox for which he coined the term *schizophrenia*—and an intermediate group. However, he thought that the paranoia described by Kraepelin was so rare that it did not warrant a separate classification. Further, he argued that schizophrenic symptoms must be suspected and carefully sought even in those cases. He believed that paraphrenia and intermediate conditions were forms of schizophrenia linked by “much that was identical,” and particularly by a common disturbance in associative processes. He also emphasized that paranoid symptoms occurred in other conditions and that to label the symptoms schizophrenic required at least one of the fundamental symptoms: loosened associations, ambivalence, inappropriate affect, and autism. Bleuler's contributions reinforced a trend toward the diagnosis of paranoid illness as a form of schizophrenia.

Sigmund Freud used the autobiographical writings of Judge Daniel Schreber to illustrate the role of psychological defense mechanisms in the development of paranoid symptoms. He proposed that Schreber's illness involved a process of denial or contradiction of repressed homosexual impulses toward his father. Persecutory and other delusions result from projecting these denied yearnings onto the environment. Freud did not differentiate subtypes of paranoid disorder, and confused the issue somewhat by proposing that the term *paraphrenia* be substituted for the term *dementia precox* or *schizophrenia*. The major impact of Freud's work was to suggest hypotheses that indicated the relationship between certain delusions and personality.

Ernst Kretschmer's work on the theory of paranoia emphasized that certain sensitive personalities, characterized by depressive, pessimistic, and narcissistic traits, developed paranoid features acutely when key or precipitating experiences occurred at critical moments in their lives. He observed that these individuals did not develop schizophrenia and had a favorable prognosis. A number of other observations, predominantly but not exclusively emanating from European clinicians (e.g., the American concept of *hysterical psychosis*), proposed connections between personality and delusion development. Those efforts, based on various theories of the cause of paranoid disturbance, have persisted despite modest empirical support. Out of such work have come terms, such as *reactive* and *psychogenic psychosis*, which have figured in various classification schemes, undermining the effort to bring international consistency in definition.

Many barriers remain to international agreement on definition. For example, the term *paraphrenia*, unlike *paranoia*, has slipped into near obscurity in North America. In the United Kingdom, however, the diagnosis of late paraphrenia is often used and it is occasionally used in the United States. This term refers to cases of late-onset paranoid symptomatology not characterized by the presence of dementia, confusion, or mood disorder. Interestingly, Kraepelin did not identify a late age of onset in his cases. The potential overlap with late-onset cases of schizophrenia has been a focus of investigation and controversy. With the removal of the DSM-III age criterion for schizophrenia (upper limit of age of onset at 45) in DSM-III-R, cases of late-onset symptoms have tended to be diagnosed as schizophrenia in the United States. Nevertheless, clinical research continues to address the puzzle of whether late-onset cases, despite considerable overlap in clinical features, arise from a variety of causes.

Current controversy is based on these historical antecedents and contemporary practices. DSM-III introduced greater rigor in the assessment by requiring clearer criteria boundaries among the varied disorders with delusions. Increased awareness that delusions result from numerous conditions has had a positive influence on the diagnostic process. Yet much of current clinical and research writing on paranoid conditions has characteristically avoided defining the terms *paranoid* and *delusion*, apparently because everyone was assumed to know what these terms mean. In popular and literary usage the term *paranoid* has come to mean insane, angrily suspicious, distrustful, or irrationally irritable. However vague the concept may be, it continues to be used in clinical work. Because it is necessary to differentiate conditions with paranoid features, a useful concept of the term is fundamental. However, the nature and definition of delusions upon which modern psychopathology and psychiatry are built remain unclear.

Shared Psychotic Disorder Jules Baillarger first described the syndrome in 1860, calling it *folie à communiquée*, although the first description is commonly attributed to Ernest Charles Lasègue and Jules Falret, who described the condition in 1877 and gave it the name of *folie à deux*. The syndrome has also been called *communicated insanity, contagious insanity, infectious insanity, psychosis of association*, and *double insanity*. Marandon de Montyel divided *folie à deux* into three groups (*folie imposée, folie simultanée*, and *folie communiquée*), and Heinz Lehmann added a fourth group, *folie induite*.

PARANOID CONCEPT

Paranoid signs and symptoms are among the most dramatic and serious disturbances in psychiatry and medicine but the term *paranoid* refers to a variety of behaviors that may not be psychopathological nor indicative of schizophrenia; hence, the meaning of the term has become obscure. Some clinicians label ordinary suspiciousness paranoid; others restrict use of the term to persecutory delusions; still others apply the term only to grandiose, litigious, hostile, and jealous behavior, despite the fact that those behaviors may be within the normal spectrum. To make the paranoid concept useful and less vague requires consideration of several points:

1. The term *paranoid* is a clinical construct used to interpret observations, and in order to apply this construct effectively, the clinician must know its meaning and be able to make accurate observations of potentially paranoid behavior.
2. Use of the term *paranoid* means the clinician has judged that the person's behavior is psychopathological. This judgment is usually based on the discovery that the person who displays such features is either disturbed or disturbing to others.
3. Although many contributions to understanding paranoid phenomena have focused on conditions in which paranoid features are central (e.g., schizophrenia for Bleuler, paranoia and dementia paranoides for Kraepelin), those features are not necessarily associated with schizophrenia and can appear in other psychiatric and medical disorders. Hence, paranoid features indicate psychopathology, but no specific cause or outcome (Table 13.2-2)

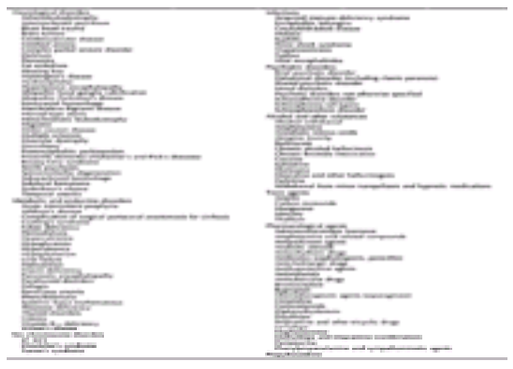

Table 13.2-2 Conditions and Agents Associated With Delusions and Other Paranoid Features

4. The observations that form the basis for judging behavior to be paranoid are of two kinds: subjective (part of the private mental experience of the patient, e.g., a delusion) and objective (observable as a manifest form of behavior, such as litigiousness, guardedness, and grandiosity). Table 13.2-3 is a list of the subjective and objective features that have traditionally been labeled paranoid and that are frequently found in association; some of these features can be manifestations of normal behavior. The judgment that such features are paranoid may rest on how extreme or inappropriate they are, their presence in combination or association with other behaviors on the list, and the presence of delusions.

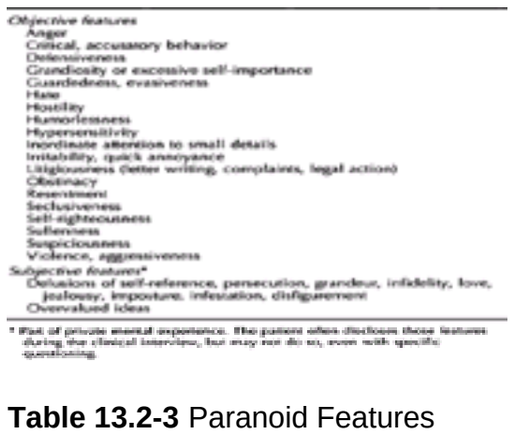

Table 13.2-3 Paranoid Features

5. The term *paranoid delusion* has traditionally referred to a wide variety of delusions, not simply those of grandeur, persecution, or jealousy. Because of recent confusion that term probably should not be used. The term *paranoid* and related terms are defined in Table 13.2-4.

Table 13.2-4 Terminology Connected with Paranoia

Delusions When Karl Jaspers formulated the concept of delusion widely used today, he suggested three criteria: (1) subjective certainty, (2) incorrigibility, and (3) falsity of content. He viewed these criteria as tentative, preferring to consider them as approximations to a definition in that they provided practical suggestions for detecting delusions rather than actually defining them. This and later contributions emphasized a certain humility about the delusion concept that has not been sustained in contemporary formulations of this psychopathological feature. Numerous, often ignored, problems compromise the clinical research utility of the delusion concept. For example, according to DSM-III-R and DSM-IV, delusion is “an incorrect inference about external reality.” This definition has certain implicit and complicating features: (1) there is a process of inference separable from the belief that the process produces, (2) this same process is used by normal persons to generate beliefs about the world, and (3) this process is impaired in delusional patients. As pointed out later in this chapter, the validity of the latter two assertions is questionable. Also, central to the concept of delusional disorder is the distinction between *bizarre* (impossible) and *nonbizarre* (possible) delusions. This distinction has been difficult to apply reliably in clinical assessment, yet on it rests considerable weight in making the diagnosis of delusional disorder. Further examples of difficulties concerning the definition of delusion have been discussed by Manfred Spitzer, who has traced the movement from philosophy to empirical science in the evolution of the definition of delusion. Awareness of the vagaries and imprecise nature of the definition of delusion is essential to clinical and research efforts.

Since the early nineteenth century delusions have been classified by content or theme. Other descriptive dimensions have gained acceptance through clinical use and some empirical research: understandability, degree of certainty, systemization, complexity, relevance to patient's life, plausibility, onset, associated psychopathology, and time course. These features are used to grasp the nature of the delusional experience, translate clinical observations into diagnostic and treatment interventions, and design research.

In clinical encounters delusions are usually easy to detect. Certain features (Table 13.2-3) of the patient's behavior may suggest the presence of delusions or help confirm the impression that the beliefs are delusional. In subtle cases, however, this task is more challenging. The clinician must make a judgment, based on the behavior and reported private mental experience of the patient, of whether or not delusional beliefs are present. Attempts to present counterevidence and argument may be useful to determine whether the patient's views can be influenced by evidence that is usually sufficient to alter the belief of a normal person. This judgment often depends on deciding whether a threshold indicative of psychopathological disorder has been passed, possibly reflected in the inappropriateness or extreme

nature of the patient's behavior, rather than the simple truth or falsity of the belief. In practice, the only effective approach to assessing delusions is to put together as comprehensive a picture as possible regarding the nature of the patient's condition. Lacking laboratory tests for delusions, clinical judgment will be required to some degree in virtually all cases. At the theoretical level, the definition of delusions is moving gradually away from its roots in philosophy and phenomenological description toward a more empirically derived set of features. This process will take considerable time to achieve a satisfactory resolution of the many issues plaguing this aspect of psychopathology.

COMPARATIVE NOSOLOGY

Certain advances have been made in the nosology of delusional disorders, but the variety of current definitions illustrates that consensus has not yet been achieved. The reasons for such differences are multiple: the principal reason is the lack of relevant data—delusional disorders occur infrequently. Typically, patients continue to function and live in the community without ever seeking clinical intervention. When they do, the condition is easily misdiagnosed because patients may have minimal overt identifying characteristics. Limited knowledge, based largely on case reports, exists; systematic, larger-scale studies are uncommon. Most of these studies are European and have employed varied classifications. Also, the fundamental concept that these disorders are distinct from schizophrenia and mood disorders has until recently been unrecognized by many psychiatrists.

Kahlbaum was the first to use the term *paranoia* to designate a diagnostically separate group of disorders. Kraepelin developed this diagnostic concept further by emphasizing the chronic and unremitting nature of paranoia and the lack of other features such as hallucinations that distinguished it from schizophrenia. In 1952 the first edition of DSM (DSM-I) defined paranoid reactions as conditions in which there are persecutory or grandiose delusions, with emotional responses and behavior consistent with the delusions, but generally lacking hallucinations. The subtypes were *paranoia* (a chronic disorder with systematized delusions) and *paranoid state* (a more acute, less persistent condition with less systematized delusions). In 1968 DSM-II largely preserved these concepts.

DSM-III Although new definitions were established in DSM-III in 1980, earlier concepts are still evident. The essential features of paranoid disorders according to DSM-III were persistent persecutory delusions or delusional jealousy not due to any other mental disorder. Included in the group of paranoid disorders were paranoia, shared paranoid disorder, acute paranoid disorder, and a residual category called atypical paranoid disorder. The boundaries between these conditions and other disorders, such as paranoid personality disorder or paranoid schizophrenia, were noted to be vague. Different types of paranoid disorders were classified on the basis of chronicity. The criteria narrowed the bounds of previous classifications by not including cases with marked hallucinations or certain delusions (e.g., hypochondriacal, erotomanic, and others).

DSM-III-R In 1987 DSM-III-R simplified the DSM-III definition, attempted to minimize the confusion associated with the term *paranoid*, and highlighted the view that the formation of delusions in the absence of schizophrenia, mood disorder, or organic disorder is the essential feature of these conditions. In contrast to DSM-III, diagnosis in DSM-III-R and DSM IV requires a month-long duration of symptoms. Subtyping is based on the predominant type of delusion, which is specified (such as jealous, erotomanic, or somatic). This latter feature broadens the category to include a variety of unusual delusions as well as the more common persecutory type. In many respects these criteria are virtually identical to Kraepelin's definition of paranoia. The two exceptions were Kraepelin's reluctance to endorse a subtype of somatic or hypochondriacal paranoia or to permit cases with hallucinations to fall within this diagnosis. Kraepelin believed that cases with hypochondriacal delusions rarely occurred in this pattern.

Shared paranoid disorder was renamed *induced psychotic disorder* in DSM-III-R and was placed in the category of psychotic disorders not elsewhere classified, along with schizophreniform, schizoaffective disorders, and brief reactive psychosis. This represents a fundamental departure from DSM-III, which classified this disorder among the paranoid disorders. The delusional content of patients with this disorder may concern not only persecution or jealousy but virtually any form of delusion, hence the change in terminology. The term *induced* may better describe the nature of the condition, but hardly resolves the puzzle of causation.

DSM-IV In 1994 a revised classification made modest changes in the DSM-III-R criteria in an attempt to refine the definition of delusional disorders. In DSM-III-R the distinction between schizophrenia and delusional disorders had been unclear and controversial. In DSM-III-R this boundary was defined by the nonbizarre qualities of delusions in delusional disorder and the absence of other active-phase symptoms of schizophrenia. Also important was the required absence of other odd or bizarre behavior apart from the delusion. Because the distinction between *bizarre* and *nonbizarre* is difficult to define and therefore to apply reliably, other terms such as *systematized* and *prominent* were suggested. In practice, however, those terms also have limitations. This problem has helped to promote the case for modifying the criteria in another way: specifically, to use the level of impaired functioning as a means of characterizing the distinction between schizophrenia (considerable impairment) and delusional disorders (relatively less impairment). However, the variability of outcomes in both disorders undermines this strategy somewhat. DSM-IV suggests that when poor functioning occurs in delusional disorder, it is the result of the delusional beliefs themselves. For example, a person quits a job because he or she believes that the fumes in the workplace are causing a cancerous growth. That person's financial situation worsens and preoccupation with repeated medical consultations enhances a downward spiral. In contrast, poor functioning in schizophrenia usually results from cognitive compromise and positive and negative symptoms, especially avolition. The resolution of how to make modifications, however, depends on the effectiveness of the criteria in defining homogeneous and valid subsets of psychotic disordered patients. For this purpose, field trials and data analyses have been used to inform the decision scientifically. Although the DSM-IV criteria reflect progress, their validity remains only partly established.

Another unsettled issue that DSM-IV attempts to resolve is the classification of delusional variants of somatoform disorder, specifically body dysmorphic disorder. In this condition the patient suffers from preoccupation with imagined or slight defects in appearance (such as skin blemishes, the size of one or more body parts); it is accompanied by impairment in social and occupational functioning, shame, and repetitive, often ritualistic behaviors. These may include skin picking, mirror checking, requests for reassurance, and attempts to camouflage the supposed deformity. In some cases, the preoccupation appears to be delusional. However, the relationship between nondelusional and delusional variants is unclear; whether the disorders are distinct or overlapping remains unknown. DSM-IV permits dual diagnosis of body dysmorphic disorder and delusional disorder when a delusional belief is present in the former condition. This resolution, in which the same symptoms are given two diagnoses, accurately reflects the available research data on the relationship of these two disorders and also underlines the need for further research to clarify these distinctions. A similar problem arises with respect to delusional variants of hypochondriasis and of obsessive-compulsive disorder, and a similar solution is applied: obsessive-compulsive disorder patients may also be diagnosed as delusional disorder.

Shared Psychotic Disorder DSM-IV renamed the DSM-III-R category *induced psychotic disorder*, calling it *shared psychotic disorder*. This change reflects the attempt to avoid the term *paranoid* and to identify the condition without reference to any presumed cause or mechanism. The goal is to define the boundaries between this condition and more common ones, such as other psychotic disorders, mood disorders with psychotic features, substance-induced psychotic disorders, and psychotic disorders due to a general medical condition.

ICD The ninth revision of *International Statistical Classification of Diseases* (ICD-9) contained more categories for paranoid disorder than the American schemes. Most paranoid disorders fall under the rubric *paranoid state*, including simple paranoid state, paranoia, paraphrenia, and induced psychosis. Additional subcategories include other and unspecified paranoid states. Acute paranoid reactions and psychogenic paranoid psychosis are classified separately. DSM-III, DSM-III-R, and DSM-IV generally reflect an atheoretical position with respect to the causes of these disorders whereas ICD-9 was less neutral. For example, psychogenic paranoid psychosis implies a kind of causal mechanism. The categories of paranoid disorder according to these classifications are summarized in Tables 13.2-5.

ICD-9 (1979)	DSM-III (1980)	DSM-III-R (1987)	ICD-10 (1992)	DSM-IV (1994)
Paranoid state, simple			Delusional disorder	
Paranoia	Paranoia	Delusional (paranoid) disorder	Delusional disorder	Delusional disorder
Paraphrenia (nonclassical paranoid state, late paraphrenia)			Delusional disorder	
Induced psychosis (folie à deux, induced paranoid disorder)	Shared paranoid disorder	Induced psychotic disorder	Induced delusional disorder	Shared psychotic disorder
Other specified states (paranoia querulans, Sensitiver Beziehungswahn)			Delusional disorder	
Unspecified paranoid states	Atypical paranoid disorder		Persistent delusional disorder, unspecified	
Acute paranoid reaction (bouffée délirante)	Acute paranoid disorder		Paranoid reaction	
Psychogenic paranoid psychosis (protracted reactive paranoid psychosis)				

Table 13.2-5 Comparative Nosology of Delusional Disorder

ICD-10 pays more attention to creating classifications similar to DSM-III-R and DSM-IV. Paraphrenia, for example, is subsumed under persistent delusional disorder but delusions must be present for about 3 months in order to diagnose delusional disorder. The subtypes of the disorder overlap with DSM-IV subtypes. For those conditions of less duration, acute and transient psychotic disorder is diagnosed. Induced (shared) delusional disorder is considered a separate designation with a phenomenology similar to persistent delusional disorder.

EPIDEMIOLOGY

Delusional disorder has been considered an uncommon if not rare condition from its earliest descriptions even though epidemiological information is meager. Recent demographic evidence covering a period from 1912 to the 1970s provides an estimate of incidence, prevalence, and related statistics (Table 13.2-6). However, this evidence was assembled using definitions that are not the same as those of DSM-III, DSM-III-R, or DSM-IV. Subsequent data will in all likelihood be somewhat different using the newer criteria. It is clear that the estimates are merely indications, but can be useful guidelines to future appraisals.

Incidence*	0.7–3.0
Prevalence*	24–30
Age at onset (range)	18–80 (mean 34–45 years)
Type of onset	Acute or gradual
Sex ratio	Somewhat more frequently female
Prognosis	Best with early, acute onset
Associated features	Widowhood, celibacy often present; history of substance abuse, head injury not infrequent

Portions of the table adapted from K S Kendler: Demography of paranoid psychosis (delusional disorder). Arch Gen Psychiatry 39: 890, 1982.
* Incidence and prevalence figures represent cases per 100,000 population.

Table 13.2-6 Epidemiological Features of Delusional Disorder

However, certain features of the data are remarkable. For example, the stability of estimated incidence has been striking over extended periods of time in this century. The prevalence of these disorders substantiates the widely held clinical impression that they are uncommon conditions (compared with mood disorders and schizophrenia) but are not rare. Some studies indicate that delusional disorder accounts for a surprising 2 to 8 percent of inpatient psychiatric admission for "functional psychosis." Patients with delusional disorders are somewhat more likely to be women (but this is an inconsistent feature), and to be more socially and educationally disadvantaged as compared to patients with mood disorders. Women tend to be older than men at the time of diagnosis. While the onset age range is wide (18 to 80), most patients are middle-aged. There is suggestive evidence that immigrant status, celibacy among men, and widowhood among women are associated with delusional disorder but all such observations need to be unambiguously replicated.

ETIOLOGY

The cause of delusional disorder is unknown. The epidemiological and clinical literature suggests that certain risk factors may be relevant to etiology and deserve further research elaboration. These risk factors are found in Table 13.2-7. Whether they are risk predictors or simply characteristics or markers of the disorder is unknown. Familial psychiatric disorder, including delusional disorder, is the best documented risk factor at present.

Advanced age
Sensory impairment/isolation
Family history
Social isolation
Personality features (e.g., unusual interpersonal sensitivity)
Recent immigration

Table 13.2-7 Risk Factors Associated With Delusional Disorder

Genetic or family studies that have begun to appear in the literature indicate the possible specific family transmission of delusional disorder. A recent study of genetic variation in deoxyribonucleic acid (DNA) sequence coding for dopamine type 4 (D_4) receptor proteins strongly suggests the involvement of the relevant gene in conferring susceptibility to delusional disorder. The comparison subjects either had schizophrenia or were normal controls.

Paranoid features, including the types of delusions encountered in these disorders, occur in a large and growing number of conditions (Table 13.2-2). Differences in classifying idiopathic delusional disorder add to the problems of understanding causation. Theories and explanations of delusions abound in the literature but empirical evidence to support those theories is limited. With so many uncertainties, any conclusions concerning the cause of delusional disorder must be made cautiously.

Delusional disorder is an uncommon, probably heterogeneous, group of illnesses whose validity has been questioned since Kahlbaum published his views. The major phenomenological feature of these conditions is the formation and persistence of delusions. It is well known that delusions occur in a variety of psychiatric and medical conditions, and that the pathogenesis of delusions is not fully understood. Hence, discussion of etiology in the delusional disorders can proceed along two lines: (1) determining the distinctiveness of the category itself, (2) examining the theories proposed to account for the pathogenesis of delusion formation per se, and (3) integrating the available evidence into testable proposals.

Distinctiveness of Delusional Disorder An issue that is central to attributing causation is whether delusional disorder represents a separate group of conditions or is an atypical form of schizophrenic and mood disorders. The relevant data come from a limited number of studies and is inconclusive. Epidemiological data suggest that delusional disorder is a separate condition; it is far less prevalent than schizophrenic or mood disorders; age of onset is later than in schizophrenia although men tend to experience the illness at earlier ages than women; and the sex ratio is different from that of mood disorder, which occurs disproportionately among women. Findings from family or genetic studies also support the theory that delusional disorder is a distinct entity. If delusional disorder is simply an unusual form of schizophrenic or mood disorders, the incidence of these latter conditions in family studies of delusional disorder patient probands should be higher than that of the general population. However, this has not been a consistent finding. A recent study concluded that patients with delusional disorder are more likely to have family members who show suspiciousness, jealousy, secretiveness, even paranoid illness, than families of controls. Other investigative efforts have found paranoid personality disorder and avoidant personality disorder to be more common in the relatives of patients with delusional disorder than in the relatives of controls or of schizophrenic patients. A recent study documented modest evidence for an increased risk of alcoholism among the relatives of patients with delusional disorder as compared to probands with schizophrenia, probands with psychotic disorder not otherwise specified, and probands with schizophreniform disorder.

Investigations into patient's natural history also lend support to the suggestion that delusional disorder is a distinct category: age of onset appears to be later than in

schizophrenia and outcome generally is better for delusional disorder patients than for schizophrenia patients. Although fraught with methodological shortcomings, premorbid personality data indicate that schizophrenia patients and patients with delusional disorder differ early in life. The former are more likely to be introverted, schizoid, and submissive; the latter extroverted, dominant, and hypersensitive. Delusional disorder patients may have below-average intelligence. Precipitating factors, especially related to social isolation, conflicts of conscience, and immigration, are more closely associated to delusional disorder than schizophrenia. These characteristics support Kraepelin's view that environmental factors may play an important etiological role. Clinical characteristics such as greater intensity of delusions, uncommon occurrence of negative symptoms, and possible association with cerebrovascular disorder in late-onset cases also suggest differences from late-onset schizophrenia. Recent observations of successful treatment with pimozide (Orap) in several subtypes of delusional disorders suggest the possibility of a common pathogenetic mechanism in these disorders. Follow-up studies indicate that the diagnosis of delusional disorder remains fairly stable: only a small proportion of cases (3 to 22 percent) are diagnosed later as having schizophrenia, and even fewer (6 percent) are diagnosed later as having a mood disorder. Outcome in terms of hospitalization and occupational adjustment is markedly more favorable for delusional disorder than for schizophrenia. When social or occupational functioning is poor in delusional disorder, it generally occurs as the result of the delusional beliefs themselves, not because of cognitive impairment or negative symptoms.

The evidence argues in favor of the distinctiveness of delusional disorder, but it is likely that at least some patients diagnosed as having delusional disorder will develop schizophrenia or mood disorders. Hence, current clinical criteria have limitations and need improvement, which may be possible with the use of laboratory techniques or more specified clinical definitions. Furthermore, the data suggest that delusional disorder is relatively chronic and is probably biologically distinct from other psychotic disorders.

PATHOGENESIS

Although a clear understanding of the pathogenesis of delusions remains an unfulfilled hope, several major theories have been advanced. Any adequate hypothesis for delusion formation must deal with certain facts: (1) delusions occur in a variety of medical and psychiatric diseases; (2) not all persons with such conditions develop delusions; (3) the types of delusions are relatively few and strikingly repetitious despite the variety of diseases; (4) delusions can clear rapidly with treatment of the underlying condition or its termination; (5) delusions can persist, and even become systematized; (6) delusions often accompany perceptual changes such as hallucinations or impaired sensory input; (7) delusions may be highly encapsulated features in persons such that their functioning may not be compromised socially, intellectually, or emotionally. Also, any adequate hypothesis must respond to two questions. First, why does the patient have a delusion? This is a question concerning the form of the psychopathology. Second, why does the patient have this particular delusion? This is a question concerning the content of the psychopathology.

There are three categories of theory in delusion formation.

1. Delusions arise in an otherwise intact cognitive system because a deviant pattern of motivational interest is present (psychodynamic mechanism, social attribution theory).
2. Delusions arise as the result of a fundamental cognitive defect that impairs the patient's capacity to draw valid conclusions from evidence (disorder of reasoning).
3. Delusions arise from normal cognitive processes directed at explaining abnormal perceptual experiences (psychobiological mechanism, anomalous experience hypothesis).

These theories need not be mutually exclusive. Delusional beliefs probably are the result of different processes involving one or more of the proposed mechanisms.

Psychodynamic Mechanism In 1911 Freud published “Psychoanalytic Notes Upon an Autobiographical Account of a Case of Paranoia (Dementia Paranoides).” His interpretation of this case, which became the foundation of the psychodynamic theory of paranoia, was based on his reading of the memoirs of the presiding judge of a Dresden appeals court, Daniel Paul Schreber, who had suffered episodes of psychiatric illness in 1884, 1885, and 1893. The second episode led to two prolonged hospitalizations from which the patient obtained discharge in 1902 following legal action, although he was still delusional. Freud asserted that Schreber's 1903 account, *Memoirs of My Nervous Illness*, offered a legitimate basis for theory, as “paranoiacs cannot be compelled to overcome their internal resistances, and ... in any case they only say what they choose to say ....” Freud argued that the written case report can take the place of personal acquaintance, and in the case of Schreber, Freud never saw the patient. Freud asserted that Schreber's case illustrated a general mechanism of delusion formation involving denial or contradiction and projection of repressed homosexual impulses that break out from the unconscious. The forms of delusion in paranoia can be represented as contradictions of the proposition “I (a man) love him (a man).” The following examples illustrate the forms of illogic.

1. Delusion of persecution. In the contradiction ‘I do not love him, I hate him,” a hatred that persons deem unacceptable at the conscious level is transformed and becomes instead: “He hates (elaborated to “persecutes”) me.” Patients can then rationalize their anger by consciously hating those persons whom they perceive to hate them.
2. Delusion of erotomania. The proposition “I do not love him—I love her” is transformed through projection to “She loves me—and so I love her.”
3. Delusional jealousy. To protect against unwarranted, threatening impulses the patient transforms the proposition in this manner: “I do not love him—she (a wife, lover) loves him.” Hence, jealous delusions represent the transformed attractions of the deluded for the lover.
4. Delusion of grandiosity (megalomania). Here the contradiction made is, “I do not love him, I love myself.”

The essence of the theory is that delusions represent attempts to manage the stirrings of unconscious homosexuality. According to the classic theory, the dynamics of unconscious homosexuality are similar for female as well as male patients.

Comment Many theorists have added to the psychodynamic lore on delusion formation from the standpoint of understanding personality factors. For example, some of the vulnerability to delusion formation may be related to deficiently developed trust, narcissistic dynamics, or exaggerated traits such as hypersensitivity.

Critique Freud's mechanism of delusions sidesteps the distinction between form and content in psychopathology. He proposes an inferential process to account for the particular delusion but does not clearly address the issue of why a delusion is formed rather than another symptom, such as hallucination. Verification of the hypothesized mechanism clearly rests on finding evidence that delusions are associated with indications of homosexual tendencies. The theory has been perpetuated in part because an absence of homosexuality can never be proved, and such tendencies can be used as a pillar, even if not a scientifically or empirically demonstrable pillar, in the psychodynamic argument. The few experimental attempts made to test the hypothesis have been inconclusive or equivocal. Although homosexual concerns have been found among some delusional patients, the variety of conditions with similar delusions argues against a common mechanism of unconscious homosexuality in all. Persons who delusional patients say are persecuting them are not always known by them, nor is the persistence of such delusions adequately accounted for in that formulation. Nevertheless, the classic approach has had immense influence and has provided important psychoanalytical concepts, such as projection, and an awareness that developmental experiences may operate to influence the content of delusional thinking. Systematic empirical study would be valuable.

Disordered Reasoning Because the definition of delusion (Table 13.2-1) emphasizes the operation of reasoning processes that have gone haywire, it is not surprising that a number of attempts have been made to establish that disorder of reasoning is related to delusion formation and that such disorders can be observed among deluded patients. Related to the psychodynamic formulation is the proposal that delusions arise on the basis of defects in formal logical reasoning. Popular in the 1950s and 1960s, this view, promulgated by Eilhard von Domarus among others, suggested that errors in logic such as the principle of identity (two subjects are identical on the grounds of identical predicates) have an etiological role. For example, “Charles Manson used drugs; I use drugs, therefore I am Charles Manson.” The empirical assessment of that proposal has failed to establish that deluded patients exhibit more defects in reasoning; rather it appears that normal and deluded persons both make similar errors of reasoning with comparable frequencies.

Two other proposals involving disturbance in reasoning have been studied recently. The first portrays the difficulty underlying delusion formation as a failure in the application of Bayesian reasoning. According to this model of developing beliefs, making choices, and drawing conclusions, delusional patients accept conclusions at levels of probability too low for acceptance by nondelusional persons. However, attempts to demonstrate that failure have had equivocal results. The second proposal suggests that the reasoning processes of delusional patients are influenced by the subject's tendency to assign meaning in a biased manner. The bias arises in making judgments about one's own behavior and that of another person by assigning motives and characteristics to the person involved. Application of this model reflecting motivational and reasoning difficulties (based on social attribution theory) has been tested, but the results do not provide sound support for the formulation.

Other Psychological Mechanisms In *Manic Depressive Insanity and Paranoia*, Kraepelin considered the delusions of paranoia to be the “morbidly transformed expression of the natural emotions of the human heart” and, more specifically, “a kind of psychological compensation for the disappointments of life.” He dismissed

the Freudian psychodynamic mechanism on the grounds that it did not refer to a clear concept of paranoia and that it was not supported by evidence. He also emphasized consitutional factors, especially disturbances of judgment, in his formulation. Other authors have made similar suggestions about the role of need fulfillment in the development of paranoia. For example, delusions of persecution might serve to maintain the self-esteem of the deluded person, according to a social attribution view about delusion formation in which a normal bias—that of assigning blame for negative outcomes to other persons or circumstances—is exaggerated.

Critique These contributions do not address the issue of pathogenesis rigorously. They explain the content of the delusion but not its form. The commonness of the risk factors or antecedent features cited repeatedly as central to delusion formation contrasts dramatically with the uncommonness of delusional disorder.

Psychobiological Mechanisms The French neurologist Gaëtan G. de Clerambault proposed in 1942 that chronic delusions resulted from abnormal neurological events. Infections, lesions, intoxication, and other forms of damage produce automatisms that puzzle or distress the patient initially and eventually demand explanation. The explanations take the form of delusions. Automatisms include hallucinations, a constant parade of memories, feelings of familiarity, false recognition, arresting of thought, disturbances in attention, bizarre tactile sensations, and even kinesthetic sensation. The view that delusions are an explanation for hallucinations is an old concept in psychiatry that has not been well formulated. The fact that hallucinations have been introduced into and retracted from the definition of paranoia over the years also reflects a lack of clarity regarding a possible connection between the two forms of psychopathology.

In 1974 Brendan Maher proposed a similar hypothesis that conceptualized delusions as explanations of anomalous experiences that arise in the environment, the peripheral sensory system, or the central nervous system. A central tenet of his view is that the processes whereby delusional beliefs are formed are similar in their essential nature to those that operate in the formation of normal beliefs and even of scientific hypotheses. Integral to the hypothesis is the assumption that components of this normal operational sequence have a neural substrate that may be activated either by sensory input (as in the hallucinatory effects of drugs) or by the effects of brain damage (as in alcoholism). The activation of any part of the sequence demands explanation and may thus give rise to delusions. The sequence, activated by disturbances in sensory experience, emotional incongruity, or central nervous system abnormalities, has the following stages: (1) anomalous experience, (2) feelings of significance, (3) testing for reality of experience, (4) developing tentative hypotheses, (5) additional observation, (6) exploring insights, and (7) confirmation of the insight by selective observation. In Maher's explanation, the patient is delusional because he or she actually experiences anomalies that demand explanation. The particular content of the delusion is drawn from the past or current circumstances, experience, and the personal and cultural background of the patient. The explanation answers questions such as the following: What is happening? Why? Why do other people deny it is happening? Why is it only happening to me? Who is responsible for it? The delusional explanation offers relief from puzzlement, and that relief works against abandonment of the explanation.

Critique The psychobiological formulation has gone largely unstudied, but there is supporting evidence in the form of studies of altered perception among patients and healthy controls experiencing sensory impairment or sensory deprivation, and among persons taking various drugs of abuse. These studies have demonstrated a high incidence of delusion formation. The failure to detect a fundamental defect in the cognitive process of delusional patients or to identify basic differences in belief formation between persons with delusions and normal controls provides indirect support as well. Indeed, delusions are formed in persons with a range of levels of intelligence and education, further supporting the view that a disturbance in the cognitive processes is not the source of the problem. Also a number of medical conditions show evidence of delusions but no history of cognitive impairment. Clearly, this hypothesis warrants further examination, and it remains to be seen how applicable it is to conditions, such as delusional disorder, in which the occurrence of hallucinations is debated. Sensory impairment and central nervous dysfunction, although apparently likely, have not been firmly established for the disorder. The anomalous experience hypothesis focuses on the psychological mechanisms underlying delusion formation, but a complementary proposal concerns the anatomic loci associated with delusional thinking. Jeffrey Cummings and others have used the growing data on the psychopathological consequences of neurological disease to suggest that delusions occur in diseases involving the limbic system—in particular, temporal lobe structures and caudate nuclei. Diseases characterized by excessive dopaminergic activity or reduced cholinergic activity also carry a heightened risk of delusion formation. Cummings further hypothesizes that the common locus of delusion formation is limbic dysfunction that predisposes the individual to misinterpretation of the environment accompanied by inappropriate perception of threat. Both disease- and patient-related factors influence the content, complexity, and timing of the delusion.

PATHOGENESIS

Although limited by the spareness of research in the area, observations of pharmacological treatment provide complementary insights into the pathogenetic puzzle. Data from treatment reports on delusional disorder suggest that pimozide (Orap) a highly specific dopamine-blocking agent, has greater effectiveness than typical antipsychotic drugs in this condition; some data even suggest that it has a unique role. There are several pharmacological effects of pimozide, in addition to dopamine receptor blockade, that may help explain its effectiveness: (1) relative lack of nonadrenergic blocking action (2) calcium channel antagonism, and (3) opioid receptor blockade. The effect of opiated receptor blockade has been proposed as relevant to reported specific effectiveness in delusional infestation partly based on observations of opiate receptor blocking interventions in delusional disorder somatic type, with delusions of infestation. Intravenous administration of the opioid agonist fentanyl (sublimaze) led to intensified cutaneous sensations whereas administration of naloxone (Narcan) an opioid antagonist, resulted in complete remission of the patient's cutaneous sensation. That pimozide is especially effective in delusional disorder, somatic type, supports the notion that its opiate receptor antagonism blocks central recognition of abnormal peripheral sensation; such a view is consistent with the anomalous experience hypothesis.

Other Relevant Factors Delusions have been linked to a variety of additional factors such as social and sensory isolation, socioeconomic deprivation, and personality disturbance. The deaf, the visually impaired, and possibly immigrants with limited ability in a new language may be more vulnerable to delusion formation than the normal population. Vulnerability is heightened with advanced age. Delusional disturbance and other paranoid features are common in the elderly. In short, multiple factors are associated with the formation of delusions, and the source and pathogenesis of delusional disorders per se have yet to be specified.

Integration The pathogenesis of delusions in general and delusional disorder in particular remains a field of hypotheses with little firm grounding. A variety of theories exist, but empirical support for any theory is markedly limited. Of those available, however, the anomalous experience hypothesis appears to be the best supported and certainly is the most consistent with research findings from other domains. Given the research explosion in neuroscience and psychopathology, this hypothesis should be explored as fully as possible. In delusional disorder, for example, the anomalous experience hypothesis needs to be further specified, for example, on what kinds of anomalous experience could lead to the jealousy delusion, the erotomanic delusion, and so forth. Studies now under way in the misidentification delusions, such as the Capgras's syndrome, provide a model for how such research might be directed. Progress may result from further studies of the neurobiology underlying successful treatment strategies in delusional disorder as well.

DIAGNOSIS AND CLINICAL FEATURES

Delusional Disorder

Diagnosing delusional disorders requires that the clinician match the features of the case to the appropriate criteria (Table 13.2-8). When the clinician has successfully ruled out other disorders, certain features of the case can help to substantiate the diagnosis of delusional disorder. The ICD-10 criteria for delusional disorder are listed in Table 13.2-9.

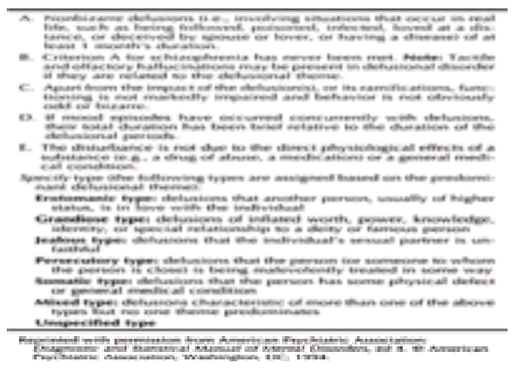

Table 13.2-8 DSM-IV Diagnostic Criteria for Delusional Disorder

Delusional disorder

A. A delusion or a set of related delusions, other than those listed as typically schizophrenic in criterion G (1) (b or d) for paranoid, hebephrenic, or catatonic schizophrenia (i.e., other than commonly impossible or culturally inappropriate), must be present. The commonest examples are persecutory, grandiose, hypochondriacal, jealous (delusional), or erotic delusions.

B. The delusional in criterion A must be present for at least 3 months.

C. The general criteria for schizophrenia are not fulfilled.

D. There must be no persistent hallucinations in any modality that there may be transitory or occasional auditory hallucinations that are not in the third person or giving a running commentary).

E. Depressive symptoms or even a depressive episode may be present intermittently, provided that the delusions persist at times when there is no disturbance of mood.

F. Most commonly used exclusion clause. There must be no evidence of primary or secondary organic mental disorder as listed under organic, including symptomatic, mental disorders, or of a psychotic disorder due to psychoactive substance use.

Specification for possible subtypes

The following types may be specified if desired: persecutory; litigious; self-referential; grandiose; hypochondriacal (somatic); jealous; erotomanic.

Other persistent delusional disorders

This is a residual category for persistent delusional disorders that do not meet the criteria for delusional disorder. Disorders in which delusions are accompanied by persistent hallucinatory voices or by schizophrenic symptoms that are insufficient to meet criteria for schizophrenia should be coded here. Delusional disorders that have lasted for less than 3 months should, however, be coded, at least temporarily, under acute and transient psychotic disorders.

Persistent delusional disorder, unspecified

Table 13.2-9 ICD-10 Diagnostic Criteria for Delusional Disorders

DSM-IV defines the core psychopathological feature of delusional disorder as persistent, nonbizarre delusions not explained by other psychotic disorders. Onset can be sudden, following a precipitating event that the patient often reports, or the disorder may emerge gradually and may become chronic. Behavioral and emotional responses are generally appropriate: neither a mood disorder nor the volitional, thinking, and emotional disturbances of schizophrenia are present (including hallucinations, which are quite restricted in delusional disorder). In general, patients with delusional disorder show little disorganization or impairment in their behavior or in the clarity of their thinking.

The delusions are unusual yet they refer to aspects of life that might occur, such as being conspired against, cheated on, physically ill, in love, jealous, and so forth. They are, as George Winokur has suggested, “possible,” rather than totally incredible and bizarre as are many of the delusions of schizophrenia. Delusions are categorized according to their content; the most common are characterized by persecution, disease, and jealousy. The delusions are fixed (persistent) and unarguable. Patients interpret facts to fit the delusion rather than modifying the delusion to fit the facts. There is systematization in the elusional thinking, meaning that a single theme or series of connected themes is present with links to the predominant delusion. Normal life and functioning gradually give way to the dominance of delusional concerns.

Many have proposed that there is a descriptive continuum between paranoid personality disorder, delusional disorder, and the paranoid subtype of schizophrenia in terms of degrees of disorganization and impairment. However, there is little evidence to support the concept that these disorders share more than overlapping psychopathology.

The presence of hallucinations in delusional disorder has been debated, with some theorists arguing that schizophrenia is a more likely diagnosis in such cases and others not, so long as the hallucinations are not marked and persistent. The resolution of this issue remains distant, but it is reasonable to consider infrequent, poorly organized, and simple hallucinations that are not a prominent part of the psychopathology to be a feature of delusional disorder. The hallucinations are usually auditory but may be visual and tend to be more common in acute cases. Other types of hallucinations may occur; however, tactile or olfactory hallucinations may be present and may even be prominent if they are related to the delusional theme.

The person's emotional contact and behavior are generally intact. The emotional response is usually consistent with the delusional concern, and the mood is often appropriately depressed, frustrated, or even intensely angry or elated. Restlessness and agitation may be present. Loquaciousness and circumstantiality, usually accompanying descriptions of the delusions, are found in some patients, but formal thought disorder as sometimes found in schizophrenia is absent. Persons with delusional disorder may behave in a remarkably normal way much of the time; they become strikingly different when the delusion is focused on, at which time thinking, attitude, and mood may change direction abruptly. A. Munro has called this shift in response a characteristic, possibly unique feature of delusional disorder. In the delusional mode the patient is hyperalert, preoccupied, and driven by the delusional concern. In the normal mode, the patients mood becomes calm, the conversation neutral, and the patient finds it easier to focus on other issues. The shift between modes can be difficult for lay persons to comprehend. Social and marital functioning are more likely to be compromised than intellectual and occupational functioning.

Associated features in delusional disorder include those of the paranoid syndrome (Table 13.2-3). The degree of hostility and suspiciousness may be such that violent or aggressive behavior results. Litigious behavior is common among such patients. However, some patients, notably those with somatic delusions, may not display hostility, anger, or even suspiciousness to any considerable degree.

MENTAL STATUS EXAMINATION The patient's complaints are brought to the attention of the clinician by the patient or a third party, such as police, family, neighbors, or a consulted physician or attorney. The patient may have attracted attention by asking for protection, quarreling with neighbors, visiting too many clinics, or similar behavior. The complaint focuses on the distressing behavior and possibly on incidental symptoms. The patient will not complain of a psychiatric condition; in fact, he or she will deny that or the presence of any psychiatric symptoms. Often to the surprise of those expecting to observe a range of mental deviances, examination leads to the discovery that thinking, orientation, affect, attention, memory, perception, and personality are intact. The patient's thinking is so clear and the delusional features are so central to his or her concerns that the clinician begins to anticipate the interview responses of the patient to the point that accurate predictions of specific actions and reactions are possible. Such predictability may distinguish the behavior of the patient with delusional disorder from behavior associated with other psychotic conditions. The patient's behavior and responses to the interview are consistent with the range of features in other paranoid conditions. There may be hostility, anger, lack of cooperation, and a sarcastic or challenging quality in most of what the patient says.

The capacity to act in response to delusions is an important dimension of the evaluation. Level of impulsiveness should be assessed and related to any potential for violent or suicidal behavior. The patient's self-righteousness, the intensity of the delusional experience, and its emotional impact on the patient may be clues to possible violent behavior; any plans for harming others, including homicide, should be inquired about. Suicidal behavior is an equally important concern. Impulses for self-harm arise in settings of frustration, demoralization, and even depression. If such thoughts exist, the patient should be asked how they were handled in the past. Jealousy and erotomania are perhaps especially important concerns in the assessment of possible aggression and violence. Stalking, history of abuse, and arrest records should be inquired about. Careful judgment and diplomatic interviewing are especially important in such presentations.

ASSESSMENT OF DELUSIONS The detection of delusions solidifies the judgment that a paranoid condition is present. Delusions are usually easy to detect. Features of behavior (Table 13.2-3) may suggest their presence. Associated psychopathological symptoms such as hallucinations, disturbed form of thought, and mood disorder may also indicate that delusions are part of the clinical picture.

The clinical challenge is clear in subtle cases. Fundamentally, the clinician must make a judgment based on available observations and the reported private mental experience of the patient. Attempts to dissuade the patient with counterevidence and counterarguments may be useful in determining whether the patient's beliefs can be influenced in ways that are usually sufficient to change a nondelusional person's mind. Spending time in discussion with the patient to grasp the nature of delusional thinking in terms of its themes, impact on the patient's life, complexity, systematization, and related features may be crucial in making the judgment. The most sensible guideline for all cases of suspected delusional thinking is to establish as comprehensive a picture as possible concerning the condition of the patient, including the patient's subjective private experience and evidence of psychopathological symptoms. Such information should reduce much of the uncertainty of the evaluative process.

PERSECUTORY TYPE The delusion of persecution is a classic symptom of delusional disorder; persecutory type and jealousy type delusions are probably the forms seen most frequently by psychiatrists. In contrast to persecutory delusions in schizophrenia, the clarity, logic, and systematic elaboration of the persecutory theme in delusional disorder leave a remarkable stamp on this condition. The absence of other psychopathology, of deterioration in personality, or of deterioration in most areas of functioning also contrasts with the typical manifestations of schizophrenia.

A 56-year old woman, X-ray technician who had emigrated as an adult from Europe, and married late in life, presented to the emergency room. Her complaints were that her husband's business partner of many years intended to get her husband to resign from the business and to destroy their home. Over a number of months she had become gradually aware that a variety of apparently inconsequential incidents (such as unusual cars parked on her isolated residential street, seeing individuals she knew at restaurants, and feeling as if she were being followed each time she drove her car) pointed to a conspiracy to disrupt and ultimately destroy their lives. Her delusion of persecution was remarkably systematized and detailed; her mood in describing this was tense and irritable. There was no evidence of hallucinations, confusion, thought disorder, or mood disorder. Cognition was intact. The patient was quite intelligent and saw the clinical consultation as a means of assisting her husband to deal with the distress of being targeted in such a manner. (The husband had accompanied his wife on these consultations. He also had experienced some delusional thinking in accord with hers.)

The patient showed no evidence that suggested suicidality or potential for violence toward others. She initially refused all medication but gradually over several months of therapy and parallel frequent legal consultations agreed reluctantly to take risperidone (Risperda) and later, for postpsychotic depression, paroxetine (Paxil). She responded within weeks to 0.5 to 1 mg of risperidone administered daily or on alternate days; she refused to take the medication continuously. Within a year, she began to focus on other issues and the emotional intensity of the delusional concerns diminished although they could be aroused with modest stimulation in conversation or from happenings in her home or neighborhood.

JEALOUS TYPE Delusional disorder with delusions of infidelity has been called *conjugal paranoia* when it is limited to the delusion that a spouse has been unfaithful. The eponym *Othello syndrome* has been used to describe morbid jealousy that can arise from multiple concerns. The delusion usually afflicts men, often those with no prior psychiatric illness. It may appear suddenly and serve to explain a host of present and past events involving the spouse's behavior. The condition is difficult to treat and may diminish only on separation, divorce, or death of the spouse.

Richard Krafft-Ebing described the symptom of delusional jealousy in alcoholics in 1891 and believed that extreme jealousy was pathognomonic for alcoholism. Other disorders with this symptom were later described. A recent retrospective analysis of 8134 psychiatric inpatients disclosed a prevalence of delusional jealousy of 1.1 percent among the major diagnostic groups. Among ICD-9 paranoid disorders, a 6.7 percent lifetime point prevalence was determined. Delusional disorder with alcohol dependence frequently shows the single delusion of jealousy, a persistent feature that sometimes remits if alcohol abuse is brought under control. In personality disorders the symptom may be confused with extreme jealousy, but other psychotic features should be absent. The prevalence of delusional jealousy among hospitalized patients with mood disorder was a surprisingly low 0.1 percent. A study of 26,000 psychiatric inpatients using DSM-III-R criteria yielded a 0.17 percent rate of delusional disorder, jealous type. Jealous delusions occur much more frequently in other disorders than in delusional disorder.

Marked jealousy (usually termed *pathological* or *morbid jealousy*) is thus a symptom of many disorders including schizophrenia (where female patients more commonly display this feature), epilepsy, mood disorders, drug abuse, and alcoholism—for which treatment is directed at the primary disorder. Jealousy is a powerful emotion; when it occurs in delusional disorder or as part of another condition it can be potentially dangerous and has been associated with violence, notably both suicide and homicide. The forensic aspects of the symptom have been noted repeatedly, especially its role as a motive for murder. However, physical and verbal abuse occur more frequently than extreme actions among individuals with this symptom. Caution and care in deciding how to deal with such presentations are essential not only for diagnosis, but also from the point of view of safety.

A 47-year-old carpenter was brought for psychiatric examination following complaints by neighbors about his loud yelling and verbal abuse of his girlfriend. The patient resented the psychiatric referral, but was willing to give an account of his concerns. His girlfriend, he complained, was having an affair with someone, but he was not sure who the interloper was. On his own, however, he had begun gathering evidence: strands of hair found in the apartment, photographs of soiled sheets, and suspicious items from the trash—all of which he claimed proved that an affair was ongoing. He revealed plans to tape-record, possibly videotape, his girlfriend's activities while he was on the job. Upon admitting that he had told his girlfriend that he would kill her if the affair persisted, he was admitted to the hospital. He was treated with a serotonin–dopamine antagonist in low dosages and responded with a reduction in the intensity of his rage and preoccupation. Eventually, he left the hospital, but only after his girlfriend had moved away. He still harbored suspicions but accepted the termination of the relationship without voluble opposition.

EROTOMANIC TYPE Patients with erotomania have delusions of secret lovers. Most frequently the patient is a woman, but men are also susceptible to the delusion. The patient believes that a suitor, usually more socially rominent than herself, is in love with her. The delusion becomes the central focus of the patient's existence and the onset can be sudden.

Erotomania, the *psychose passionelle*, is also referred to as *de Clérambault's syndrome* to emphasize its occurrence in different disorders. Besides being the key symptom in some cases of delusional disorder, it is known to occur in schizophrenia, mood disorder, and other organic disorders. There is no mention of erotomania in DSM-III: the condition was termed *atypical psychosis*. DSM-III-R reinstated the condition, and it remains in DSM-IV.

Patients with erotomania frequently show certain characteristics: they are generally but not exclusively women, unattractive in appearance, in low-level jobs, and they lead withdrawn, lonely lives being single and having few sexual contacts. They select secret lovers who are substantially different from themselves. They exhibit what has been called *paradoxical conduct*, the delusional phenomenon of interpreting all denials of love, no matter how clear, as secret affirmations of love. The course may be chronic, recurrent, or brief. Separation from the love object may be the only satisfactory means of intervention. Although men are less commonly afflicted by this condition than women, they may be more aggressive and possibly violent in their pursuit of love. Hence, in forensic populations men with this condition predominate. The object of aggression may not be the loved individual but companions or protectors of the love object who are viewed as trying to come between the lovers. The tendency toward violence among men with erotomania may lead initially to police rather than psychiatric contact. In certain cases resentment and rage in response to an absence of reaction from all forms of love communication may escalate to a point that the love object is in danger.

A 29-year-old male financial analyst, while having lunch in a downtown restaurant observed the arrival of a well-known local media personality, an attractive woman about his age. He experienced several moments of eye contact with the woman and became convinced that she had fallen in love with him. There ensued a barrage of flowers, letters, phone calls, and even several attempts to meet with her at her workplace. The woman rebuffed all such efforts and eventually called the police. The man was arrested on a stalking charge after he was observed following the woman to her residence. He was angry and threatening to the police, finally admitting that he had purchased a handgun but refusing to give a reason for the purchase. He was remanded to a forensic psychiatric unit, treated with pimozide, and eventually discharged on a court-supervised probation.

SOMATIC TYPE Delusional disorder with somatic delusions has been called *monosymptomatic hypochondriacal psychosis*. The condition differs from other conditions with hypochondriacal symptoms in degree of reality impairment. In delusional disorder the delusion is fixed, unarguable, and presented intensely, because the patient is totally convinced of the physical nature of the disorder. In contrast, persons with hypochondriasis often admit that their fear of illness is largely groundless. The content of the somatic delusion may vary widely from case to case. Munro has described the largest series of cases and has used the content of delusions to define three main types: (1) delusions of infestation (including parasitosis); (2) delusions of dysmorphophobia, such as of misshapenness, personal ugliness, or exaggerated size of body parts (this category seems closest to that of body dysmorphic disorder); and (3) delusions of foul body odors or halitosis. This latter category, sometimes referred to as *olfactory reference syndrome*, appears somewhat different from the category of delusions of infestation in that patients with the former have an earlier age of onset (mean 25 years), male predominance, single status, and absence of past psychiatric treatment. Otherwise the three groups, although individually low in prevalence, appear to overlap.

The frequency of these conditions is low, but they may be underdiagnosed because patients present to dermatologists, plastic surgeons, and infectious disease specialists more often than to psychiatrists in the unremitting search for curative treatment. This may partially account for Kraepelin's skepticism about the occurrence of this form of paranoia. Several recent reports indicate that pimozide (a diphenylbutyliperidine and highly specific dopamine blocker) and certain serotonin-specific reuptake inhibitors may be effective in treatment of such disorders, even in cases with a variety of delusional themes. There may be a heightened association of shared psychotic disorder involving primary cases of hypochondriacal delusion; one series reported a quarter of cases with such an association.

Patients with this condition have a poor prognosis without treatment. It affects both sexes roughly equally. A previous history or family history of psychotic disorder is uncommon. In younger patients, a history of substance abuse or head injury is frequent. Although anger and hostility are commonplace, shame, depression, and avoidant behavior are even more characteristic. Suicide, apparently motivated by anguish, is not uncommon.

A 40-year-old single unemployed man is referred by his primary care physician because of repeated consultations related to his complaint of hair loss. A dermatologist evaluated the patient, found no pathology, and told the patient that the minimal hair loss was normal. The patient refused to accept this judgment and demanded a further consultation. Because of managed-care restrictions, the patient consulted two additional specialists with his own (meager) funds with similar results. He had quit his job because of embarrassment about the hair loss and had become increasingly indebted financially. The psychiatric consultation infuriated him but he cooperated because he thought that the hair loss had begun with some “pills” he had been prescribed several years previously for anxiety and insomnia and that a psychiatrist might have something to add to understanding his case, including perhaps an antidote that might relieve the loss of hair. Treatment with an antidepressant agent proved unsatisfactory and the patient was started on an atypical antipsychotic drug with modest success. He complained less frequently about the hair loss and eventually began to express concern about his loneliness and his fear of being a burden to his aging parents, whom he lived with for financial reasons. His insight, however, remained limited and he intermittently voiced his concerns about his appearance and hair loss to his psychiatrist.

GRANDIOSE TYPE Delusions of grandeur (*megalomania*) have been noted for years. They were described in Kraepelin's paranoia and have been associated with conditions fitting the description of delusional disorder. Whether this subtype occurs in clinical practice sufficiently enough to warrant a classification is debatable.

A 51-year-old man was arrested for disturbing the peace. Police had been called to a local park to stop him from carving his initials and those of a recently formed religious cult into various trees surrounding a pond in the park. When confronted, he had scornfully argued that, having been chosen to begin a new townwide religious revival, it was necessary for him to publicize his intent in a permanent fashion. The police were unsuccessful at preventing the man from cutting another tree and made the arrest. Psychiatric examination was ordered at the state hospital, and the patient was observed there for several weeks. He denied any emotional difficulty and had never received psychiatric treatment. There was no history of euphoria or mood swings. The patient was angry about being hospitalized and only gradually permitted the doctor to interview him. In a few days, however, he was busy preaching to his fellow patients and letting them know that he had been given a special mandate from God to bring in new converts through his ability to heal. Eventually, his preoccupation with special powers diminished and no other evidence of psychopathology was observed. The patient was discharged, having received no medication at all. Two months later he was arrested at a local theater, this time for disrupting the showing of a film that depicted subjects he believed to be satanic.

MIXED TYPE The category of mixed type applies to patients with two or more delusional themes. However, this diagnosis should be reserved for cases in which no single delusional type predominates.

UNSPECIFIED TYPE The category of unspecified type is reserved for cases in which the predominant delusion cannot be subtyped within the previous categories. A possible example is certain delusions of misidentification, for example, Capgras's syndrome, named after the French psychiatrist who described the *illusion des sosies* or the illusion of doubles. The delusion in Capgras's syndrome is the belief that a familiar person has been replaced by an impostor or persons. Others have described variants of the Capgras's syndrome, namely the delusion that persecutors or familiar persons can assume the guise of strangers (*Frégoli's phenomenom*) and the very rare delusion that familiar persons could change themselves into other persons at will (*intermetamorphosis*). Each disorder is not only rare but is highly associated with schizophrenia, dementia, epilepsy, and other organic disorders. Reported cases have been predominantly in women, have had associated paranoid features, and have included feelings of depersonalization or derealization. The delusion may be shortlived, recurrent, or persistent. It is unclear whether delusional disorder can appear with such a delusion. Certainly, the Frégoli and intermetamorphosis delusions have bizarre content and are unlikely, but the delusion in Capgras's syndrome is a possible candidate for delusional disorder. The role of hallucination or perceptual disturbance in this condition needs to be explicated.

Shared Psychotic Disorder Shared psychotic disorder (also referred to over the years as *shared paranoid disorder, induced psychotic disorder, folie à deux*, and *double insanity*) was first described by Lasegue and Falret in 1877. It is probably rare, but incidence and prevalence figures are lacking and the literature consists almost entirely of case reports. The disorder is characterized by the transfer of delusions from one person to another. Both persons are closely associated for a long time and typically live together in relative social isolation. In its most common form, *folie imposée* (which is covered by the DSM-IV criteria in Table 13.2-10), the individual who first has the delusion (the primary case) is often chronically ill and typically is the influential member of a close relationship with a more suggestible person (the secondary case) who also develops the delusion. The secondary case is frequently less intelligent, more gullible, more passive, or more lacking in self-esteem than the primary case. If the pair separates, the secondary case may abandon the delusion, but this outcome is not uniformly seen. The occurrence of the delusion is attributed to the strong influence of the more dominant member. Old age, low intelligence, sensory impairment, cerebrovascular disease, and alcohol abuse are among the factors associated with this peculiar form of psychotic disorder. A genetic predisposition to idiopathic psychoses has also been suggested as a possible risk factor. The ICD-10 criteria for induced delusional disorder are given in Table 13.2-11.

A. A delusion develops in an individual in the context of a close relationship with another person(s), who has an already-established delusion.
B. The delusion is similar in content to that of the person who already has the established delusion.
C. The disturbance is not better accounted for by another psychotic disorder (e.g., schizophrenia) or a mood disorder with psychotic features and is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Table 13.2-10 DSM-IV Diagnostic Criteria for Shared Psychotic Disorder

A. The individual(s) must develop a delusion or delusional system originally held by someone else with a disorder classified in schizophrenia, schizotypal disorder, persistent delusional disorder, or acute and transient psychotic disorders.
B. The individuals concerned must have an unusually close relationship with one another, and be relatively isolated from other people.
C. The individual(s) must not have held the belief in question before contact with the other person, and must not have suffered from any other disorder classified in schizophrenia, schizotypal disorder, persistent delusional disorder, or acute and transient psychotic disorders in the past.

Table 13.2-11 ICD-10 Diagnostic Criteria for Induced Delusional Disorder

Other special forms have been reported, such as *folie simultanée*, where two people become psychotic simultaneously and share the same delusion. Occasionally, more than two individuals are involved (e.g., *folie à trois, quatre, cinq*; also *folie à famille*), but such cases are especially rare. The most common relationships in *folie à deux* are sister-sister, husband-wife, and mother-child, but other combinations have also been described. Almost all cases involve members of a single family.

There is some question whether patients with such conditions are truly delusional rather than highly impressionable, as frequently there is merely passive acceptance of the delusional beliefs of the more dominant person in the relationship until they are separated, at which point the unusual belief may remit spontaneously. In the DSM-IV criteria the requirement that the secondary case not have a psychotic disorder prior to onset of the induced delusion illustrates the relevance of this question. Also, the psychopathology of secondary cases varies. In DSM-III such patients were required to meet the criteria for paranoid disorder (i.e., show evidence of disturbed personality and perhaps evidence of other psychiatric disorder, mental subnormality, or dementia); some cases may fit the definition of delusional disorder.

A 40-year-old woman consulted physicians to help cure her problem of disagreeable body odor. The physicians failed to satisfy the woman's hopes of diagnosis and treatment, because they found nothing wrong with her. They did occasionally recommend psychiatric consultation, which she refused. Her husband, a quiet, retiring man of 35, accompanied his wife to all medical specialist consultations. When questioned, he shared his wife's concerns about body odor and provided many examples of how distressing this problem had become. When he was told that there really was nothing wrong with his wife, he objected repeatedly and proclaimed that the doctors were incompetent. A psychiatrist was called to the clinic to see the couple and found consistent stories from both. The woman accepted a recommendation for hospitalization on the psychiatry-medical unit, and the husband returned home. After weeks of evaluation and treatment, the woman was discharged. The husband had stopped visiting her, and when informed that his wife would be coming home he said that he thought she had been cured of her problem. However, 3 months later the couple was once again visiting different specialists.

A 52-year-old man was referred by the court for inpatient psychiatric examination after being charged with disturbing the peace. He had been arrested for disrupting a trial, complaining of harassment by various judges. He had walked into a courtroom, marched to the bench, and begun to berate the probate judge. While in the hospital, he told in detail of conspiratorial goings-on in the local judiciary. A target of certain judges, he claimed he had been singled out for a variety of reasons for many years: he knew what was going on; he had kept records of wrongdoings; and he understood the significance of the whole matter. He refused to elaborate on the specific nature of the conspiracy. He had responded to it with frequent letters to newspapers, the local Bar association, and even to a Congressional subcommittee. His mental state, apart from his story and a mildly depressed mood, was entirely normal. A family interview revealed that his wife and several grown children had shared the belief in a judicial conspiracy directed against the patient for a number of years. There was no change in delusional thinking in the patient or the family after 10 days of observation and the patient refused follow-up treatment.

The intensity of conviction is governed by the presence of the primary case in the life of the secondary case. Protection is provided by others who share the delusion and believe that the response is reasonable. Munro has found that shared psychotic disorder is frequently associated with delusional disorder, somatic type. In the second case described for persecutory delusional disorder, the husband, a somewhat passive and isolated man, shared his wife's convictions. With her treatment, he also became less concerned about a conspiracy and began to share his doubts about the whole matter with his therapist.

A recent summary of the Japanese literature indicated that in 97 cases of *fulie à deux*, the phenomenology and epidemiology were similar to those in western reports.

PATHOLOGY AND LABORATORY EXAMINATION

Pathology As in most psychiatric conditions, there is no evidence of localized brain pathology to correlate with clinical psychopathology in patients with delusional disorder. These patients seldom die early and show no consistent abnormalities on neurological examination. Delusions can complicate many disorders and virtually all brain disorders. Certain disorders produce delusions at rates greater than that expected in the general population: for example, epilepsy (especially of the temporal lobe), degenerative dementias (dementia of the Alzheimer's type and vascular dementia), cerebrovascular disease, extrapyramidal disorders, and traumatic brain injury.

Although many types of delusions have been reported in patients with brain disorders, there appear to be particular connections between delusion phenomenology and certain kinds of brain dysfunction. For example, patients with more severe cortical impairment tend to experience more simple, transient, persecutory delusions. This type of delusional experience is characteristic of conditions such as Alzheimer's disease, dementia and metabolic encephalopathy that are also associated with significant cognitive disturbance. More complex (i.e., elaborate and systematic) delusional experiences tend to be more chronic, intensely held, resistant to treatment, and associated with neurological conditions producing less intellectual impairment and strong affective components. Those features occur in patients with neurological lesions involving the limbic system or subcortical nuclei rather than cortical areas. That, coupled with the observation of response of some patients to drug treatment, such as pimozide and other medications, provides a rational basis on which to hypothesize the presence of subcortical pathology, possibly involving systems subserving temporolimbic areas. Available evidence suggests that if there is a lesion, it will be subtle.

Imaging studies have begun to yield subtle findings about delusional disorder. In one study using quantitative volumetry in magnetic resonance imaging, 16 patients with delusional disorder showed lateral ventricle enlargement greater than in subjects with schizophrenia ($N = 31$) and almost twice that of age-matched healthy controls ($N = 35$). Although this study showed no evidence of cortical infarcts (cerebrovascular injury), other studies have suggested that unsuspected cerebral infarction may occur in a high proportion of late-onset cases with delusional disorder. A further examination of these 16 delusional disorder subjects revealed that the degree of physiological right-left asymmetry was significantly greater in the temporal lobes.

Another study has tentatively concluded that eye-tracking dysfunction in the saccadic system is present in delusional disorder, possibly reflecting some attentional impairment related to voluntary saccadic eye movement areas. Despite the subtle nature of such findings, future empirical studies, guided by etiological hypotheses, could lead to breakthroughs. Given the low incidence of delusional disorder, intensive studies of specific cases and of conditions with delusions from known causes (and with identifiable neuropathologies) offer useful beginning points. Recent studies of misidentification syndromes (e.g., Capgras's syndrome) offer the prospect of developing more refined models of neuropathological mechanisms for delusional disorder.

Laboratory Examination A range of assessments is often necessary, but several have a high likelihood of detecting key factors in the case. The use of drug-screening measures is particularly valuable given the marked delusional responses induced by a number of substances, especially alcohol, amphetamines, cocaine, and other central nervous system stimulants.

Neuropsychological assessment may help to disclose evidence of impaired intellectual functioning suggestive of brain abnormalities. The assessment of intelligence may show discrepancies between verbal and performance scores as well as scatter in overall performance. Limited data on delusional disorder (especially the more chronic forms) suggest that average or marginally low intelligence is characteristic of patients with this condition. A preliminary comparison of patients with late-onset delusional disorder and schizophrenia has indicated neuropsychological impairment to be somewhat less for the former group. Projective testing such as the Rorschach test has limited value in making the diagnosis but may confirm features consistent with it. Deviation on the paranoia scale of the Minnesota Multiphasic Personality Inventory-2 (MMPI-2) has strong correlations to paranoid features and may help substantiate the diagnosis or raise it as a possibility.

DIFFERENTIAL DIAGNOSIS

Delusional Disorder Because delusional disorders are uncommon, idiopathic, and possess features characteristic of the full range of paranoid illnesses, differential diagnosis has a clearcut logic: delusional disorder is a diagnosis of exclusion. There are many conditions to consider (Table 13.2-4), especially the more common disorders associated with paranoid features (Table 13.2-12). To avoid premature diagnosis, careful evaluation is required.

Alcohol abuse
Drug abuse (especially CNS stimulants)
Anticholinergic toxicity
Sedative-hypnotic withdrawal
Delirium
Dementia
HIV infection
Brain tumor
Epileptic disorder
Mood disorders
Schizophrenia/schizoaffective disorders

Table 13.2-12 More Common Disorders Associated With Paranoid (Delusional) Features

Clinical assessment of paranoid features requires three steps. Initially, the clinician must recognize, characterize, and judge as pathological the presence of paranoid features. Next, the clinician should determine whether they form a part of a syndrome or are isolated. Finally, a differential diagnosis should be developed. The first of

the three steps must be pursued thoroughly. The clinician must be aware that a range of objective traits or behaviors (Table 13.2-3) is often found in paranoid illness and may constitute the only clue that a paranoid illness is present. Patients with paranoid symptoms are frequently unwilling to reveal their subjective experiences to examiners or to cooperate in the clinical investigation. Careful interviewing of the patient and other informants may disclose evidence that the behavior is clearly psychopathological; in other cases, however, that conclusion must await further observations. Sometimes investigation is required to determine whether the belief is indeed delusional or not. Premature acceptance that the patient has delusional disorder has at times been an embarrassment to some clinicians who learn that the patient was not deluded. If the judgment that the patient is delusional seems unassailable, then careful elaboration of the nature of the delusion is called for. The delusional thinking should be examined for its fixity, logic, encapsulation, degree of systematization and elaboration, and its effect on planning and action.

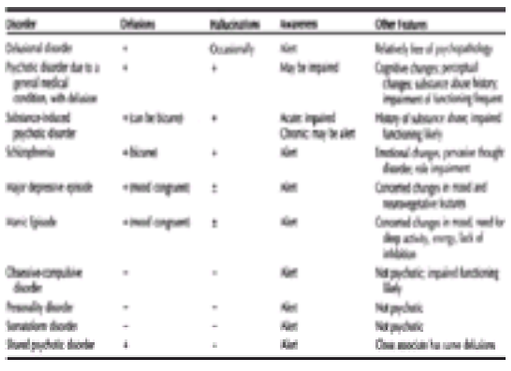
Having determined that a paranoid condition is present, the clinician should attend to premorbid characteristics (personality, adjustment, symptom development, medical problems, and so forth), the course, and associated symptoms to detect patterns of syndromic psychopathology or isolated symptom presentations—this is step two. The discovery of clouded consciousness, perceptual disturbance, other psychopathology, physical signs, or confusing symptoms may suggest different causes for paranoid features. Isolated acute paranoid symptoms, on the other hand, often appear early in medical illness.

Finally, the clinician should resist the temptation to make the diagnosis of schizophrenia or delusional disorder prematurely in cases where paranoid features are present because these features occur regularly in a variety of psychiatric and medical illnesses. Consequently, awareness of the multiple causes of paranoid features (step one) is essential to completing the differential diagnosis (step three).

Certain principles should guide effective assessment. First, it is important to have knowledge of the paranoid features and patterns of the clinical disorders in which they occur. For example, a small percentage (perhaps 10 percent) of schizophrenia cases have their onset after age 40, and most idiopathic psychiatric conditions do not begin after age 50. Second, the premorbid status of the patient should be determined. Generally, a normal premorbid state suggests that acute paranoid features are the consequence of medical disease. Third, an abrupt change in personality, mood, ability to function, and mental state should be noted because this may indicate complications resulting from medical disease. Fourth, in those cases in which there is evidence that the patient has been refractory to psychotropic medication or psychotherapy, the continuing presence of paranoid features should alert the clinician to consider alternative diagnoses.

The final diagnosis in cases where paranoid features are prominent should be made only following: (1) a complete medical and psychiatric history with special attention (because of their high prevalence) to alcohol and other drug substance use (including drugs of abuse, prescribed drugs, and over-the-counter medication use history); (2) a thorough physical examination, including neurological and mental status examinations; (3) appropriate laboratory studies, particularly serological, toxicological, endocrine, microbiological, radiological, and electroencephalographic studies.

There are certain delusional conditions that, because of their frequency and seriousness, should be routinely considered in the differential diagnosis, as among the most likely sources of delusions (Table 13.2-13). For example, delirium, dementia, psychotic disorder due to a general medical condition, and substance-induced psychotic disorder should receive special attention. Awareness of the potential for patients with each of these disorders to present with delusions in a state of clear consciousness prior to the elaboration of the defining syndromal symptoms should be kept in mind.



Disorder	Delusions	Hallucinations	Awareness	Other Features
Delusional disorder	+	Occasionally	Alert	Relatively free of psychopathology
Psychotic disorder due to a general medical condition, with delusions	+	+	May be impaired	Cognitive changes; perceptual changes; substance abuse history; impairment of functioning frequent
Substance-induced psychotic disorder	+ (can be bizarre)	+	Acute: impaired Chronic: may be alert	History of substance abuse; impaired functioning likely
Schizophrenia	+ Bizarre	+	Alert	Emotional changes, pervasive thought disorder, role impairment
Major depressive episode	+ (mood congruent)	±	Alert	Concurrent changes in mood and neurovegetative features
Manic Episode	+ (mood congruent)	±	Alert	Concurrent changes in mood; need for sleep; activity, energy, lack of inhibition
Obsessive-compulsive disorder	–	–	Alert	Not psychotic; impaired functioning likely
Personality disorder	–	–	Alert	Not psychotic
Somatoform disorder	–	–	Alert	Not psychotic
Shared psychotic disorder	+	–	Alert	Close association has same delusions

Table 13.2-13 Differential Diagnosis of Delusional Disorder

Psychotic Disorder Due to a General Medical Condition, With Delusions Delusions arise in a number of organic diseases and syndromes, many of which are listed in Table 13.2-2. What they frequently have in common is a disturbance of perception, particularly of visual and auditory functioning. Physical, neurological, and mental status studies as well as laboratory examinations will usually detect the organic causes of delusions. Each evaluation should focus on perceptual disturbance. Medical conditions associated with delusions should be searched for according to the guidelines outlined concerning differential diagnosis.

Substance-Induced Psychotic Disorder, With Delusions Drug intoxications are particularly relevant to this disorder. Substances of abuse, such as amphetamines, hallucinogens, phencyclidine, and cocaine; over-the-counter drugs, such as sympathomimetics; and prescribed drugs, such as steroids, methyldopa (Aldomet) and levodopa (Dopar, Larodopa) can cause psychotic disorder, with delusions, sometimes without prominent cognitive impairment. In acute states, confusion, disorientation, and clouding of consciousness may be evident; in chronic cases the picture may be more difficult to distinguish from delusional disorder because cognitive changes are less pronounced. A careful drug history and screen may establish the diagnosis. A history of alcohol abuse or dependence is so common that it should always be considered; alcoholism is often associated with jealousy, persecutory ideas, and poor impulse control.

Cognitive Disorders Dementia should be considered when paranoid features occur, particularly in older persons. Mental status examination should uncover characteristic cognitive changes absent in delusional disorder. Delirium, with its fluctuating course, confusion, memory impairment, and transient delusions, contrasts with the clarity of mental functioning and the persistence of delusions in delusional disorder and should be considered in acute cases with paranoid features.

Schizophrenia Delusions may be the presenting feature of schizophrenia and this diagnosis should be considered when the delusions are implausible or bizarre, affect is blunted or incongruous with thinking, auditory and possibly visual hallucinations are prominent, thought disorder is pervasive, or role functioning is impaired. Patients with paranoid schizophrenia may have somewhat less bizarre delusions, but role functioning is impaired; also prominent auditory hallucinations are often present, unlike in delusional disorder.

Shared Psychotic Disorder The delusions and symptoms of shared psychotic disorder may resemble those of delusional disorder; however, the delusions arise in the context of a close relationship with a delusional person, are identical in content to the delusions of that person, and diminish or disappear when secondary and primary cases are separated.

Mood Disorders With Psychotic Features The persistent and profound dysphoric mood of patients with depression often points to the proper diagnosis; in delusional disorder, affect may be intense, but is not itself an overwhelming or preoccupying experience to the patient. Delusions in depression, if present, are frequently related to mood (mood-congruent delusions) and usually indicate *severe* depression. For example, patients with feelings of worthlessness or guilt may consider that persecution against them is justified as a punishment for their evil ways. Somatic delusions may be puzzling to differentiate if the clinician fails to consider associated psychopathological features. If delusions occur exclusively during mood episodes, the diagnosis is mood disorder with psychotic features. *Depression* refers to a host of signs and symptoms, and usually has a constellation of neurovegetative features (affecting appetite, sleep, libido, energy, and so forth) that are not part of delusional disorder. Moreover, depression is frequently cyclical and is often associated with a positive family history of mood disorder. Patients with delusional disorder, in contrast, are remarkably free of symptoms other than the delusion. Chronic demoralization may result from repeated failure to obtain the kind of response desired in delusional disorder. Not infrequently, mood symptoms that meet the criteria for a mood episode are present in a delusional condition. Delusional disorder is diagnosed only if the total duration of all mood episodes remains brief relative to the total duration of the delusional disturbance. There is some evidence to suggest that depression is the most common comorbid condition in delusional disorder.

Manic Episode Manic delusions, often grandiose and therefore mood congruent, occur in the severest stages of this illness. This could mislead the diagnostician, but the cyclical nature, the marked change in mood (often euphoric or irritable at a very intense level), the reduced need for sleep, increased energy, easy distractibility, lack of focused concentration ability, lack of social inhibition, and increased activity level of manic episodes should be decisive in distinguishing that condition from

delusional disorder.

Obsessive-Compulsive Disorder Severe forms of this disorder should be considered in the differential diagnosis, especially obsessive-compulsive disorder with poor insight. Preoccupation with fear, unusual rituals, and obsessional beliefs may be puzzling, yet the pervasive effects of the condition on functioning differ from the experience of delusional disorder. Moreover, delusions and hallucinations should be absent. In practice, this differential diagnosis may be difficult to determine without a period of observation. In some cases it may be necessary to make the diagnosis and that of delusional disorder.

Somatoform Disorders Severe forms of body dysmorphic disorder may be difficult to distinguish from delusional disorder. The degree of conviction about imagined physical disfigurement may be the only guide for differential diagnosis. Lack of other features of psychopathology, often present in such cases, may also help to make the distinction.

Hypochondriasis may also be distinguished on the basis of absence of delusions, although many of the behaviors associated with delusional disorders, somatic type, may occur. Usually such patients reveal some doubt or uncertainty about the validity of their health preoccupations. Their overvalued beliefs about disease or affliction may clearly resemble delusional disorder, somatic type; severe cases may require considerable diagnostic effort, and as in obsessive compulsive disorder, also require a second diagnosis of delusional disorder.

Paranoid Personality Disorder Individuals with paranoid personality disorder by definition have abundant paranoid features. They are persistently oversensitive, ready to take offense, suspicious, resentful, rigid, and frequently self-centered. Rather than delusions, such persons tend to report strongly held ideas (overvalued ideas); generally, however, they are believed to be free of delusions, which is the most useful differential feature. There is some evidence that this personality pattern occurs often enough in families of probands with delusional disorder to suggest a possible genetic connection between the two.

Schizoid Personality Disorder and Schizotypal Personality Disorder Paranoid features may occur in patients with these personality disorders as well. The pervasive disturbance in personality functioning and the absence of delusions and other psychotic features are usually definitive distinguishing characteristics. Delusional disorder has generally not been associated with this type of premorbid pattern of personality.

Disorders of Aging Any discussion of differential diagnosis of paranoid features is incomplete unless consideration is given to the occurrence of paranoid features in the elderly. Paranoid features develop frequently in the elderly, and assessment in such cases should be particularly thorough because information about paranoid features among the aged is limited. There are several facts worth knowing: (1) the association of depressive illness with paranoid features is high enough to warrant suspicion of mood disorder in all cases with paranoid features: (2) there appears to be a late-onset syndrome sometimes labeled *late paraphrenia* or *late-onset schizophrenia* in which paranoid characteristics and hallucinosis frequently occur (this diagnosis, however, is warranted only when no other disorder can be diagnosed): (3) the sudden onset of acute paranoid features in the elderly can be a sign of cerebrovascular injury or other medical illness; (4) many of the medical conditions associated with delusions have increased incidence in the elderly population; for example, delusions can arise in the early course of presenile dementia and senile dementia conditions when deficits in clinical examination probes or neuropsychological performance may be inconspicuous; (5) perhaps most important for the general clinician is to recognize sources of increased risk of paranoid disorder among older individuals. It is now known that many factors contribute to the incidence of paranoid features in the aged, including lack of stimulating company, isolation, physical illness, the aging process itself, loss of hearing, and loss of visual acuity, each of which should be carefully assessed. Delusional disorder may be present in the elderly, may even have its onset in the elderly, but the frequency of other causes of paranoid features calls for a prudent, systematic search.

Shared Psychotic Disorder Malingering, factitious disorder with predominantly psychological signs and symptoms, psychotic disorder due to a general medical condition, and substance-induced psychotic disorder need to be considered in the differential diagnosis of shared psychotic disorder. The boundary between shared psychotic disorder and generic group madness, such as among the victims of the Jonestown massacre in Guyana, is unclear.

COURSE AND PROGNOSIS

Delusional Disorder Onset can begin in adolescence but generally occurs from middle to late adulthood with variable patterns of course, including lifelong disorder in some cases. Studies generally indicate that delusional disorder does not lead to severe impairment or change in personality, but rather to a gradual, progressive involvement with the delusional concern. Suicide has been associated with such disorders, although most patients live a normal life span. The base rate of spontaneous recovery may not be as low as previously thought, especially because only the more severely afflicted patients are referred for psychiatric treatment. Retterstol's personal follow-up investigation of a large series of cases has provided much of the viewpoint on the natural history of the disorder.

The more chronic forms of the illness (patients presenting with features for more than 6 months) tend to have their onset early in the fifth decade. Onset is acute in nearly two-thirds of the cases, and gradual in the remainder. In 53 percent the delusion has disappeared at follow-up, is improved in 10 percent, and is unchanged in 31 percent. In more acute forms of the illness the age of onset is in the fourth decade, a lasting remission occurs in over half of patients, and a pattern of chronicity develops in only 10 percent; a relapsing course has been observed in 37 percent.

Thus the more acute and earlier the onset of the illness, the more favorable the prognosis. The presence of precipitating factors signifies a positive outcome, as does female sex and being married. In terms of prognosis, the persistence of delusional thinking is most favorable for cases with persecutory delusions, and somewhat less favorable for delusions of grandeur and jealousy. However, outcome in terms of overall functioning appears somewhat more favorable for the jealousy subtype. Such patients may experience fewer hospitalizations and are less likely to have severe psychotic or schizophrenic deteriorations. Work status at follow-up has indicated that the majority of patients are employed. These observations, although limited to few cases, provide some basis for optimism: perhaps half of cases with delusional disorders may remit, but relapse and chronicity are common.

Comorbidity Depression can be diagnosed as a coexistent disorder in the course of delusional disorder. Evidence indicates that depression is an independent disorder in such cases, that is, the disorders appear to be coincidental in their combination rather than related etiologically. This judgment must be regarded as somewhat tentative, but the clinical value of recognizing comorbid (and often treatable) conditions is straightforward.

Shared Psychotic Disorder The nature of the disorder suggests that separation of the submissive person who has shared psychotic disorder (the secondary case) from the dominant person (the primary case) should result in the resolution and disappearance of the psychotic symptoms in the submissive person. Often, the submissive person requires treatment with antipsychotic drugs, just as the dominant person needs antipsychotic drugs for the psychotic disorder. Because the persons are almost always from the same family, they usually live together after being released from hospital. If separated, the patient will experience a possible remission; if not separated, the patient may have a similar prognosis as the primary case.

TREATMENT

Delusional Disorder Delusional disorder has generally been regarded as resistant to treatment and interventions have often focused on managing the morbidity of the disorder by reducing the impact of the delusion on the patient's (and family's) life. However, in recent years the outlook has become less pessimistic or restricted in planning effective treatment for these conditions. The goals of treatment are to establish the diagnosis, to decide on appropriate interventions, and to manage complications (Table 13.2-14). Fundamental to the success of these goals is an effective and therapeutic doctor-patient relationship, which is far from easy to establish. The patients do not complain about psychiatric symptoms and often enter treatment against their will; even the psychiatrist may be drawn into their delusional nets.

Rule out other causes of paranoid features
Confirm the absence of other psychopathology
Assess consequences of delusion-related behavior
Demoralization
Despondency
Anger, fear
Depression
Impact of search for "medical diagnosis," "legal solution," "proof of infidelity," etc. (i.e., financial, legal, personal, occupational, etc.)
Assess anxiety and agitation
Assess potential for violence, suicide
Assess need for hospitalization
Institute pharmacological and psychological therapies
Maintain connection through recovery

Table 13.2-14 Diagnosis and Management of Delusional Disorder

Psychosocial Treatments There is not enough evidence to substantiate the claims for any particular school or approach in talking with the patient. Insight-oriented therapy is usually contraindicated, but a combination of supportive psychotherapeutic approaches and possibly cognitive-behavioral interventions is sensible. It is unlikely that there is any psychiatric condition that requires greater diplomacy, openness, and reliability from the therapist. Considerable skill is required to deal with the profound and intense feelings that accompany these disorders.

Awareness of the fragile self-esteem and unusual sensitivity of these patients is essential for general management and somatic treatment. Clinical experience indicates that direct questioning about the veracity of the delusion, apart from carefully establishing its nature and the evidence to support it during clinical evaluation, is seldom helpful. Although forging an alliance may be especially difficult, responding to the patient's distress rather than to the delusion itself may be effective. Understanding that fear and anxiety serve to stimulate hostility may be the key to adopting a flexible approach that promotes empathy but maintains physical and emotional distance. Patients with the disorder suffer; they often feel demoralized, miserable, isolated, and abandoned. They may face rejection at home, from police or medical specialists, or on the job. However, they can be approached, and their treatment can focus on these experiences.

The goals of supportive therapy are to allay anxiety and initiate discussion of troubling experiences and consequences of the delusion, thereby gradually to develop a collaboration with the patient. In some patients this strategy allows the psychiatrist to suggest means of coping more successfully with the delusional thinking. For example, psychiatrists might encourage patients to keep their delusions to themselves because others might feel surprised, dismayed, or amazed, all at considerable cost to the patient. It may be possible to provide educational intervention to help amenable patients to understand how factors such as sensory impairment, social and physical isolation, and stress contribute to making matters worse. In all such approaches, the overriding aim is to assist in a more satisfying general adjustment.

Cognitive approaches have attempted to reduce delusional thinking through modification of the belief itself, focusing on the associated reasoning or the reality testing of the deluded patient. Unlike noncognitive behavioral approaches that center attention on reduction of verbal behavior (talking about the delusion), this strategy seeks a more lasting and clinically meaningful intervention through multiple techniques that keep the relationship with the patient collaborative. These techniques include distancing, homework, and exploration of emotions associated with various delusions. The effectiveness of cognitive and behavioral therapies has not been studied enough to justify recommendation. Additionally, it is important to determine the long-term as well as the short-term impact of these treatments; nevertheless, they are promising enough to justify continued assessment.

Somatic Treatment Delusional disorder is a psychotic disorder by definition, and the natural presumption has been that the condition would respond to antipsychotic medication. Because controlled studies are limited and the disorder is uncommon, the results required to support this practice empirically have been only partially obtained.

The disparate findings in the recent literature on delusional disorder treatment have been summarized recently, with several qualifications. Of approximately 1000 articles published since 1961, the majority since 1980, 257 cases of delusional disorder (consistent with DSM-IV criteria) of which 209 provided sufficient treatment detail to make comparison, were assessed. Overall treatment results indicated that 80.8 percent of cases either recovered fully or partially. Pimozide (the most frequently reported treatment) produced full recovery in 68.5 percent and partial recovery in 22.4 percent of cases (*N* = 143) treated whereas there was full recovery in 22.6 percent and partial recovery in 45.3 percent of cases (*N* = 53) treated with typical neuroleptic agents [e.g., thioridazine (Mellaril), haloperidol (Haldol), chlorpromazine loxapine (Thorazine), perphenazine (Trilafon), and others]. The remaining cases (*N* = 13) were noncompliant with any treatment, a finding the authors regard as an underestimation (6.2 percent). There were no specific conclusions drawn regarding treatment with selective serotonin reuptake inhibitors, (SSRIs), although a number of such reports have been published. While treatment of the somatic subtype generated the largest number of reports, these authors' meta-analysis indicated that the patterns of response were similar across all subtypes of delusional disorder. Follow-up data and personal experience indicated that long-term, possibly permanent, administration of medication is necessary to maintain remission.

The results of treatment with the serotonin-dopamine antagonists (i.e., clozapine [Clozaril], risperidone olanzapine [Zyprexa], and others) is preliminary. Two known cases of the persecutory subtype have been treated successfully with risperidone and there are published reports of clozapine effectiveness in the persecutory subtype (*N* = 2) and the somatic subtype (*N* = 2), and of risperidone effectiveness in the somatic subtype (*N* = 1). Unfortunately, systematic case series will develop slowly, but these preliminary results suggest that the atypical neuroleptic agents may add to the available treatment options.

Given the limited samples available, case reports are especially valuable; although many authors recommend multisite trials (to augment the small numbers of cases available at any one site), it would be beneficial for further single case reports to be published in the meanwhile. The existing literature could be improved with more attention paid to diagnosis, prior treatments, outcome, and level of compliance, as well as dosage schedules, adverse effects, length of treatment, as well as the reasons for selecting or changing particular agents. Use of (*N* = 1) single case research design strategies might also enhance the generalizability of findings.

The impression is growing that antipsychotic drugs are effective, and a trial, especially with pimozide or a serotonin-dopamine antagonist is warranted. Certainly, trials of antipsychotic medication make sense when the agitation, apprehension, and anxiety that accompany delusions are prominent.

Delusional disorders respond less well generally to electroconvulsive treatment than do major mood disorders with psychotic features. Some cases may respond to SSRIs, especially cases of body dysmorphic disorder with delusional concerns (Table 13.2-15). Where differential diagnosis is unclear between delusional disorder and psychotic depression, a trial of combined therapy with antipsychotic and antidepressant medications therapy may be worthwhile. When standard strategies are unsuccessful, trials of lithium (Eskalith) or of anticonvulsant medication such as carbamazepine (Tegretol) probably should be considered. However, no systematic information to support such approaches is yet available.

Dopamine receptor antagonists (particularly pimozide)
Serotonin-dopamine antagonists
Selective serotonin reuptake inhibitors

Table 13.2-15 Pharmacological Agents With Reports of Successful Use in Delusional Disorder

Somatic treatment is difficult to implement on two levels, The patients' insistence on lack of psychiatric problems may be an insurmountable barrier to initiating treatment, and their sensitivity to all adverse effects may constitute an additional frustrating factor in their care. Noncompliance continues to be a frequent observation in published clinical studies. An open and clear approach to warn patients about and to assist them through possible unpleasant experiences is essential, but the intrinsic nature of active resistance to psychiatric intervention also requires attention. In general, some patients, especially younger patients with delusional disorder, respond to supportive management and somatic treatment. Unfortunately, others, especially the elderly, may be refractory to attempts to reduce their delusional thinking. In all cases goals that are realistic and modest are the most sensible. As most of the difficulty of this disorder results from the effects of the patient's actions concerning the delusions, any preventive approach in that domain has considerable value.

Hospitalization Most delusional disorder patients can be treated effectively in outpatient settings; hospitalization may be necessary when there is potentially dangerous behavior or unmanageable aggressiveness. The patient may show signs of poor impulse control, excessive motor and psychic tension, unremitting anger, brooding, suicidal tendencies, and even threats of self-harm or aggression toward others. Suicidal ideation and planning are also potential grounds for hospitalization. Follow-up studies report suicide above the population base rate; patients with erotomania, jealousy, and persecutory delusions are particularly at risk. Once the psychiatrist decides to hospitalize the patient, it is preferable to inform the patient tactfully that voluntary hospitalization is necessary. If this strategy fails, legal means must be undertaken to commit the patient to a hospital.

Shared Psychotic Disorder The initial step in treatment is minimally the temporary separation of the affected person from the source of the delusions, the dominant partner. This step may not only be therapeutic but diagnostic when evidence of reduced delusional thinking and preoccupation accrue. The patient may need significant support to compensate for the loss of that person. The patient with shared psychotic disorder should therefore be carefully observed for the remission of the delusional symptoms. Antipsychotic drugs can be used if the delusional symptoms have not abated in 1 or 2 weeks.

Psychotherapy with nondelusional members of the patient's family should be undertaken, and psychotherapy with both the patient with shared psychotic disorder and the dominant partner may be indicated later in the course of treatment. In addition, the mental disorder of the dominant partner should be treated. The clinician might use family therapy and social support to modify the family dynamics and to prevent the recurrence of the syndrome. It is often useful to make sure that the family unit is exposed to input from outside sources to decrease the family's isolation. In short, a comprehensive approach emphasizing support and, when necessary, medication is useful.

SUGGESTED CROSS-REFERENCES

Conditions to be differentiated from delusional disorders are discussed in Chapter 12 on schizophrenia, in Chapter 14 on mood disorders, in Chapter 16 on somatoform disorders, in Chapter 24 on paranoid personality disorder, in Chapter 5 on obsessive-compulsive disorder, and in Chapter 10 on mental disorders due to a general medical condition. Aging and psychiatric disorders in the elderly is covered in Chapter 51.

13.3 ACUTE AND TRANSIENT PSYCHOTIC DISORDERS AND CULTURE-BOUND SYNDROMES

JUAN E. MEZZICH, M.D., FH.D., KEH-MING, LIN, M.D., M.P.H., AND CHARLES CAMPBELL HUGHES, IH.D.

While schizophrenia and mood disorders have commanded attention for many years and are likely to continue doing so for the foreseeable future, several other types of psychotic conditions are emerging as significant. Among these are psychotic disorders associated with general medical diseases and with the use of psychoactive substances as well as a complex group of acute and brief psychotic disorders.

Interest in the latter group stems from several factors. One concerns the phenomenological intricacy of disorders in this group. While all basically share loss of touch with reality or bizarre behavior as core psychopathology, they may diverge extensively in other aspects of their symptomatological profile. Another factor involves geographical epidemiology, with a disproportionately high frequency of acute and brief psychoses reported in the developing countries of the Americas, Asia, and Africa. A third factor involves cultural framework. Most of the syndromic or nosological predecessors of the acute and brief psychoses have been described in defined cultural contexts, whether as *bouffée délirante* in France, psychogenic psychosis in Scandinavia, cycloid psychosis in Germany, or the variety of transient psychoses reported in the traditional societies of the developing world.

The crucial role of the last factor connects the nosological category of acute transient psychoses to the culture-bound syndromes. The importance of cultural framework is certainly relevant to the full range of psychiatric disorders, both from clinical psychopathological and epidemiological perspectives, but it is most distinctive and illustrative in reference to culture-bound syndromes of both psychotic and nonpsychotic types.

DEFINITION AND COMPARATIVE NOSOLOGY

ICD-10 The acute psychoses described in northern European countries and in developing countries have been, for the first time, accommodated and organized in the 10th revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10), under the category of acute and transient psychotic disorders. The conditions are formulated and arranged according to the following principles, in order of priority:

1. An acute onset (less than 2 weeks) as the key criterion for the whole group. Acute onset denotes a change within 2 weeks or less from a state without psychotic features to a clearly abnormal psychotic state (not necessarily at its peak severity).
2. The presence of typical syndromes. Those include, first, a rapidly changing and variable state called polymorphic, prominent in acute psychoses described in several countries, and, second, the presence of typical schizophrenic symptoms.
3. The presence or absence of associated acute stress (within 2 weeks of the first psychotic symptoms).

P>Complete recovery usually occurs within 1 to 3 months (depending on the specific disorder), often within a few weeks or days. Only a small proportion of patients with these conditions develop persistently disabling states.

DSM-IV The evaluation of a psychotic patient requires consideration of the possibility that the psychotic symptoms result from a general medical condition (e.g., a brain tumor) or the ingestion of a substance (e.g., phencyclidine). Those two situations are classified in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) as psychotic disorder due to a general medical condition and substance-induced psychotic disorder, respectively. DSM-IV also includes a diagnosis of catatonic disorder due to a general medical condition to emphasize the special considerations regarding the differential diagnosis of catatonic symptoms.

DSM-IV also includes psychotic disorder not otherwise specified for psychotic disorders that do not meet the criteria for any other specific psychotic disorder. In previous editions of DSM these were called atypical psychoses.

ETIOLOGY

Both psychosocial and biological factors appear to play significant roles in the causation of acute brief psychoses and culture-bound syndromes. More than one factor may be present in any particular case, including a combination of psychosocial and biological factors.

Psychosocial Factors The diagnosis of psychotic disorders depends primarily on an accurate and thoughtful assessment of delusions, hallucinations, and bizarre psychomotor behaviors. Culture profoundly influences the meaning and nature of symptoms in the psychotic disorders reviewed in this chapter as well as the characteristics and meaning of the context and the consequences of the behaviors at hand. Attention to cultural framework can help one interpret behaviors properly and minimize misdiagnosis and diagnostic ambiguity in cross-cultural clinical situations. Lacking adequate information on what constitutes normal behavior patterns or culturally sanctioned idioms of distress, clinicians evaluating patients with different cultural, ethnic, or religious backgrounds are likely to misidentify less severe complaints or behaviors as delusional, hallucinatory, or bizarre. Similarly, they are likely to suspect the existence of major psychopathology in patients with fleeting psychotic manifestations.

Spiritual and religious beliefs can present major diagnostic dilemmas for clinicians. Beliefs in witchcraft and sorcery are common in many societies and may or may not be delusional. Spiritism, Santeria, and various other religious movements and different forms of shamanism practiced in many parts of the world encourage and sanction personal communication and active involvement with the dead, with spirits, and with the various deities. Such supernatural and mystical practices and experiences do not necessarily indicate psychopathology. However, such culturally congruent beliefs often also exert substantial pathoplastic influences on symptom formation in psychotic patients. Similarly, possession and trance phenomena are frequently seen in most non-Western societies, and it is often difficult to determine whether those experiences, in a particular case, are part of an ongoing psychotic process or are culturally and contextually appropriate.

Among the social factors that have been the subject of empirical research in recent years is (particularly among women) departure from the parental village for a number of reasons (e.g., marriage) and return to the parental village, including participation in events such as births and weddings. Investigators have also found a history of job stress (particularly among men) associated with the emergence of clinical manifestations.

Other social factors can also significantly influence symptom formation in psychiatric patients, thereby complicating the diagnosis of psychotic conditions. Sustained exposure to racist and discriminatory behaviors tends to increase vigilance and suspiciousness among members of ethnic minorities, and it may contribute to a higher propensity for paranoid symptoms in such persons. Paranoid symptoms are also more prevalent among those, such as refugees, who are forced to live in an unfamiliar cultural milieu. Fear of political persecution is a reality of life for persons living under oppressive regimes, and it may contribute to a higher prevalence of paranoid ideation in such societies. Because of those complications, it is often difficult to determine whether paranoid experiences among recent immigrants and sojourners are reactive or indicate a more serious and enduring psychotic process.

Biological Factors A variety of biological factors can have etiological involvement in the development of acute grief psychoses and culture-bound syndromes. One is infectious diseases, especially prevalent in developing countries. Empirical research documents the presence of fever in a disproportionately high number of patients with acute transient psychotic disorders.

Physical conditions (e.g., cerebral neoplasms, particularly of the occipital or temporal areas) can induce hallucinations. Sensory deprivation, as occurs in blind and

deaf persons, can also result in hallucinatory or delusional experiences. Lesions involving the temporal lobe and other cerebral regions, especially the right hemisphere and the parietal lobe, are often associated with delusions.

Psychoactive substances are common causes of psychotic syndromes. The most commonly involved substances are alcohol, indole hallucinogens (e.g., lysergic acid diethylamide [LSD], amphetamines, cocaine, mescaline, phencyclidine [PCP], and ketamine. Many other substances, including steroids and levothyroxine (Levoxyr, synthroid) can be associated with substance-induced hallucinations.

DIAGNOSIS AND CLINICAL FEATURES

ICD-10 ICD-10 provides general criteria for acute and transient psychotic disorders as well as criteria for four specific disorders (Table 13.3-1). ICD-10 also includes two residual categories for acute and transient psychotic disorders.

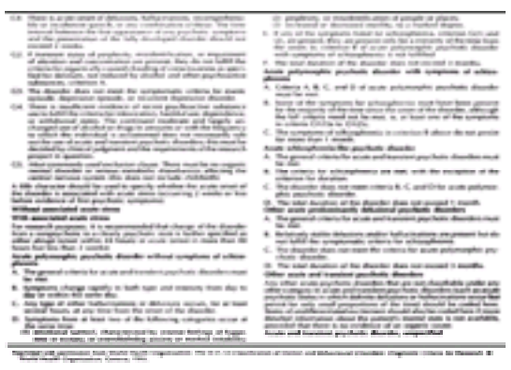

Table 13.3-1 ICD-10 Diagnostic Criteria for Acute and Transient Psychotic Disorders

Acute Polymorphic Psychotic Disorder Without Symptoms of Schizophrenia Acute polymorphic psychotic disorder without symptoms of schizophrenia is characterized by obvious but variable, rapidly changing hallucinations, delusions, and perceptual disturbances, often accompanied by emotional turmoil (happiness and ecstasy or anxiety and irritability). The criteria for manic episode, depressive episode, or schizophrenia are not met. The disorder tends to have an abrupt onset (less than 48 hours) and then a rapid resolution of symptoms. If symptoms persist for more than 3 months, the diagnosis should be changed (e.g., to persistent delusional disorder or some other nonorganic psychotic disorder). The diagnosis accommodates *bouffée délirante* and cycloid psychosis, both either unspecified or without symptoms of schizophrenia, as the following excerpt from the *ICD-10 Casebook* illustrates.

Mrs. Charrière is a 25-year-old Frenchwoman.

Problem Mrs. Charrière was brought by ambulance to a hospital emergency department in the city where she lived. Her husband reported that she had been perfectly normal until the previous evening, when she had come home from work complaining that “strange things were going on” at her office. She had noticed that her colleagues were talking about her, that they had been quite different all of a sudden, and that they had started behaving as if they were acting a part. Mrs. Charrière was convinced that she had been put under surveillance and that someone was listening in on her telephone conversations. All day she had been feeling as if she were in a dream. When she looked in the mirror, she had seemed unreal to herself. She had become increasingly anxious, incoherent, and agitated during the course of the day and had not been able to sleep at all during the night. She had spent most of the night looking out of the window. Several times she pointed at the crows in a nearby tree and told her husband, “The birds are coming.”

In the morning, Mr. Charrière found his wife on her knees as if she were praying. She knocked her head repeatedly against the floor and talked in a rambling way, declaring that she had been entrusted with a special mission, that her boss was a criminal, there were spies everywhere, and something terrible would happen soon. All of a sudden she calmed down, smiled at her husband, and told him that she had decided to convert from Catholicism to Islam. At that stage she became quite elated, started laughing and shouting, and declared that she and her husband could pray to the same god from then on. Shortly afterward she was terrified again and accused her husband of trying to poison her.

History Mrs. Charrière was brought up in a town in the west of France, where her parents owned a small restaurant. She did well in school, went on to college, and trained as an interpreter. During her training she met her future husband, who had come to France from Algeria to train as an interpreter himself. Because both she and her husband were agnostics, the fact that they came from different religious backgrounds had never been a problem. She took a job with an administration related to the European Communities, and her husband found a position with an international interpreting company. The couple were doing well, they had bought a nice house on the outskirts of Mrs. Charrière's home town, and were planning to have a child in the near future.

Mrs. Charrière's parents were in good health. She had a brother and two sisters. At age 18 her younger sister had had a nervous breakdown and in the ensuing years had been hospitalized repeatedly in a psychiatric hospital with a diagnosis of schizophrenia.

Both Mrs. Charrière and her husband refrained from drinking alcohol and were strongly opposed to any kind of drugs, including prescription medicines.

Mr. Charrière described his wife as an outgoing, sociable, and perfectly normal woman. However, he was quite worried about what was happening, all the more since she appeared to have symptoms resembling those he had observed in his sister-in-law.

Findings On admission Mrs. Charrière was frightened and bewildered but was oriented in time, place, and person. She was restless and constantly changed position, standing and sitting, moving about the room, shouting and screaming, weeping and laughing. She talked in a rambling way, shifting from one subject to another without any transition. Something criminal was going on at her office, she said, and she had discovered a secret plot. There were microphones hidden everywhere, she added, and “the birds are coming.” She wondered whether the physician was a real physician or “a spy in disguise.” She went on to speak about “my mission,” declared that Jesus had been a false prophet, that Muhammad was the real prophet, and that she would convince the world of what was right and wrong. She then began to explain that the truth was to be found in numbers. The digit “3” signifies good, she said, and the digit “8” represents evil. Suddenly she started to weep, explaining that her parents had died and that she wished to join them in heaven.

During the first days of hospitalization, Mrs. Charrière continued presenting a rapidly changing symptomatology. Her mood frequently shifted from sadness to elation, and the content of her delusions changed from persecution to mysticism. On several occasions she came out of her room and complained that she had heard people speaking about her, even when there was no one in the vicinity. When asked to describe what she was hearing, she spoke of voices coming from the corridor. She firmly denied that the voices might emanate from within her own body.

The physical examination did not reveal any abnormality. Results of blood tests, including thyroid function, were within normal limits, as were all other special investigations such as an electroencephalogram and brain scan.

Course Mrs. Charrière was treated with 30 mg of haloperidol (Haldol) during the first week, and with half this dose for the following week. After 2 weeks all of her symptoms had disappeared, and she was discharged on medication. She was seen once a week in the outpatient department for another month, during which the medication was progressively reduced and then stopped completely. Two months after the onset of the delusional episode, the patient continued to be free of symptoms.

Discussion The significant features of Mrs. Charrière's disorder were acute polymorphous delusions, rapidly changing mood disturbances, perplexity, depersonalization, and derealization without clouding of consciousness, and occasional auditory hallucinations. The disorder developed to its peak in 24 hours and was resolved in a few weeks, with complete recovery within 6 weeks. The patient had no psychiatric history.

Discussion The significant features of Mrs. Charrière's disorder were acute polymorphous delusions, rapidly changing mood disturbances, perplexity, depersonalization, and derealization without clouding of consciousness, and occasional auditory hallucinations. The disorder developed to its peak in 24 hours and was resolved in a few weeks, with complete recovery within 6 weeks. The patient had no psychiatric history.

The psychiatrist who dealt with this case made a diagnosis of *bouffée délirante*. This concept goes back to the French psychiatrist Valentin Magnan, whose pupil Paul Legrain, proposed the following diagnostic criteria: an acute onset of the disorder “like a bolt from the blue” in the absence of a psychosocial stressor; the presence of unsystematized and rapidly changing “polymorphic” delusions; the presence of emotional turmoil with intense and changing feelings of anxiety, happiness, or sadness; the presence of perplexity, depersonalization, or derealization without clouding of consciousness; and resolution of the disorder with complete recovery within 2 months.

In the ICD-10, the subtyping of acute and transient psychotic disorders rests on the acuteness of onset, the presence of typical syndromes, and the presence of associated stress. In the case of Mrs. Charrière, the onset was abrupt (i.e., the symptoms appeared within less than 48 hours), the syndrome was polymorphic, there were no typically schizophrenic symptoms, and the onset of the disorder was not associated with acute stress. Therefore, Mrs. Charrière's disorder must be coded as acute polymorphic psychotic disorder, without symptoms of schizophrenia, and without associated acute stress. (Reprinted with permission from *ICD-10 Casebook*.)

Acute Polymorphic Psychotic Disorder With Symptoms of Schizophrenia Acute polymorphic psychotic disorder with symptoms of schizophrenia is as polymorphic as the preceding disorders, but is additionally characterized by the consistent presence of typical schizophrenic symptoms. If the schizophrenic symptoms last more than 1 month, the diagnosis should be changed to schizophrenia. The disorder accomodates the concepts of *bouffée délirante* and cycloid psychosis, both with symptoms of schizophrenia.

Acute Schizophrenia-Like Psychotic Disorder Acute schizophrenia-like psychotic disorder is characterized by the consistent and stable presence of typical schizophrenic symptoms, without the polymorphic character of the foregoing disorders. If the schizophrenic symptoms last more than 1 month, the diagnosis should be changed to schizophrenia.

Other Acute, Predominantly Delusional Psychotic Disorders The other disorders are characterized by relatively stable delusions or hallucinations, without fulfilling the criteria for either schizophrenia or the acute polymorphic psychotic disorders. If the delusions persist for more than 3 months, the diagnosis should be changed to persistent delusional disorder and, if only the hallucinations persist, to other nonorganic psychotic disorder. The disorder accommodates the concepts of psychogenic paranoid psychosis and paranoid reaction.

Halime is a 22-year-old student. She is in her first year of medical school in Egypt.

Problem Accompanied by her mother, Halime came to see the physician at the psychiatric outpatient clinic. She was complaining about her nose. For the preceding week, from time to time she could smell a foul odor and was very afraid that it came from herself. She reported hearing voices talking about her behavior and telling her what to do. She had become extremely irritable and was unable to sleep. All these problems began 10 days after returning to her home in Alexandria on summer vacation from the medical school. She could find no obvious reason for the foul smell and the voices, but she thought the condition might be the result of witchcraft. She had developed a friendship with a young man, a fellow student at the medical school, and suddenly, just before the vacation, he had asked her to marry him. She was very surprised, became frightened, and had refused, which had upset him. She now suspected that her boyfriend had caused a spell to be cast on her because of her refusal. Halime's family said her condition was gradually getting worse. The foul smell and the voices seemed to affect her more each day.

History Halime was the first of two children born to a family of average income in Alexandria. Her father was a mechanic and seemed to be a rather shy and gentle person. The mother was ambitious and expressed great concern for her daughter's education. Her family reported that they had great hope that their first child would be a boy. The parents treated Halime as if she were a boy for the first 3 years of her life until the birth of a second child, which was a son. There was no information about mental disorders in the family.

Halime was introverted, thoughtful, and rather stubborn, with only a few friends. She had a high moral standard and had never dated or had sexual relations. She was doing very well at medical school and was determined to become a great physician in a culture where there is still some resistance to women physicians.

She had always been physically strong and had excellent health.

Findings On admission to the clinic, Halime was found to be very self-conscious and tried to avoid being seen by other people. She appeared tense and sad and seemed close to tears. She was reluctant and mentioned with hesitation some “extraordinary experiences.” These included the foul smell, which was like burned meat, and the voices that kept commenting on her behavior. She said the voices described what she was doing “here and now” and added comments. One example she gave of what the voices were saying was, “You are now speaking to the physician. You hope that he can help you, don't you? No hope. We shall overcome.” She explained that she believed this was the result of the witchcraft to which she had been subjected. She seemed able to differentiate in her mind between normal and abnormal perceptual experiences. She stated that she was able to make this distinction but was unable to do anything about the voices.

She showed emotional response of normal modulation, and no abnormalities of speech were observed. She was fully oriented as to time, place, and person and showed no impairment of memory. Her attention seemed sharpened, but her concentration was slightly diminished.

Careful physical and neurological examinations revealed no abnormality. An electroencephalogram with nasopharyngeal electrodes and a computed tomography scan also showed only normal results, and laboratory investigations, including thyroid parameters, were all normal.

Course Halime was prescribed haloperidol (3 mg per day) and a hypnotic. In the course of 4 days, the voices and the foul smell gradually disappeared. At the next visit to the clinic a week later, she complained of drowsiness and fatigue, aching and stiffness in the muscles, and difficulties with concentration. Her haloperidol was reduced to 1 mg per day, and the hypnotic was discontinued. After this she gradually improved, and after an additional 2 weeks she appeared well and was able to manage without medication.

Discussion After a sudden proposal of marriage less than 2 weeks before, Halime developed within just a few days a psychotic disorder with olfactory and auditory hallucinations and with commenting voices mentioning her in the third person. Her explanation about witchcraft cannot for certain be considered delusional in a culture where there is widespread belief in this phenomenon, although someone of her educational level would be expected to consider such belief as a superstition. Otherwise, Halime showed remarkable insight into the nature of her condition, with little or no impairment of her sense of reality. She showed no major disturbance of consciousness. No sign of organic etiology was observed, and psychoactive substance use was not suspected. She did not meet the symptomatic criteria for an affective episode.

On antipsychotic treatment she had a complete remission within 3 weeks. Thus, she had an acute and transient psychotic disorder. The symptomatology was not polymorphic but included a schizophrenic first-rank symptom of commenting voices. The subtype, therefore, will be schizophrenia-like disorder. The psychotic disorder followed, within 2 weeks, an event that may be considered stressful to a young female in Halime's cultural setting.

The full diagnosis therefore will be other acute predominantly delusional psychotic disorder, without associated acute stress. (Reprinted with permission from *ICD-10 Casebook*.)

Mr. Dubois is a 43-year-old Frenchman.

Problem Mr. Dubois was convinced that he was being watched and that someone was listening in on his telephone conversations. He was referred for psychiatric consultation by his family physician because he became increasingly anxious and felt that “strange things” were going on around him.

The problems had begun a week earlier, when Mr. Dubois started having doubts about whether his father, who had died more than 5 years before, was really dead or was still alive and being held hostage by the local municipal council, of which he had been a member until shortly before his death. After all, Mr. Dubois thought, his father had been the most honest man in the world, and it was likely that he had vehemently opposed a shady deal that the council had decided to pursue despite his misgivings.

Mr. Dubois had the impression that people looked at him “in a knowing way” or talked or behaved as if they wanted to convey secret messages. On several occasions, when he was alone, he heard voices whispering something he was not able to understand and noticed that normally static objects seemed to move before his eyes.

History Mr. Dubois came from a small industrial town. His father worked in the local steel factory and was very active in the labor union. The son was a bright student. He went to college and trained as a primary school teacher. He took up a teaching position in his home town, got married, had two children, and led a quiet and rather uneventful life.

The patient's father died of a heart attack at the age of 65. Although he had already retired from his job at that time, he had remained active in local politics. He had been a member of the municipal council until a few months before his death and had left the council only because he was compelled to resign as a result of some disagreements with his colleagues. He had felt very bitter about what he considered an unfair ousting, became morose, and hardly went into town afterward. In the view of his family, the forced resignation from the council contributed greatly to his death.

Mr. Dubois's mother was alive and well, and he had a brother who lived abroad. There was no history of mental illness in the family.

The patient felt quite depressed after his father's death but did not have any other psychiatric symptoms before his current episode. His physical health had always been excellent. He had never smoked, did not take drugs, and drank no alcoholic beverages except for an occasional beer or glass of wine.

Mrs. Dubois described her husband as hard-working, conscientious, and somewhat rigid in his opinions and with a tendency to bear grudges.

Findings On arrival at the psychiatrist's consulting room, Mr. Dubois was anxious, distressed, and bewildered but oriented in time, place, and person. He talked in a coherent way and, although initially suspicious, eventually gave a detailed account of what he had experienced during the previous week. He was convinced that there was a conspiracy against his family and that it had to do with his father's political activities. He remembered his father's funeral, but he was convinced that the coffin must have been empty. In his opinion the conspirators had kidnapped his father and had been holding him as a hostage all these years. Now they had decided to destroy the rest of the family. The patient admitted that he had been under stress for some time, that he had too much work, and that he had let himself get involved in too many activities both at school and outside of school. During the previous week he had not been able to sleep for more than a few hours each night, and he felt exhausted. He did not feel depressed, and in particular he had no feelings of self-reproach or guilt and no thoughts of suicide. He was aware, however, that something was wrong and agreed to stay in the hospital.

The physical examination did not reveal any abnormality. The results of blood tests, including thyroid function, were within normal limits, as were all other special investigations such as an electroencephalogram and brain scan.

Course Mr. Dubois was treated with a haloperidol (30 mg) during the first week, with the dose halved for the second week. After 2 weeks all of the symptoms had disappeared, and Mr. Dubois was discharged on medication. He was seen once a week in the outpatient department for another month, during which the medication was progressively reduced and then stopped completely. Six months after the onset of his delusional episode, the patient continued to be free of symptoms.

Discussion The significant features of Mr. Dubois's disorder were acute delusions, together with occasional auditory hallucinations and disturbance of visual perception. The disorder developed to its peak in a few days and was resolved in a few weeks, with complete recovery occurring within 6 weeks. The patient had no psychiatric history.

The patient was convinced that his father, who had died 5 years before, was in fact alive and held hostage by a group of conspirators. Although extremely improbable, his delusions cannot be considered theoretically and physically completely impossible and thus bizarre (as in a schizophrenia-like disorder).

Mr. Dubois's disorder otherwise meets the general criteria of an acute and transient psychotic disorder. It developed in a few days and could not be attributed to an organic mental disorder or a metabolic disturbance affecting the central nervous system, or to a mood disorder or the use of a psychoactive substance.

The symptoms did not change rapidly in both type and intensity, so they cannot be coded as acute polymorphic disorder. Because Mr. Dubois does not fulfill the symptomatic criteria for schizophrenia, the most probable diagnosis is other acute predominantly delusional psychotic disorder. The onset of the disorder was preceded by a period of overwork, but this did not amount to significant stress.

Other Acute and Transient Psychotic Disorders Other acute psychotic disorders not classifiable under the preceding categories are included in this category provided there is no evidence of an organic cause. Examples include acute psychoses with definite but fleeting delusions or hallucinations, and states of undifferentiated excitement.

Miss Maruyami is Indonesian. She is 30 years old and single and lives with her widowed mother.

Problem Miss Maruyami was brought to the psychiatric hospital by an uncle and two brothers-in-law, who had to hold her tightly to prevent her from running away. They almost had to carry her. She was hissing, spitting, and kicking about with her legs so that she was hardly able to walk.

Four days earlier she had returned from the market in a state of agitation and mild confusion. She claimed that one of the merchants had accused her of shoplifting, and, when she protested, he had further accused her of being an idler and a prostitute who ought to be sent to jail. Since then she had appeared restless, irritable, suspicious, and hardly able to sleep. At night she went about the house checking the locks and peeping through the windows at the neighbor's house in which she could see some shadows and lights move about. She felt that something hostile was going on and that the neighbor was spying on her because he wanted to rape her and kill her. She did not dare leave the house, and she refused to take any food or water; she claimed it had an odd taste because it had been poisoned by the neighbor. She also tried to prevent her mother from eating and drinking, and she threw away the food and vegetables. She became increasingly disturbed, sat staring wildly ahead of her, and hardly responded when her mother talked to her. When a sister and a brother-in-law came to persuade her to see a physician, she recognized them only with difficulty and ran to her room and locked herself up. On the night of her admission to the hospital, she suddenly left the house and attacked a passing neighbor with a large stone, knocking him to the ground. As the man lay there, Miss Maruyami hit him again and would have continued to do so if other neighbors had not restrained her.

History Miss Maruyami grew up in a middle-class neighborhood in Jakarta. She was the youngest of six daughters. At school she was a good student but had only a few friends and usually kept to herself. She did not continue her education after her junior high school year because her parents had financial problems. Since then she had stayed at home and helped her mother look after the house.

Her father, a merchant, died 10 years earlier when he was 60. Her mother is age 65 and is alive and well. Miss Maruyami's sisters are all married, but she is single and lives with her mother in a small house. Her relationship with her parents and sisters was good, although she was not particularly close to them. She was always a quiet person, spending much of her time lost in her thoughts, apparently daydreaming. She seemed shy and self-conscious, especially in public. She was noticeably overweight and often expressed fears that people were staring at her because of her obesity. These fears and suspicions became more marked as she grew older. Physically she was in good health, had never been to the hospital, and received no medication.

Findings On her admission Miss Maruyami was in a state of psychomotor excitement with aggressive and violent outbursts. When left alone she became more quiet and sat staring ahead of her, with sudden startling reactions to minor noises. She did not know the time or the place, but was fairly oriented as to her personal data. Her speech was restricted and somewhat incoherent. She refused to have physical or laboratory examinations, but accepted an injection of 10 mg of haloperidol and 5 mg of biperiden (Akineton). After this she became quiet and relaxed and finally fell asleep. The following day she seemed considerably improved. She was fully oriented but slightly perplexed, with partial amnesia about the previous few days. She only partly remembered her persecutory delusions. Confronted with the incident at the marketplace, she had a prolonged crying spell; became mildly excited, with fluctuations in attention and awareness of her surroundings; and finally again became herself.

She did not remember having hallucinations or other unusual experiences. She no longer believed that the neighbors wanted to kill her, and she wanted to get back home to her mother. She was discharged after 3 days, during which she continued to be quite natural without further medication.

Physical and neurological examinations, an electroencephalogram, and laboratory tests were all normal.

The neighbor, who had suffered a minor concussion of the head as a result of the attack, was not severely wounded. Being married to a distant relative of Miss Maruyami's mother, he did not want to bring the incident to the attention of the legal authorities.

Discussion Miss Maruyami developed a peracute psychotic disorder with persecutory delusions and possibly also with hallucinations, severe psychomotor excitation with violent behavior, and transient states of confusion. The disorder developed immediately after an event that she experienced as severely traumatic. She recovered with complete remission occurring within 1 week. It is a matter for discussion whether her transient states of confusion actually fulfill the criteria for organically caused clouding of consciousness. Otherwise, no signs of organic disorder were observed. Psychoactive substance abuse was not suspected. Miss Maruyami therefore most probably had an acute and transient psychotic disorder but did not fulfill the symptomatic criteria for an affective episode. The symptomatology was mixed and atypical, not pointing to any specific subtypes of acute psychotic disorders. The most likely diagnosis, therefore, is probably other acute and transient psychotic disorder.

It may further be discussed whether the traumatic event described would be considered as severely stressful to most people in similar circumstances within the same culture. In Miss Maruyami's case, she seems to have been made particularly susceptible by the presence of pronounced personality traits of introversive seclusion and hypersensitive self-consciousness, which with the present information is not sufficient for a subsidiary diagnosis of a personality disorder.

The diagnosis therefore would be other acute and transient psychotic disorder, with associated acute stress.

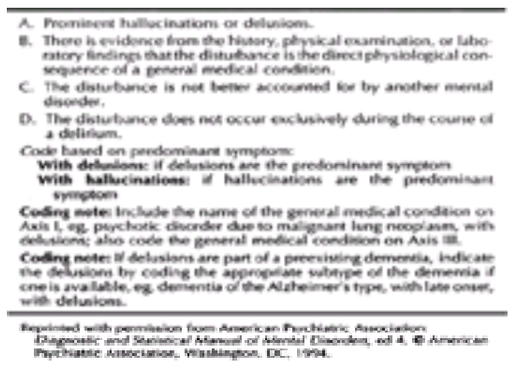
Acute and Transient Psychotic Disorder, Unspecified The residual category accommodates such concepts as brief reactive psychosis not otherwise specified. ICD-10 also includes another residual category for psychoses that do not meet the criteria for any other ICD-10 psychotic disorder (Table 13.3-2).

Psychotic disorders that do not meet the criteria for schizophrenia or for psychotic types of mood (affective) disorders, and psychotic disorders that do not meet the symptomatic criteria for persistent delusional disorder should be coded here (persistent hallucinatory disorder is an example). Combinations of symptoms not covered by the previous categories, such as delusions other than those listed as typically schizophrenic under criterion G1(1)b or d for schizophrenia (ie, other than completely impossible or culturally inappropriate) plus catatonia, should also be included here.

Table 13.3-2 ICD-10 Diagnostic Criteria for Other Nonorganic Psychotic Disorders

DSM-IV

Psychotic Disorder Due to a General Medical Condition The DSM-IV diagnosis of psychotic disorder due to a general medical condition (Table 13.3-3) combines into one diagnosis the two similar diagnostic categories in the revised third edition of DSM (DSM-III-R), organic delusional disorder and organic hallucinosis. The phenomena of the psychotic disorder are defined in DSM-IV by further specifying the predominant symptoms. When the diagnosis is used, both the medical condition and the predominant symptom pattern should be included in the diagnosis (e.g., psychotic disorder due to a brain tumor, with delusions). The DSM-IV criteria further specify that the disorder does not occur exclusively while the patient is delirious or demented and that the symptoms are not better accounted for by another mental disorder.



A. Prominent hallucinations or delusions.
B. There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct physiological consequence of a general medical condition.
C. The disturbance is not better accounted for by another mental disorder.
D. The disturbance does not occur exclusively during the course of a delirium.

Code based on predominant symptom:
With delusions: if delusions are the predominant symptom
With hallucinations: if hallucinations are the predominant symptom

Coding note: Include the name of the general medical condition on Axis I, eg, psychotic disorder due to malignant lung neoplasm, with delusions; also code the general medical condition on Axis III.

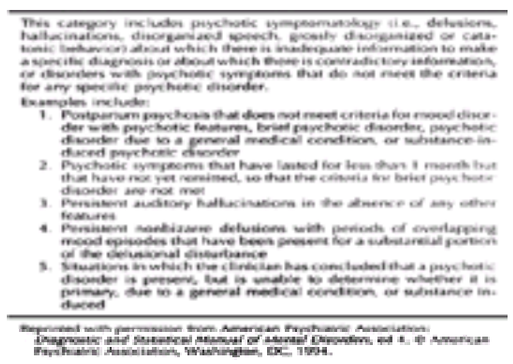
Coding note: If delusions are part of a preexisting dementia, indicate the delusions by coding the appropriate subtype of the dementia if one is available, eg, dementia of the Alzheimer's type, with late onset, with delusions.

Table 13.3-3 DSM-IV Diagnostic Criteria for Psychotic Disorder Due to a General Medical Condition

Substance-Induced Psychotic Disorder DSM-IV has combined the various DSM-III-R diagnostic categories that relate to psychoactive substance–induced psychotic disorders into a single diagnostic category, substance-induced psychotic disorder (Table 13.3-4). The diagnosis is reserved for persons who have substance-induced psychotic symptoms in the absence of reality testing. Persons who have substance-induced psychotic symptoms (e.g., hallucinations) but who have retained reality testing should be classified as having a substance-related disorder (e.g., phencyclidine intoxication with perceptual disturbances). The intent of including the diagnosis of substance-induced psychotic disorder with the other psychotic disorder diagnoses is to prompt the clinician to consider the possibility that a substance is causally involved in the production of the psychotic symptoms. The full diagnosis of substance-induced psychotic disorder should include the type of substance involved, the stage of substance use when the disorder began (e.g., during intoxication or withdrawal), and the clinical phenomena (e.g., hallucinations or delusions).

Table 13.3-4 DSM-IV Diagnostic Criteria for Substance-Induced Psychotic Disorder

Psychotic Disorder Not Otherwise Specified The psychotic disorder not otherwise specified category is used for patients who have psychotic symptoms (e.g., delusions, hallucinations, and disorganized speech and behavior) but who do not meet the diagnostic criteria for other specifically defined psychotic disorders. In some cases the diagnosis of psychotic disorder not otherwise specified may be used when not enough information is available to make a specific diagnosis. DSM-IV has listed some examples of the diagnosis to help guide clinicians (Table 13.3-5).



This category includes psychotic symptomatology (i.e., delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior) about which there is inadequate information to make a specific diagnosis or about which there is contradictory information, or disorders with psychotic symptoms that do not meet the criteria for any specific psychotic disorder.

Examples include:
1. Postpartum psychosis that does not meet criteria for mood disorder with psychotic features, brief psychotic disorder, psychotic disorder due to a general medical condition, or substance-induced psychotic disorder
2. Psychotic symptoms that have lasted for less than 1 month but that have not yet remitted, so that the criteria for brief psychotic disorder are not met
3. Persistent auditory hallucinations in the absence of any other features
4. Persistent nonbizarre delusions with periods of overlapping mood episodes that have been present for a substantial portion of the delusional disturbance
5. Situations in which the clinician has concluded that a psychotic disorder is present, but is unable to determine whether it is primary, due to a general medical condition, or substance-induced

Table 13.3-5 DSM-IV Psychotic Disorder Not Otherwise Specified

Culture-Bound Syndromes Perhaps the most dramatic example of the difficulties in applying Western-based nosological concepts and criteria cross-culturally can be found in the ongoing controversy surrounding the culture-bound syndromes. As pointed out by the United States National Institute of Mental Health Culture and Diagnosis Group, the term “culture-bound syndrome” denotes recurrent, locality specific patterns of aberrant behavior and troubling experiences that appear to fall outside conventional Western psychiatric categories. These include categories in folk nosological systems (often organized in relation to perceived cause and symptom clusters) as well as idioms of distress or culturally salient expressions for securing social support and communicating symptoms.

A variety of disorders discussed in the cross-cultural psychiatric and anthropological literature do not conform with conventional DSM-IV or ICD-10 diagnostic categories. In previous diagnostic classifications such disorders were often called atypical psychoses or were placed in the category psychotic disorder not otherwise specified. Taken as a whole, however, labeling these seemingly bizarre and culturally different patterns of disorder psychotic is somewhat problematic. The symptoms displayed include many clinical expressions of lesser severity than those of typical psychotic disorders. Frequently the diagnosis of a psychotic disorder is made simply on the basis of category label rather than a close examination of the symptomatic data. Further discussion of these disorders are discussed with a selection of such syndromes in Table 13.3-6.

Table 13.3-6 Culture-Bound Syndromes

While all psychiatric diagnoses are influenced by their cultural context, perhaps the most dramatic example of the difficulty in applying Western-based nosological concepts and criteria cross-culturally can be found with respect to the so-called culture-bound syndromes. The controversy arises over the issue of whether the assumptions embedded in Western diagnostic schemes (e.g., DSM or ICD) relating to concepts of normality and the assemblages of symptoms characteristic of a discrete disorder are universally applicable in all cultural settings.

The term “culture-bound syndrome” evolved, in fact, to denote recurrent, locality-specific patterns of aberrant behavior and troubling experiences that appear to fall outside conventional Western psychiatric categories. The descriptive phrases formerly used to refer to such phenomena include “cultural and ethnic psychoses and neuroses” and “atypical and exotic psychotic syndromes.” The *culture-bound syndrome* is now generally accepted to refer to culturally based and named patterns of symptoms of mental distress or maladaptive behavior that are prominent in folk belief and practice. Such patterns have etiologies framed by lay cultural assumptions, which in numerous cases are based upon the effects of sorcery, breach of taboo, intrusion of a disease object, intrusion of a disease-causing spirit, or loss of soul. The psychodynamics often represent an exaggerated or pathological reaction to conflicts engendered by central values and behavioral norms in the society. Since they are embedded in the group's ethnomedical practice, institutionalized patterns of diagnoses and societal response typically include treatment by indigenous healers.

Assessment of such syndromes must start with recognition that each human society has an indigenous body of beliefs and practices directed at explaining and treating disease and disorder, and patients internalize that worldview during the process of enculturation. They share their experiences and deal with distress through the currency of commonly understood symbols and meanings. In that light, the diagnostic encounter itself can be used as a point of entry into the patient's world, a “classroom for investigation and discovery.” One cannot become an anthropological expert about each and every possible cultural group but one can try to learn by asking patients to share the cultural norms as they understand them.

PATHOLOGY AND LABORATORY EXAMINATIONS

A large number of general medical problems may cause or exacerbate patients' psychotic conditions, often involving confusing and puzzling presentations. They include such conditions as infections (including human immunodeficiency virus [HIV] infection), head trauma, endocrine disorders (Cushing's and Addison's diseases and disorders of the thyroid and parathyroid glands), autoimmune diseases (systemic lupus erythematosus), vitamin deficiencies, seizure disorder, genetic diseases (Wilson's disease, acute intermittent porphyria), drug and toxin exposures, and the effects of psychoactive drugs. Those conditions are usually included in the differential diagnosis of any psychotic disorder, but they should be given more careful consideration when the patient's symptom profile is polymorphic or inchoate. For such patients laboratory tests should include not only the routine chemistry panels (electrolytes, glucose determination, complete blood counts, renal and liver functions) and urinalysis, but also thyroid function test, syphilis tests, and determination of serum cortisol concentration, vitamin B_{12} and foliate concentrations, and calcium and phosphate concentrations. In addition to a chest X-ray and an electrocardiogram (ECG), an electroencephalogram (EEG) should also be considered. An EEG with sleep deprivation and nasopharyngeal leads also has been recommended. Computerized EEG (brain mapping), magnetic resonance imaging (MRI), single photon emission computered tomography (SPECT), and neuropsychological testing may yield useful information.

Psychosocial assessment should include a careful review of the patient's life history, with special attention to the patient's personality traits and recent stresses. A detailed assessment of family history and dynamics should also be included. Contextual factors, such as psychosocial stressors and supports, should be carefully appraised, along with the ability of the person to perform basic roles (e.g., occupationally, with family and socially).

COURSE AND PROGNOSIS

Patients with an acute and transient psychotic disorder usually experience complete recovery within 1 to 3 months (depending on the specific disorder), often within a few weeks or days, and only a small proportion of patients develop persistently disabling states.

Limited data on the longitudinal course of patients with culture-bound syndromes suggest that some of them eventually develop clinical features compatible with a diagnosis of schizophrenia, bipolar disorder, cognitive disorder, or other psychotic disorders. Thus gathering information from all possible sources is crucial. Since clinical pictures evolve over time, thorough reevaluations should be conducted periodically to refine the diagnosis and improve clinical care.

TREATMENT

The treatment plan for any patient must be individualized, but that principle is particularly important when dealing with cases of acute and transient psychotic disorders and culture-bound psychotic disorders. Because these conditions are intricate and heterogeneous, no standard treatment strategy exists that can be applied to most cases. However, a number of general principles are crucial for the cases of those patients.

Careful evaluation, clinical observation, and comprehensive information gathering are the cornerstones of treatment planning for any psychiatric or general medical disorder. Longitudinal assessments are particularly important in the management of patients who are experiencing acute and transient psychotic disorders and culture-bound disorders. A multiaxial assessment using such schemas as those in ICD-10 and DSM-IV can substantially enhance the validity of diagnosis and the effectiveness of clinical care. A systematic evaluation of the cultural framework of the individual's identity, illness explanations, social context and functioning, and the doctor-patient relationship can be conducted along the lines of DSM-IV.

Because all the disorders discussed in this section share the presence of psychosis, pharmacotherapy frequently involves the use of antipsychotic drugs. Some evidence indicates that the dosage of antipsychotic drugs necessary for acute transient psychotic disorders is significantly lower than that required for other psychotic conditions, especially schizophrenia. It is thus prudent to use the lowest dose that can control the patient's symptoms. Since acute and transient psychotic disorders are often episodic, intermittent use of antipsychotic drugs, guided by the emergence of psychotic symptoms, is worth considering.

Depending on the clinical features of particular patients, many other psychiatric medicines have also been recommended. They include benzodiazepines for controlling agitation, lithium (Eskalith, Lithobid) for modulating mood swings, and antidepressants for ameliorating depressive symptoms. These medicines are often used in conjunction with antipsychotic agents. Anticonvulsants such as carbamazepine (Tegretol) have been reported effective in treating a number of psychotic patients with atypical features.

Limited research has been conducted to date on the efficacy of various psychosocial interventions for managing acute and transient psychotic disorders and culture-bound disorder, but it seems reasonable to consider findings from studies involving other psychotic conditions. These include approaches based on expressed emotion concepts, psychoeducational and skill-competence training, and Thomas McGlashan's phase-specific theory on the need for stimulation in schizophrenic patients (the avoidance of excessive stimuli in the acute phase and the uses of structured activities and stimuli in later phases). It is important to consider involving the family in therapy and to establish a supportive and trusting therapeutic relationship.

The importance of cultural issues in the evaluation and treatment of atypical psychoses can hardly be exaggerated, especially when dealing with patients from non-Western and ethnic minority populations. Cultural information is not only crucial for accurate diagnosis, but also indispensable in the formulation of treatment plans. Treatment approaches that do not take the patient's sociocultural background into account are likely to fail, no matter how well intentioned the therapists may be. For example, in cultures in which family and group harmony and unity are valued over individual independence, the rigid application of Western-based psychotherapeutic techniques may exacerbate, rather than ameliorate, the patient's psychopathological condition. Consideration of the intercultural elements in the clinician-patient relationship is also fundamental for establishment of rapport and effective engagement of the patient and the family in the treatment process.

One promising avenue is collaboration with indigenous healers. Several researchers have reported on their success in the use of indigenous and traditional healers in the treatment of psychiatric patients, especially those whose psychotic conditions are substantially connected to culture-specific beliefs (e.g., fear of voodoo death). Others have mentioned the potential pitfalls and problems in such collaboration. Decisions about involving indigenous healers should be individualized and thoughtfully planned, taking into consideration the setting, the thoughtfulness and flexibility of the available healers, the type of psychopathology, and the patient's characteristics. The World Health Organization (WHO) has long advocated implementation at the local level of a policy of close collaboration between the

conventional health system and traditional medicine, particularly between individual health professionals and traditional practitioners.

Wohl has stressed the implications for therapeutic practice of the need to understand the cultural dynamics of a patient's background. While this is important for therapy with any patient, it is particularly necessary in the treatment of a suspected culture-bound syndrome:

Much of the time in the practice of psychotherapy, culture remains silent, part of a non instrusive background, an invisible yet pervasive feature of the context of psychotherapy ... Psychotherapies differ as the cultures in which they were born and nurtured differ, and each bears the indelible imprint of its culture source. Psychotherapy and the human relationships that comprise both its subject matter and the medium in which it is performed have embedded within them values, rules, assumptions, myths, and rituals of a particular culture. Psychotherapy is thus inescapably bound to a particular cultural framework.

Treatment of a culture-bound syndrome poses several diagnostic challenges, the first of which is determining whether the symptomatology represents a culturally appropriate adaptive response to a situation (although it may be different from the therapist's). What are clinicians to do if confronted with a series of symptoms in a patient that do not fit their conventional diagnostic model? Clinicians are well advised to (1) know or search out the demographics of the local population or catchment area being served; (2) recognize that there is always a local pattern of conceptualization, naming, vocabulary, explanation, and treatment of patterns of distress that afflict a community, including mental disorders; and (3) talk with the family, get instructed in local customs; or search out other modes of documentation.

But while the observed symptom may be familiar in a general sense to the clinician (although pathoplastically different), what separates such an event from conventional understanding is the meaning of the symptom for patients and those who share their cultural background. Determining that meaning and particularly their belief about what has caused the distress, is an important entry point in facilitating therapeutic management and enhancing adherence to the treatment plan. As part of taking the history, ask these patients what they think could have caused the problem, requesting the “patient's explanatory model”: (1) What do you think has caused your problem? (2) Why do you think it started when it did? (3) What do you think your sickness does to you? How does it work? (4) How severe is your sickness? Will it have a short or long course? (5) What kind of treatment do you think you should receive?

Such insight into the dynamics of the patient's world facilitates the clinician's efforts to adapt his or her techniques (e.g., general activity level, mode of verbal intervention, content of remarks, tone of voice) to the cultural background of clients; communicate acceptance of and respect for the patients in terms that make sense within their cultural frame of reference; and be open to the possibility of more-direct intervention in the life of the patient than conventional approaches might suggest.

In conclusion, the treatment of patients experiencing acute transient psychotic disorders and culture-bound syndromes, even more than that of patients with other psychiatric disorders, should be personalized and comprehensive, using judiciously all biological, psychological, and social therapies pertinent to the problem at hand and keeping in mind the cultural framework of the patients and their families.

SUGGESTED CROSS-REFERENCES

Culture-bound syndromes are discussed further in Section 4.1 on anthropology and psychiatry. Cultural psychiatry is also discussed in Section 4.4. The influences of culture on the nature of and responses to psychiatric disorders are discussed in Section 4.2 on sociology and psychiatry. Section 4.3, on evolutionary biology and psychiatry, is also relevant. Section 9.2 covers international perspectives on psychiatric diagnosis. Section 13.1 is devoted to other psychotic disorders, including brief psychotic disorder.

13.4 POSTPARTUM PSYCHIATRIC SYNDROMES

RUTA NONACS, M.D., PH.D. AND LEE S. COHEN, M.D.

During the postpartum period up to 85 percent of women experience some type of mood disturbance (Table 13.4-1). For most women the symptoms are transient and relatively mild; however, some women experience a more disabling and persistent form of mood disturbance. Although postpartum mood disorders are relatively common, depressive symptoms that emerge during the postpartum period are frequently overlooked by patients and their caregivers. Puerperal affective illness places both the mother and infant at risk and has been associated with significant long-term effects on child development and behavior. Therefore, prompt recognition and treatment of puerperal mood disorders are essential.

Disorder	Prevalence	Onset	Characteristic Symptoms
Postpartum blues	30 to 85 percent	Within first week	Mood lability, tearfulness, insomnia, anxiety
Postpartum depression	10 to 15 percent	Usually insidious, within first 2 to 3 months	Depressed mood, excessive anxiety, insomnia
Puerperal psychosis	0.1 to 0.2 percent	Usually within first 2 to 4 weeks	Agitation and irritability, depressed mood or euphoria, delusions, depersonalization, disorganized behavior

Table 13.4-1 Classification of Postpartum Mood Disorders

HISTORY

Although Hippocrates is often acknowledged as the first to have recognized postpartum mental illness, historians have noted that what Hippocrates described as a mania related to lactation was more likely delirium associated with puerperal sepsis, which was relatively common in ancient Greece. There was virtually no mention of puerperal mental illness until the 1700s and 1800s, when case reports of “puerperal insanity” began to appear in the French and German medical literature. In 1818 Jean Esquirol was the first to provide detailed, quantitative data on 92 cases of puerperal psychosis drawn from his studies at the Salpetriere during the Napoleonic Wars. However, it is Victor Louis Marce, a French physician, who is best known for his descriptions of postpartum psychiatric illness. In his famous text published in 1856, *Traite de la Folie des Femmes Enceintes,* he laid the foundation for modern conceptualizations of mental illness related to pregnancy and the postpartum period. He was also the first to suggest that physiological changes associated with the puerperium influence maternal mood.

Although puerperal psychosis was familiar to most clinicians by the late nineteenth century, less attention was given to milder forms of puerperal illness. It was not until the 1960s that B. Pitt first described an “atypical” depression (later called “maternity blues”) that affected mothers soon after childbirth and, in contrast to puerperal psychosis, was relatively mild and short-lived. The concept of a more severe form of nonpsychotic depressive illness (i.e., postpartum depression) emerged during the 1970s. Large, population-based studies, which relied upon structured interviews and standardized diagnostic criteria to identify psychiatric illness in new mothers, demonstrated high rates of mild to moderate depression in women during the first 6 months after delivery.

Recent studies have consistently identified the postpartum period as a time of increased risk for the development of psychiatric illness in women. One of the most frequently cited studies on affective illness during the puerperium described a sharp peak in the number of psychiatric admissions during the first 3 months after delivery. Subsequent studies indicate that women who present with significant psychiatric symptoms during the postpartum period suffer most commonly from a mood disorder, either major depressive disorder or a bipolar disorder. During the postpartum period women appear to be at much higher risk for the development of psychiatric illness than at other times in their lives.

Various investigators have argued that postpartum mental illness consists of a group of psychiatric disorders that are specifically related to pregnancy and childbirth and therefore exists as a distinct diagnostic entity. However, recent evidence suggests that affective illness that emerges during the puerperium does not differ significantly from affective illness occurring in women at other times. This opinion is reflected in the fourth edition of *Diagnostic and Statistic Manual of Mental Disorders* (DSM-IV), which includes postpartum psychiatric illness as a subtype of either bipolar disorder or major depressive disorder.

DEFINITION

Postpartum psychiatric illness is typically divided into three categories: (1) postpartum blues, (2) nonpsychotic postpartum depression, and (3) puerperal psychosis (Table 13.4-1). It is helpful to conceptualize these disorders as existing along a continuum, as there may be significant overlap between these three diagnostic subtypes. Although these subtypes vary in severity, it is not clear if they actually represent three distinct disorders.

ETIOLOGY

The puerperium is a period during which significant physiological and psychosocial changes occur. The extent to which a rapidly changing hormonal environment influences the emergence of mood illness has been considered by many. In fact, it was Victor Louis Marce who first suggested, long before the emergence of the modern field of endocrinology, that a physiological transition occurring after delivery may play an important role in the pathogenesis of puerperal illness. Other investigators have emphasized the importance of biological vulnerability to psychiatric illness during the puerperium and have suggested that some individuals may be more susceptible to the physiological changes characteristics of the postpartum period. However, the impact of psychosocial factors in the development of mood disorder during the postpartum period cannot be underestimated. Given the multiplicity of these factors and the complexity of their interactions, it has been extremely difficult to identify risk factors for puerperal psychiatric illness and to reliably predict who will experience postpartum mood disturbance.

Demographic Variables Many groups have investigated the relationship between risk for postpartum blues and depression and various demographic variables including age, marital status, parity, education level, and socioeconomic status; however, there is little consistent evidence to suggest that any particular demographic factor places a woman at increased risk for puerperal affective illness. Although most studies do not find a strong relationship between age and risk for puerperal illness, there is at least one report of high rates (26 percent) of postpartum depression in adolescent mothers.

It has been significantly more difficult to identify risk factors for puerperal psychosis, given the low prevalence of this subtype of postpartum illness. Some reports suggest that primiparous women are more vulnerable to postpartum psychosis than multiparous women. Other studies suggest that various obstetrical complications

(e.g., prolonged labor, caesarean section, stillbirth) may increase the likelihood of postpartum psychosis.

Psychosocial Factors Psychosocial variables appear to play an important role in determining vulnerability to affective illness during the postpartum period. Many studies have sought to link certain personality traits and coping styles with risk for postpartum illness but have yielded inconsistent findings. In contrast, several groups have demonstrated that stressful life events during pregnancy or near the time of delivery appear to increase the likelihood of postpartum depressive illness. One of the most consistent findings is that among women who report marital dissatisfaction or inadequate social supports, postpartum depressive illness is more common.

History of Psychiatric Illness Although it has been difficult to identify specific demographic and psychosocial variables that consistently predict risk for postpartum illness, there is a well-defined association between all types of postpartum psychiatric illness and a personal history of mood disorder (Table 13.4-2). At highest risk are women with a history of postpartum psychosis; up to 70 percent of women who have had one episode of puerperal psychosis will experience another episode following a subsequent pregnancy. Similarly, women with histories of postpartum depression are at significant risk, with rates of postpartum recurrence as high as 50 percent. Women with bipolar disorders also appear to be particularly vulnerable during the postpartum period, with rates of postpartum relapse ranging from 20 to 50 percent.

Disorders	Risk of Relapse at Future Pregnancy
Postpartum Psychosis	70%
Postpartum Depression	50%
Bipolar I Disorder	20–50%
Major Depressive disorder	30%

Table 13.4-2 History of Psychiatric Illness and Risk for Puerperal Relapse

The extent to which a history of major depressive disorder influences risk for postpartum illness is less clear. As compared to women who have experienced only nonpuerperal depressive episodes, women with histories of postpartum depression are clearly at greater risk. Women with histories of mild to moderate affective illness who remain euthymic during pregnancy are probably at lower risk for postpartum depression than women with severe, recurrent depression. For all women (with or without histories of major depression), the emergence of depressive symptoms during pregnancy increases the likelihood of postpartum depression.

Hormonal Factors The postpartum period is characterized by a rapid shift in the hormonal environment. Within the first 48 hours after delivery, estrogen and progesterone concentrations fall dramatically; similarly, cortisol concentrations drop after delivery. As these steroid hormones have been implicated in the pathogenesis of nonpuerperal mood disorders, many investigators have proposed a role for these hormones in the emergence of a mood disorder during the postpartum period.

Progesterone Several anecdotal reports have suggested that mood disturbance during the puerperium may be related to declining concentrations of progesterone and have suggested a beneficial effect of progesterone hormone replacement in the treatment of postpartum psychiatric illness. However, several studies have found no consistent differences in postpartum progesterone concentrations between depressed and nondepressed women.

Estrogen Several studies have explored the relationship between postpartum estrogen levels and risk for postpartum blues and depression and have suggested that postpartum estrogen deficiency may result in postpartum mood disturbance. Although some studies have observed lower estrogen levels in women who developed postpartum blues and depression, most of the studies have yielded negative findings.

Cortisol Concentrations of cortisol, which are high late in pregnancy, peak during labor and delivery. Cortisol concentrations drop rapidly after delivery and then return to baseline levels gradually over the next month. While disturbances in the hypothalamic-pituitary-adrenal axis may play an important role in at least some cases of nonpuerperal major depression, recent studies do not consistently support a relationship between cortisol levels and postpartum blues or depression. The dexamethasone (Dexacidin) suppression test does not appear to distinguish between depressed and nondepressed women during the acute puerperium.

Thyroid Hormones Thyroxine concentrations are high during pregnancy and fall during the postpartum period. Abnormalities in thyroid function tests are relatively common findings during the postpartum period, and clinical hypothyroidism is present in up to 10 percent of women after childbirth. Although thyroid dysfunction, particularly hypothyroidism, may produce psychiatric symptoms, no studies have consistently reported an association between postpartum depression or blues and thyroid dysfunction (either hypothyroidism or hyperthyroidism).

DIAGNOSIS AND CLINICAL FEATURES

Postpartum psychiatric disorders have not been listed separately in recent revisions of the DSM, and no specific criteria for the diagnosis of postpartum psychiatric illness have been provided. According to DSM-IV, postpartum psychiatric illnesses may be indicated with a postpartum onset specifier. The specifier with postpartum onset may be used to describe a major depressive, manic, or mixed episode (in major depressive disorder or bipolar I or II disorder) or brief psychotic disorder, when the episode occurs within the first 4 weeks after delivery (Table 13.4-3). In contrast, the Marce Society, an international scientific organization dedicated to the study of postpartum psychiatric disorders, defines postpartum psychiatric illness as any episode occurring within the first year after childbirth.

Specify if:
With postpartum onset (can be applied to the current or most recent major depressive, manic, or mixed episode in major depressive disorder, bipolar I disorder, or bipolar II disorder, or to brief psychotic disorder)
Onset of episode within 4 weeks postpartum.

Table 13.4-3 DSM-IV Criteria for Postpartum Onset Specifier

Given the prevalence of mood disturbance during the puerperium, it is most striking that diagnoses of postpartum mood disorders are so commonly missed. The emergence of mood disorder during the puerperium is often overlooked or ignored by both patients and their caregivers. Some studies report that less than one-third of women with postpartum illness seek professional help. It is common for women to report the persistence of depressive symptoms for many months before the initiation of treatment. Although the symptoms of depression may remit spontaneously, many women are still depressed at 1 year after childbirth. The reasons for this delay in treatment are not well understood. What is clear, however, is the significant impact of untreated depression on both mother and infant. Untreated depression may contribute to the development of a more chronic and refractory mood disorder in the mother. There are also significant data that demonstrate the adverse effects

of maternal depression on the cognitive, emotional, and social development of the child. Given these significant risks, prompt recognition and treatment of postpartum mood disorders are essential.

Postpartum Blues Many women experience mild depressive symptoms during the first week after delivery, which are commonly known as postpartum blues or “baby blues.” Depending on the criteria used to diagnose the blues, prevalence estimates range from 30 to 85 percent. Women with postpartum blues report a variety of symptoms, including dysphoria, mood lability, irritability, tearfulness, anxiety, and insomnia. These symptoms typically peak on the fourth or fifth day after delivery and remit spontaneously by the tenth postpartum day. Postpartum blues are relatively benign and are, by definition, time-limited. While the occurrence of postpartum blues does not necessarily reflect psychopathology in the mother, some women with blues will go on to develop postpartum depression. Women with histories of mood disorder require close monitoring, as some data suggest that blues may herald the development of major depressive disorder in women who have had previous episodes of affective illness. Symptoms of the blues that persist beyond the second postpartum week require further evaluation to rule out the evolution of a more serious affective illness.

Postpartum Depression Major depressive disorder is relatively common during the postpartum period. Both retrospective and prospective community-based studies have revealed rates of postpartum minor and major depression in the range of 10 to 15 percent. These rates of depression reported in puerperal cohorts are similar to those observed in nonpuerperal populations of women.

While some women report the acute onset of symptoms shortly after delivery, depression more commonly develops insidiously over the first 6 postpartum months. A significant proportion of women actually experience the onset of depressive symptoms during pregnancy. The signs and symptoms of postpartum depression are generally indistinguishable from those characteristic of nonpsychotic major depressive disorder that occurs in women at other times. Dysphoric mood, irritability, anhedonia, insomnia, and fatigue are frequently reported; somatic complaints are also common. Ambivalent or negative feelings toward the infant are often reported, and it is common for a woman with postpartum depression to express doubts or concerns about her ability to care for her child. In its most severe form, postpartum depression may result in profound dysfunction. Suicidal ideation is frequently reported; however, suicide rates appear to be relatively low in women who become depressed during the postpartum period.

Although few studies have evaluated the prevalence of comorbid psychiatric illness in this population, severe anxiety and obsessionality are prominent in women with puerperal illness. Symptoms of generalized anxiety, panic disorder, and obsessive-compulsive disorder are often observed in women with postpartum depression.

Puerperal Psychosis Puerperal psychosis is the most severe form of postpartum psychiatric illness. In contrast to postpartum blues and depression, puerperal psychosis is a rare event that occurs in approximately 1 to 2 per 1000 women after childbirth. Its presentation is often dramatic, with onset of psychosis as early as the first 48 to 72 hours postpartum. Most women with puerperal psychosis develop symptoms within the first 2 to 4 weeks after delivery.

In women with this disorder, psychotic symptoms and disorganized behavior are prominent and cause significant dysfunction. Puerperal psychosis resembles a rapidly evolving affective psychosis with manic, depressive, or mixed features. The earliest signs are typically restlessness, irritability, and insomnia. Women with this disorder typically exhibit a rapidly shifting depressed or elated mood, disorientation or depersonalization, and disorganized behavior. Delusional beliefs often center on the infant and include delusions that the child may be defective or dying, that the infant has special powers, or that the child is either Satan or God. Auditory hallucinations that instruct the mother to harm or kill herself or her infant are sometimes reported. Although most believe that this illness is indistinguishable from an affective (or manic) psychosis, some have argued that puerperal psychosis may be clinically distinct in that it is more commonly associated with confusion and delirium than nonpuerperal psychotic mood disorder.

Screening Severe postpartum depression and psychosis are easily recognized; however, milder or more insidious forms of depressive illness are frequently missed. Even severe depressive symptoms that arise during the puerperium may be dismissed by both patients and caregivers as normal or natural consequences of childbirth. Since it is difficult to reliably predict which women in the general population are likely to develop puerperal illness, it is advisable to screen all women for depression during the postpartum period. The greatest obstacle to the diagnosis of postpartum depression is the extent to which clinicians fail to inquire about affective symptoms in women during the postpartum period.

The standard postpartum obstetrical visit at 6 weeks and subsequent pediatric appointments are ideal times to screen for postpartum depressive illness. Screening for mood disorders during the postpartum period may, however, be more difficult than at other times. Many of the neurovegetative signs and symptoms characteristic of major depression (e.g., sleep and appetite disturbance, diminished libido, low energy) are also observed in nondepressed women during the acute puerperium. Various rating scales that have been used to facilitate the diagnosis of depression in nonpuerperal cohorts (e.g., Beck Depression Inventory) have not been validated in puerperal populations. In contrast, the Edinburgh Postnatal Depression Scale (EPDS) is a 10-item, self-rated questionnaire (Table 13.4-4) that has been used extensively for the detection of postpartum depression and has demonstrated satisfactory sensitivity and specificity in women during the postpartum period. Although not commonly employed, the EPDS could easily be integrated into the routine evaluation of women in both obstetrical and pediatric settings and would alert the physician to those women who are in need of a more thorough psychiatric evaluation.

Table 13.4-4 Edinburgh Postnatal Depression Scale (EPDS)

DIFFERENTIAL DIAGNOSIS

Various medical illnesses may mimic psychiatric illness during the postpartum period. Hypothyroidism is relatively common in women after delivery and may cause a constellation of symptoms resembling major depressive disorder. Women with a preexisting psychiatric illness may experience exacerbation of symptoms during the puerperium. Furthermore, any psychiatric illnesses may emerge for the first time during the postpartum period. Schizophrenia or schizoaffective disorder, particularly when characterized by prominent positive symptomatology, may be difficult to distinguish from puerperal psychosis. Whereas mood disorders are the most common type of postpartum psychiatric illness, anxiety symptoms are common during the postpartum period and many present either with or without a coexisting mood disorder. The postpartum period may represent a time of increased risk for the development of panic disorder and obsessive-compulsive disorder.

COURSE AND PROGNOSIS

The duration of postpartum illness appears to be variable. Puerperal episodes are often relatively short-lived and last no more than 3 months. Many women, however, have a more prolonged illness, and several studies suggest that depressive episodes tend to be longer and more severe in those with histories of major depressive disorder; some reports suggest that duration may be related to the severity of illness.

In general, women with postpartum mood disorders have a good prognosis. In about half of the cases, puerperal depression or psychosis represents the first onset of psychiatric illness. Although there appears to be a subpopulation of women who have only puerperal episodes of psychiatric illness, the majority of women with a postpartum mood disorder will go on to have nonpuerperal episodes of psychiatric illness. Rates of recurrence appear to be particularly high in women with bipolar disorders.

Postpartum mood disorders are associated with recurrent psychiatric illness in the mother. The failure to treat may contribute to the emergence of a long-term and more treatment refractory mood disorder. There is data to suggest that the outcome is better in those that receive treatment early during the course of illness.

There is a growing body of literature that demonstrates the detrimental effect of maternal depression on child development. Attachment difficulties are common in new mothers and may be quite severe in women with postpartum depression or psychosis. Long-term follow-up studies have shown that behavioral difficulties were more common in the children of mothers who suffered from postpartum depression. These children also performed worse on structured tests of cognitive ability than children who had mothers who were not depressed. One of the most disastrous outcomes involves harm to the infant. Child abuse and neglect are more common among women who suffer from postpartum psychiatric illness. Infanticide is relatively uncommon; however, it is more likely to occur in women who present with psychotic symptoms.

TREATMENT

Like nonpuerperal depressive illness, postpartum mood disorders present along a continuum. Patients may experience mild or moderate symptoms, or they may present with a more severe depression, characterized by prominent neurovegetative symptoms and marked impairment of functioning. A clinician's approach to the patient should be guided by the type and severity of the symptoms and the degree of functional impairment. However, before initiating psychiatric treatment, medical causes for mood disturbance (e.g., thyroid dysfunction, Sheehan's syndrome) must be excluded. Initial evaluation should include a thorough history, physical examination, and routine laboratory tests.

Postpartum Blues As postpartum blues are usually mild in severity and resolve spontaneously, no specific treatment other than support and reassurance is indicated. Although the symptoms may be distressing, they typically do not affect the mother's ability to function and to care for her infant. Psychiatric consultation is generally not required; however, the patient should be instructed to contact her obstetrician or primary care provider if the symptoms persist longer than two weeks to ensure the early identification of a more severe affective illness. Women with histories of psychiatric illness, particularly postpartum depression, should be monitored more closely, as they are at higher risk for significant puerperal illness.

Postpartum Depression Although postpartum depression is relatively common, few studies have systematically assessed the efficacy of nonpharmacological and pharmacological therapies in the treatment of this disorder. However, there are no data that suggest that postpartum depression should be managed differently than nonpuerperal major depressive disorder. There is, nonetheless, an apparent tendency to treat women with postpartum depression with less urgency than nonpuerperal patients, which places both the mother and infant at risk. In the absence of systematically derived data, depression that emerges during the postpartum period demands the same intensity of treatment as depression that occurs at other times; the earlier the treatment is initiated, the better the prognosis.

Nonpharmacological Therapy Nonpharmacological therapies are frequently employed in the treatment of postpartum depression; however, there are limited data to support the efficacy of these interventions. Although studies that have assessed the use of insight-oriented psychotherapy in the treatment of postpartum depression have yielded inconsistent findings, more structured types of individual psychotherapy have shown promise.

Interpersonal therapy is a time-limited and interpersonally oriented psychotherapy that has been used successfully (in nonpuerperal cohorts) to treat acute episodes of depression. This modality of therapy focuses primarily on interpersonal relationships and has been adapted for the treatment of postpartum depression. In this setting, interpersonal therapy may be used to address the following issues: role transition, disruption of relationships with the spouse and other social supports, and interaction with the infant. In a recent pilot study, interpersonal therapy was shown to be effective for the treatment of women with mild to moderate postpartum major depressive disorder.

Cognitive-behavioral therapy may also be useful in this setting. A recent randomized, placebo-controlled treatment trial demonstrated that short-term cognitive behavioral therapy was as effective as treatment with fluoxetine (Prozac) in women with postpartum depression. Sessions were structured to focus on issues specific to new mothers with postpartum depression: inability to cope with the demands of caring for a child, perceived lack of support, absence of enjoyable activities. A significant reduction in depressive symptoms was observed in women after six sessions of cognitive-behavioral therapy delivered over a 12-week period.

These nonpharmacological interventions may be particularly useful for those patients who are reluctant to use psychiatric medications or for patients with milder forms of depressive illness. These interventions would ideally be performed in the home by a visiting nurse or another trained individual. Further investigation is required to determine the efficacy of this modality in women who suffer from more severe forms of postpartum mood disturbance.

Pharmacological Therapy To date, few studies have assessed the efficacy of antidepressant medications in the treatment of postpartum mood disturbance. The majority of these studies have been open trials, although more recent investigations have employed a double-blind design. Several studies have demonstrated the efficacy of antidepressant medications (e.g., fluoxetine, sertraline [Zoloft] venlafaxine [Effexor]) in the treatment of postpartum major depressive disorder. In all of these studies, standard antidepressant doses were effective and well tolerated.

The choice of an antidepressant drug should be guided by the patient's prior response to antidepressant medication and a given medication's adverse effect profile. Fluoxetine and the other selective serotonin reuptake inhibitors (SSRIs) are ideal first-line agents because they are anxiolytic, generally nonsedating, and well tolerated. Tricyclic drugs are frequently used and, because they tend to be more sedating, may be more appropriate for women who present with sleep disturbance. Given the severity of anxiety symptoms in women with postpartum depression, the adjunctive use of a benzodiazepine (e.g., clonazepam [Klonopin], lorazepam [Ativan]) may be very helpful.

Women who plan to breastfeed must be informed that all psychiatric medications, including antidepressant drugs, are secreted into the breast milk. Concentrations in the breast milk appear to vary widely; however, there is no data to suggest that one antidepressant agent is safer than another for women who are nursing. Available data on the use of tricyclic drugs, fluoxetine, and sertraline during breastfeeding suggest that severe complications related to neonatal exposure to psychotropic medications in breast milk appear to be rare; however, the long-term effects of even trace amounts of medication on the developing brain are not known.

Inpatient Hospitalization In cases of severe postpartum depression, inpatient hospitalization may be required, particularly for patients who are at risk for suicide. In the United Kingdom innovative treatment programs involving joint hospitalization of the mother and baby have been successful; however, mother-infant units are much less common in the United States. In women with severe postpartum illness, electroconvulsive therapy (ECT) should be considered early because it is safe and highly effective. In choosing a treatment strategy, it is important to consider the impact of prolonged hospitalization of the mother on infant development and attachment.

Hormonal Therapy The postpartum period is associated with rapid shifts in the reproductive hormonal environment, most notably a dramatic fall in estrogen and progesterone levels. With increasing evidence to suggest that gonadal steroids modulate neurotransmitter systems involved in the pathogenesis of mood illness, many have proposed a role for hormonal manipulation in the treatment of postpartum mood disturbance. Some authors have suggested that progesterone is helpful in the management of postpartum depression; however, systematically derived data do not demonstrate its usefulness in this setting. A.J. Gregoire and colleagues described a beneficial effect of exogenous estrogen therapy in women with postpartum depression. Although this study was small and was confounded by the inclusion of patients treated with antidepressant medication prior to receiving hormonal therapy, it is the first study to demonstrate that estrogen alone (or possibly when used as an adjunct to an antidepressant agent) may be useful in the treatment of postpartum depression. At this point it is unclear which patients are likely to respond to this type of hormonal therapy. In cases of moderate to severe depression, first-line pharmacological treatment should be an antidepressant medication.

Puerperal Psychosis Puerperal psychosis is a psychiatric emergency that typically requires inpatient treatment; however, systematically derived guidelines for the treatment of this disorder are lacking. Given the well-established relationship between puerperal psychosis and bipolar disorders, some have argued that postpartum psychosis is indistinguishable from a manic psychosis and should be treated similarly. Short-term treatment with an antipsychotic medication as well as a mood stabilizer is appropriate. Most groups have used lithium in the treatment of postpartum psychosis; the efficacy of other mood stabilizers (i.e., valproic acid [Depakene], carbamazepine [Tegretol]) in this setting is not known. Breastfeeding is typically avoided in women treated with lithium, as it is secreted at high levels into the breast milk and may cause neonatal toxicity. ECT (often bilateral) is well tolerated and rapidly effective. Failure to treat puerperal psychosis aggressively places both the mother and infant at increased risk for harm. Rates of infanticide associated with untreated puerperal psychosis have been estimated to be as high as 4 percent; the risk for suicide in this population is also extremely high.

Although some authors recommend the discontinuation of psychotropic medications soon after the psychosis clears, others suggest a longer duration of treatment, arguing that women are at risk for psychiatric illness for up to 1 year after childbirth. Prolonged exposure to conventional antipsychotic agents should be minimized,

given the risk of tardive dyskinesia. When neuroleptic medications are discontinued, they should be tapered slowly and with close observation for early signs of recurrence. Treatment with a mood stabilizer should be maintained beyond the resolution of active symptoms to reduce risk for relapse. The appropriate duration of treatment with a mood stabilizer has not been well established. Whether all patients with puerperal psychosis should subsequently receive maintenance treatment with a mood stabilizer for an indefinite period of time is controversial, although several studies suggest that recurrent mood illness (most commonly bipolar disorder) is the rule following an episode of puerperal psychosis.

Prevention It is not possible to reliably predict which women in the general population will experience postpartum mood disturbance. The identification of women at greatest risk for puerperal illness improves the likelihood of early diagnosis and treatment and provides an opportunity to limit morbidity in the mother and her infant. It is possible to identify certain subgroups of women who are more vulnerable to postpartum mood disorder. Women with histories of affective illness are at particular risk for puerperal worsening of mood. Risk for puerperal relapse as a function of subtype is summarized in Table 13.4-2.

As it is possible to identify certain subgroups of women who are at risk for postpartum illness, many investigators have explored the appropriateness of prophylactic intervention. Several studies have demonstrated that women with histories of bipolar disorders or puerperal psychosis benefit from prophylactic lithium therapy instituted just prior to delivery (at 36 weeks gestation) or no later than the first 48 hours postpartum. Prophylactic lithium appears to significantly reduce relapse rates, as well as to diminish the severity and duration of puerperal illness.

Yet to be adequately investigated is the extent to which other populations of women may also benefit from pharmacological prophylaxis. A pilot study described a beneficial effect of prophylactic antidepressants administered to women with histories of postpartum depression. The efficacy of prophylactic antidepressants in women with recurrent, nonpuerperal depression is currently under investigation.

Psychosocial interventions, such as psychoeducational and supportive groups, are frequently included in the care of women during the postpartum period. The extent to which these interventions are effective in preventing postpartum mood disturbance has not been systematically studied. Several investigators have explored the use of psychoeducational groups during pregnancy and the postpartum period and have demonstrated a significant reduction in the incidence of postpartum depression in women who received this intervention, as compared to untreated controls.

Interpersonal therapy has been used successfully in nonpuerperal cohorts with major depressive disorder to prevent recurrence. Although not yet studied in puerperal populations, IPT and similar techniques may be performed prophylactically during the postpartum period and may be of some value. Those providers who routinely participate in acute and short-term postpartum care (e.g., visiting nurses) may be ideally suited to screen for and intervene in cases of postpartum distress or mood disturbance.

In summary, prophylaxis against postpartum depressive illness may be conceptualized along a continuum where some women are at low risk for puerperal illness whereas others appear to be at high risk for puerperal decompensation. This spectrum of patients at risk for puerperal mood disturbance and the potential role of pharmacological and nonpharmacological prophylaxis is outlined in Table 13.4-5. While a less aggressive “wait-and-see” approach is appropriate for women with postpartum blues or women without histories of psychiatric illness, women at high risk, particularly those with histories of postpartum illness, deserve close monitoring as well as specific prophylactic measures. Further characterization of these subgroups of women and the prophylactic treatments suited to each is clearly warranted.

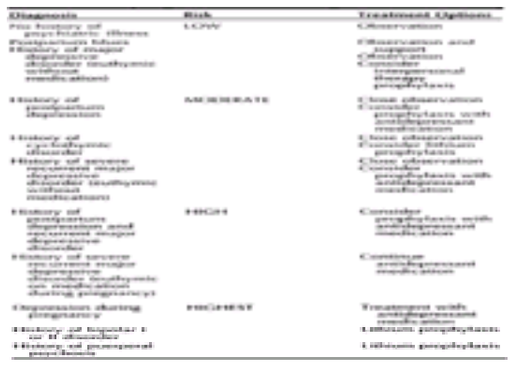

Table 13.4-5 Risk Factors and Treatment Options for Postpartum Mood Disturbance

SUGGESTED CROSS-REFERENCES

Further information on the reproductive endocrinology of pregnancy and the postpartum period and guidelines for the use of psychotropics during pregnancy and lactation can be found in Section 28.2 on psychiatry and reproductive medicine. Mood disorders are discussed at length in Chapter 14, and brief psychotic disorder is discussed in Section 13.1. Psychopharmacology is covered in Chapter 31.

CHAPTER 14. MOOD DISORDERS

14.1 MOOD DISORDERS: INTRODUCTION AND OVERVIEW

HAGOP S. AKISKAL, M.D.

For nearly 2500 years mood disorders have been described as the most common diseases of mankind, but only recently have they commanded major public health interest. The World Health Organization has ranked depression fourth in a list of the most urgent health problems worldwide. The U.S. Agency for Health Care Policy and Research, a federal agency concerned with medical practice from a public health perspective, devoted 2 volumes to depression among the first 10 it has published on such topics as pain, hypertension, diabetes mellitus, and coronary artery disease. A University of California psychiatrist, Kenneth Wells, demonstrated that the disability induced by depression compares with and often exceeds those of such diseases. Depressive disorders afflict at least 20 percent of women and 12 percent of men at some time during their lives. Despite the availability of effective treatments, many persons with mood disorders are disabled, and rates of suicide (which occurs in about 15 percent of depressive disorders) are high in both young and (especially) elderly men. Although depressive disorders are more common in women, more men than women die of suicide.

The suboptimal outcome of mood disorders documented in recent research reports cannot be ascribed to underdiagnosis and undertreatment alone for several reasons. First, Gerald Klerman and colleagues have suggested that the incidence of mood disorders may be increasing in younger age groups, especially in cohorts born in the 1960s, and may be associated with rising rates of alcohol and substance abuse. Second, mood disorders, once believed to be essentially adult disorders, are increasingly diagnosed in children and adolescents. Third, clinical studies suggest higher rates of chronicity, recurrence, and refractoriness than previously believed. For instance, chronicity, reported by Emil Kraepelin to occur in no more than 5 percent in the early twentieth century in Germany, is now seen in 15 to 20 percent of affectively ill patients in Western countries. Nonetheless, outcome studies coming from university centers tend to overestimate the proportion of cases with less favorable prognosis, and undeniably, many patients seen in private practice experience a favorable outcome. Also, a recent report indicates that depressed patients treated by psychiatrists in private settings receive much better care than those in other settings.

THE SCOPE OF MOOD DISORDERS

In Europe where the concept of mood disorders has historically embraced a broad spectrum of disorders, two British schools of thought have been influential. The Maudsley school—Aubrey Lewis and his followers—has promoted a continuum model, from anxiety disorders to mild neurotic depressions to severe endogenous and psychotic depressions. The Newcastle school, led by Martin Roth, has sharply demarcated those conditions from one another. Although vestiges of both approaches are still influential in clinical and basic research, their significance is presently overshadowed by continental European studies that subdivide mood disorders on the basis of polarity: unipolar (depressive episodes only) and bipolar (depressive episodes plus manic, hypomanic, or mixed episodes). That subdivision, supported by studies in the United States, has served as the basis for much recent research into the classification of mood disorders, as reflected in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) and the 10th revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10). Despite such official sanction, many authorities today continue to see considerable continuity between recurrent depressive and bipolar disorders.

Emerging data also tend to favor a continuum between juvenile and adult mood disorders. This is based on the pioneering contributions by Elva Poznanski at the University of Michigan, as well as the work of Leon Cytrin and colleagues at the National Institute of Mental Health (NIMH), and Joachim Puig-Antich conducted at Columbia University in New York. Childhood bipolarity, too, is receiving increasing clinical attention, thanks to the seminal work of Elizabeth Weller and colleagues, originally conducted at Ohio State University. Finally, the work of Gabrielle Carlson and Michael Strober (when they collaborated at the University of California at Los Angeles) and clinical observations by this author on the juvenile offspring of adult bipolar disorders patients have led to a greater appreciation of the bipolar nature of complex clinical presentations of affective illness in children.

Current concepts of mood disorders in the United States embrace a wide spectrum, including many conditions previously diagnosed as schizophrenia, personality disorder, or neurosis. The diagnostic shift occurred in part as a result of the U.S.-U.K. Diagnostic Project, which demonstrated that schizophrenia was being diagnosed at the expense of mood disorders (Fig. 14.1-1). Conceptual boundaries were further broadened by the availability of new and effective treatments and by the unacceptable risk for tardive dyskinesia and suicide in persons with misdiagnosed mood disorders. More generally, present research interest in mood disorders in the United States emanated from a landmark 1969 NIMH conference on the psychobiology of affective illnesses: the NIMH Collaborative Depression Study—a long-term prospective project deriving directly from recommendations made at the conference—has legitimatized the broader perspective.

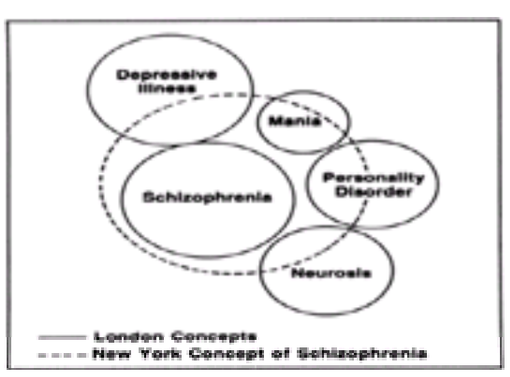

FIGURE 14.1-1 Comparison of British (London) and United States (New York) concepts of schizophrenia. (Reprinted with permission from Cooper JE, Kendell RE, Garland BJ, Sharpe L, Copeland JRM, Simon R: *Psychiatric Diagnosis in New York and London.* Oxford University Press, London, 1972.)

Unfortunately, findings published by Martin Keller and collaborators in the 1980s documenting gross undertreatment of mood disorders continue to describe the current treatment landscape worldwide. Whatever changes have occurred in diagnostic practice do not appear to have significantly affected the morbidity and mortality of mood disorders. This is all the more scandalous because the 1990s have seen new classes of user-friendly antidepressant and mood-stabilizing agents as well as depression-specific psychotherapies. In the author's opinion, this state of affairs results in part from the fact that both specialized and primary care training in mood disorders have failed to keep pace with recent advances.

The situation is analogous to adult-onset diabetes with approximately 50 percent of cases undetected or inadequately controlled, both of which seem to lag behind the field of hypertension, in which early detection and treatment have significantly reduced complications such as stroke. Efforts by patient advocacy organizations—often in concert with national psychiatric organizations and governmental mental health agencies—appear to be increasing public and government awareness of mood disorders. But ultimately, the challenge is to provide all primary care physicians with the requisite hands-on experience in this prevalent group of disorders.

Since mood disorders underlie 50 to 70 percent of all suicides, effective treatment of these disorders on a national level should, in principle, drastically reduce this major complication of mood disorders. A small-scale Swedish study has yielded promising results in this regard. In addition, clinical findings in recurrent mood

disorders have clearly shown the value of lithium prophylaxis in the prevention of suicide as well as overall mortality.

DEFINITIONS

Mood disorders encompass a large group of psychiatric disorders in which pathological moods and related vegetative and psychomotor disturbances dominate the clinical picture. Known in previous editions of DSM as affective disorders, the term *mood disorders* is preferred today because it refers to sustained emotional states, not merely to the external (affective) expression of the present emotional state. Mood disorders are best considered as syndromes (rather than discrete diseases) consisting of a cluster of signs and symptoms sustained over a period of weeks to months, that represent a marked departure from a person's habitual functioning and tend to recur, often in periodic or cyclical fashion.

Major Depressive Disorder and Bipolar Disorder Major depressive disorder (unipolar depression) is reported to be the most common mood disorder. It may manifest as a single episode or as recurrent episodes. The course may be somewhat protracted—up to 2 years or longer—in those with the single-episode form. Whereas the prognosis for recovery from an acute episode is good for most patients with major depressive disorder, three out of four patients experience recurrences throughout life, with varying degrees of residual symptoms between episodes. Bipolar disorders (previously called *manic-depressive psychosis*) consists of at least one hypomanic, manic, or mixed episode. *Mixed episodes* represent a simultaneous mixture of depressive and manic or hypomanic manifestations. Although a minority of patients experience only manic episodes, most bipolar disorder patients experience episodes of both polarity. Manias predominate in men, depression and mixed states in women. The bipolar disorders were classically described as psychotic mood disorders with both manic and major depressive episodes (now termed bipolar I disorder), but recent clinical studies have shown the existence of a spectrum of ambulatory depressive states that alternate with milder, short-lived periods of hypomania rather than full-blown mania (bipolar II disorder). Bipolar II disorder, which is not always easily discriminable from recurrent major depressive disorder, illustrates the need for more research to elucidate the relation between bipolar disorder and major depressive disorder.

Dysthymia and Cyclothymia Clinically, major depressive episodes often arise from a low-grade, intermittent, and protracted depressive substrate known as dysthymic disorder. Likewise, many instances of bipolar disorders, especially ambulatory forms, represent episodes of mood disorder superimposed on a cyclothymic background, which is a biphasic alternating pattern of numerous brief periods of hypomania and numerous brief periods of depression. Dysthymic and cyclothymic disorders represent the two prevalent subthreshold mood conditions roughly corresponding to the basic temperamental dysregulations described by Kraepelin and Ernst Kretschmer as predisposing to affective illness.

It is not always easy to demarcate full-blown syndromal episodes of depression and mania from their subthreshold counterparts commonly observed during the interepisodic periods. The subthreshold conditions appear to be fertile terrain for interpersonal conflicts and postaffective pathological character developments that may ravage the lives of patients and their families. In North America many such patients end up being labeled with borderline personality disorder, which unfortunately often tends to obscure the affective origin of the presenting psychopathology.

Cyclothymic and dysthymic conditions also exist in the community without progression to full-blown mood episodes. As such, they are best considered, respectively, as trait bipolar and trait depressive conditions. Understanding the factors that mediate transition from trait to clinical state is important for preventing manic and major depressive episodes.

Other Subthreshold Mood States Epidemiological studies both in Europe and North America have also revealed other subsyndromal conditions with depressive and hypomanic manifestations with few symptoms (oligosymptomatic mood states) and of short duration (brief episodes). Variously referred to as “minor,” “subsyndromal,” “brief,” or “intermittent,” these descriptions do not merely represent arbitrary lowering of diagnostic thresholds, but herald increasing realization of their importance in early detection of at-risk individuals, as has happened in other medical fields (e.g., diabetes mellitus and essential hypertension). If disabling mood disorders afflict 5 to 8 percent of the general population (Epidemiologic Catchment Area [ECA] study), milder but still clinically significant mood disorders would raise lifetime rates to 17 percent (National Comorbidity Study [NCS]); if subclinical mood states are added, that figure doubles to involve a third of the general population (as reported, for instance, by Kenneth Kendler and colleagues).

Comorbidity Mood disorders overlap considerably with anxiety disorders. As summarized in an NIMH monograph, anxiety disorders can occur during an episode of depression, may be a precursor to the depressive episode, and, less commonly, may occur during the future course of a mood disorder. Those findings suggest that at least some depressive disorders share a common diathesis with certain anxiety disorders. More-recent clinical experience suggests intriguing comorbidity patterns between bipolar II disorder on one hand and panic, obsessive-compulsive, and social phobic states on the other. Furthermore, bipolar I and II disorders are particularly likely to be complicated by use of alcohol, stimulants, or both. In many cases the alcohol or substance abuse represents an attempt at self-treatment of the mood disorder. Finally, physical illness—both systemic and cerebral—occurs in association with depressive disorders with a greater frequency than expected by chance alone. Unless properly treated, such depression negatively impacts on the prognosis of the physical disorder. More provocatively, there is current reawakening in the contribution of cerebral and cardiovascular factors to the origin of late-onset psychotic depressions (previously classified as “involutional melancholia”).

An integrated framework of pathogenesis is necessary for understanding psychopharmacological, somatic, and psychotherapeutic approaches in the clinical management of patients with mood disorders. A historical perspective on current developments is also a valuable lesson in the study of mood disorders.

GRECO-ROMAN DESCRIPTIONS OF MELANCHOLIA AND MANIA

Much of what is known today about mood disorders was described by the ancient Greeks and Romans, who coined the terms *melancholia* and *mania* and noted their relation. The ancients also hypothesized a temperamental origin for those disorders. Much of modern thinking about mood disorders (e.g., the work of the French and German schools in the middle and latter part of the nineteenth century, which influenced current British and American concepts) can be traced back to these ancient concepts.

Melancholia Hippocrates (460–357 BC) described melancholia (“black bile”) as a state of “aversion to food, despondency, sleeplessness, irritability, and restlessness.” Thus, in choosing the name of the condition, Greek physicians (who may have borrowed the concept from ancient Egyptians) postulated the earliest biochemical formulation of any mental disorder. They believed that the illness often arose from the substrate of the somber melancholic temperament which, under the influence of the planet Saturn, made the spleen secrete black bile, ultimately leading to mood darkening through its influence on the brain. Greek descriptions of the clinical manifestations of depression and of the temperament prone to melancholia are reflected in the DSM-IV and in the subdepressive lethargy, self-denigration, and habitual gloom of the person with dysthymic disorder.

One Hippocratic aphorism recognized the close link between anxiety and depressive states: “Patients with fear of long-standing are subject to melancholia.” According to Galen (131–201 AD), melancholia manifested in “fear and depression, discontent with life, and hatred of all people.” A few hundred years later another Roman, Aurelianus, citing the now lost works of Soranus of Ephesus, amplified the role of aggression in melancholia (and its link to suicide) and described how the illness assumed delusional coloring: “Animosity toward members of the household, sometimes a desire to live and at other times a longing for death, suspicion on the part of the patient that a plot is being hatched against him.”

In addition to natural melancholia, which presumably arose from an innate predisposition to overproduce the dark humor and led to a more severe form of the malady, Greco-Roman medicine recognized such environmental contributions to melancholia as immoderate consumption of wine, perturbations of the soul due to the passions (e.g., love), and disturbed sleep cycles. Autumn was considered the season most disposing to melancholy.

Mania A state of raving madness with exalted mood was noted by the ancient Greeks, although it referred to a somewhat broader group of excited psychoses than in modern nosology. Its relation to melancholia was probably noted as early as the first century BC, but according to Aurelianus, Soranus discounted it. Nonetheless, Soranus had observed the coexistence of manic and melancholic features during the same episode, consisting of continual wakefulness and fluctuating states of anger and merriment, sometimes of sadness and futility. Soranus thus seemed to have described what today are called mixed episodes in DSM-IV and ICD-10. Natural melancholy was generally considered a chronic disorder, but Soranus noted the tendency for attacks to alternate with periods of remission.

Although others prior to him hinted at it, Aretaeus of Cappadocia (ca. 150 AD) is generally credited with making the connection between the two major mood states: “It appears to me that melancholy is the commencement and a part of mania.” He described the cardinal manifestations of mania as it is known today:

> There are infinite forms of mania but the disease is one. If mania is associated with joy, the patient may laugh, play, dance night and day, and go to the

> market crowned as if victor in some contest of skill. The ideas the patients have are infinite. They believe they are experts in astronomy, philosophy, or poetry.

Aretaeus described the extreme psychotic excitement that could complicate the foregoing clinical picture of mania:

> The patient may become excitable, suspicious, and irritable; hearing may become sharp... get noises and buzzing in the ears; or may have visual hallucinations; bad dreams and his sexual desires may get uncontrollable; aroused to anger, he may become wholly mad and run unrestrainedly, roar aloud; kill his keepers, and lay violent hands upon himself.

Noting the fluctuating nature of symptoms in the affectively ill, Aretaeus commented

> They are prone to change their mind readily; to become base, mean-spirited, illiberal, and in a little time extravagant, munificent, not from any virtue of the soul, but from the changeableness of the disease.

Aretaeus was thus keenly aware of the characterological distortions so commonly manifested during the different phases of cyclical mood disorders.

Finally, consolidating the knowledge of several centuries, Aretaeus described mania as a disease of adolescent and young men given intermittently to “active habits, drunkenness, lechery” and an immoderate lifestyle (what today might be called cyclothymic disorder). Exacerbations were most likely to occur in the spring.

Affective Temperaments The concept of health and disease in Greco-Roman medicine was based on harmony and balance of the four humors, of which sanguine humor was deemed the healthiest. But even a desirable humor like blood, which made people habitually active, amiable, and prone to jest, could in excess lead to the pathological state of mania. The melancholic temperament, dominated by black bile and predisposed to pathological melancholia, was described as lethargic, sullen, and given to brooding or contemplation; its modern counterparts are depressive personality disorder (now in a DSM-IV appendix) and its clinical expression as dysthymic disorder (included in both ICD-10 and DSM-IV). A long tradition dating back to Aristotle (384–322 BC) attributed creative qualities to the otherwise tortured melancholic temperament in such fields as philosophy, the arts, poetry, and politics. The remaining two temperaments, choleric and phlegmatic, were less desirable, as yellow bile made people choleric (irritable, hostile, and given to rage) and phlegm made them phlegmatic (indolent, irresolute, and timid). The choleric and phlegmatic temperaments would probably be recognized today as borderline personality disorder and avoidant or schizoid personality disorder, respectively.

Many of the original Greek texts on melancholia were transmitted to posterity through medieval Arabic texts such as those of Ishaq Ibn Imran and Avicenna (and their Latin rendition by Constantinus Africanus). In describing different affective states, Avicenna developed the theory of the temperaments to its fullest. He speculated that a special form of melancholia supervened “if black bile be mixed with phlegm” when the illness was “coupled with inertia, lack of movement, and quiet.” Further, mania was not necessarily linked to the sanguine (what today is termed “hyperthymic”) temperament, as many forms of excited madness were believed to represent a mixture of black and yellow bile.

Avicenna further observed that the appearance of anger, restlessness, and violence heralded the transition of melancholia to mania. Those elaborations on Galen's tempermental types might be considered the forerunners of current personality dimensions, deriving mood states from various mixtures of neuroticism and introversion-extroversion. (What both ICD-10 and DSM-IV describe as cyclothymic disorder represents the intense mood lability of high neuroticism coupled with cyclic alternation between extroversion and introversion). Speculation on how diverse depressive phenomena could be understood as a mix of humors anticipated modern multiple-transmitter hypotheses of depression. Ishaq Ibn Imran summarized the existing knowledge of melancholia by considering the interaction of genetic factors (“injured prenatally as the result of the father's sperm having been damaged”) with a special temperament given to “mental overexertion”—though not necessarily physical overactivity—that in turn was associated with “disruption of the correct rhythms of sleeping and waking.” Those views, too, have a very modern ring to them.

MODERN ERA

The first English text (Fig. 14.1-2) entirely devoted to affective illness was Robert Burton's *Anatomy of Melancholy*, published in 1621. A scholarly review of medical and philosophical wisdom accumulated in past centuries, it also anticipated many modern developments. The concept of affective disorder endorsed by Burton was rather broad (as it always has been in the United Kingdom), embracing mood disorders and many disorders today considered somatoform disorders, including hypochondriasis. Although he described “causeless” melancholias, Burton also categorized the various forms of love melancholy and grief. Particularly impressive was his catalogue of causes, culminating in a grand conceptualization:

FIGURE 14.1-2 Frontispiece of Robert Burton's *Anatomy of Melancholy* (1621).

> Such as have Saturn misaffected in their genitures such as are born of melancholy parents as offend in those six non-natural things, are of a high sanguine complexion are solitary by nature, great students, given to much contemplation, lead a life out of action, are most subject to melancholy. Of sexes both, but men more often. Of seasons of the year, autumn is most melancholy. Jobertus excepts neither young nor old.

Burton's six nonnatural things referred to such environmental factors as diet, alcohol, biological rhythms, and perturbations induced by passions such as intense love. Burton himself did not definitively indicate age prevalences. Like nearly all of his predecessors, he favored male (rather than the currently reported female) preponderance. Finally, Burton considered both the melancholic (contemplative) and the sanguine (hot-blooded) temperaments to be substrates of melancholia. Burton's work thus linked certain forms of depression with the softer expressions of the manic disposition, or bipolar II disorder, from which he himself appears to have suffered.

The eighteenth and nineteenth centuries introduced humane hospital care of the mentally ill, thereby permitting systematic clinical observation of the psychopathology and outcome of mood disorders.

Concept of Affective Disorder Although Celsus (ca. AD 30) had described “forms of madness that go no further than sadness,” the French alienist Jean-Philippe Esquirol (1840) may have been the first psychiatrist in modern times to suggest that a primary disturbance of mood might underlie many forms of depression and related paranoid psychoses. Until Esquinol's work, melancholia had been categorized as a form of insanity (i.e., ascribed to deranged reasoning or thought disturbance). Esquirol's observations on melancholic patients led him to postulate that their insanity was partial (dominated by one delusion, a monomania) and that “the symptoms were the expression of the disorder of the affections. The source of the evil is in the passions.” He coined the term “lypemania” (from the Greek, “sorrowful insanity”) to give nosological status to a subgroup of melancholic disorders that were affectively based. Esquirol cited Benjamin Rush (1745–1813), the father of American psychiatry, who had earlier described tristimania, a form of melancholia in which sadness predominated.

Esquirol's influence led other European psychiatrists to propose milder states of melancholia without delusions, which were eventually categorized as simple melancholias and ultimately as primary depressions. Such descriptions culminated in the Anglo-Saxon psychiatric term “affective disorder,” coined by Henry Maudsley

(1835–1918), the renowned British psychiatrist after whom the London hospital is named.

Manic-Depressive Illness and the Question of Psychogenic Depressions Although the connection between mania and depression had been sporadically rediscovered since it was first described 2000 years ago, the clinical work that finally established “circular insanity” (Jean-Pierre Falret's term) as “folie à double forme” (Jules Baillarger's term) was undertaken by these two Esquirol disciples in the 1850s. That accomplishment built on Philippe Pinel's reforms, which championed humane treatment of the mentally ill in Paris around the turn of the eighteenth century and emphasized systematic clinical observations of patients, detailed in case records. French alienists made longitudinal observations on the same patient from one psychotic attack into another. Further, Esquirol had introduced chronicling events in statistical tables. Thus, the Hippocratic approach to defining a particular case by its onset, circumstances, course, and outcome was applied by French alienists in studying the affectively ill. The humanitarian reforms introduced in the nineteenth century ensured that standards of general health and nutrition would improve the outlook for the mentally ill—especially those with potentially reversible disorders such as affective disorders—who could now be discharged from the asylums. The French school then, by segregating the nondeteriorating mood disorders from the dementing types of insanity, paved the way for the Kraepelinian system.

Kraepelin's (1856–1926) unique contribution was not so much grouping together all the forms of melancholia and mania, but his methodology and painstaking longitudinal observations, which established manic-depressive illness as a nosological entity and (he hoped) a disease entity. His rationale was (1) the various forms had a common heredity measured as a function of familial aggregation of homotypic and heterotypic cases; (2) frequent transitions from one form to the other occurred during longitudinal follow-up; (3) a recurrent course with illness-free intervals characterized most cases; (4) the superimposed episodes were commonly opposite to the patient's habitual temperament; that is, mania was superimposed on a depressive temperament and depression was superimposed on a hypomanic temperament; and (5) both depressive and manic features could occur during the same episode (mixed states). Kraepelin's synthesis was developed as early as the sixth (1899) edition of his *Lehrbuch der Psychiatrie* and most explicitly stated in the opening passages of the section on manic-depressive psychosis in the eighth edition (published in four volumes, 1909–1915):

> Manic-depressive insanity includes on the one hand the whole domain of so-called periodic and circular insanity, on the other hand simple mania, the greater part of the morbid states termed melancholia and also a not inconsiderable number of cases of confusional insanity. Lastly, we include here certain slight and slightest colorings of mood, some of them periodic, some of them continuously morbid, which on the one hand are to be regarded as the rudiment of more severe disorders, on the other hand, pass over without boundary into the domain of personal predisposition.

For Kraepelin, the core pathology of clinical depression consisted of lowered mood and slowed (retarded) physical and mental processes. In mania, by contrast, the mood was elated and both physical and mental activity accelerated. His earlier observations on what he termed “involutional melancholia” (referring to 40- to 65-year-old patients with extreme anxiety, irritability, agitation, and delusions) had led him to separate that entity from the broader manic-depressive rubric. But, in the eighth edition of *Lehrbuch der Psychiatrie*, he united melancholia with the manic-depressive group, with the justification that it was a special form of mixed state and that follow-up conducted by his pupil Dreyfus had demonstrated unmistakable excited phases.

The classification of depressive disorders is still evolving. Karl Leonhard in 1957, Jules Angst in 1966, Carlo Perris in 1966, and George Winokur, Paula Clayton, and Theodore Reich in 1969, working independently in four different countries, proposed that depressive disorders without manic or hypomanic episodes (major depressive disorder) that appear in middle age and later are distinct from depressive episodes that begin at earlier ages and alternate with manic or hypomanic episodes (bipolar disorder). The main difference between the two affective subtypes is the greater familial loading for mood disorder—especially for bipolar disorder—among bipolar disorder probands.

Kraepelin had conceded the occurrence of psychogenic states of depression occasioned by situational misfortune. Manic-depressive illness, on the other hand, he believed to be hereditary. Yet he could not document postmortem anatomopathological findings in the brains of manic-depressive patients. Therefore, manic-depression had to be considered a functional mental disorder in which brain disturbances were presumed to lie in altered physiological functions. Such biological factors were deemed absent in the psychogenic depressions. Thus, Kraepelin's classification of mood disorders is both dualistic and unitary. It is dualistic to the extent that he designated them as either psychologically occasioned or somatically caused. It is unitary with respect to disorders in the latter group, which have been termed *endogenous affective disorders* (i.e., due to internal biological causes). In other words, Kraepelin restricted the concept of clinical depression to what DSM-IV terms “major depressive disorder with melancholic features.” Moreover, he postulated a continuum between that condition and what DSM-IV and ICD-10 now term “bipolar disorders.”

As summarized in Table 14.1-1, endogenous depressions have been contrasted with those of exogenous cause (i.e., external and, presumably, psychogenic causes). Transitions between the two groups are so frequent, however, that the two-type thesis of depression has been largely abandoned in official classifications in North American psychiatry. In one study conducted by the author's mood clinic team in Memphis during the 1970s, 100 patients with neurotic depression (the prototype of exogenous depression), prospectively followed over 3 to 4 years, developed episodes with endogenous, psychotic, and even bipolar features (Table 14.1-2). Nonetheless, the endogenous-exogenous dichotomous grouping still has some adherents worldwide who continue to research its potential for clinical predictions. Such research generally attempts to validate the various subtypes on the basis of their clinical characteristics rather than presumed cause. Today most mood disorders experts would probably agree that depressive illness has endogenous and exogenous components in most patients presenting clinically. Consensus would be less likely on how to delimit clinical depressive disorder from comorbid disorders such as the various anxiety disorders, substance use disorders, and personality disorders. Clarifying the boundaries between those disorders has emerged as a principal challenge in the classification of mood disorders.

Manic-depressive	Psychogenic
S (somatic) type	J (justified) type
Autonomous	Reactive
Endogenous	Exogenous
Psychotic	Neurotic
Acute	Chronic
Major	Minor
Melancholic	Neurasthenic
Typical	Atypical
Primary	Secondary
Biological	Characterological

Table 14.1-1 Overlapping Dichotomies of Affective Disorders That Are Not Necessarily Synonymous

Diagnosis and Outcome	N*
Manic episode	4
Hypomanic episode	14
Psychotic depression	21
Endogenous depression	36
Episodic course	42
Unstable characterological features	24
Social invalidism	35
Suicide	3

* The total exceeds 100 because more than one outcome was possible in each patient.

Table 14.1-2 Three- to Four-Year Prospective Follow-up in Neurotic Depressions (N = 100)

Cartesian thinking in seventeenth-century France conceptually separated mind from body, thereby providing physicians autonomy over the somatic sphere, free from interference by the Church. The dichotomous paradigm ensured that study of the two aspects of the human organism would not be confounded by the complexities of mind-body interactions. That is one reason why Kraepelin's descriptive observations have proved valuable to subsequent generations of clinicians. Further, his approach exemplifies the best tradition of scientific humanism in medicine: description and diagnostic categorization of an individual patient are necessary for the physician to apply the knowledge gained from past observation of similarly described and diagnosed patients. One limitation to the Kraepelinian approach is that because of its biological reductionism, it is not sufficiently articulate to account for mind-body interactions in the genesis of mental disorders.

Depressions as Psychobiological Affective Reaction Types Bridging the divide between psyche and soma was the ambition of Swiss-born Adolf Meyer (1866–1950), who dominated psychiatry from his chair at Johns Hopkins University during the first half of the twentieth century. Meyer coined the term "psychobiology" to emphasize that both psychological and biological factors could enter into the causation of depressive and other mental disorders. Because of the nascent state of brain science during Meyer's time, he was more adept at biography than biology and therefore paid greater attention to psychosocial causation. He preferred the term *depression* (pressed down) to *melancholia* because of its lack of biological connotation. He conceived of depressive states in terms of unspecified constitutional or biological factors interacting with a series of life situations beginning at birth or even at conception. From that viewpoint arose the unique importance accorded personal history in depressive reactions to life events.

Meyer's terminological revision left a somewhat confusing legacy in that the term *depression* is now applied to a broad range of affective phenomena ranging from sadness and adjustment disorders to clinical depression and bipolar disorders. Repercussions can be seen in the low threshold for diagnosing major depressive disorder in DSM-IV, which makes it difficult to differentiate major depressive disorder from transient life stresses that produce adjustment disorder with depressed mood. Nosological nuances to which Meyerians paid little attention, such as the difference between melancholic depression and more mundane depressions, are not just a matter of semantics. To the extent that those two forms of depression are seen in different clinical settings, hypotheses based on one population may not apply to the other. For instance, uncontrollable traumatic events may have taught study subjects to feel helpless or to view the world in a negative light, but that does not equate with clinical depression; nor does the process appear to be specific to depression. Failure to make such nosological distinctions further clouds interpretations of the results of trials comparing psychotherapy and pharmacotherapy for depressive disorders.

On the other hand, the Meyerian emphasis on biographical factors for the patient represented a more practical approach to depth psychology. Recent sociological interpretations of depression can also be traced to Meyer's work. But in the final analysis, the Meyerian concern for the uniqueness of the individual has proved heuristically sterile. It deemphasizes what is diagnostically common to different individuals, thereby obscuring the relevance of accrued clinical wisdom for the index patient. For that reason the Meyerian approach, after enjoying clinical popularity for several decades in North America, has given way to neo-Kraepelinian rigor. However, the psychobiological vision of bridging biology and psychology, one of the major preoccupations of psychiatric thought and research today, owes much to Meyer's legacy.

CONTEMPORARY MODELS OF DEPRESSION

From classical times through the early part of the twentieth century, advances in understanding mood disorders involved conceptual shifts from supernatural to naturalistic explanations, from reductionistic, unitarian theories of causation to pluralistic theories, and from dualism to psychobiology. Knowledge of those conceptual developments provides a useful base from which to scrutinize more-recent models and concepts of mood disorder, developed later in the twentieth century. The new approaches, derived from competing theoretical positions, have generated models for understanding various aspects of mood disorders, particularly depressive disorders (Table 14.1-3).

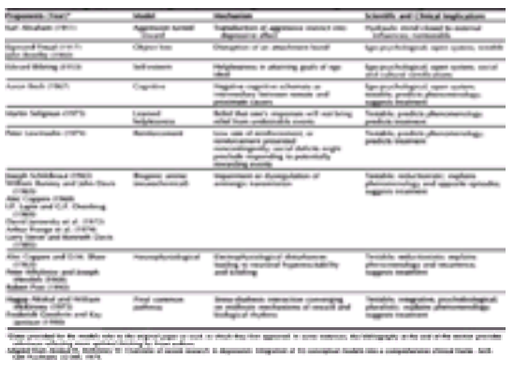

Table 14.1-3 Contemporary Major Models of Depression

The formative influence of early experience as it is dynamically shaped by emerging mental structures during development is the common denominator for the psychoanalytic concepts of psychopathological phenomena. By contrast, behavioral approaches in their more traditional formulations focus on the pathogenetic impact of proximate contexts. The cognitive approaches, which are akin to the behavioral-pathogenetic tradition, nonetheless concede that negative styles of thinking might mediate between proximate stressors and more remote experiences. All three schools—psychoanalytic, behavioral, and cognitive—emphasize psychological constructs in explaining the origin of mood disorders. The biological models, on the other hand, are concerned with defining the somatic mechanisms that underlie or predispose to morbid affective experiences. The schism between psychological and biological conceptualizations is an instance of the mind-body dichotomy that has characterized the Western intellectual tradition since Descartes. After all, psychological and somatic approaches represent merely convenient investigational strategies that attempt to bypass the methodological gulf between mental and neural structures. The ultimate aim is to understand how mood disorders develop within the psychoneural framework of a given person.

Aggression-Turned-Inward Model Sigmund Freud was initially interested in a psychoneural project for all mental phenomena. Limitations of the brain sciences of the day led him to adopt instead a model that relied on a concept of mental function borrowed from physics. The notion that depressed affect is derived from retroflexion of aggressive impulses directed against an ambivalently loved internalized object was actually formulated by his Berlin disciple Karl Abraham and later elaborated by Freud. Abraham and Freud hypothesized that turned-in anger was intended as punishment for the love object that had thwarted the depressed patient's need for dependency and love. Because, in an attempt to prevent the traumatic loss, the object had already been internalized, the patient now became the target of his or her own thanatotic impulses. A central element in those psychic operations was the depressed patient's ambivalence toward the object, which was perceived as a frustrating parent. Aggression directed at a loved object (parent) was therefore attended by considerable guilt. In the extreme such ambivalence, guilt, and retroflexed anger could lead to suicidal behavior.

According to that model, depression was an epiphenomenon of the transduction of thanatotic energy, a reaction that took place in the closed hydraulic space of the mind. Freud's earlier writings had similarly portrayed anxiety as derived from the transformation of dammed-up sexual libido. Although Freud envisioned that psychoanalytic constructs would one day be localized neuroanatomically, the hydraulic mind is a metaphor that does not refer to actual physiochemical space in the brain.

The conceptualization of emotional behavior as an arena of incompatible forces confined to a psyche that is relatively impervious to current influences outside the organism is the major liability of the aggression-turned-inward model and perhaps of orthodox psychoanalysis itself. Although the sexual energy transduction hypothesis of anxiety has been discarded in modern psychoanalytic thought, in modified version the aggression-turned-inward model continues to be used in clinical conceptualization today. The lingering popularity of the model may be due in part to its compatibility with the clinical observation that many depressed patients suffer from lack of assertion and outwardly directed aggressiveness. Yet a substantial number of hostile depressed patients are also encountered in clinical practice (indeed "depression with anger attacks" has been recently described), and clinical improvement in most patients typically leads to decreased, not increased, hostility. Those observations shed doubt on the aggression-turned-inward mechanism as a universal explanation for depressive behavior. Finally, little evidence exists to support the contention that outward expression of anger has therapeutic value in clinical depression.

Outwardly directed hostility in depression is not a new clinical observation: Greco-Roman physicians had noted it. Hostility is best considered a manifestation rather

than a cause of depressive disorder, especially when the disorder is attended by mixed bipolar features. The hostility of the depressed patient can also be understood as an exaggerated reaction to frustrating love objects, as secondary to self-referential attribution, or simply as nonspecific irritability of an ego in affective turmoil; this could in part be a function of a concurrent personality disorder from the erratic cluster. Such common-sense explanations that do not invoke unobservable hydraulic transmutations have greater appeal from heuristic and clinical perspectives.

Object Loss and Depression Object loss refers to traumatic separation from significant objects of attachment. Ego-psychological reformulations of the Abraham-Freud conceptualization of depression have paid greater attention to the impact of such losses on the ego, deemphasizing the id-libidinal and related hydraulic aspects. The depressant impact of separation events often resides in their symbolic meaning for a person rather than in any arbitrary objective weight that the event may have for clinical raters. However, love loss, bereavement, and other exits from the social scene, as defined by the London psychiatrist Eugene Paykel, are presently the concepts most commonly used in practice and research.

Although love melancholy had been described since antiquity, the two affective states were systematically compared for the first time in Freud's 1917 paper on mourning and melancholia. According to current data, the transition from grief to pathological depression occurs in no more than 10 percent of adults and 20 percent of children. These figures suggest that such transition occurs largely in persons predisposed to mood disorders.

John Bowlby of the Tavistock Clinic, London, did a comprehensive clinical investigation of the attachment that the child establishes with the mother or mother substitutes during development, a bond considered the prototype for all subsequent bonds with other objects. Like many psychoanalytic explanations of adult symptom-formation, the object loss model is formulated as a two-step hypothesis, consisting of early breaks in affectional bonds, which provide the behavioral predisposition to depression, and adult losses, which are said to revive the traumatic childhood loss and so precipitate depressive episodes. However, the role of proximate separations in provoking depressive reactions rests on more solid clinical evidence than the hypothesized sensitization resulting from developmental object loss. That realization has led Bowlby to regard childhood sensitization resulting from early deprivation as a generic characterological vulnerability to a host of adult psychopathological conditions.

Compared with aggression turned inward, object loss is more directly relevant to clinical depression; yet it is still pertinent to question whether it is an etiological factor. Studies at the Wisconsin Primate Center have indicated that optimal homeostasis with the environment is most readily achieved when the individual is securely attached to significant others, and the dissolution of such ties appears relevant to the emergence of a broad range of psychopathological disturbances rather than depression per se. A related methodological question is whether object loss operates independently of other etiological factors. For instance, a history of early breaks in attachment may reflect the fact that one or both of the patient's parents had mood disorder, with resultant separation, divorce, suicide, and so forth.

On balance, the ego-psychological object loss model is conceptually superior to its id-psychological counterpart. In postulating an open system of exchange between a person and the environment, the model permits consideration of etiological factors other than separation, such as heredity, character structure, and adequacy of social support—all of which might modulate the depressant impact of adult separation events. Conceptualizing the origin of depression along those lines is in the mainstream of current ideas of adaptation, homeostasis, and disease. An important treatment implication is the value of social support in preventing relapse and mitigating chronicity of depression. That is indeed an ingredient in the interpersonal psychotherapy of depression, which can be conceptualized as a form of brief, focused, and practical psychodynamic therapy.

Loss of Self-Esteem and Depression Reformulation of the dynamics of depression in terms of the ego suffering a collapse of self-esteem represents a further conceptual break with the original id-psychological formulation; depression is said to originate from the ego's inability to give up unattainable goals and ideals. The model further posits that the narcissistic injury that crushes the depressed patient's self-esteem is imposed by the internalized values of the ego rather than the hydraulic pressure of retroflected thanatotic energy deriving from the id. Because the construct of the ego is rooted in social and cultural reality, loss of self-esteem may result from symbolic losses involving power, status, roles, identity, values, and purpose for existence. Thus, the existential and sociocultural implications of depression conceived as a derivative ego state provide the clinician with a far more flexible and pragmatic tool for understanding depressed persons than the archaic hydraulic metaphors related to libidinal vicissitudes. That model represents one of the first attempts to formulate depression in terms that subsequent psychological theory and research could operationalize in more testable form.

Self-esteem is part of the habitual core of the individual and hence is integral to the personality structure. Indeed, low self-esteem conceived as a trait is a major defining attribute of the depressive (melancholic) personality. While it is understandable how such individuals can easily sink into melancholia in the face of environmental adversity, it is not obvious why persons with apparently high self-esteem (e.g., those with hypomanic and narcissistic personalities) also succumb to melancholy with relative ease. To explain such cases, one must invoke an underlying instability in the system of self-esteem that renders it vulnerable to depression. The opposite is also known to occur; that is, manic episodes may develop from a baseline of low self-esteem, as in the case of bipolar disorder patients with antecedent traits of shyness, insecurity, and dysthymia.

The foregoing considerations suggest that the vicissitudes of self-esteem deemed central to the model of depression as loss of self-esteem are manifestations of a more fundamental mood dysregulation. In classical psychoanalysis, such dysregulation is considered of constitutional origin. In general, attempts by psychoanalytic writers to account for bipolar oscillations have not progressed beyond metapsychological jargon, with the possible exception of denial of painful affects as a mechanism in the phenomenology of mania.

Cognitive Model The cognitive model, developed by Aaron Beck at the University of Pennsylvania, hypothesizes that thinking along negative lines (e.g., thinking that one is helpless, unworthy, or useless) is the hallmark of clinical depression. In effect, depression is redefined in terms of a cognitive triad, according to which patients think of themselves as helpless, interpret most events unfavorably vis-à-vis the self, and believe the future to be hopeless. In more recent formulations in academic psychology, these cognitions are said to be characterized by a negative attributional style that is global, internal, and stable and to exist in the form of latent mental schemata that generate biased interpretations of life events.

Because the cognitive model is based on retrospective observations of already depressed persons, it is virtually impossible to prove that causal attributions such as negative mental schemata precede and hence predispose to clinical depression; they can just as readily be regarded as subclinical manifestations of depression. The theoretical importance of the cognitive model lies in the conceptual bridge it provides between ego-psychological and behavioral models of depression. It has also led to a new and widely accepted system of psychotherapy that attempts to alter the negative attributional style, to alleviate the depressive state, and, ultimately, to fortify the patient against future lapses into negative thinking, despair, and depression.

The cognitive model, therefore, has the cardinal virtue of focusing on key reversible clinical dimensions of depressive illness, such as helplessness, hopelessness, and suicidal ideation, while providing a testable and practical psychotherapeutic approach. That approach, however, is less likely to succeed in patients with the full-blown melancholic manifestations of a depressive disorder. It is doubtful that negative cognitions alone could account for the profound disturbances in sleep, appetite, and autonomic and psychomotor functions encountered in melancholic depressions. Further, conceptualizing a multifaceted malady such as depression largely or solely as a function of distorted cognitive processes is reminiscent of pre-Esquirolian notions that emphasized impaired reasoning in the development of depression.

Learned Helplessness Model The learned helplessness model is in some ways an experimental analogue of the cognitive model. The model proposes that the depressive posture is learned from past situations in which the person was unable to terminate undesirable contingencies. The model is based on experiments in dogs that were prevented from taking adaptive action to avoid unpleasant electrical shock and subsequently showed no motivation to escape such aversive stimuli, even when escape avenues were readily available. Armed with evidence from many such experiments, a University of Pennsylvania psychologist, Martin Seligman, postulated a trait of learned helplessness (a belief that it is futile to initiate personal action to reverse aversive circumstances) formed from the cumulation of past episodes of uncontrollable helplessness.

The learned helplessness paradigm is a general one and refers to a broader mental disposition than depression. Thus, it is potentially useful in understanding such diverse conditions as social powerlessness, defeat in sporting events, and posttraumatic stress disorder. In addition, past events might shape a characterological cluster, consisting of passivity, lack of hostility, and self-blame, relevant to certain depressive phenomena. The low hostility observed in some patients during clinical depression could, for instance, be ascribed to the operation of such factors. Learned helplessness could thereby provide plausible links between aspects of personal biography and clinical phenomenology in depressive disorders. Therapeutic predictions for alleviating depression and related psychopathological states capitalize on new cognitive strategies geared to modifying expectations of uncontrollability and the negative attributional style. This illustrates how insights gained from experimental paradigms can be fruitfully combined to address clinical disorders.

Nonetheless, the clinician should be wary of unwarranted clinical extrapolations. For instance, some therapists have argued that the depressed patient's passivity is manipulative, serving to obtain interpersonal rewards. It has also been claimed that such factors have a formative influence on the development of the depressive character. That interpretation appears more relevant to selected aspects of depression than to the totality of the disorder. Depressive behavior and verbalizations clearly have a powerful interpersonal impact, but casting depression as merely a masochistic lifestyle developed to secure interpersonal advantages represents a mechanistic circular argument that could be viewed as disrespectful of the clinical agony of patients with mood disorders. Finally, although most formulations focusing on helplessness have emphasized acquisition through learning, recent experimental research in animals tends to implicate genetic factors in the vulnerability to learning to behave helplessly. The value of the helplessness paradigm may reside in its utility to predict a variety of subthreshold affective disturbances generic to civilian reactions to adversity and trauma.

Depression and Reinforcement Other behavioral investigators, notably Oregon psychologist Peter Lewinsohn, have developed clinical formulations of depression that hinge on certain deficits in reinforcement mechanisms. According to the reinforcement model, depressive behavior is associated with lack of appropriate rewards and, more specifically, with receipt of noncontingent rewards. The model identifies several contributory mechanisms. Some environments may consistently deprive persons of rewarding opportunities, thereby placing them in a chronic state of boredom, pleasurelessness, and, ultimately, despair. That reasoning, however, may offer more insight into social misery than clinical depression. A more plausible postulated mechanism is the provision of rewards that are not in response to the recipient's actions; in other words, the gratis provision of what a person considers undeserved rewards may lead to lowering of self-esteem. Predisposition to depression is formulated in terms of deficient social skills, which are hypothesized to decrease a person's chances of responding to potentially rewarding contingencies in any environment. Indeed, recent research on the relation between personality and depression suggests that such deficits might underlie certain depressive states. Therefore, psychotherapeutic approaches designed to enlarge a patient's repertoire of social skills may prove valuable in preventing some types of depression.

The concepts of depression that have been derived from behavioral methodology and developed in the past several decades are scientifically articulate and therefore testable approaches to clinical depression. Yet, the important distinction between depression on self-report inventories and clinical depression is sometimes overlooked. Further, the behavioral model does not address the distinct possibility that reinforcement deficits may in part represent the psychomotor deficits of depressive illness. Nevertheless, by focusing on reward mechanisms, the behavioral model provides a conceptual bridge between purely psychological and emerging biological conceptualizations of depression.

Biogenic Amine Imbalance Formulation of sophisticated biological explanations of mood disorders had to await development of neurobiological techniques that could probe parts of the brain involved in emotions. Although the complex physiology of the limbic-diencephalic centers of emotional behavior generally cannot be directly observed in humans, much has been learned from animal work. The limbic cortex is linked with both the neocortex, which subserves higher symbolic functions, and the midbrain and lower brain centers, which are involved in autonomic control, hormonal production, and sleep and wakefulness. Norepinephrine-containing neurons are involved in many functions that are profoundly disturbed in melancholia, including mood, arousal, appetite, reward, and drives. Other biogenic amine neurotransmitters that mediate such functions are the catecholamine dopamine, especially important for pleasure, sex, and psychomotor activity, and the indoleamine serotonin, involved in the regulatory control of affects, aggression, sleep, and appetite, among others. Cholinergic neurons, secreting acetylcholine at their dendritic terminals, are generally antagonistic in function to catecholaminergic neurons.

Although the opioid system might, on experimental and theoretical grounds, also serve as one of the neurochemical substrates for mood regulation, in the author's opinion no cogent model of mood disorders involving that system has appeared to date. Likewise, biochemical formulations of mood disorders have paid relatively little attention to the major excitatory brain neurotransmitter glutamate and the inhibitory neurotransmitter g-aminobutyric acid (GABA).

Biogenic Amine Hypotheses Joseph Schildkraut at Harvard University and William Bunney and John Davis at NIMH published the first formal hypothesis connecting depletion or imbalance of biogenic amines (specifically norepinephrine) and clinical depression. The serotonin counterpart of the model was emphasized in the models proposed by Alec Coppen in England and I. P. Lapin and G. F. Oxenkrug in Russia. Both catecholamine and indoleamine hypotheses were essentially based on two sets of pharmacological observations. First, reserpine (which decreases blood pressure by depleting biogenic amine stores) precipitates clinical depression in some patients. Second, antidepressant medications (which alleviate clinical depression) raise the functional capacity of the biogenic amines in the brain. This style of thinking is known as the pharmacological bridge, extrapolating from evidence on mechanism of drug action to the neurotransmitter pathologies presumed to underlie a given psychiatric disorder. Such pharmacological strategies have been of heuristic value in developing research methods for investigation of mood disorders and schizophrenia. Indeed, the research methodology developed by the relatively few investigators working in the area in the past three decades is among the most elegant in the history of psychiatry.

Variations of the biogenic amine model assign somewhat different relative weights to the biogenic amines norepinephrine and serotonin in the development of pathological mood states. Arthur Prange and colleagues at the University of North Carolina formulated a permissive biogenic amine hypothesis in which serotonin deficits permit expression of catecholamine-mediated depressive or manic states. That hypothesis was supported by subsequent animal research showing that an intact serotonin system is necessary for optimal functioning of noradrenergic neurons. Omission of tryptophan from the diet of antidepressant-responsive depressed patients may annul the efficacy of the antidepressant; among healthy volunteers, that special diet also induces sleep electroencephalographic characteristics of clinical depression. Although such findings are provocative, the precursor-loading strategy to increase the brain stores of serotonin (e.g., with L-tryptophan) has not been unequivocally successful in reversing clinical depression. Dietary loading with catecholamine precursors has fared even worse than serotonin-precursor loading in the treatment of depression.

The cholinergic-noradrenergic imbalance hypothesis proposed by David Janowsky and colleagues represents yet another attempt to elucidate the roles of biogenic amines. This hypothesis, along with the related cholinergic supersensitivity hypothesis developed by J. Christian Gillin, has been tested extensively at the University of California at San Diego. Subsequent formulations by Larry Siever and Kenneth Davis at the Mount Sinai Hospital in New York have refocused on noradrenergic dysregulation. The model envisions oscillation from one output mode to the other at different phases of depressive illness. In a provocative extrapolation from that model, bipolar depression would have low noradrenergic output, but many instances of major depressive disorder, just like some anxiety disorders, could be biochemically conceptualized as high-output conditions.

Despite more than three decades of extensive research and indirect evidence, however, no deficiency or excess of biogenic amines in specific brain structures has been shown to be necessary or sufficient for the occurrence of mood disorders. It has been possible neither to confirm the putative role of central norepinephrine in depression nor to discard it altogether. The role of dopamine as formulated by the Italian pharmacologist Gian Luigi Cessa, though studied less extensively than that of norepinephrine, deserves greater recognition: it might have relevance to atypical and bipolar depression as well as mania.

Except for preliminary data from a small brain imaging study showing blunted serotonin responsivity in prefrontal and temporoparietal areas in unmedicated major depressive disorder patients, the evidence for serotonergic disturbance in depression is based on indirect evidence. Moreover, the putative permissive role of serotonin is better documented for aggressive suicide attempts. Serotonergic dysfunction might subserve other conditions characterized by lack of inhibitory control, among them obsessive-compulsive disorder, panic disorders, bulimia nervosa, certain forms of insomnia, alcoholism (alcohol abuse or dependence), and a host of impulse-ridden personality disorders. Such considerations have led Dutch psychiatrist Herman van Praag and his colleagues to postulate a dimensional neurochemical disturbance generic to a large group of disorders within the traditional nosology. This hypothesis might be variously regarded as a challenge to psychiatric nosology or as a statement of the need to supplement clinical classification with biochemical parameters.

It is implied that the foregoing biochemical faults are genetically determined. Although biogenic amine models of mood disorders were developed retrospectively from the pharmacologic action of antidepressant and thymoleptic agents, they have stimulated development of new classes of antidepressants with more selective action on specific neurotransmitter receptors. Their introduction has virtually revolutionized the treatment of depression. Yet the fundamental biochemistry of mood disorders is still far from being understood. Curiously, though selective in action, the new compounds working on the serotonin system have broad effectiveness in a variety of mood-related conditions such as dysthymic disorder, obsessive-compulsive disorder, panic disorder, social phobia, borderline personality disorder, and bulimia nervosa. Such data indirectly favor the hypothesis of an underlying biological commonality to several of these disorders. New antidepressants with dual action on both serotonergic and noradrenergic receptors and emerging data on their possible greater efficacy in melancholic depressions do suggest that the biochemistry of mood disorders involves more-complex dysregulation than is implied in single-neurotransmitter hypotheses. The work of George Henninger and colleagues at Yale University further suggests that monoamines better explain how antidepressants facilitate recovery from depression than the fundamental causes of depression.

Emerging biochemical paradigms are moving away from distal biochemical lesions to focus on molecular perturbations closest to the putative genetic underpinnings of mood disorders. Originally tied to the mechanism of action of mood stabilizers in bipolar disorder, such work is exploring second messenger systems, phosphorylation G proteins, signal transduction, deoxyribonucleic acid (DNA) transcription, and messenger ribonucleic acid (RNA) translation. Again, the search for biochemical

mechanisms is inseparable from the putative mechanism of action of thymoleptic agents.

Neuroendocrine Links Functionally inadequate mobilization of neurotransmitters in the face of continued or repeated stress, as indirectly reflected in pathological modification of noradrenergic and serotonergic receptor function, could represent neurochemical final common pathways of homeostatic failure. Such mechanisms could also provide links with psychoendocrine dysfunction; the hypothesized neurotransmitter deficits may underlie the disinhibition of the hypothalamic-pituitary-adrenal axis, characterized by steroidal overproduction, the most widely studied endocrine disturbance in depressive illness. When challenged with dexamethasone (Decadron), the altered axis resists suppression, thereby offering Bernard Carroll's team (then at the University of Michigan) the possibility of developing the dexamethasone suppression test (DST) for melancholia (subsequently shown to have uncertain specificity for melancholia). That line of research has culminated in the demonstration by the Emory University's Charles Nemeroff of increased concentrations of corticotropin-releasing factor (CRF) in the cerebrospinal fluid of patients with major depressive disorder. CRF also appears relevant to the pathophysiology of anxiety disorders, such as panic disorder.

Another neuroendocrine index of noradrenergic dysregulation, blunted growth hormone response to the a_2-adrenergic receptor agonist clonidine, likewise points to limbic-diencephalic disturbance. However, studies performed in the United States suggest that it is positive in both endogenous depression and severe anxiety disorder (panic disorder). Thyroid-stimulating hormone (TSH) blunting upon thyrotropin stimulation, another common neuroendocrine disturbance in depression, also shows limited specificity.

What is remarkable, however, is that the DST, clonidine (Catapres), and thyrotropin challenge data in aggregate identify most persons with clinical depression. Such evidence of midbrain disturbance argues for considering clinical depression to be a legitimate disease. The disease concept of depression is further buttressed by computed tomography scans showing enlarged pituitary and adrenal glands.

Stress and Depression The concept of a pharmacological bridge implies two-way traffic. The hypothesized chemical aberrations may be primary or biologically induced. Provision should also be made, however, for the likelihood that psychological events that precipitate clinical depression might induce or initiate neurochemical imbalance in vulnerable subjects. That suggestion is supported by studies in animals, in which separation and inescapable frustration effect profound alterations in the turnover of biogenic amines and in postsynaptic receptor sensitivity. Thus, in genetically predisposed persons, environmental stressors might more easily lead to perturbations of limbic-diencephalic neurotransmitter balance. Finally, in vulnerable individuals, especially during the formative years of childhood, psychological mechanisms might more easily perturb midbrain neurochemistry. Traumatic experiences appear particularly potent in this regard.

Neurophysiological Approaches

Neuronal Hyperexcitability Lithium is known to replace intracellular sodium and hyperpolarize the neuronal membrane, thereby decreasing neuronal excitability. Abnormalities in neuronal electrolyte balance (an excess of residual sodium, defined by radioisotope techniques) and hypothesized secondary neurophysiological disturbances were the focus of British investigations by Alec Coppen and colleagues in the early 1960s. The existing data appear compatible with the hypothesized movement of excess sodium into the neuron during an episode of mood disorder and redistribution toward the pre-illness electrolyte balance across the neuronal membrane during recovery. Intraneuronal sodium leakage is postulated in both depressive and manic disorders but deemed more extreme in the latter. Because the harmonious activity of the neuronal cell and, by implication, that of a group of neurons depends on the electrical gradient maintained across its membrane by differential distribution of sodium, abnormalities in sodium concentrations and transport are hypothetically relevant to the production of an unstable state of neurophysiological hyperexcitability. In formulating their thesis of neurophysiologic arousal in melancholic states, Joseph Mendels and Peter Whybrow (both of whom at various times worked at the University of Pennsylvania) have capitalized on the foregoing electrolyte disturbances. The view that mania represents a more extreme electrophysiological dysfunction in the same direction as depression violates the common-sense notion of symptomatological opposition between the two kinds of disorder, yet it may in part account for the existence of mixed states in which symptoms of depression and mania coexist. The NIMH team led by Frederick Goodwin first showed that a substantial minority of depressed patients with a bipolar substrate respond to lithium salts, which further supports the concept of a neurophysiological common denominator to mania and depression. Perturbations of calcium metabolism also appear limited to bipolar patients. Therapeutic implications of this observation (e.g., the use of calcium channel inhibitors in bipolar I disorder) have not yielded consistent results. Finally, rubidium, another alkali metal, has been explored in the depressive phase of bipolar disorders, again with inconclusive results.

Rhythmopathy European studies have shown that depressed patients are phase advanced in many biological rhythms, including the latency to the first rapid eye movement (REM) in sleep. Shortened REM latency, which has been extensively studied by David Kupfer and colleagues at the University of Pittsburgh, has been proposed as another laboratory test for depressive disorder. Formulations of circadian rhythms by Thomas Wehr and Norman Rosenthal, working at NIMH, have focused on abnormalities on brain regulation temperature, activity, and sleep cycles. Others have investigated the role of the pineal hormone melatonin. These neurophysiologic considerations have paved the way for new therapeutic opportunities.

Sleep deprivation and exposure to bright white light can correct phase disturbances and thereby terminate depressive episodes, especially in patients with periodic and seasonal depressions. Daniel Kripke, working at the University of California at San Diego, has shown that the average citizen is light deprived and that phototherapy can benefit many forms of depression. Although the specificity and efficacy of these neurophysiological indexes and manipulations for clinical depression require more extensive research, cumulatively they point to midbrain dysregulation as the likely common neurophysiological substrate of depressive disorders. The foregoing considerations further suggest that the ancient Greeks, who ascribed melancholia to malignant geophysical influences, did not indulge in mere poetic metaphor. The ancients had observed the disturbed circadian patterns and advocated their readjustment to restore euthymia.

Affective Dysregulation A major challenge for research in mood disorders is to characterize the basic molecular mechanisms that underlie the neurophysiological rhythmopathies, which in turn might account for the recurrent nature of the affective pathology as envisioned by Kraepelin. This means that in the most typical recurrent forms of the disorders, the constitutional foundations (manifested as cyclothymic and dysthymic traits) are so unstable that the illness may run its entire course more or less autonomously, with the environment largely serving to turn on and off the more florid phases (episodes). The Parisian psychiatrist Jean Delay, a pioneer in psychopharmacology in the 1950s, has also emphasized affective dysregulation as the fundamental pathology in the spectrum of mood disorders. Robert Post (at NIMH) has hypothesized that the electrophysiological substrates could be so kindled that an oligoepisodic disorder initially triggered by environmental stressors could assume an autonomous and polyepisodic course. He hypothesizes that this phenomenon might occur because neuronal perturbations brought about by stressors in the early course of mood disorders get incorporated into the DNA. This fascinating kindling hypothesis, however, does not seem to pertain to common mood disorders, but those with extreme cyclicity. The monograph on manic-depressive illness by Goodwin and Kay Jamison presents in-depth arguments for this cyclical paradigm of thymopathy.

THEORETICAL SYNTHESIS

Pathophysiological Understanding Modern psychobiology attempts to link experience and behavior to the central nervous system. Building conceptual bridges between the psychological and biological approaches to mood disorders requires sophisticated strategies that go beyond the Cartesian notion of limited mind-body interactions through the pineal gland and the generalizations of the Meyerian school.

In collaboration with William McKinney in 1973, the author developed the conceptual framework that considers the affective syndromes as the final common pathway of various psychological and biological processes. The overarching hypothesis is that psychological and biological etiological factors converge in reversible deficits in the diencephalic substrates of pleasure and reward. Those areas of the brain subserve the functions that are disturbed in melancholia and mania. The integrative model links the central chemistry and physiology of reward mechanisms with the object loss and behavioral models of depression, both of which give singular importance to the depressant role of loss of rewarding interpersonal bonds. A key element of the model is the circadian disturbances observed since ancient times in both depressive and manic syndromes. Both syndromes are conceptualized as clinical manifestations of a disordered limbic system with its subcortical and prefrontal extensions. Brain-imaging studies in melancholic patients by Wayne Drevets at Washington University have tentatively visualized limbic disturbances extending into subcortical structures and occurring primarily in those with a familial diathesis for depression. The amygdala plays a key role in this model. Clinical experience and research data suggest that multiple factors described below converge to produce dysregulation leading to the final common pathway of clinical depression and mania.

Heredity Current evidence indicates a significant genetic role in the causation of bipolar and recurrent major depressive disorders. Although it is not known exactly what is inherited, recent research suggests that heritability involves a broad spectrum of disorders, including milder depressive states. Genetic heterogeneity is likely, and may involve inheritance of a single dominant gene with variable penetrance or in greater likelihood, polygenic inheritance. Different genetic mechanisms will probably involve more than one disorder (e.g., depression and generalized anxiety; bipolar I disorder, stimulant abuse, and alcohol dependence; bipolar II disorder, mood disorder with seasonal patern, bulimia nervosa, and borderline personality).

Developmental Predisposition Parents with mood disorders are often in conflict, which may lead to separation, divorce, and suicide. It can be said that heredity often determines the type of environment into which the child predisposed to mood disorder is born. Developmental object loss, although not specifically involved in causing mood disorder, might modify the expression of the illness, possibly by leading to earlier onset, more-severe episodes, and an increased likelihood of personality disorder and suicide attempts.

Temperament Since ancient times, persons prone to mania and melancholia have been described as possessing certain temperamental attributes, representing variations on the theme of what today is subsumed under cyclothymic, dysthymic, and anxious-inhibited temperaments. Many monozygotic twins discordant for full-blown mood disorders studied by Aksel Bertelsen's Danish research team exhibited affective instability with temperamental moodiness, which strongly suggests that such attributes are genetically determined. Research conducted by Kendler's team at the Medical College of Virginia further suggests that several of the temperamental attributes might be transmitted as part of the genetic liability to mood disorders. The author's research has identified such temperaments in the prepubertal offspring of parents with bipolar I disorders, suggesting that they precede by years to decades the overt onset of major mood disorder episodes. The high expressed emotion atmosphere and the negative critical remarks by relatives and affectively unstable patients documented in the recent psychological literature on mood disorders often reflect the interpersonal clashes between patients and their temperamentally intense relatives. Thus, temperaments appear intimately involved in generating much interpersonal friction, emotional arousal, and sleep loss (just to cite common perturbations) thereby eliciting many of the life stressors that precipitate affective episodes. The use of stimulant drugs either to self-treat lethargy or enhance hypomanic traits could further contribute to episode precipitation.

Life Events Most individuals do not develop clinical depression when exposed to environmental adversity. Such adversity seems to play a pathogenic role primarily in those with an affective diathesis. Actually, the work of Kenneth Kendler at the Medical College of Virginia indicates that genetic factors might underlie the depressive disorder patients' susceptibility to life events. Furthermore, current data suggest that social stressors in the onset of depression are more relevant to the first few episodes of the illness. The evidence linking such events to mania is less robust. At any rate, stressful events often appear to be triggered by the temperamental instability that precedes clinical episodes. Interpersonal losses are common events in the lives of individuals with intense temperaments.

Indeed, a recent study by Peter McGuffin's team at the Institute of Psychiatry, London, raised the possibility that one mechanism by which heredity produces depression is by creating environmental adversities in the lives of individuals predisposed to this illness. This work is now replicated by independent groups of investigators. Whatever the origin of environmental adversity, it is common clinical experience that loss represents an important, perhaps even central, theme in clinical depression. Variables that seem to modulate the impact of adult losses include concurrent life events, resultant changes in lifestyle, lack of interpersonal support, deficient social skills, and the symbolic meaning of the putative loss. The research program of George Brown and his followers in London capitalizes on the foregoing considerations, particularly the importance of early and proximate losses in socioeconomically disadvantaged women who lack supportive relationships. However, that conceptualization downplays the degree to which the social context of the depression reflects the dysthymic temperamental liabilities of those depressed women. Recent research indicates that even social support is determined to a considerable degree by the genetic mechanisms that underlie mood disorders.

Biological Stressors Many physical diseases and pharmacological agents are known to precede the onset of both depressive and manic episodes. Like psychosocial stressors, however, they do not generally seem to cause de novo episodes but mobilize them in persons with a personal and family history of mood disorders. Thyroid disturbances have an important role in practice, because they seem to underlie some cases with rapid cycling in bipolar females.

Sex Clinical and epidemiological studies concur in suggesting that women are at higher risk for mood disorders, with the risk highest for depression. This now appears in part a function of anxious-depressive traits represented by neuroticism. These traits have strong genetic determinants. Women have higher concentrations of monamine oxidase (the enzyme that breaks down monamine transmitters) in the brain and more precarious thyroid status. In addition, low estrogen and high progesterone concentrations have been postulated as possible mediating factors in postpartum depressions, premenstrual accentuation of affective instability, and women's vulnerability to the depressant effect of steroidal contraceptives. Personality factors might also be relevant to the sex differences in depression. In recent collaborative work with University of Pisa psychiatrist Giulio Perugi, the author has proposed the hypothesis that female sex might favor greater expression of dysthymic attributes, whereas hyperthymic traits appear favored by male sex. Those considerations tend to parallel, respectively, the “ruminative” and “active” cognitive response styles reported by Stanford's Susan Nolen-Hoeksema to distinguish the sexes. What specific sex-related biographical factors might interact with sex-related biological factors to produce such trait differences is presently largely unknown. An intriguing possibility is that women, because of their temperamental inclination to depressive cognitions, might more adversely respond to childhood adversities, as well as being more specifically vulnerable to adult stressors related to bonding with men and child rearing. Research by Mark George and colleagues has raised the provocative possibility that women overrespond to sad circumstances over a lifetime, thereby permanently altering anterior limbic and prefrontal brain function in a depressive direction.

The integrative model presented here (Fig. 14.1-3) goes beyond the general provisions of the unified approach developed a quarter century earlier. It is submitted that at least in the highly recurrent forms of the malady, affective temperaments represent the intermediary stage between remote (hereditary) and proximate (stressful) factors and that limbic-diencephalic dysfunction is best characterized as the biological concomitant of the clinical manifestations of the affective syndromes. Like the temperamental dysregulations, these biological disturbances represent a putative stage in the pathogenetic chain. They emerge as temperamental instabilities that react to, provoke, or invite life events, substance use, and alterations in circadian rhythms, which in turn appear to usher in the behavioral, emotional, and cognitive manifestations of the illness.

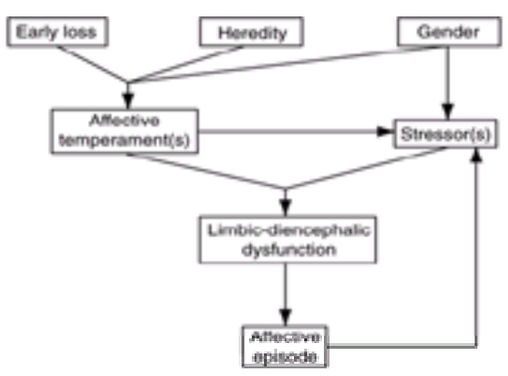

FIGURE 14.1-3 An integrative pathogenetic model of mood disorders.

THERAPEUTIC PERSPECTIVES The foregoing integrative model envisions the joint use of somatic-pharmacological and psychosocial interventions. Although the milder forms of mood disorders can be managed with psychotherapy, somatic treatments are usually required to reverse the biological disturbances in melancholia before the patient can respond to interpersonal feedback. Depressive disorders with psychotic features often necessitate more definitive somatic interventions such as electroconvulsive therapy. Continued psychopharmacological treatment is also effective in decreasing rates of relapse and future recurrence in most.

Psychosocial therapy by skilled clinicians can provide support, combat demoralization, change maladaptive self-attributions, and improve conjugal and vocational functioning. Whether such therapy can also modify personality traits to fortify the patient against new episodes is a future research challenge. In the author's view, it may prove more profitable to attempt to help patients explore professional and object choices that match their temperamental proclivities and assets, which in turn might provide them greater harmony and adaptation in life. Although much needs to be learned about the indications for medication and psychotherapy in different subtypes of mood disorders, research to date not only does not support a negative interaction between the two forms of treatment but on selected parameters suggests additive and even synergistic interaction. There is a great need for patients, their families, and clinicians to understand how a biologically driven illness like depression should be approached from a pragmatic psychotherapeutic perspective.

The challenge for psychiatric research in the decade ahead is to elucidate the basic mechanisms whereby the predisposing, precipitating, and mediating variables reviewed here and others yet to be identified interact to produce the final common path of decompensation in melancholia. Because of the heterogeneity of depressive conditions presenting as a psychobiological final common clinical syndrome and because antidepressant agents, irrespective of specificity to one or another biogenic amine, are about equally effective in two-thirds of those with depressive disorders, the antidepressant agents may be acting not on the primary lesions of these disorders but on a neurochemical substrate distal to the underlying biological faults. The choice of antidepressants is still highly determined by the

side effect profile least objectionable to a given patient's physical status, temperament and lifestyle. That so many different classes of antidepressants—with different mechanisms of action—have been marketed in the 1990s represents indirect evidence for heterogeneity of biochemical lesions. The investigation of central neurotransmitter receptor function continues to occupy much current effort to delineate the putative mechanism of antidepressant action and side effects of classic agents as well as the new compounds which have made the treatment of depression “clinician and patient friendly.” Whether study of specific recepters will unravel the molecular mystery of depression remains to be seen. During the past decade, studies have begun on antidepressant and mood-stabilizing effects on molecular mechanisms believed to be closer to the “genetic underpinnings” of mood disorders. Herein is the promise of the future, a new generation of psychiatrists conversant with both clinical phenomenology and molecular biology. Data suggest that the biological specificity of genetic factors in mood disorders might be translated into distinct temperamental dysregulations, which in turn might predispose to different affective subtypes.

Returning to the therapeutic arena, mounting evidence indicates that in depressed patients with bipolar disorder, antidepressants might provoke mixed episodes, hypomanic episodes, or both, and possibly increase later cycling. The kindling-sensitization model suggests the utility of anticonvulsant medication on episode escalation and might represent yet another example of pathophysiological intervention. Whatever the merit of this model, the last decade has witnessed intense clinical and research interest and Food and Drug Administration approval of clinical introduction of divalproex (Depakene) for bipolar I disorder, and many other promising anticonvulsants are being developed for that disorder. Anticonvulsant mood stabilizers appear to possess a broad spectrum of activity on bipolar disorders, including mixed dysphoric and rapid-cycling forms. Lithium, by contrast, seems more specific to euphoric mania.

Psychoeducational interventions geared to disturbed rhythms of the disorder represent another example of rational therapeutics. Mood clinics should help patients and their significant others to dampen stimulation so that it is kept at an optimal level for depressed patients with cyclothymic traits. All offending drugs (e.g., cocaine, caffeine, and sedative-hypnotic agents) should gradually be eliminated, and circadian disruptions and sleep loss minimized. The greater challenge is learning how to curb the ill-advised actions of patients with cyclical depressions. Psychoeducation and psychotherapy have the task of ameliorating the resulting social problems. Compliance with mood-stabilizer regimens that for many would attenuate episodes and prevent such sequelae is difficult to achieve. Research on compliance-enhancing techniques is needed for the more efficient use of mood stabilizers.

It is tempting to suggest that biogenic amines, the “humors” of modern psychobiology, play the same heuristic role as the ancient humors did for many centuries. The black humor, appropriately evoked in the construct of melancholia in DSM-IV, may not have the same claim for etiological relevance to depressive disorders as norepinephrine and serotonin, but at least has a classical heritage. Dopamine, by contrast, may represent the sanguine humor that drives hypomanic temperaments and manic behavior. When genetic factors contributing to clinical depression and mania are discovered, in all likelihood they will be more linked to temperamental dispositions than to fullblown affective disease phenotypes. The clinician will still need to interpret the myriad of influences that impinge on such inclinations to produce disease in an individual patient. That is, fundamental scientific advances in mood disorders, rather than diminishing the role of practitioners, will actually increase it.

In any discipline, scientific truth is a function of its technology, but understanding the phenomena under consideration is a matter of philosophical temperament that seeks integration and the hope for a unified vision. Research into the causes and treatment of mood disorders has generated abundant recent data suitable for integration into theory and practice, and conceptualizing the origin and treatment of mood disorders can no longer be justified on the grounds of ideological preference alone.

SUGGESTED CROSS-REFERENCES

Anxiety disorders are covered in Chapter 15. The other sections of Chapter 14 cover the various aspects of mood disorders in detail. Epidemiology is the subject of Section 14.2; neurobiologic aspects are the focus of Section 14.4; Section 14.3 is a discussion of genetic aspects; psychodynamic aspects are the subject of Section 14.5. Clinical features are covered in Section 14.6, somatic treatment in Section 14.7 and Section 14.8, and a discussion of psychosocial treatments concludes the chapter in Section 14.9.

14.2 MOOD DISORDERS: EPIDEMIOLOGY

DAN G. BLAZER II, M.D., FH.D.

INTRODUCTION

Since the 1980s community-based epidemiologic studies of mood disorders throughout the world have been significantly influenced by two large community-based surveys in the United States, the 1981 Epidemiologic Catchment Area Study and the 1991 National Comorbidity Survey. Not only did these surveys provide estimates of the prevalence and distribution of discrete psychiatric disorders (in synchrony with the shifting orientation from symptom burden to operational psychiatric diagnoses reflected in the third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DMS-III) and its successors, they also demonstrated the feasibility of identifying psychiatric patients by use of assessment procedures that could be administered by nonprofessional interviewers. ECA investigators used the Diagnostic Interview Schedule (DIS) and NCS investigators used a modified version of the Composite International Diagnostic Interview (CIDI). These case assessment procedures have now been used in countries throughout the world, including Canada, Finland, Korea, Taiwan, and New Zealand.

Most of the data presented in this chapter derive from community-based estimates of the frequency, distribution, and correlates of depressive symptoms and major depressive disorder as estimated from these studies. Bipolar disorders receive less attention than they do in clinical studies because community-based epidemiological data are sparse. The lifetime prevalence of mood disorders is high in Western society. Estimates of the lifetime prevalence of mood disorders are presented in Table 14.2-1.

Mood Disorder		Lifetime Prevalence
Depressive disorders		
Major depressive disorder (MDD)	Recurrent, with full interepisode recovery, superimposed on dysthymic disorder	10–25% for women; 5–12% for men
		2–3% of persons with MDD
Dysthymic disorder	Recurrent, without full interepisode recovery, superimposed on dysthymic disorder (double depression)	25–30% of persons with MDD
		3–6%
Bipolar disorders		
Bipolar I disorder		0.4–1.6%
Bipolar II disorder		<1%
	Bipolar I disorder or bipolar II disorder, with rapid cycling	5–15% of persons with bipolar disorder
Cyclothymic disorder		0.4–1.0%

Table 14.2-1 Lifetime Prevalence of Some DSM-IV Mood Disorders

CASE IDENTIFICATION

Case identification (i.e., determining who should be diagnosed as experiencing a mood disorder versus who is only expressing a normal fluctuation in mood) has been at the center of debate regarding the true frequency of mood disorders in the community. This debate derived largely from the significant variance in the estimates of the current and lifetime prevalence of major depressive disorder in the ECA and NCS studies, as demonstrated in Figure 14.2-1, Figure 14.2-2, Figure 14.2-3 and Figure 14.2-4. This debate has relevance to clinicians who treat patients experiencing mood disorders, for they must distinguish normal variations in mood from the mood disorders. The diagnostic criteria for the specific mood disorders in the DSM, which has gone through four editions since its inception, are not easily applied in epidemiological studies. Some diagnostic categories, such as adjustment disorder with depressed mood, cannot be operationalized in standardized interviews because the criteria require a subjective clinical judgment (e.g., the mood disturbance must be related to a specific stressor). Other diagnoses are too inclusive when applied to community samples (e.g., major depressive disorder). Patients identified by current diagnostic criteria are therefore a heterogeneous mix with little clinical relevance beyond symptom severity. In other words, the borderline between clinical depression and normal fluctuation in mood is fuzzy. Even the presence or absence of a symptom may be disputed.

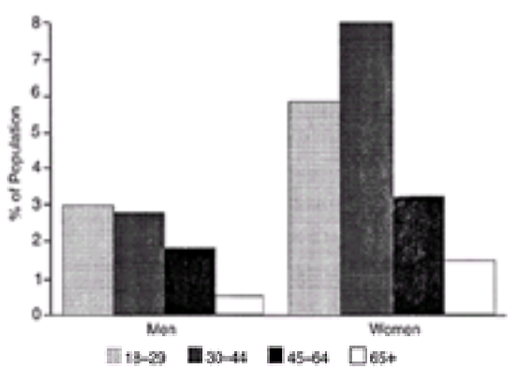

FIGURE 14.2-1 Current prevalence of major depressive disorders by age and gender. (Data derived from the Epidemiologic Catchment Area Study.)

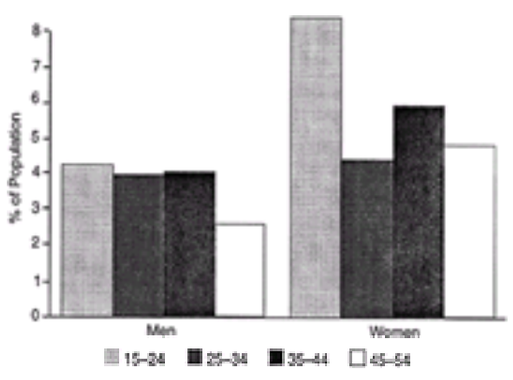

FIGURE 14.2-2 Current prevalence of major depressive disorders by age and gender. (Data derived from the National Comorbidity Survey.)

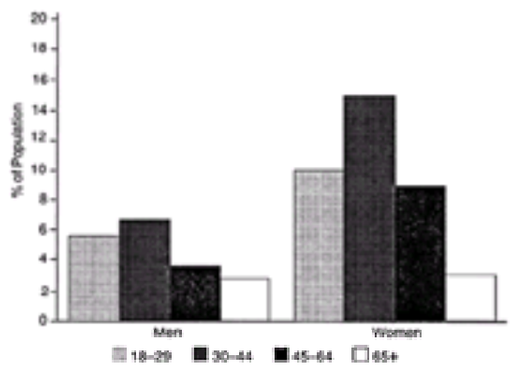

FIGURE 14.2-3 Lifetime prevalence of major depressive disorders by age and gender. (Data derived from the Epidemiologic Catchment Area Study.)

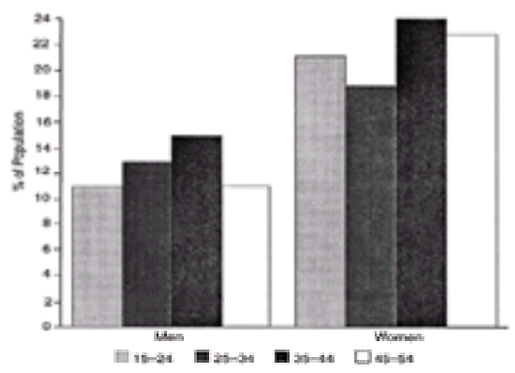

FIGURE 14.2-4 Lifetime prevalence of major depressive disorders by age and gender. (Data derived from the National Comorbidity Survey.)

Some persons in community samples may exhibit depressive syndromes that do not fit the DSM diagnostic system (e.g., for major depressive disorder or dysthymic disorder), but they nevertheless suffer disabling depressive symptoms. Much attention has been focused in recent years on so-called minor or subsyndromal depressive disorder, a syndrome defined by symptoms that are less severe than those of major depressive disorder and of shorter duration than those of dysthymic disorder. The frequency of minor depression was estimated to be nearly 4 percent in the ECA study. Minor depression has generally been divided into two categories: less severe episodes that occur in conjunction with major depressive disorder and symptoms that occur spontaneously. Persons identified in community surveys as experiencing minor depressive disorder have been shown in prospective studies to be at greater risk for time lost at work and increased use of general health services than persons without depressive symptoms. In addition, their risk factor profile is similar to that for major depressive disorder.

Another problem that complicates estimation of the frequency of mood disorders in the community is deterioration of memory over time. Recall of past symptoms is only modestly accurate compared with clinical records of previous depressive episodes. The threshold for reporting a symptom of depression may be higher in a community than in a clinical setting because clinicians often probe for evidence of a symptom that the patient initially denies. Most interview instruments used in epidemiological surveys to identify DSM diagnoses, such as the DIS used in the ECA, were developed in clinical settings and were standardized with classic patients who present to psychiatric treatment settings. In contrast, the modified version of the CIDI used in the NCS (see below) was designed to probe for past history of symptoms more thoroughly than he DIS, because the emphasis of the CIDI was on identifying affected persons in the community who were not experiencing clinically significant depressive symptoms and who had never sought psychiatric treatment. As the threshold for case identification is lower with the CIDI, the estimate of both current and lifetime prevalence of mood disorders is higher. Most persons identified as having mood disorder in the community with the CIDI experience little disruption in function and do not seek psychiatric treatment. Should persons who meet strict fourth edition of DSM (DSM-IV) criteria when interviewed by nonclinicians and asked in detail about past and present symptoms be considered to have true cases of mood disorder, especially major depressive disorder? Therein lies much of the debate.

Comorbidity presents another problem to psychiatric epidemiologists who study mood disorders in community settings. More often than not, symptoms of anxiety and depression overlap. Many subjects receive concurrent diagnoses of major depressive disorder, dysthymic disorder, and generalized anxiety disorder. Most community survey subjects cannot accurately remember whether depression or anxiety was the first syndrome experienced. Do major depressive disorder and generalized anxiety disorder coexist, or is anxiety an epiphenomenon of major depressive disorder? That question remains unanswered.

Nevertheless, development of standardized instruments for case identification in the community, such as the DIS and CIDI, has made it possible to investigate empirically the utility of psychiatric diagnosis. For example, when investigators do not agree upon the frequency of mood disorder with seasonal pattern (i.e., seasonal affective disorder) they can explore their disagreements by using the same criteria and diagnostic instruments for case identification. A recent study demonstrated that though a seasonal pattern of mood swings is common among persons in the community (approximately 8 percent), the frequency of mood disorder with a seasonal pattern, as defined by DSM-IV, is less than 1 percent, even when the most liberal interpretation of the criteria is applied.

DISTRIBUTION OF CASES

Estimates of the prevalence of major depressive disorder by age and gender from the ECA and NCS studies are presented in Figure 14.2-1 and Figure 14.2-2. The DIS was administered for case finding in the ECA study to over 18,000 community and institutionalized subjects (18 + years of age) at five sites throughout the United States—New Haven, East Baltimore, St. Louis, the Piedmont of North Carolina, and Los Angeles. The large numbers of subjects and oversampling of subjects not accurately represented in previous studies, such as African-Americans, Hispanics, and elderly persons, enabled much better estimates of the actual distribution of cases. Over 8000 subjects (15 to 54 years of age) from a nationwide sample were administered a modified version of the CIDI in the NCS study.

Age, Sex, and Residence The most striking finding from the ECA study was a much higher prevalence of all the mood disorders among persons under the age of 45 than in persons 45 years of age and older. Rates were comparable across ECA sites, except for a lower prevalence in North Carolina. The North Carolina sample was composed of both urban and rural residents. Persons in urban areas were as likely to be diagnosed with a mood disorder in North Carolina as in urban areas at other ECA sites. In contrast, rural subjects in North Carolina had much lower rates of major depressive disorder than rural subjects at other ECA sites. In the NCS study, variance by age and geographic location was much less prominent.

The most consistent finding across epidemiological studies of the mood disorders, confirmed by the ECA and NCS studies, is the relatively higher prevalence of major depressive disorder in women than in men. The sex differences are consistent across the life cycle but are much more prominent in young adult and middle-aged persons than in elderly persons and childhood depressive disorders. Because alcohol abuse and mood disorders are often inherited in the same family and alcohol abuse and dependence is more prevalent in men than in women, some have theorized that depressive disorders and alcohol abuse/dependence are phenotypic variants of the same genotype. Little empirical evidence supports this theory.

Sex differences begin in early adolescence and persist at least until midlife. However, women with a previous history of a depressive episode are no more likely to experience a new episode than men with a previous history of a depressive episode. This suggests that the higher risk in women results from women having a higher

risk of experiencing major depressive disorder for the first time. Psychosocial explanations for the higher prevalence of major depressive disorder among women are thus considered the most likely explanation of the sex differences. Epidemiologists have identified stressors that may contribute to increased stress experienced by women, such as maintaining multiple roles as homemaker, professional, wife, and mother.

Race and Ethnicity As illustrated in Figure 14.2-5, the prevalence of the mood disorders does not vary significantly by race or ethnicity. In most epidemiological studies of psychiatric disorders, racial differences in the rates can be explained by socioeconomic and educational differences. The ECA was the first study in Western society that permitted direct comparison of whites, African-Americans, and Hispanics. Previous comparisons, which could not control for geographical differences, were subject to significant bias because prevalence estimates clearly vary by place of residence. The NCS results are similar to the ECA results, though as noted, the overall rates are higher.

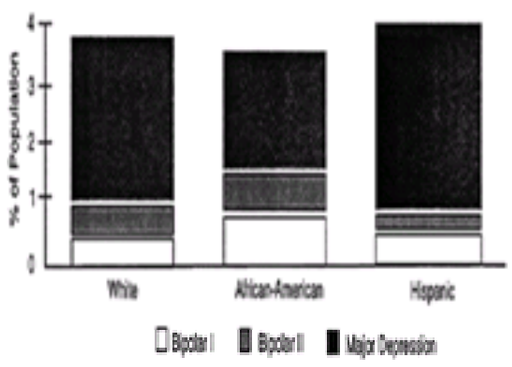

FIGURE 14.2-5 Current (1-year) prevalence of major depressive disorder by race or ethnicity. (Data derived from the Epidemiologic Catchment Area Study.)

International Studies Perhaps the most frequently cited epidemiologic study prior to the ECA and NCS studies was the Stirling County Study from Nova Scotia, Canada. The current prevalence of major depression was estimated to be 4.7 percent in men and 6.0 percent in women. Most studies in developed countries estimate the distribution of major depressive disorder to be greater in women than in men, in young adulthood than in midlife and old age, in urban residents than in rural residents, and among single or divorced persons than among married persons. Few studies document a racial difference when social class and education are controlled. In a recent comparison of population-based epidemiologic studies in 10 countries—the United States, Canada, Puerto Rico, France, West Germany, Italy, Lebanon, Taiwan, Korea, and New Zealand—the lifetime prevalence for major depressive disorder ranged from 1.5 percent in Taiwan to 19 percent in Beirut. Current prevalence ranged from 0.8 percent in Taiwan to 5.8 percent in New Zealand. The difference in prevalence estimates across countries suggests that cultural differences or differences in risk factors may influence the expression of major depression.

Depressive Symptoms The differential frequency of clinically significant depressive symptoms parallels that of major depressive disorder, although the age differences are not nearly so great. In most studies, 8 to 20 percent of community-study participants report depressive symptoms at a level above the cutoff used to screen for major depressive disorder, such as 16 + on the Center for Epidemiologic Studies Depression Scale (CES-D). As with all good screening tests, many potential patients are screened out with more-specific case-identification techniques, such as a standardized diagnostic instrument. Therefore, many persons who appear positive on screening do not meet criteria for specific DSM-IV mood disorders. Those who do appear positive on screening for depressive symptoms, however, experience higher mortality rates, higher disability rates, and poor social functioning.

Incidence Because major depressive disorder is common and tends to remit and recur, the incidence is relatively high. The annual incidence of major depressive disorder in the ECA study was 1.59 percent overall. The distribution by age and gender is presented in Figure 14.2-6. A survey in Lundby, Sweden, revealed an annual first incidence of depression (depression in persons who never experienced depression before) of 0.43 percent in men and 0.76 percent in women. Up to the age of 70, the cumulative probability of a first episode of depression was 27 percent in men and 45 percent in women, making depression one of the most important public health problems (Fig. 16.2-7).

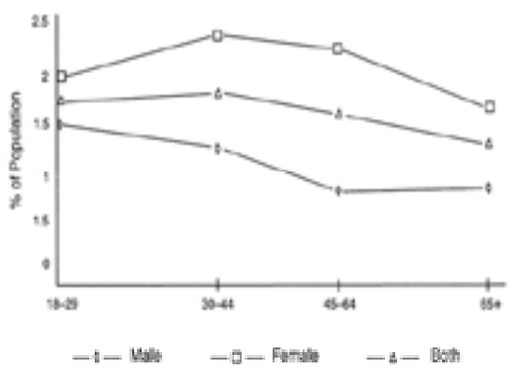

FIGURE 14.2-6 Annual incidence of major depressive disorders by age and gender. (Data derived from the Epidemiologic Catchment Area Study.)

Setting The prevalence of major depressive disorder is much higher in treatment settings than in the community at large. Most investigators find that 10 to 15 percent of persons in acute hospital settings and long-term care facilities meet the criteria for the diagnosis of major depressive disorder. An additional 20 to 30 percent of persons in treatment settings report clinically significant subsyndromal depression (minor depression). The similarities between those patients with major depressive disorder to patients found in psychiatric treatment settings has yet to be documented. Although some depressed medically ill patients respond to antidepressant therapy and brief psychotherapy, many have comorbid conditions that render traditional therapies ineffective.

Depression is also more prevalent in primary care settings than in the general population. Using case-identification methods similar to those in the ECA study, the current prevalence of depression is about twice that found in the general population. In most surveys of primary care clinics, over 20 percent of patients report clinically significant depressive symptoms. Major depressive disorder is diagnosed in one-third to one-half of these outpatients. Young women are at greatest risk for depression in primary care, and most persons who report depressive symptoms to a health care professional report them to a primary care physician.

HISTORICAL TRENDS

The higher prevalence of depression in younger age groups than in older ones has led to the hypothesis that birth cohorts born after World War II are at appreciably greater risk for major depressive disorder than older birth cohorts in advanced Western society. The trend has been observed not only in the United States but also in Sweden, Germany, Canada, and New Zealand.

A number of observations made prior to the ECA study suggest that prevalence rates of depressive disorders are changing. Relevant factors include a progressively lower age of onset of depressive disorders reported in community studies, an increase in childhood mood disorders seen by pediatricians and mental health workers, a decrease in deaths from suicide among the elderly (until about 1980), and a lower average age of onset for depressive disorders in clinical samples since World War II. For example, the risk of first-onset depression was higher for younger birth cohorts than for older birth cohorts in Sweden (Fig. 14.2-7). The trends in suicide data parallel the trends in mood disorders (i.e., suicide rates are much higher in younger persons today than they were in younger persons 30 years ago). Suicide rates in older adults have increased by 25 percent since 1980.

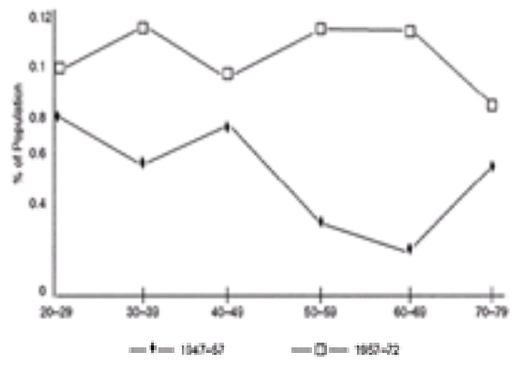

FIGURE 14.2-7 Risk of contracting a first-onset depressive disorder for younger birth cohorts and older birth cohorts in Sweden. (Data derived from Hagnell O, Lanke J, Rorsman B, Ojesjo L: Are we entering an age of melancholy? Depressive illnesses in a prospective study epidemiological study over 25 years: The Lundby Study, Sweden. Psychol Med *12:*279, 1982.)

Factors That Influence Historical Trends Three factors influenced historical trends in the relative prevalence of mood disorders by age: period effect, age effects, and cohort effects.

Period effects are changes in the prevalence of an illness secondary to environmental stressors on the population or particular age groups within the population at a specific period in history. (For example, the uncertainty of employment among college graduates and the trend among younger persons to delay marriage during the 1990s may place young adults at greater risk for depression and suicide because of economic impairment and lack of affiliative relations.)

Age effects are the biological and psychosocial factors that predispose an individual to develop a particular disorder during a specific part of the life cycle. (For example, the genetic predisposition to develop major depressive disorder is probably greatest during the 30s, whereas the predisposition to develop a bipolar disorder is greatest during the 20s.) Age-related changes in the brain, such as increased subcortical hyperintensities on brain magnetic resonance imaging, may also be associated with mood disorders. Perhaps the most consistently observed age effect relevant to mood disorders that has been observed during the 20th century is the positive association between age and suicide among white males in the United States.

Cohort effects are the relative differences in rates of illness across different generations. A cohort is usually defined by the year or decade of birth. Persons born in a given year may be at greater risk for an illness, such as major depressive disorder, throughout their lives. Suicide data reveal marked cohort trends throughout the 20th century. (For example, persons currently 75 to 85 years of age [approximately the birth cohorts of 1915 to 1925] have exhibited lower suicide rates at all ages than either the 1900 or the 1940 birth cohorts.)

Considerable statistical and methodological problems confound sorting out the relative contribution of period, age, and cohort effects upon the prevalence and incidence of mood disorders by age. First, these effects undoubtedly interact. Stressors during a particular period interact with age-related vulnerability. (For example, the current high rate of substance abuse among adolescents may reflect both the vulnerability of adolescents to substance abuse, an age effect, and the greater availability of drugs to adolescents, a period effect.) Second, older persons may not recognize major depressive episodes as such and so do not report them, thus setting the threshold for identifying depression among community-dwelling elders higher. Yet age does not appear to affect the rate of hospitalization for mood disorders. The more severe cases of major depressive disorder are hospitalized, regardless of age, and the relative cohort differences persist in hospitalization rates.

Most investigators have explained the current data as reflecting a period effect. They argue that the risk for depressive disorders increased dramatically for all ages from about 1965 to 1975 but has since stabilized at a higher incidence. Young persons are more vulnerable to that period effect, however, and therefore carry the greatest burden of depressive disorders. A young person who experiences a major depressive episode is likely to exhibit ongoing and severe depressive episodes for many years. Therefore, clinicians can expect to see the current cohort of younger persons bear the burden of major depressive disorder for a long time. Despite being the healthiest and most affluent generation of the 20th century, younger persons may be placed at greater risk for major depressive disorder by a number of environmental risk factors, including increased urbanization, increasing social isolation and anomie, changes in occupational roles and career trajectories for both men and women, increased secularization, and increasing geographic mobility.

IDENTIFICATION OF CAUSES

The risk factors for bipolar I disorder and major depressive disorder identified from community- and clinically based epidemiological studies are summarized in Table 14.2-2. Most have been replicated, yet some most interesting hypotheses about risk for mood disorders have failed to hold up with repeated study. For example, an increased risk for major depressive disorder was discovered in an isolated community of Hutterites who live near the border between the United States and Canada, suggesting that the rigid moral control they exert predisposes community members to depression. Most community studies, however, fail to find that identification with or participation in particular religious groups is associated with an increased risk for major depressive disorder. In contrast, virtually every community survey has demonstrated increased risk for major depressive disorder and depressive symptoms in persons who report negative life events.

Risk Factor	Bipolar I Disorder	Major Depressive Disorder
Gender	No effect	Women at greater risk than men
Race/ethnicity	No effect	No effect
Age	Young at greater risk	Young at greater risk
Socioeconomic status (SES)	Higher SES at somewhat greater risk	Lower SES at greater risk
Marital status	Separated and divorced at greater risk	Separated and divorced at greater risk
Family history	Persons with family history at greater risk	Persons with family history at greater risk
Childhood experiences	Bipolar patients may come from families with low perceived prestige in their community	Evidence that early parental death and disruptive childhood environment leads to major depression
Stressful life events	Negative stressful events associated with increased risk	Negative stressful events associated with increased risk
Chronic stress	No known effect	Chronic stress associated with increased risk
Absence of a confidant	No known effect	Absence of confidant leads to increased risk, especially in women
Residence	Greater risk in suburbs than in inner city	Greater risk in urban areas than in rural areas

Table 14.2-2 Risk Factors for Bipolar I Disorder and Major Depressive Disorder

DEMOGRAPHIC FACTORS

Sex Almost all community-based epidemiological surveys of mood disorders that compare prevalence by sex find that women are twice as likely as men to experience an episode of major depressive disorder. Few investigators discount this finding as an artifact of prejudice in the diagnostic criteria for major depressive disorder or of increased help-seeking behavior among women. Yet female sex has not been demonstrated to be a risk factor per se. The social environment of women and a higher threshold for reporting depressive symptoms in men may account for the increased association. Yet, as discussed above, no mechanism for this apparent increased risk has been established.

Age The average age of onset for both major depressive disorder and bipolar disorders falls between 20 and 40 years. Recent studies also confirm that major depressive disorder can occur in childhood. Bipolar I disorder typically has an earlier age of onset than major depressive disorder, with an average of 30 years. Yet both major depressive disorder and bipolar disorder can first occur at any time during adulthood. Nothing suggests that young age per se places a person at greater risk for the mood disorders (though genetic factors may have their greatest influence at a younger age). Social factors appear to place younger persons at greater risk than elderly persons. Biological predisposition to major depressive disorder may actually increase with age.

Race and Ethnicity Race or ethnicity has not proved to be a significant risk factor for either bipolar I disorder or major depressive disorder. In some community surveys, African-Americans experience a higher prevalence of depressive symptoms. The racial difference usually disappears, however, when other factors, such as socioeconomic status, age, and residence, are controlled. Because treatment for mood disorders is less common for African-Americans than for whites, prevalence studies based on treatment samples usually contain proportionately more whites. Rates for major depression were estimated as higher among Hispanics than among whites and African-Americans in the NCS study in controlled analyses. To date, too few Asians have been included in community-based studies in North America and Europe to permit comparative estimates of risk for Asians. The similarity in overall rates across racial or ethnic groups does not necessarily mean a similarity across all symptoms. For example, older African-Americans have been found more likely to complain of interpersonal problems when depressed and less likely to complain of depressed mood than older whites.

Socioeconomic Status The findings from community-based studies relating to socioeconomic status as a risk factor for-depression are mixed. The overall ECA studies found only a weak correlation between major depressive disorder or bipolar disorders and lower socioeconomic status. The North Carolina ECA study, however, found a consistent relation between socioeconomic status and major depressive disorder, even when multiple potential confounders, such as race and residence, were controlled. In the NCS study, both lower income and education were associated with higher prevalence of major depression. Studies prior to the ECA and NCS found a consistent positive relation between lower socioeconomic status and depression. In one classic study reported by A.B. Hollingshead and Frederick C. Redlich, depressive symptoms were strongly associated with the lower social classes. In a more recent study, working-class women from an eastern suburb of London were much more likely to suffer depressive symptoms than women from higher social classes.

Marital Status Marital status appears to be one of the most consistent risk factors for both depressive symptoms and major depressive disorder. Rates for major depressive disorder are highest among separated and divorced persons and lowest among single and married persons. Recent widowhood is associated with higher rates of major depressive disorder across the life cycle. The risk appears to vary with sex. Single women have lower rates of depression than married women, whereas married men have lower rates than single men. However, the investigator must not confound marital status with the loss of a spouse through death or divorce (a stressful life event). If a woman was widowed during the 6 months prior to the study, then the event not the status is perhaps the causative factor. In addition, cause and effect may be reversed (e.g., depressive illness may place a person at greater risk for divorce). In most studies, however, separated or divorced status places a person at greater risk for depression, even if the marital breakup occurred long before the assessment. The ECA studies, unlike previous studies, also documented a much higher prevalence of bipolar disorders among separated and divorced persons than among those who were single. The highest rates, however, were found among those who were cohabiting, even when adjusting for age, sex, and race or ethnicity. The association of the mood disorders and marital status is also reflected in the association of mood disorders with household size. Major depressive disorder is twice as common among persons living alone than among those who live with others. In persons not living alone household size is not associated with depression.

Marital status may not be the proximal causative factor. The perception of social support and lack of conflict within the social network are critical factors in protecting against mood disorders. Longitudinal studies of the social network and neuroses have shown that the most important predictors of depression are not the objective characteristics of the network but rather the perception of how adequately the network assisted the person. Large-scale community-based investigations of the risk factors for major depressive disorder cannot disentangle the subtleties of the complex interactions between persons and their social network. (For example, dissolution of a difficult marriage may relieve long-standing depressive symptoms.)

Family History Most epidemiological studies of treatment samples have shown a consistent increase in family history of mood disorders among subjects, especially in first-degree relatives. A family history of suicide and alcoholism has also been repeatedly found to be more common among depressed subjects than among controls. Most experts attribute the increased risk for depression when family history is positive to a genetic predisposition; yet shared family environment may also contribute to the increased risk. Genetic transmission is much more firmly established for bipolar I disorder than for major depressive disorder. In family members of bipolar subjects, both bipolar disorder and major depressive disorder are more prevalent.

Early Childhood Experience Much attention has been directed to the association of early childhood experience with onset of mood disorders later in life. Although the complexities of a psychodynamic investigation of childhood traumas cannot be applied in community-based epidemiological studies, even cursory investigation of childhood experiences has revealed correlates. Parental loss before adolescence is a well-documented risk factor for adult-onset depression. A deprived and disrupted home environment also constitutes a risk. Methodological problems make objective study of childhood trauma and deprivation difficult. Some events (e.g., divorce or separation of parents) can be documented reliably, but others (e.g., parental neglect) are quite subjective. The report of parental neglect by a depressed adult may vary depending on the respondent's emotional state at the time of the interview.

Personality Attributes Personality attributes are closely associated with early childhood experience as a risk for mood disorders in later life. Persons predisposed to develop a depressive disorder lack energy, are more introverted, worry, are more dependent, and are hypersensitive. Major depressive disorder is also frequently comorbid with the Axis II disorders; yet the study of the relation of depression and personality is confounded by the time at which personality is studied. Epidemiologists rarely have the opportunity to assess personality before the onset of the first episode of depression. If personality is assessed during an episode of depression, then the depressive symptoms mask certain personality traits and exaggerate others. When a person has experienced and recovered from a depressive episode, its impact on personality makes accurate assessment of premorbid personality difficult. (For example, the personality characteristics associated with depression are exactly those that might emerge in response to the experience of a serious psychiatric disorder.)

Social Stressors Social stressors have received more attention than other risk factors for major depressive disorder across the life cycle, except sex. Three kinds of social stressors can be distinguished: life events, chronic stress, and daily hassles. Life events are the kind most often explored in epidemiological studies. They are identifiable, discrete changes in life patterns that disrupt the usual behavior and threaten the person's well-being. Bereavement, the reaction to loss of a loved one, is the prototypic stressful life event. Chronic stress includes long-term conditions that challenge the person, including financial deprivation, ongoing interpersonal difficulties (e.g., conflict in the workplace), and persistent threat to security (e.g., living in a dangerous neighborhood). Daily hassles are ordinary but stressful occurrences that are ubiquitous in modern life (e.g., managing household finances and unpleasant interactions with neighbors).

Most epidemiological studies reveal a relation between stressful life events, especially negative events, and the onset and outcome of major depressive disorder. Nevertheless, the use of stressful life event scales such as the Schedule of Recent Events introduces many potential biases into the study of stressors and depression. Such scales usually tally the number of events and weight them according to a predetermined algorithm. Most schedules weight events on the basis of normative data from the population. Because the data usually derive from weightings provided by young adults, they do not necessarily apply across the life cycle. (For example, retirement in late life may be a positive event, whereas premature retirement in midlife may present problems that can precipitate a depressive disorder.)

The perception of the event is probably more important than the event itself. More-sensitive measures of stressful events document not only the event itself but the subject's response to it. Was the event perceived to be positive or negative? Even the death of a spouse may be viewed as a positive event if it occurred after a protracted and disabling illness during which the subject was the caretaker. Was the event perceived to be important or unimportant? For some older persons a move may be extremely traumatic, especially if it is the first move in half a century. For others, a move may be a usual and relatively unimportant event, especially in a society in which mobility is becoming more the norm. Was the event expected or unexpected? If income decreases at retirement at a rate expected by the retiree, then the loss of income is much less stressful than if a person is forced to take an unexpected cut in salary while still in the workforce.

The accumulation of stressful negative life events does appear to predispose a person to episodes of major depressive disorder. In a study from New Haven, depressed patients had an average increased frequency of eight life events during the 6 months preceding the onset of depressive symptoms. Those events included marital arguments, marital separation, starting a new type of work, change in work conditions, serious personal illness, death of an immediate family member, serious illness of family members, and a family member leaving home. Stressful events are also associated with the persistence of depressive disorders. In a study from England, adverse events during the year following the initial episode of depression were associated with a poorer outcome of the episode. The adverse effects of life events may be offset by neutralizing events. (For example, if a woman loses her job but soon after finds another job with equal pay and benefits, then the adverse event is neutralized.)

In addition, the impact of a stressful life event may vary depending upon when that event occurs in the natural history of a mood disorder. Persons experiencing a recurrent major depressive disorder are less likely to report a stressful event associated with the onset of episodes after the first two episodes of depression. The phenomena of kindling may become the predominant impetus for recurrent depressive episode.

Chronic stress can place a subject at greater risk for major depressive disorder than specific stressful life events. The stress of service in the Persian Gulf War led to increased frequency of major depressive disorder among military personnel. As long as soldiers are deployed, they have difficulty recovering from the major

depressive episode. In addition, the long-term effects of being deployed also may increase the risk of depression following military service. Persons usually have more difficulty coping with a chronic stressful situation than with specific events.

Few studies document the association of daily hassles with the onset of major depressive disorder. Yet, impulsive acts such as a suicide attempt may be closely associated with daily hassles to which the subject cannot adapt within the context of a stressful life event or chronic stress. That is, daily hassles may be the straw that breaks the camel's back.

Social Support Factors in the social environment that may modify the effects of social stressors have received increased attention in the epidemiological investigation of both physical and psychiatric disorders. One factor is social support, the provision of meaningful, appropriate, and protective feedback from the social environment that enables a person to negotiate environmental stressors. In theory, social support is an attractive concept, for it is potentially more amenable to intervention than environmental stressors. The roots of the construct social support go back at least to the early twentieth century, when Emile Durkheim proposed that persons who are not integrated into society (the condition called “anomie”) are at greater risk for suicide. Social support has four components: the social network, social interaction, perceived social support, and instrumental support. The social network is assessed by identifying those individuals or groups of individuals (e.g., a spouse and children) who are available to the subject. The absence of a spouse is a risk factor for major depressive disorder.

Social interaction is assessed by determining the frequency of interactions between the subject and other network members. A number of studies confirm that social isolation (i.e., a deficit in social interaction) places a subject at greater risk for depression. Yet the quality of the interaction appears to be more important than the frequency of interaction. Perceived social support is assessed by determining the subjective evaluation by the individual of the dependability of the social network, the ease of interaction with the network, the sense of belonging to the network, and the sense of intimacy with network members. The association of major depressive disorder and expressed absence of a confidant exemplifies the relation between perceived inadequate support and depression.

Instrumental support is assessed by determining the concrete and observable services that are provided to the subject by the social network (for example, cooking meals, financial assistance, and nursing services for the physically ill). Although such support is essential to the well-being of the young and the elderly in society, few studies document the association of depression with a deprivation of instrumental support. The physical health of the person is a confounding factor. The need for instrumental support is usually not recognized until the person exhibits an actual need for such services. In addition, the perception of the availability of those services in a time of crisis may not reflect the actual availability.

The construct of social support is strongly influenced by the construct of social integration. An integrated society is a social system that ensures the patterns of interpersonal behavior that are essential to the survival and welfare of its members. Those patterns enable persons to obtain what is needed for subsistence and protection against weather and disease, control hostility and other forms of social disruption, create new members and their education and communication, store information, and permit decision making and united action. Alexander Leighton and his colleagues undertook the most ambitious epidemiological studies of social integration and mental health in a survey of communities in Nova Scotia. Social scientists and anthropologists studied each community to determine its relative integration versus disintegration. At all ages, the rates of depressive disorders (and other psychiatric disorders) were higher in disintegrated communities. Studies of social integration are not as proximal to the individual as studies of social stressors and social support because measures of social integration are not specific to the individual. Studies of integration are ecological, for they document that the overall functioning of the community is associated with the overall level of psychopathology.

Most ecological studies in psychiatric epidemiology have been limited to comparisons of communities by traditional parameters, most commonly, urban versus rural residence. The hypothesis is that rural communities are less stressful than urban communities. In the ECA study of North Carolina, major depressive disorder was twice as common in the urban community, with the largest differences among the young (under 45 years of age) and among women. Those urban-rural differences in prevalence persisted even when the comparison was controlled for race, socioeconomic status, marital status, and age. Nevertheless, most ecological studies fail to demonstrate that after adjusting for other factors, communities determined to be socially integrated protect against mood disorders. The reason, probably, is that investigators are usually studying diverse communities and thus the concept of social integration is probably not relevant in complex societies in which communities are layered upon one another or are patterned together in a mosaic that cannot be easily disaggregated.

Another risk factor for depression is unemployment. At present, most men and women under the age of 65 are in the labor force. Men and women who were unemployed for at least 6 months during the 5 years prior to the ECA survey were more than three times as likely as others to report symptoms of an episode of major depressive disorder during the year prior to the survey. In the NCS study, the rate of major depression was three times higher in persons not working than in those working. Homemakers were nearly three times more likely to experience major depression than the employed as well.

The multiple risk factors for mood disorders form a web of causation. Each factor cannot only affect the subject directly but can interact with other factors. Mathematical models of causative factors are therefore useful for determining the relative importance and complex interaction of those factors. Models include linear and logistic regression analyses.

An example is presented in Table 14.2-3. In this logistic regression analysis, sex, education, income, marital status, employment, and household composition are the control (or adjusted) variables. The net effect of risk factors in the NCS is presented as an odds ratio, an approximation of the relative risk of persons with the characteristic developing a major depressive episode compared with that of persons without the characteristic. For example, the risk for females is 1.36 times greater than that for males.

Characteristic	Odds Ratio	95% Confidence Level
Sex	1.00	–
Male		
Female	1.36*	1.01–1.84
Education (years)		
0–11	1.93*	1.14–3.25
12	1.93*	1.14–3.25
13–15	1.93*	1.14–3.25
16 or more	1.00	–
Marital status		
Married	0.42*	0.28–0.61
Separated/widowed/divorced	1.00	–
Never married	0.58*	0.38–0.88
Employment		
Working	1.00	–
Student	1.00	–
Homemaker	2.40*	1.54–3.75
Other	2.54*	1.51–4.28

Table 14.2-3 Adjusted Odds Ratios for Prevalence of Current (30-day) Major Depressive Episode, by Selected Demographic Characteristics

PROGNOSIS

Two recent studies have concentrated on the public health impact of depressive disorders, because of their chronic and disabling nature. In the first, over 1000 patients in a variety of primary care settings were screened for depression. Patients with either depressive disorder or depressive symptoms (without a diagnosis of a specific mood disorder) tended to have worse physical, social, and role functioning. When their objective health status was controlled, they perceived their current health to be worse than did patients who were not depressed, and they reported more physical pain. The poor functioning associated with depressive symptoms, with or without a diagnosis of a mood disorder, was comparable to or worse than that in eight major chronic medical conditions. The number of days in bed with depressive symptoms was significantly greater than with hypertension, diabetes, or arthritis.

In the second study, the ECA sample in North Carolina, persons with a diagnosis of major depressive disorder or dysthymic disorder and with symptoms of minor depressive disorder were followed for 1 year. Compared with asymptomatic individuals, persons with major depressive disorder had a fivefold greater risk of disability, and persons with minor depressive disorder had one-and-one-half times the risk. Persons with minor depressive disorder were at greater risk of developing major depressive disorder at 1-year follow-up.

A number of *natural history* studies of mood disorders have been performed on clinical samples. The most extensively studied cohort derives from the Psychobiology

of Depression Study and consists of over 500 young adult and middle-aged subjects diagnosed with either bipolar I disorder or major depressive disorder. Following diagnosis about 50 percent of subjects recovered during the first year, but fewer than 30 percent of the others recovered during subsequent years. Comorbid dysthymic disorder with a slow onset accompanying psychotic symptoms was associated with less likelihood for recovery. Relapse rates are high for major depressive disorder immediately following recovery. Superimposed dysthymic disorder and a history of three or more major depressive episodes were associated with relapse. Bipolar I disorder patients with only manic episodes had better outcomes than those with major depressive disorder. However, bipolar I patients with a mixed episode (depression and mania) or with rapid cycling had worse outcomes than those with major depressive disorder.

USE OF HEALTH SERVICES

Health services for mood disorders are provided in general health care settings and in specialty settings. Most mental health visits reported by subjects in the ECA study, regardless of disorder, occurred in primary care settings for older persons and in specialty settings for younger persons. Women use mental health services in both settings about twice as often as men. Visits are about equally distributed between general medical providers and mental health specialists. Persons who were depressed used health services more frequently than those with no psychiatric disorder.

SUGGESTED CROSS-REFERENCES

An overview of epidemiology is given in Section 5.1. Social origins of mood disorders are discussed in Section 4.2. Classification of mental disorders is presented in Chapter 9. Specific review of the genetics of mood disorders can be found in Section 14.3. The role of stress in the etiology of psychiatric disorders is discussed in Section 25.9. Suicide is discussed in detail in Section 29.1. The epidemiology of psychiatric disorders in late life is reviewed in Section 51.1b.

14.3 MOOD DISORDERS: GENETICS

JOHN R. KELSOE, M.D.

The familial nature of mood disorders has been a widely observed phenomenon since antiquity. However, only in the last century have systematic studies been conducted that document the degree and nature of this familiality as well as its genetic determinants. In the past two decades molecular genetic technology has brought a new era in the understanding of a wide range of genetic traits and disorders. The application of this technology promises a new, more fundamental understanding of biological etiology of mood disorders and may also produce revolutions in both diagnosis and treatment. Yet mood disorders and other psychiatric disorders are difficult problems for genetic analysis, and early attempts at such analysis using both epidemiological and molecular tools have yielded sometimes contradictory and confusing results. However, as the volume of data increases and more sophisticated analytical methods are used these large problems should become more tractable so the benefits of this approach can be realized.

GENETIC EPIDEMIOLOGY

By determining the rates of illness in different types of relatives, genetic epidemiological studies can provide much information about the familial and genetic nature of a disorder. The questions that can be addressed include: Are mood disorders familial? Are they genetic? What portion of the etiology is genetic? How are the genes for mood disorder transmitted? How do different forms of mood disorder differ in their genetic transmission? How are different forms of mood disorder related to each other?

Numerous such studies conducted over the last century provide much information about the genetic transmission of mood disorders. However, these studies have various methodological limitations. Foremost among these is the range of diagnostic methods used. Many of these studies were conducted before the distinction between depressive (unipolar) and bipolar disorders, and hence results of these studies pool both illnesses. Similarly, many of these studies preceded the introduction of operationalized diagnostic criteria. Therefore, it may not be clear exactly how the diagnoses were made, making it difficult to compare or pool results across studies. Of the studies that distinguish unipolar and bipolar disorder, bipolar disorder has received more attention because of its greater degree of familiality.

Another methodological issue important to such studies is ascertainment bias. If the results of a study are to be meaningfully generalized to the population, the subjects must be selected in a systematic and nonbiased fashion. For example, if *probands* (the first ill subject identified in a family) are selected on the basis of their strong family history, then the results of a family study may inaccurately indicate a strong familial rate of illness in the population. A similar error will be made if ill family members are preferentially selected for study. Systematic ascertainment methods attempt to avoid such bias by studying all patients who present within a certain environment, such as a mood disorders clinic.

Many of these studies are also limited by use of the family history method. In this approach, the rates of illness in family members of probands are determined by systematically questioning probands about their families. Though several excellent standardized instruments for the family history method exist, this method is inherently less accurate than using direct interviews of each family member to make a diagnosis.

Family Studies Family studies address the question of whether a disorder is familial. More specifically, is the rate of illness in the family members of someone with the disorder greater than that of the general population? Typically, all subjects with the disorder in a given environment or population are identified and questioned about illness in their first-degree relatives. The rates of illness are then compared with either the rates in the general population or the rates in first-degree relatives of control subjects. Rates of illness are typically adjusted for age to indicate the morbid risk (i.e., the risk that an individual will develop an illness at some point of his or her life).

Table 14.3-1 illustrates several such studies of bipolar disorders. They indicate a morbid risk of bipolar disorder in first-degree relatives of bipolar disorder probands that ranges between 3 and 8 percent. Compared with a 1 percent rate in the general population, this reflects a substantial familial increase. Similarly, studies of families of probands with depressive disorder (unipolar) reveal morbid risks for depressive disorders among first-degree relatives which are two to three times those of the general population. These data argue strongly for the familial nature of mood disorders. Furthermore, depressive disorders generally occur at a higher rate in the families of probands with bipolar disorders, and the rate of bipolar disorder is elevated in the families of probands with depressive disorders. In fact, depressive disorders are typically the most common mood disorder in families of probands with bipolar disorders. This familial overlap suggests some common genetic underpinnings between these two forms of mood disorder.

Study	Relatives at Risk (N)	Morbid Risk (%)	
		Bipolar	Depressive (Unipolar)
Dunner et al, 1980	1199	4.2	8.2
Gershon et al, 1982	598	8.0	14.9
Rice et al, 1987	557	5.7	23.0*
Sadovnick et al, 1994	1102	3.5	5.7

* Observed rates rather than morbid risk.

Table 14.3-1 Selected Family Studies of Bipolar Disorders

Twin Studies The family study data clearly indicate that mood disorders are familial. However, such studies cannot distinguish whether genetic or environmental factors mediate the familial transmission. Families might share a variety of different environmental factors that could transmit the illness. Such factors might be behavioral but could also be shared exposure to infectious agents, toxins, or other brain insults. Twin studies provide the most powerful approach to separating genetic from environmental factors, or “nature” from “nurture.” Many strategies for twin studies have been used, but most commonly both monozygotic (MZ) and same-sex dizygotic (DZ) twin pairs are identified in which one twin has a mood disorder. The other twins are then examined to determine the proportion of twin pairs in which both twins are affected, termed the *concordance rate.* Typically, twin pairs are selected who have been raised together, so that environmental factors are shared equally. A difference in concordance rate between the MZ and DZ pairs, therefore, reflects the role of heritable genetic factors. An alternative powerful strategy is to study twin pairs raised apart; however, such samples are much more difficult to obtain.

Table 14.3-2 summarizes several twin studies of mood disorders. Considering depressive and bipolar disorders together, these studies find that the concordance rate for mood disorder in the MZ twins is two to four times that in the DZ twins. These are the most compelling data for the role of genetic factors in mood disorders.

Further, the concordance rate for MZ twins is not 100 percent. Thus nonheritable environmental factors also play a significant role in mood disorders. In studies that distinguish bipolar from unipolar disorders, the MZ to DZ concordance ratio for bipolar-bipolar pairs is higher than that for unipolar-unipolar pairs, which indicates greater genetic involvement in bipolar disorders than in unipolar depressive disorders. Furthermore, the rate of depressive disorders is elevated in monozygotic cotwins of probands with bipolar disorders, and to a lesser extent, the rate of bipolar disorders is elevated in the cotwins of probands with depressive disorders. This is consistent with the family data, and it argues for a genetic overlap between bipolar and depressive disorders.

	Monozygotic Twins		Dizygotic Twins	
Study	Twin Pairs (N)	Concordance (%)	Twin Pairs (N)	Concordance (%)
Rosanoff et al, 1935	23	69.6	67	16.4
Kallman, 1954	27	92.6	55	23.6
Bertelsen, 1979	55	58.3	52	17.3
Kendler et al, 1993	154	69.7	326	34.9

Table 14.3-2 Selected Twin Studies of Mood Disorders

Adoption Studies Adoption studies provide an alternative approach to separating genetic and environmental factors in familial transmission. A variety of limitations of twin studies have been raised, including the argument that parents treat monozygotic twins and DZ twins differently, so environment is not equally shared. Adoption studies have been conducted using a variety of experimental designs, but the most common is the adoptee-as-proband strategy. In this approach, probands are identified who have a mood disorder and who were adopted away at birth, thus separating nature and nurture. The rates of psychiatric illness are then determined in both the biological and adoptive parents.

Only a limited number of such studies have been reported, and their results have been mixed. Julien Mendlewicz and John Ranier found a threefold increase in the rate of bipolar disorders in the biological relatives of probands with bipolar disorders. They also observed a twofold increase in the rate of depressive disorders in biological relatives. Similarly, in a Danish sample, Paul Wender and coworkers reported a threefold increase in the rate of unipolar disorder and a sixfold increase in the rate of completed suicide in the biological relatives of mood disorder probands. Other studies, however, have been less convincing. Using affectively ill mothers as probands, Remi Cadoret found a nonsignificant trend toward increased unipolar depressive disorders in the adopted children. In a Swedish sample, Anne-Liis Von Knorring and coworkers found no increase in mood disorders in the biological parents of adoptees with mood disorders. Overall, these results support the role of genetics and are consistent with the twin data. The difficulty of obtaining subjects and the resulting small sample sizes may help explain why these data are weaker than the twin data.

MODE OF TRANSMISSION

If mood disorders are in large part caused by genetic factors, then what is the nature of its genetic transmission? Segregation analysis of the family study data has been used to attempt to answer this question. Are mood disorders the result of one or a few genes transmitted in a mendelian fashion? Or do many genes interact within each individual to predispose to illness? Different modes of transmission result in different patterns of inheritance of illness. By examining these patterns in families, one may attempt to distinguish the different possible modes of transmission. For example, in a simple dominant genetic disorder, one expects to observe that half of the children of an affected parent are also affected. In a recessive disorder, only one-quarter of the children of two nonaffected carriers should be affected. More-complex modes of inheritance involving multiple genes result in other patterns of illness that can be sought in the family data. Typically, in segregation analysis, the predicted patterns of several different models of transmission are tested to see which best fits the observed family data.

The results of such analyses have been mixed. Several such analyses have been inconclusive and excluded all tested models of transmission. Other, more recent analyses using large samples and more-sophisticated genetic models have supported the presence of an autosomal dominant major locus. Most such studies have focused on bipolar disorders because of their greater heritability. However, a recent segregation analysis of early-onset, recurrent depressive disorder has supported the presence of major gene effects with autosomal recessive or codominant modes of transmission. Other studies have supported a multifactorial-threshold model for mood disorders. In these models, the additive effects of multiple genes produce a unitary predisposition common to all mood disorders. Different mood disorders result at different thresholds in this single underlying genetic liability. X-linkage has also been argued based on the observation that female relatives of probands with bipolar disorders have a twofold higher risk for disorders than males. This is also supported by evidence for decreased male to male transmission of bipolar disorders. Drawing any definitive conclusions from such complex and inconsistent data is difficult. The complexity likely results from the presence of multiple genes with multiple modes of transmission. In the face of such heterogeneity, the sample sizes and statistical methods used may have limited power to demonstrate a given mode of transmission consistently. The data do suggest that of the many genes probably operating in mood disorders, some have a major effect on predisposition, and in bipolar disorders these major genes are likely to have autosomal dominant or perhaps X-linked inheritance. Consistent with such heterogeneity, recent analyses have argued for more-complex modes of transmission in which multiple genes interact to predispose to illness.

Several other intriguing results emerge from the family study data. Subjects with mood disorders are more likely to marry spouses who also have mood disorders than is expected by chance. This is termed *assortative mating*, and it leads to a higher rate of families in which the illness can be traced to both the mother's and the father's side of the family than would be expected by chance. Such bilineal families may play an important role in the interaction of multiple genes in the population. Family studies have also indicated that the rate of mood disorders is increasing over time in the population, termed the *cohort effect* (Fig. 14.3-1). Among family members of probands with bipolar disorders, those born more recently have a higher risk for bipolar disorders and an earlier age of onset. The cause of the cohort effect is unknown. It has been speculated to be a result of changing environmental stresses in our society, an artifact of recollection, or possibly an indication of a genetic effect termed *anticipation.*

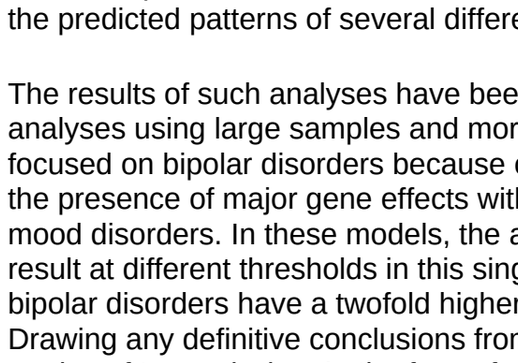

FIGURE 14.3-1 Age-related penetrance curves for bipolar disorder. The risk for bipolar disorder among relatives of bipolar disorder probands is depicted as a function of age. The probability of having bipolar disorder, or penetrance, increases with age. The cohort effect is illustrated by the different age-dependent risk curves for relatives within three different age groups. Relatives born more recently have a higher rate of bipolar disorder and an earlier age of onset. (Reprinted with permission from Rice J, Reich T, Andreasen NC, Endicott J, van Eerdewegh M, Fishman R, Hirshfeld RM, Klerman GL: The familial transmission of bipolar illness. Arch Gen Psychiatry *44:*441, 1987.)

GENETIC RELATIONSHIPS WITHIN THE SPECTRUM OF MOOD DISORDERS

The genetic relation between the various forms of mood disorder has received much study and debate. Bipolar and depressive disorders are widely considered to have some sort of common genetic underpinning, though its exact nature is unclear. The twin and family data reviewed above argue for more depressive disorders occurring in the twins or other relatives of probands with bipolar disorders than is expected by chance. However, it is less clear that bipolar disorders occur in the relatives of probands with depressive disorders at an elevated rate. Twin studies indicate that polarity is usually consistent in MZ twins (i.e., bipolar-bipolar or unipolar-unipolar pairs are much more common than bipolar-unipolar pairs. Yet bipolar-unipolar pairs do occur. These data suggest that bipolar and unipolar disorders are genetically neither completely identical nor completely distinct. Rather, there is a partial genetic similarity. A possible model for the relationship between these genes and disorders is illustrated in Figure 14.3-2. In this model, some or all of the genes for bipolar disorders may also result in depressive disorders. In addition, a larger pool of genes predisposes only to depressive disorders. Therefore, the rate of unipolar disorder would be clearly elevated in families with bipolar disorder. However, because only a minority of cases of unipolar disorder result from bipolar genes, only a small increase in the rate of bipolar disorders would be seen in the relatives of probands with depressive disorders. Such overlapping relationships between genes and disorders may also occur for other forms of mood disorders. A more definitive understanding of these relationships will likely require identification of the specific genes involved.

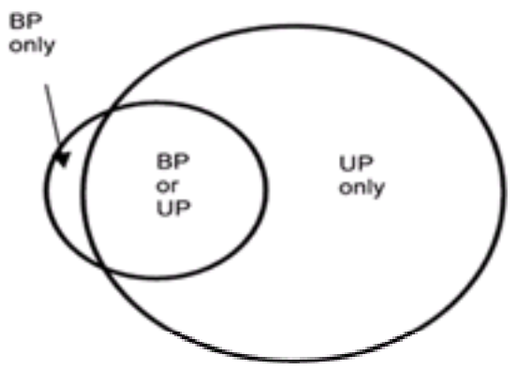

FIGURE 14.3-2 This model of the relation between genes for bipolar and depressive disorders posits that most genes for bipolar disorders can predispose to either bipolar or depressive disorders. A larger set of genes predisposes only to unipolar disorder. Hence, a subset of those with depressive disorders carries genes that may also predispose to bipolar disorders.

This model predicts that a portion of those with unipolar disorder carry genes that may also predispose to bipolar disorder. Such patients have been said to have “bipolar III” disorder by some writers and have been the subject of much discussion and investigation. They are presumably identified by a family history of bipolar disorder or a history of developing hypomania or mania only in response to antidepressant treatment. Similarly, Hagop Akiskal and coworkers have described a hypomanic-like personality style termed *hyperthymic temperament.* Depressive disorder patients with hyperthymic temperament likely carry some bipolar disorder genes. Such hyperthymic-depressive patients are more likely to have a family history of bipolar disorder and to develop mania spontaneously. These depressive disorder patients with a bipolar disorder genetic diathesis may also be more likely to respond to lithium augmentation of antidepressant treatment.

Other forms of mood disorders have also been postulated to be at least somewhat genetically distinct. Several studies have reported that though the risk for bipolar I disorder is similar in the relatives of probands with bipolar I or bipolar II disorder, the risk for bipolar II disorder is greater than that for bipolar I disorder in the relatives of probands with bipolar II disorder. This suggests that bipolar II disorder to some extent breeds true and that a subset of the genes for bipolar disorders predispose preferentially to bipolar II disorder. However, studies of patients with rapid-cycling bipolar disorder find that rapid cycling in the proband does not affect the risk for mood disorders or rapid cycling in relatives. This argues that rapid cycling is not a distinct genetic subform of bipolar disorder.

The genetic relation of schizoaffective disorder to mood disorders is a complex question that involves the role of psychosis in the genetics of mood disorders. The genetic nature of schizoaffective disorder also bears on the genetic relation between schizophrenia and mood disorders. Studies examining familial risks in relatives of schizoaffective disorder patients have led to inconsistent results, some finding an increased risk of schizophrenia and some an increased risk of bipolar disorder. A possible explanation is that patients with schizoaffective disorder represent a mixture, some with bipolar and some with schizophrenia diatheses. This notion is supported by data that show an increased rate of bipolar disorders among relatives of probands with the bipolar type of schizoaffective disorder. The rate of schizophrenia has also been reported to be increased among the relatives of probands with the depressive type of schizoaffective disorder. Alternatively, it has been proposed that the Kraepelinian distinction between the disorders is not valid and that schizophrenia and mood disorders lie at the extremes of a spectrum of a common genetic liability. Recent linkage studies (reviewed below) may be beginning to support the existence of some genetic loci common to both schizophrenia and bipolar disorders.

INTERPRETATIONS OF THE GENETIC FEATURES OF MOOD DISORDERS

The above data argue that mood disorders are not simple genetic traits. No one gene consistently causes illness in all cases in a simple and predictable fashion. In genetic terms, there is not a 1 to 1 relation between the expressed trait (phenotype) and genes (genotype) transmitted in a simple mendelian fashion. Therefore, mood disorders are said to be complex genetic disorders rather than simple mendelian traits. What factors contribute to this complexity?

The twin data argue compellingly that genes account for only 50 to 70 percent of the etiology of mood disorders. Environment or other nonheritable factors must explain the remainder. Thus, a predisposition or susceptibility to disease is inherited. The probability that someone will manifest a trait, given that they have a certain genotype, is termed the *penetrance* of the gene. Mood disorders are said to have “reduced penetrance” (less than 100 percent). Furthermore, the penetrance of the mood disorder genes increases from a low risk for illness in childhood to a maximum in adulthood. The cohort effect (Fig. 14.3-1) further complicates the relation of penetrance to age, causing penetrance to vary with the date of birth. Therefore, families of people with mood disorders likely include individuals who have the genes for mood disorder but do not develop the disease. These are termed *nonpenetrant carriers.* The converse of this situation is individuals who have mood disorder but do not have the genes. Individuals with purely environmentally caused disease are termed *phenocopies.* These factors conspire to produce an indirect relationship between genes and disease.

Variable expressivity refers to the phenomenon of the same gene or group of genes resulting in a variety of different forms of illness. The twin data clearly demonstrate this for mood disorders. Monozygotic twins with identical genomes are observed with one twin exhibiting bipolar and the other unipolar disorder. Nonheritable factors must play a role in the specific manifestation of the predisposition to mood disorder. Such variability in expression is not unique to psychiatric disorders. In neurofibromatosis, for example, ill individuals range in manifestations and severity from those with only pigmented retinal lesions to others with multiple large tumors—a range in expression that results from the same disease gene.

Of the various factors complicating the genetic transmission of mood disorders, the most significant and the most challenging for gene mapping efforts is genetic heterogeneity. *Heterogeneity* refers to the likely occurrence of multiple genes in the etiology of illness. Only the identification of multiple disease genes can convincingly demonstrate genetic heterogeneity. However, the segregation analyses described above strongly suggest its presence. There are several critical questions about the nature of heterogeneity in mood disorders. How many genes are involved? How large an effect does each gene have? How do the genes interact to produce illness? These questions suggest a variety of models of heterogeneity, which can be broadly grouped into those in which disease results from a few genes with major effects (major loci) and those in which disease derives from the combined action of many genes with small effects (polygenic or oligogenic). The answers to these questions are not currently known for mood disorders. However, segregation analyses suggest a mixture of genes of both large and small effect, which are transmitted in a variety of ways.

Evidence for several other complex forms of genetic transmission has also been reported for mood disorders. Some studies of bipolar disorder have indicated that the illness is more likely to be transmitted through mothers than through fathers. Such *parent-of-origin effects* imply a genetic phenomenon called *imprinting.* In imprinting, a genetic locus is processed differently in male and female meioses so that different traits result from maternal and paternal transmission. For example Angelman and Prader-Willi syndromes are two different mental retardation syndromes that result from different maternal or paternal imprinting of the same locus on chromosome 15.

Rather than yielding different phenotypes, the bipolar data suggest that the penetrance of bipolar genes may be affected by imprinting.

Another nonmendelian genetic phenomenon reported in mood disorders is anticipation. In disorders displaying *anticipation*, the severity of the illness increases and the age of onset decreases with successive generations. Anticipation is generally associated with genetic mutations involving trinucleotide repeat expansions. In such disorders (e.g., Huntington's disease or fragile X mental retardation), the defective gene contains a region of deoxyribonucleic acid (DNA) in which a three-nucleotide sequence is repeated a variable number of times. For reasons currently not well understood, the number of repeats increases in successive generations until the gene's function is disrupted and illness results. Anticipation involving both increasing severity of illness and decreasing age of onset has been reported for bipolar disorder. Indirect evidence for the presence of trinucleotide repeat expansions has also been reported; however, no specific gene manifesting such a mutation has been described.

COMPLEX GENETIC DISORDERS

Simple Mendelian Traits Complex genetic disorders are simply those that are not transmitted in classical mendelian patterns. A review of mendelian transmission thus provides a useful background for understanding complex genetic traits. Simple mendelian traits display genetic homogeneity; one gene transmits the trait with complete penetrance. Figure 14.3-3 illustrates the three primary modes of mendelian transmission. In genetic terminology, different forms of a given gene are termed *alleles.* A disease gene may have either a normal, nonmutated allele or a mutated, disease-causing allele. In dominant genetic disorders, only one copy of the disease allele is necessary to cause illness. Dominant illnesses are typically transmitted vertically from grandparent to parent to child. In the simplest case, half of the children of an affected parent will have the disease. In recessive disorders, both copies of the disease gene must be defective for disease to result. Heterozygotes with only one disease allele are nonaffected carriers. Disease typically results from the mating of two nonaffected carriers. One-quarter of the resulting children will be homozygous for the disease allele and hence ill. Recessive illnesses typically appear in a horizontal pattern in families (i.e., in cousins). The nature of the mutation in the gene determines whether it is transmitted in a dominant or recessive fashion. Recessive mutations typically deactivate genes that are expressed in excess. Therefore, an adequate amount of gene product can be produced by only one functioning copy. In dominant disorders, the amount of gene product expressed may be critical. A reduction in gene dosage, resulting from only one functioning copy, leads to illness. Alternatively, a dominant mutation may result in overfunctioning of the gene, which results in illness. In X-linked disorders the disease gene is located on the X chromosome. These may be either dominant or recessive. X-linked dominant disorders are more common in women, while X-linked recessive disorders are more common in men. Father to son transmission is impossible in X-linked disorders, since the father transmits the Y sex chromosome to sons.

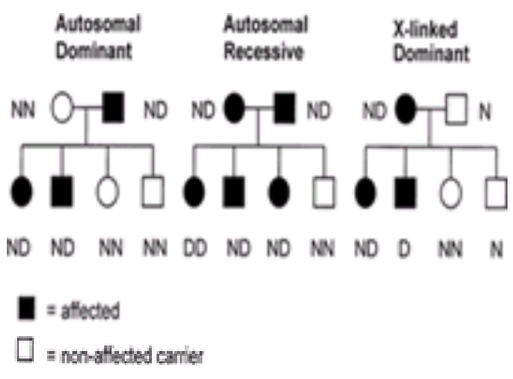

FIGURE 14.3-3 Mendelian transmission. Simple mendelian disorders are transmitted by three different modes. Dominant disorders require only one copy of the disease allele for a family member to be affected. In recessive disorders, both copies of the disease gene must be defective. In X-linked disorders, the disease gene is carried on the X chromosome.

Heterogeneity Models Of the various factors that distinguish complex disorders from mendelian ones, the most important is the presence of multiple genes, or genetic heterogeneity. Multiple genes may combine to produce illness in a variety of different ways, as illustrated in Figure 14.3-4. These heterogeneity models fall into two categories based on genetic effect size. In single major locus models, only one disease gene is necessary to produce illness in a given individual. In an interfamilial heterogeneity model, one gene transmits the predisposition to illness in each family. However, there are different predisposing genes in different families. In an intrafamilial heterogeneity model, any one of multiple genes within the same family can transmit the illness.

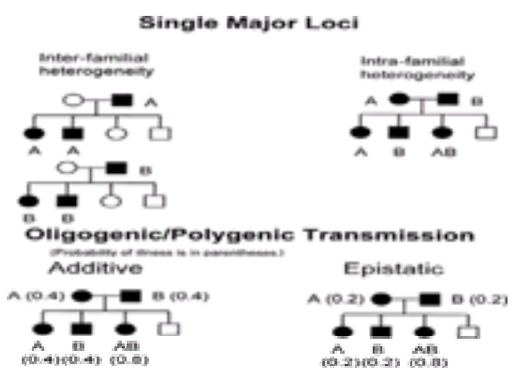

FIGURE 14.3-4 Several different models for the role of multiple genes in genetic disorders. In single major locus heterogeneity models, a single gene is primarily responsible for the predisposition to illness in an individual. However, different single major loci may act in different families or within the same family. In oligogenic models, multiple genes each of smaller effect typically interact to produce the susceptibility to illness. In an additive model, the effects of these genes simply add together. In epistatic models, the overall effect exceeds the sum of each gene acting separately.

In oligogenic or polygenic transmission models, multiple genes of smaller effect interact to predispose to illness. In these models, one gene by itself is unlikely to cause illness. Rather, the probability of illness increases with the number of different genes involved. The terms “oligogenic” and “polygenic” are distinguished simply by whether a smaller or larger number of genes, respectively, are involved. In an additive polygenic model, each gene contributes a certain probability (penetrance) of manifesting the disorder. The total genetic liability to illness is then the sum of the probabilities contributed by all the polygenes. In Figure 14.3-4, under the additive model, the disease alleles for genes A and B alone each convey a 40 percent probability of illness. Individuals who carry the disease alleles for both A and B have an 80 percent risk for illness. The total risk is simply the sum of the risks for each individual polygene. In the epistatic model, the disease alleles at genes A and B each convey a relatively small effect alone. However, individuals with the disease alleles for both A and B have a risk for illness that exceeds the sum of risks for A and B. In the example in Figure 14.3-4, A and B each convey a 20 percent risk alone. The affected daughter with the AB genotype, however, has an 80 percent risk for illness. Epistatic interactions have been observed in many organisms and frequently reflect a “two-hit” effect on a biological system. For example, a neurotransmitter system may be able to tolerate a defect in gene A by increasing the activity of gene B. Similarly gene B may be able to compensate for a defect in A, so that individuals with defects in A or B alone may have only a limited risk for illness. However, if both A and B are defective, the system cannot compensate, and the risk for illness escalates.

Quantitative Traits One of the many difficulties in psychiatric genetics studies is the definition of “affected.” Variable expressivity results in a variety of disorders from similar genotypes, and is frequently not clear which of these disorders should be considered “affected” for the purposes of genetic analyses. An alternative to such dichotomous definitions of phenotype is the use of quantitative phenotypes. Many biological variables are obvious quantitative phenotypes (e.g., blood pressure or height). However, it is not immediately obvious which mood disorder is “worse” or “more” than another. Nevertheless, quantitative phenotypes have been applied with some success to mood disorders. An example is the multiple-threshold model. Though quantitative phenotypes can result from single major loci, the concept has evolved historically in connection with polygenic traits. In such models, each polygene contributes in either an additive or epistatic fashion to the value of the

quantitative phenotype. Quantitative models offer a useful alternative to the dichotomous approach to phenotype. However, the basic problem is that mood disorder phenotypes are more complex than either the dichotomous or quantitative genetic models.

POSITIONAL CLONING OF COMPLEX DISORDERS

Positional cloning refers to the use of molecular genetic methods to identify disease genes based on their chromosomal location. Such studies, directed at the identification of specific disease genes, are the focus of most recent research on the genetics of mood disorders. The methods and strategies of positional cloning are reviewed in more detail elsewhere in this text, but a brief description here prefaces a review of the problems faced in such studies of mood disorders and some of their potential solutions.

DNA markers are segments of DNA of known chromosomal location that are highly variable among individuals. They are used to track the segregation of specific chromosomal regions within families affected with a disorder. When a marker is identified whose alleles consistently cosegregate with disease in families, it is said to be *genetically linked*, which implies that a gene for the disorder is physically near the marker on a chromosome. The Human Genome Project has provided thousands of such markers and precisely mapped them to chromosomal locations. By using several hundred markers, one can systematically survey the genome in search of markers linked to a disease. In this fashion, novel disease genes can be identified on the basis of their chromosomal location rather than their physiological function. This ability to identify novel genes without relying on knowledge of their function or the pathophysiology of the disorder makes positional cloning a powerful approach. This approach has led to the successful identification of genes for numerous diseases such as Huntington's disease and cystic fibrosis.

The statistics of linkage analysis are either parametric or nonparametric. *Parametric analyses* assume a certain model of inheritance (e.g., dominant or recessive) and then test the marker data for the probability of fitting that assumed model. The statistic typically generated is the LOD score. The *LOD score* is the logarithm of the odds for linkage divided by the odds against linkage. A LOD score of 3 represents odds of 10^3 or 1000 to 1 in favor of linkage. The appropriate threshold for statistical significance of LOD scores varies with the nature of the analysis and is currently under some debate, but is in the range of 3.0 to 3.6. Nonparametric analyses do not require an assumption of model of inheritance. Instead, affected family members are tested for significantly increased sharing of marker alleles. The affected sib pair method and the affected pedigree member method exemplify this approach. Parametric methods generally have greater power to detect linkage if the correct model is used. Nonparametric methods have less power but are not vulnerable to error resulting from the use of an incorrect model of inheritance.

When a chromosomal region is identified by genetic linkage studies in families, the disease gene has typically been localized to a region of between 5 and 30 million base pairs of DNA, which might contain several hundred genes. Genetic association studies are then sometimes used to locate the disease gene more precisely within this region. In these studies, markers are tested for significant differences in the frequencies of their alleles between unrelated groups of affected subjects and control subjects. Such differences may be observed if the DNA-sequence variation at the marker is the disease causing mutation itself. Alternatively, the marker allele may have no functional impact, but be so physically close to the disease causing mutation that they have been propagated together through the population. The marker allele and disease mutation are then said to be in *linkage disequilibrium.* In addition to fine mapping, association is also commonly used to test the role of a candidate gene whose known function suggests its possible involvement in the disorder. Physical mapping methods are also used to identify the exact disease gene. These methods involve cloning large regions of DNA and screening them for the presence of genes and possible disease-causing mutations in those genes.

Difficulties of Mapping Complex Disorders Simple mendelian traits show a 1 to 1 correspondence between genotype and phenotype. Everyone in a family who has the disorder has the gene, and everyone who has the gene has the disorder. This allows extraction of maximal information regarding the possible cosegregation of marker and disorder in linkage studies. However, both reduced penetrance and phenocopies loosen the connection between genotype and phenotype and thus reduce the statistical power of linkage methods to identify genes. In complex disorders, it is neither clear that nonaffected individuals did not receive the disease allele nor that affected ones did. Thus one needs to study larger samples of families.

Variable expressivity and difficulty in diagnosis introduce further uncertainty in modeling genetic transmission. It is not clear which of the spectrum of mood disorders should be considered “affected.” If the definition of affected is too narrow, then valuable information from family members with more subtle forms of illness may be lost. However, if the definition of affected is too broad, then error may be introduced by inclusion of too many phenocopies. Most linkage studies currently use a hierarchy of different definitions of illness, ranging from narrow to broad. For example, a narrow model might include as affected only those with bipolar disorder. A broad model would include bipolar disorder and recurrent major depression. The difficulty in making behavioral diagnoses adds further complexities. Psychiatric diagnoses rely on the accuracy of the subject's memories and judgments about behavior that depend on the individual's life and environment.

Other difficulties arise out of the limitations of statistical methods. The most powerful statistical methods currently available are based on mendelian models of transmission. However, it seems clear that mood disorders are not transmitted according to these simple models. Currently most linkage studies are conducted using a variety of genetic models (e.g., dominant and recessive). However, only limited information is available about the robustness of applying these methods to nonmendelian and heterogeneous forms of transmission. Furthermore, recent simulation studies have indicated that even when linkage is established, a much larger chromosomal region is implicated in complex disorders than in mendelian ones. This makes the job of fine mapping and gene identification substantially larger.

The greatest problem facing positional cloning studies is clearly heterogeneity. If mood disorders result from a relatively small number of genes with large effect, then they will be identified soon. However, if a large number of genes with small effect are involved, identifying them will require large sample sizes or a different approach altogether. Current data suggest that the number of genes probably lies somewhere between these extremes. The cost of heterogeneity in terms of sample size is illustrated in Figure 14.3-5. This simulation study, using affected sib pairs, indicates that if a gene is present in less than 25 percent of families under study, the total number of families required to detect linkage increases significantly.

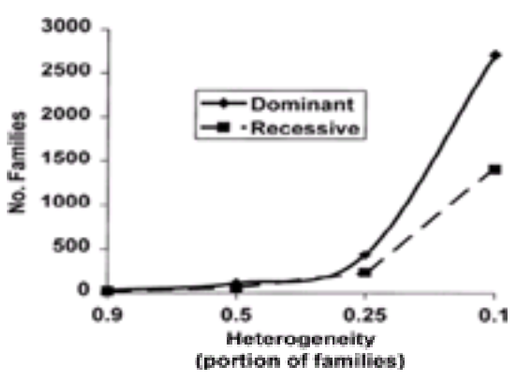

FIGURE 14.3-5 Sample sizes required to detect linkage for different degrees of heterogeneity. The number of families with affected sib pairs required to detect linkage is depicted as a function of the degree of genetic heterogeneity. This power analysis for genetic linkage studies was performed by computer simulation of both an autosomal dominant and a recessive disorder with 50 percent penetrance. If a gene for a disorder occurs in less than 25 percent of families, the number of families required to detect it in a linkage study goes up substantially. (Reprinted with permission from Martinez MM, Goldin LR: The detection of linkage and heterogeneity in nuclear families for complex disorders: One versus two marker loci. Am J Hum Genet *44:*552, 1986.)

Solutions for Mapping Complex Disorders Despite these problems, recently developed tools and strategies for linkage studies of complex traits promise to make the challenges of mood disorders more tractable. Many of these new developments involve using more-sophisticated statistical methods. Parametric methods have recently been developed that can model the interaction of two genes simultaneously. In this way, the power of parametric analytical methods can be applied to more-complex modes of inheritance. However, as more genes are included, the number of possible models for their interaction increases. This may make the choice of the correct model both more difficult and more important.

For these reasons, nonparametric methods have recently received increasing attention. Since they do not depend on assumptions about the mode of transmission, they are less vulnerable to error resulting from use of the wrong model. However, they have lower statistical power to detect genes than do parametric methods using the correct model. Much effort has been focused on developing new nonparametric methods with greater statistical power. There is no current agreement on which

approach is superior. As a result, many investigators use both approaches.

Various approaches to refining the phenotype may improve the odds of success in linkage studies. Studying subforms of illness, whose genetic distinctness is supported by epidemiological data, may allow investigators to reduce the number of genes under study. For example, bipolar II disorder or lithium-responsive illness may represent distinct subsets of bipolar genes. Such subforms of illness may be easier to map. Intermediate phenotypes may also be useful in this regard. *Intermediate phenotypes* are biologic markers associated with illness that segregate in families. Sleep electroencephalographic (EEG) measures and sensitivity to various pharmacological challenges exemplify such possible markers. Intermediate phenotypes can be used to identify psychiatrically well family members who carry susceptibility genes. In this way, these biological markers display higher penetrance than the psychiatric disorder itself and, therefore, retrieve more genetic information from family members. Furthermore, they may also reflect biologically distinct subforms of illness.

The rapid progress of the Human Genome Project will provide new tools for genetic studies. The quality of markers and maps continues to improve. It is likely that within the next several years, all human genes will be identified and mapped, which will be invaluable for the identification of disease genes. The next wave of the Human Genome Project will develop a dense set of markers that will ultimately enable genome-wide association studies. By studying tens of thousands of markers in thousands of ill and control subjects, genes of small effect may be identified. Until recently, such an approach was not considered feasible; however, now both the dense map of markers and the technology for high-throughput screening seem in sight. Methods are now being developed to array genes or DNA markers on microchips allowing the simultaneous detection of thousands of markers. Ultimately, one can expect that most sequence variation in all human genes will be known. This knowledge combined with large samples for association studies should enable detection of virtually all genes involved in mood disorders, even if current linkage strategies are not successful.

RESULTS OF GENETIC LINKAGE AND ASSOCIATION STUDIES

To date the search for genes for mood disorders has focused primarily on bipolar disorder because of the stronger evidence for its genetic basis. In its early years, this search exhibited a series of ups and downs of reported findings and subsequent nonreplications that was likened to the highs and lows of the illness itself. Such high-profile nonreplications led to frustration among investigators and concern that false-positive linkage results might be common. Many investigators argued for highly conservative thresholds for the statistical significance of linkage results to guard adequately against such events. However, subsequent experience has indicated that strongly positive results are relatively uncommon. Furthermore, simulation studies indicate that nonreplications should be expected, even for real loci, until enough data are accumulated to demonstrate linkage convincingly.

Recently a number of positive results have emerged that are quite encouraging in terms of the ability of linkage analysis to identify genes for bipolar disorder. As more of the genome has been surveyed in larger sets of families, several loci have yielded modest evidence for linkage, which is being independently replicated in multiple datasets. It seems likely that at least some of these loci reflect the locations of real susceptibility genes; therefore, it seems appropriate to expect some nonreplications. The road to linkage success may involve neither too-readily dismissing modestly positive results nor too readily accepting strongly positive results but rather seeking independent confirmation. Some of the more prominent of these possible bipolar loci are summarized in Table 14.3-3 and reviewed below. The most notable aspect of the summary in Table 14.3-3 is the number of loci that have support from multiple independent datasets. Only time, further data, and the identification of actual disease genes will determine which of these are real disease loci.

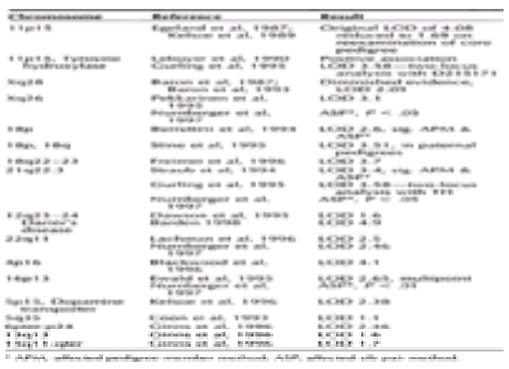

Table 14.3-3 Summary of Loci Potentially Linked to Bipolar Disorders

THE HIGHS AND LOWS OF PAST BIPOLAR LINKAGE STUDIES

Chromosomes 11 and X The first molecular genetic linkage study of mood disorder was conducted in the Old Order Amish population of southeastern Pennsylvania. Bipolar disorders are no more common or different in presentation in the Amish than in the general population. The Amish were chosen for study because they were genetically isolated. The current population of approximately 30,000 Amish are descended from about 50 couples who immigrated nearly 300 years ago from Germany and Switzerland. Since that time, for religious reasons, this group has remained isolated from the surrounding population. The primary advantage of studying such a group is the reduced genetic heterogeneity that results from a founder effect with subsequent genetic isolation. Other advantages of studying this group are its large families and the virtual absence of substance abuse. In 1987, Janice Egeland and coworkers reported evidence for linkage of bipolar disorders to markers at the insulin and Harvey *ras* loci on 11p15. Their data yielded an LOD score of nearly 5, or odds of 100,000 to 1 in favor of linkage. However, numerous other studies in different populations failed to replicate this result. Subsequently, reexamination of an updated and expanded version of the same Amish pedigree substantially reduced the evidence for linkage. Recently, however, association and linkage studies of the nearby tyrosine hydroxylase locus have supported the existence of a bipolar disorder locus in this region.

A similar scenario played out in studies of the X chromosome. Much epidemiological data has suggested a possible X-linked locus for bipolar disorder. In 1987, Meron Baron and coworkers examined two nonmolecular X chromosomes markers, color blindness and glucose-6-phosphate dehydrogenase (G6PD), for linkage to bipolar disorder in a set of Israeli families. They found very strong evidence for linkage to these markers on Xq28. However, as with the Amish study, numerous other studies failed to replicate this result in different samples. Subsequently, the evidence for linkage was substantially reduced when several more-informative molecular genetic markers were examined. More recently, however, several studies have implicated a nearby region, Xq26, in studies of American and Finnish families. Therefore, despite their checkered history, evidence remains for both the 11p15 and Xq26–28 regions, but more data will be required to confirm these possible linkages.

Chromosome 18 One of the most intriguing regions for possible bipolar susceptibility loci is on chromosome 18. Currently this region has the strongest data for linkage, because of the number of independent replications. Evidence for linkage to the pericentrometric region of chromosome 18 was first found by Wade Berrettini and coworkers in a series of 21 North American pedigrees. Subsequently, other studies replicated this finding and identified two more-distal regions on 18q. Some of these reports have found that the evidence for linkage was stronger in families with paternal or mixed transmission than in those with only maternal transmission. These data suggest a parent-of-origin effect at this locus. Other studies have argued that the evidence for linkage to chromosome 18 markers is strongest in families with comorbid panic disorder. Such data begin to suggest that different susceptibility loci may predispose to different forms of bipolar disorder with distinct clinical presentations. It is currently unclear whether these three different reported regions reflect three different susceptibility loci or if one or more reflect false-positive results. However, given the amount of independent data implicating this chromosome, it seems very likely that at least one locus for bipolar disorder resides on chromosome 18.

Other Promising Genetic Loci Several other chromosomal regions have been implicated by multiple studies and may harbor bipolar susceptibility loci. Linkage to the marker PFKL on chromosome 21q was first reported by Richard Straub and coworkers, with most of the evidence coming from one extended pedigree. Subsequently, linkage to this region was replicated in several other studies. A locus for bipolar disorder on chromosome 12 was implicated initially by the serendipitous observation of cosegregation of bipolar disorder and a dermatological disorder, Darier's disease, in a Welsh family. Subsequently, Darier's disease was mapped to chromosome 12. Based on this observation, a set of Welsh families with bipolar disorder and without Darier's disease were studied, and modest evidence for linkage to the same region of chromosome 12 was obtained. Recently, Nicholas Barden and coworkers implicated this same region in a study of a large family from a population isolate in Quebec.

A region on 22q is interesting because it has been implicated in both bipolar disorder and schizophrenia. This region was originally investigated in schizophrenia because of the observation of psychosis in adolescents with the 22q11 deletion syndrome, velocardiofacial syndrome. Several studies have reported evidence of linkage of markers in this region to schizophrenia; other investigators have examined adolescents with velocardiofaciol syndrome and observed rapid-cycling mood disorders. Based on these data, Herbert Lachman and coworkers studied this region in a set of bipolar disorder families and found evidence suggesting linkage. A subsequent study of an expanded version of this family set has further strengthened this result. The National Institute of Mental Health (NIMH) consortium also reported evidence for linkage of bipolar disorders to 22q. Similar to these results on chromosome 22, the same regions on chromosome 13 and 18 have also been implicated in studies of both bipolar disorders and schizophrenia. This raises the intriguing possibility that some genes may play a role in the susceptibility to both disorders. Confirmation of this idea awaits further replication and the definitive identification of disease genes. However, if confirmed, these results may indicate a greater degree of genetic commonality between these two disorders than had been thought.

The dopamine transporter has been implicated in bipolar disorders in a recent linkage study by John Kelsoe and coworkers. Its role as an important regulator of dopamine neurotransmission and the site of action of such stimulants as cocaine and amphetamine, make the dopamine transporter a compelling candidate gene. This gene has also been associated with attention-deficit/hyperactivity disorder in children, which occurs with greater frequency in families with bipolar disorder.

Several complete genome surveys were reported recently that have added substantially to the bipolar linkage data now available. Several additional loci were implicated by these studies including markers on 5q and 4p. A genome survey of the Old Order Amish recently provided data for possible loci on chromosomes 6, 13, and 15. The NIMH Consortium for Linkage Studies of Bipolar Disorder recently reported its initial findings in one of the largest such datasets examined to date, suggesting new loci on chromosomes 1, 6, 7, and 10. Perhaps more importantly, their data support previously reported loci on 16, 21, 22, and X. Such possible replications imply that some genes for mood disorders have relatively large effect and will be detectable by current linkage strategies.

GENETIC COUNSELING

Based on the observation of psychiatric illness in their own families or the increasing public awareness of psychiatric genetics, patients frequently ask clinicians three questions: Are mood disorders genetic? What is the risk to my children or grandchildren? Is there a blood test for the gene? The answer to the last question is the easiest, currently no blood test is available. However, such a test is likely to be available in the future, and it will raise a variety of serious practical and ethical issues. The answer to the first question is also easy: Yes, mood disorders are genetic, a position defended by the large body of epidemiological data summarized in this chapter. However, patients must understand that mood disorders are only partly genetic. The twin studies argue strongly that only 50 to 70 percent of the etiology of mood disorders is genetic. Therefore, a predisposition to illness is inherited that interacts with other, nonheritable factors.

The risk to children and grandchildren is a difficult question that deserves the greatest consideration. The family data indicate that if one parent has a mood disorder, a child's risk for mood disorder is between 10 and 25 percent. If both parents are affected, this risk roughly doubles. A careful family history is needed for more accurate prediction of risk for a specific family. Several factors from the family history should be considered. The more members of the family that are affected, the greater the risk to a child, particularly if the disorder is in both parents' families. The risk is greater if the affected family members are first-degree relatives rather than more distant relatives. A family history of bipolar disorder conveys a greater risk for mood disorders in general and a much greater risk for bipolar disorder specifically. The presence of more-severe illness in the family also probably conveys a greater risk. All these factors should be considered in forming an estimate of risk for the concerned parent.

Equally important to providing the estimate of risk is providing guidance in interpreting and responding to that information. Patients' reactions to risk information vary greatly depending on their own experience with the illness. Some will be relieved to find it so low, others fearful because it is so high. One must emphasize that their child carries a risk or predisposition to illness, not a certainty of illness. One can also describe the range of illness from mild to severe that could result and the availability and efficacy of treatment. Ultimately, the use of such information in family planning is a highly personal decision. Some patients may choose not to have children. For existing children, parents should be told about the typical age of onset, presenting symptoms, and the importance of early recognition and treatment. However, this must be balanced with the goal of not labeling the child or being overly protective.

FUTURE DIRECTIONS

The gradual accumulation of a large body of data led to the successful identification of possible disease loci described above. Therefore, in the near future, gene mapping studies will likely continue to use current strategies. As still more data are accumulated, more reported loci will likely be confirmed, while others will prove false. It currently seems promising that many genes for mood disorders can be identified through such large, though tractable, projects. The development and study of the large samples required will necessitate large collaborative efforts between multiple groups of investigators using common diagnostic and genetic methods. The recent NIMH consortium is a model for such future collaborations.

The variety of methodological advances and alternative approaches detailed above may further advance the project. Larger sets of family and genotypic data will enable application of new, more-sophisticated statistical methods. Larger datasets will also permit the possible subdividing of the disease into subforms based on clinical or biological measures. The rapid advance of the Human Genome Project will greatly facilitate this work by providing a much denser set of markers, a detailed physical map of the genome, and more efficient genotyping and sequencing methods. Ultimately, the identification and mapping of all human genes, the complete sequence of the human genome, and a catalog of human genetic variation will enable development of powerful novel approaches to complex disorders. Such tools and large samples will likely permit identification of most genes for mood disorders in the next several decades.

What will be the implications of this knowledge? The most immediate impact may well be on public opinion. Psychiatrically ill persons have long suffered from the stigma and discrimination that portions of the public impose out of fear and ignorance. Acceptance of major mental illnesses as brain disorders has been slow. The definitive identification of genetic causes may be highly beneficial to public understanding and acceptance.

This knowledge should also have a dramatic impact on our understanding of pathophysiology and approaches to treatment for mood disorders. Most current theories of pathophysiology are based on the mode of action of therapeutic agents, which were for the most part discovered serendipitously. The site of action of therapeutic drugs is not necessarily either the site of the genetic defect or the primary site of the pathophysiology. Identification of disease genes may point to entirely new systems involved in the pathophysiology or components of currently implicated systems that were previously unknown. It is hoped that such an understanding may lead to the rational drug design long sought by patients, clinicians, and pharmaceutical companies. The result may be new drugs that act by completely novel mechanisms, possibly with greater efficacy and specificity. Further down the genetic road lies the prospect of gene therapy for mood disorders. In this approach, DNA is used as a therapeutic agent, delivered to the relevant tissues by engineered viruses or other vectors. Such artificially delivered DNA can provide the correct version of a defective disease gene. Alternatively, a disease process might be ameliorated by changing the expression of other regulatory genes. Such an approach goes straight to the root of biology and pathology and offers the prospect of an extremely powerful and completely new treatment modality. Application to psychiatric disorders faces formidable problems and is likely to occur in the relatively distant future. However, trials of gene therapy for other, simpler disorders are going on today.

The identification of disease genes will probably have a major impact on diagnosis and nosology. Just as the diagnosis of jaundice has given way to a classification scheme based on pathophysiology, in the future, the diagnosis of major mood disorders may be specific to disease mechanism. Mechanism-specific diagnoses may dictate the use of different, more specific and effective treatments. The field of pharmacogenetics promises genetic tests able to predict the best pharmacological treatment for specific patients based on an understanding of genetic differences in drug response. But such knowledge will also carry danger and responsibility. Premorbid DNA testing could become available that would indicate the degree of genetic vulnerability to major mood disorders. Those with psychiatric disorders will then face the same issues of genetic testing currently faced by families with Huntington's disease or breast cancer. Will at-risk family members want such information? How will they use it? How will they cope with it? How can psychiatrists assist them in these decisions? How can patients be protected from discrimination based on such information?

In summary, genetic studies promise a new era of understanding and treatment of mood disorders. Identification of genes will not elucidate pathophysiology. It will merely point the way for the application of modern neuroscience methods in the equally large task of understanding mechanisms. Recent results suggest that such guidance may not be far away.

SUGGESTED CROSS-REFERENCES

A general review of basic molecular genetics is provided in Section 1.10. Principles of population genetics are discussed in Section 1.17. The concepts and methods of linkage analysis and their application to psychiatry are reviewed in Section 1.18. The epidemiology of mood disorders is discussed in Section 14.2.

14.4 MOOD DISORDERS: NEUROBIOLOGY

MICHAEL E. THASE, M.D.

The role of physical or biological factors in the pathogenesis of depression has been suspected since antiquity. However, it has only been in the latter half of the twentieth century that the technology and experimental methodology have been available to study these processes in mood disorder. During the past 40 years knowledge about the biology of the depressive disorders has grown by leaps and bounds as experimental methods have advanced from studies assaying peripheral specimens to investigations employing more direct measurements of cerebral metabolism, receptor function, and gene activity; regarding mania and bipolar disorders, however, there is comparatively less data.

CLINICAL PHENOMENOLOGY AND THE BRAIN

The signs, symptoms, and subjective experiences of depressed people have long suggested dysfunction of core neurobiological processes. At one level depression involves multiple disturbances of information processing. People who are severely depressed automatically interpret experiences negatively and their access to memories is similarly biased. Cognition and problem-solving skills are further compromised by poor concentration, loss of abstraction, and decreased ability to perform effortful mental tasks. The virtual monologue of negative thoughts and images is often difficult to disrupt and, unlike normal sadness, ventilation to a confidante typically has little beneficial effect. In more extreme cases, delusions or hallucinations grossly distort reality testing. Mental life is thus disturbed by simultaneous excesses and deficits of activity in specific cortical regions, including the hippocampus, prefrontal cortex, and other limbic structures.

Many severe depressions are characterized by a loss of mood reactivity. In essence, something that should elicit an uplift in mood does not do so. One correlate of this phenomenon is an apparent loss of reinforcer salience. Hedonic deficits also are apparent in a loss of gusto for food or sex and there can be significant weight loss, especially in the elderly. These disturbances point to abnormalities in neuroregulatory circuits involving the hypothalamus, nucleus accumbens, and thalamus.

Another correlate of decreased mood reactivity is a fixity or slowing of expression, initiation of activity, and spontaneous movement. This loss of animation, called *psychomotor retardation*, is sometimes confounded by a superimposed state of “driven” psychomotor agitation. These stereotypic behaviors characteristically include biting at the nailbeds or lips, a furrowed brow, tugging at one's hair, and purposeless scratching, in addition to the pacing and frequent postural shifts that accompany most states of dysphoric arousal. Like hedonic deficits, psychomotor disturbances are more commonly observed in older people with depression, with agitation typically seen in the most severe or psychotic depressive syndromes. These observable signs point to the probable involvement of circuits joining prefrontal cortex, thalamus, striatum, and basal ganglia.

Almost all depressed people report fatigue and an inability to feel refreshed by sleep. Some, particularly those under age 40, sleep excessively, whereas others, especially those over age 50, cannot maintain sleep or awaken spontaneously 1 to 2 hours earlier than desired. For those with such “terminal” insomnia, the morning hours are typically the worst of the day (i.e., *diurnal mood variation*). Such circadian disturbances strengthen the likelihood of thalamic dysregulation and also suggest abnormalities in the pons and medulla.

These signs and symptoms often coaggregate, which has formed the basis for several of the classical clinical subtypes of depression. Thus, anhedonia and psychomotor disturbances are more commonly associated with weight loss, middle and terminal insomnia, preservative ruminations, and diurnal mood disturbance, a constellation of the syndrome classified as an endogenous, autonomous, biological, psychotic, or vital depressive subtype. The fact that such depressions are slow to remit spontaneously, yet relatively responsive to electroconvulsive therapy (ECT), clearly reinforce perceptions of underlying biological abnormalities. Such depressions often appear to arise without provocation by a significant stressor, hence the presumption of an autonomous or endogenous etiology. The apparent stability of this syndrome over the centuries is recognized explicitly by the contemporary use of the ancient Greek term *melancholia*, even though black bile is no longer considered to be an etiological factor.

The depressions of early adult life tend to be “nonendogenous” and often seem to be imbedded with manifold psychosocial problems. Of course, an early age of onset may distort personality development and shape one's reportoire of coping skills, which increases the probability of handling stressors poorly. Moreover, such patients seem to elicit, provoke, or stumble into a disproportionately greater number of stressors. Historically, the association of an early age of onset with comorbid anxiety generally further solidified impressions of a conflicted or “neurotic depression.” The presumed lesser role of biological factors in neurotic depression was further suggested by less than gratifying responses to ECT and, when available, to tricyclic drugs. In addition to the nonendogenous and neurotic appellations, these early-onset depressions traditionally have been described as reactive, personal, or exogenous disorders. Many of these depressions run a chronic course that fluctuates between major and minor (dysthymic) levels.

Emerging data on the utility of new antidepressant drugs, particularly serotonergic agents, suggests that biological abnormalities of a different kind might be associated with nonendogenous depression.

A subset of nonendogenous depression was further described by “reverse” neurovegetative symptoms, namely, increased appetite, weight gain, and hypersomnolence. Such symptoms were considered uncommon in the late 1950s and 1960s and hence were referred to as *atypical.* However, as the average age of onset of depression declined into the early 20s and both research and practice has shifted to ambulatory settings, these atypical features are now commonplace. Reverse neurovegetative features are common in several forms of recurrent depression, including seasonal type (winter pattern), bipolar disorders, and major depressive disorder. These subtypes are characterized by an early age of onset and relatively poorer responses to tricyclic medications, as compared to monoamine oxidase inhibitors (MAOIs). Such observations suggest that differences in phenomenology could reflect more specific pathophysiological alterations that affect treatment response.

GENETIC FACTORS

Mood disorders clearly run in families and, as a result, both genetic and environmental influences must be considered. At present, it is well established that bipolar I disorder is more heritable than the other mood disorders, that an early age of onset is associated with greater heritability, and that heritable risk decreases in proportion to the amount of genetic material shared by members of a pedigree. Thus, identical twins have greater heritable risk than fraternal twins, who have a risk comparable to siblings and parents. First-degree relatives, in turn, have greater risk than half-siblings, grandparents, or cousins. Research on fraternal and identical twins or use of the adopted-away paradigm further suggests that heritable risk transcends environmental influences. Thus, vulnerability to mood disorders is, in some fashion, encoded in human deoxynucleic acid (DNA). The next generation of molecular genetic studies should help to identify the specific genes and gene products that influence this risk.

Although the significance of inherited vulnerability cannot be disputed, considerable variability exists both within and across groups with comparable risks. For example, in some at-risk pedigrees, alcohol use disorders and sociopathy are more common among male probands than depression. Among women, there is some evidence that environmental experiences may influence whether a generalized anxiety disorder or a depressive disorder is expressed. The late-onset mood disorders (i.e., those beginning past age 60) have relatively low rates of heritability. Even identical twins do not have 100 percent concordance of bipolar I disorder. Genetics therefore constitutes just one pathway of vulnerability or, perhaps more accurately, a foundation upon which other biopsychosocial risk factors may be expressed.

ETIOLOGY OF EMOTIONAL RESPONSES

The mood disorders are conditions in which normal emotional responses are distorted into more extreme and persistent manifestations. Some consider normal sadness to be an analogue of depressed mood, and elation the normal counterpart of manic euphoria. Continuity between normal and pathological mood states is illustrated by grief or bereavement. Grief is a universal experience, yet it can segue almost inexorably into a state that is so extreme and disabling that professional attention is warranted. Although there are less obvious natural parallels to mania, it is not uncommon for hypomania to go unrecognized. For others, the intensity of new romantic love is associated with changes in perception, cognition, behavior, and judgment that border on manic excitement. The euphorogenic effects of cocaine and other psychostimulants amply document that the “hard wiring” for manic states exists and is expressed if the individual is exposed to the right neurochemical milieu.

Predipositions to various emotional states, mood set points, appear to be partly heritable; this background emotional tone is referred to as *temperament.* Of particular importance to our current topic is a temperament characterized by excessive reactivity and behavioral inhibition, which can be recognized in infancy and is associated with enduring vulnerability to both depression, and anxiety, in adolescence and young adulthood. Similarly, onset of dysthymic traits in childhood presages extremely high rates of depressive and bipolar disorders in adolescence and adulthood. Modern theories of temperament and personality converage around several dimensions, including harm avoidance (neuroticism or behavioral inhibition). In bipolar disorders cyclothymic, extraverted, and novelty-seeking traits are more relevant.

There is now considerable evidence that the basic emotions are manifest across human cultures. The capacity to recognize such emotions in others can be observed so early in infancy that innate processes are undoubtedly implicated. Sadness and crying, for example, may be viewed as universal distress signals. Behaviors consistent with basic emotional states can also be observed in other mammals. For example, certain behavioral predispositions towards aggressivity (or passivity) and social dominance (or subordination) appear to extend across vertebrate species. By virtue of the large neocortex, *Homo sapiens* are distinguished by the capacity to integrate, abstract, and synthesize complex symbolic representations of life experiences; to communicate experiences in direct, abstract, and elaborated forms; and to develop and maintain a self-concept that guides behavior in relation to others and an anticipated future. The domains of competence are similarly broader and diverse. Whereas a highly competent primate may earn a position of dominance if placed in a new group, only the human may seek such a position by drafting a curriculum vitae and lobbying vigorously, and only humans can intentionally misrepresent their competence or motivations, or be affected by the larger social network's knowledge of their past performances.

The importance and intensity of human attachment bonds serves to facilitate the protracted task of childrearing and the necessary advantages of kinship. Indeed, for hundreds of thousands of years *Homo sapiens* adapted in a world in which the average life expectancy was less than 40 years and the infant mortality rate approached 50 percent. Although perhaps politically incorrect, it is not simply social Darwinism to suggest that necessary divisions of labor increased the chances of viable offspring and shaped evolution of gender differences in affectivity, affiliative behavior, and nuturance. Humans are also the slowest to mature of the mammals and functionally the most vulnerable and dependent upon caregivers for the longest period of time.

Having evolved over at least 900,000 years, humans must now deal with the massive changes in environment and social structure that have taken place much too rapidly for natural selection to keep pace. In relative terms, the breathtaking sociocultural and technological changes of the twentieth century have occurred in less than one ten-thousandth of human experience! The resulting complexity of human social systems thus often overtaxes the integrative capacities of the large human neocortex. When such capacities are overwhelmed, humans have to cope and adapt with neural mechanisms that are phylogenetically similar to those of other mammals and vertebrates.

STRESS AND ANIMAL MODELS OF DEPRESSION

Studies of rodents, dogs, cats, and nonhuman primates have confirmed that acute stress responses are characterized by activation of central and peripheral components of two interactive psychoneuroendocrine systems, the cortical-hypothalamic-pituitary-adrenocortical axis and the cortical-sympathomedullary axis. Although such acute stress responses are more akin to fear and anxiety than depression, it is the concepts of uncontrollability and inescapability that link the responses of other mammals to stress to human depression. Whereas stress acutely signals threat, it is loss, the anticipation of loss, or hopelessness that elicits sadness and despair.

Acute stress activates noradrenergic cell bodies in the locus ceruleus, whose axons trigger increased noradrenergic output by the adrenal medulla. At a behavioral level there is heightened arousal, increased perceptual vigilance, and inhibition of consummatory activities such as hunger and sex.

Stress also elicits synthesis and release of corticotropin-releasing hormone from neurons in the hypothalamus and cerebral cortex. This hormone activates the pituitary-adrenocortical components of stress response by causing increased release and synthesis of cortisol, adrenocorticotrophic hormone, and other glucocorticoids, and it synergistically enhances locus ceruleus activity as well.

The acute response to stress is counterbalanced by homeostatic or adaptive mechanisms. These include feedback inhibition by glucocorticoid receptors in the hippocampus and pituitary, down-regulation of postsynaptic noradrenergic receptors, and inhibitory autoreceptors and heteroreceptors on presynaptic norepinephrine neurons. Parallel input from serotoninergic (5-HT) and g-aminobutyric acid (GABA) neurons also exert dampening or inhibitory effects.

Exposure to prolonged, inescapable stress is associated with numerous adaptations and changes in neurobehavioral responses. Although corticosteroid levels may remain elevated, levels of norepinephrine, serotonin dopamine, and GABA in the brainstem and forebrain eventually decrease. Animals trapped in such a state cease trying to resist or escape, and show decreased grooming and appetitive behavior outside of the experimental situation. There are significant individual differences in development of such learned helplessness, as well as differences across pedigrees, or strains, and species. Nevertheless, antidepressant drugs have been shown to prevent, attenuate, or reverse learned helplessness across species.

Studies of the experiences of primates in the wild are more relevant to the stresses faced by people than a rat's response to inescapable painful electric shock. These naturalistic studies demonstrate that a fall from a dominant role within a primate social hierarchy is associated with increased cortical-hypothalamic-pituitary-adrenocortical activity and decreased 5 serotonin neurotransmission. In the wild, subordinate animals with low concentrations of the serotoninergic metabolites 5-hydroxyinoleacetic acid (5-HIAA) are likely to be more aggressive and less sexually active. Moreover, when social status is manipulated by creating a new group from a cohort of subordinate primates, a dominance hierarchy will emerge and the winner will experience a corresponding increase in serotonergic function. Conversely, during times of adversity such as drought or famine, the socially dominant primate experiences an increase in cortical-hypothalamic-pituitary-adrenocortical activity.

Early Adversity Physical, verbal, and sexual abuse have an indelible effect on the life trajectory. Although maltreatment has been well documented in the pathogenesis of posttraumatic stress disorder and borderline personality disorder, it now appears that such a history is also associated with an increased risk of depression.

Studies of animal models confirm that lasting alterations in neuroendocrine behavioral response can result from severe early stress. More recently this vulnerability has been linked to possible enduring changes in gene expression. Animal studies indicate that even transient periods of maternal deprivation can have a similar effect on subsequent response to stress. Early loss and neglect, a correlate of having been raised by parents with a mood disorder, is not uncommon in the history of mood disorder patients. How to integrate these clinical observations with the data on early stress in animals remains a challenge.

MONOAMINE DISTURBANCES

The area of scientific inquiry chosen is dependent on the knowledge base and experimental paradigms available to the investigator. In the early 1960s it was possible to measure catecholamine metabolites in body fluids and the principal indoleamine metabolite 5-HIAA in cerebrospinal fluid. However, the visualization of the functional brain was essentially impossible because waking electroencephalograms (EEGs) provided little useful information aside from documentation of epilepsy or diffusing slowing associated with delirium.

In addition, there were multiple lines of evidence from pharmacological studies implicating perturbations of monoamine systems in both therapeutic and iatrogenic effects of drugs on mood and behavior. Relevant pharmacotherapies of the time included tricyclic antidepressants, MAOIs, dextroamphetamine (Dexedrine), and the

amine-depleting compound reserpine (Serpasil).

Although the early biogenic amine hypotheses have undergone much revision, the critical importance of norepinephrine and 5-HT in the pathophysiology and physiology of mood disorders remains unquestioned. A second important monoamine, dopamine, has received less emphasis and there is also strong evidence of dysfunction in some forms of depressions. Since the mid-1960s there has been a shift in focus away from single neurotransmitters towards neurobehavioral systems, neural circuits, and more intricate regulatory mechanisms. Moreover, postsynaptic receptor families, presynaptic autoreceptors and heteroreceptors, second messengers, and gene transcription factors were not known when the original monoamine hypotheses were formulated.

Noradrenergic Systems Noradrenergic neurons have their cell bodies in the locus ceruleus of the brainstem and project rostrally to the cerebral cortex, limbic system, basal ganglia, hypothalamus, and thalamus (Fig. 14.4-1). This diffuse distribution belies norepinephrine's role in initiating and maintaining limbic and cortical arousal, as well as in modulation of the function of other neurotransmitters. Noradrenergic projections to the hippocampus have recently been implicated in behavioral sensitization to stress, and prolonged activation of the locus cerulus contributes to the state of learned helplessness. The locus ceruleus also is the origin of neurons that project to the adrenal medulla, the principal source of norepinephrine into the peripheral blood circulation.

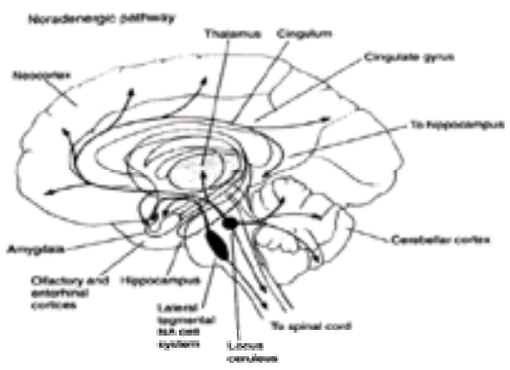

FIGURE 14.4-1 A lateral view of the brain demonstrates the course of the major nonadrenergic pathways emanating from the locus ceruleus and from the lateral brain stem tegmentum. (Reprinted with permission from Kandel ER, Schwartz JH, Jessell TM, editors: *Principles of Neural Science*, ed 3. Appleton & Lange, Stanford, CT, 1991.)

Novel stimuli increase the activity of the locus ceruleus, which in turn is decreased during vegetative functions, such as eating or sleeping. Cognitive processes can amplify or dampen sympathoadrenal responses to internal or external stimuli. Thus, the perception of stress is relayed via the appropriate cortical structures through the thalamus to the locus ceruleus and sympathoadrenal components of the acute stress response.

Stimulation of the medial forebrain bundle, the second major norepinephrine pathway in the brain, elicits increased levels of goal-directed and reward-seeking behavior. Sustained stress also eventually results in decreased levels of norepinephrine in the medial forebrain bundle, which may account for anergia, anhedonia, and diminished libido in depression. Increased noradrenergic output also stimulates inhibitory a_2-adrenergic heteroreceptors on serotonergic neurons.

Serotoninergic Systems Serotoninergic neurons project from the brainstem dorsal raphe nuclei to the cerebral cortex, hypothalamus, thalamus, basal ganglia, septum, and hippocampus (Fig. 14.4-2). Serotonin pathways have both inhibitory and facilitatory functions in the brain. For example, much evidence suggests that 5-HT is an important regulator of sleep, appetite, and libido. Serotonergic neurons projecting to the suprachiasmatic nucleus of the hypothalamus help to regulate circadian rhythms (e.g., sleep-wake cycles, body temperature, and hypothalamic-pituitary-adrenocortical axis function). Serotonin also permits or facilitates goal-directed motor and consummatory behaviors in conjunction with norepinephrine and dopamine. Moreover, serotonin inhibits aggressive behavior across mammalian and reptilian species.

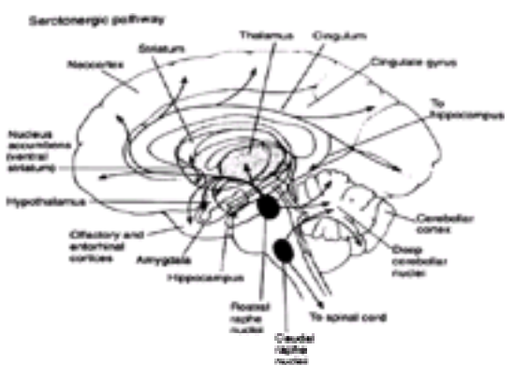

FIGURE 14.4-2 A lateral view of the brain demonstrates the course of the major serotonergic pathways. Although the raphe nuclei form a fairly continuous collection of cell groups throughout the brain stem, they are graphically illustrated here as two groups, one rostral and one caudal. (Reprinted with permission from Kandel ER, Schwartz JH, Jessell TM, editors: *Principles of Neural Science*, ed 3. Appleton & Lange, Stanford, CT, 1991.)

There is some evidence that serotonin neurotransmission is partly under genetic control. Nevertheless, acute stress increases serotonin release transiently, whereas chronic stress eventually will deplete serotonin stores. Chronic stress may also increase synthesis of 5-HT_{1A} autoreceptors in the dorsal raphe nucleus, which further decrease serotonin transmission. Elevated glucocorticoid levels tend to enhance serotonergic functioning and thus may have significant compensatory effects in chronic stress.

Dopaminergic Systems There are four relatively discrete dopamine pathways in the brain (Fig. 14.4-3). The tuberoinfundibular system projects from cell bodies in the hypothalamus to the pituitary stalk, exerting inhibitory control over prolactin secretion. The nigrostriatal system originates from cell bodies in the substantia nigra and projects to the basal ganglia, regulating involuntary motor activity. The cell bodies of the mesolimbic pathway are located in the ventral tegmentum and project to almost all limbic regions: the nucleus accumbens, amygdala, hippocampus, medial dorsal nucleus of the thalamus, and cingulate gyrus. The mesolimbic dopamine pathway modulates emotional expression, learning and reinforcement, and hedonic capacity. The fourth dopamine pathway, also originating in the ventral tegmentum's mesocortical pathway, which projects to the orbitofrontal and the prefrontal cortical regions, helping to regulate motivation, concentration, initiation of goal-directed and complex, executive cognitive tasks. Decreases in mesocortical and mesolimbic dopamine activity have obvious implications in the cognitive, motor, and hedonic disturbances associated with depression. Moreover, dopamine activity appears to be potentiated by nicotinic inputs and glucocorticoids, and dopamine concentrations are correlated with brain serotonin activity.

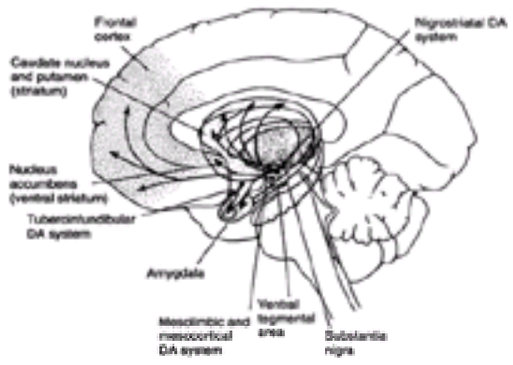

FIGURE 14.4-3 A lateral view of the brain demonstrates the course of the four major dopaminergic tracts. (Reprinted with permission from Kandel ER, Schwartz JH, Jessell TM, editors: *Principles of Neural Science*, ed 3. Appleton & Lange, Stanford, CT, 1991.)

Biogenic Amine Function After nearly 30 years of research it can be concluded that subsets of depressed people manifest one or more abnormalities of monoamine neurotransmission. Decreased central norepinephrine activity can be inferred, in part, from decreased urinary excretion of the metabolite 3-methoxy-4-hydroxyphenylglycol. A partly overlapping subgroup of patients has elevated circulating levels of norepinephrine and its metabolites. This suggests a dissociation of norepinephrine activity in the brain's medial forebrain bundle and the sympathomedullary systems peripheral activities. Increased noradrenergic activity also is reflected by blunted a_1, b, and b-coupled second messenger (i.e., cyclic adenosine monophosphate) responses. Further, an acute response to noradrenergically active antidepressants (i.e., desipramine, nortriptyline, or bupropion) may be transiently reversed by the norepinephrine synthesis inhibitor a-methyl-paratyrosine.

Serotonin dysfunction has been documented in overlapping subgroups of patients using a variety of methods, ranging from low cerebrospinal fluid (CSF) levels of 5-HIAA to decreased cerebral metabolism. Serotonin dysfunction also is reflected by blunted responses to specific serotonin (5-hydroxytryptamine [5-HT]) HT_{1A} subtype 1A ($5\text{-}HT_{1A}$) agonists (e.g., ipsapirone) and nonselective agonists (e.g., L-tryptophan or dex-fenfluramine), decreased neuroendocrine responses, and decreased serotonin uptake sites on blood platelets. Decreased serotonin neurotransmission can be inferred from the findings of cortical-hypothalamic-pituitary-adrenocortical and EEG sleep studies. In functional terms, a state of a relative hypofrontality of cerebral blood flow and glucose metabolism in the brain is fully consistent with decreased neurotransmission by 5-HT neurons projecting from the dorsal raphe nuclei. In support of this observation, dietary depletion of L-tryptophan will induce this abnormality in a subset of vulnerable patients. Tryptophan depletion also reverses acute responses to selective serotonin reuptake inhibitors. Increased sensitivity to dopamine, perhaps mediated by elevated glucocorticoid levels, may contribute to the development of delusions and hallucinations.

Other Neurotransmitters Cholinergic neurons containing acetylcholine are distributed diffusely throughout the cerebral cortex, and have reciprocal or interactive relationships with all three monoamine systems. Abnormal levels of choline, which is a precursor to acetylcholine, are seen in the brains of some depressed patients, perhaps reflecting abnormalities in cell phospholipid composition. Cholinergic agonist and antagonist drugs have differential clinical effects on depression and mania. Agonists can produce lethargy, anergia, and psychomotor retardation in normal subjects; exacerbate symptoms in depression; and reduce symptoms in mania. These effects generally are not sufficiently robust to have clinical applications and adverse effects limit their clinical utility. Via their serotonergic or adrenergic effects, antidepressant drugs may decrease cholinergic function, although direct anticholinergic effects are unrelated to antidepressant activity.

In an animal model of depression, a strain of mice that is supersensitive to cholinergic effects has been found to develop learned helplessness more quickly and cholinergic supersensitivity has been shown to be attenuated by manipulation of adrenergic activity. Conversely, cholinergic agonists can induce changes in cortical-hypothalamic-pituitary-adrenocortical activity and sleep EEG studies that mimic those associated with severe depression. Indeed, some remitted patients with bipolar or depressive disorders, as well as their never-ill first-degree relatives, have a trait-like increased sensitivity to cholinergic agonists.

GABA has an inhibitory effect on ascending monoamine pathways, particularly the mesocortical and mesolimbic systems. Reductions of GABA have been observed in plasma, CSF, and brain GABA concentrations in depression. Animal studies have also found that chronic stress can reduce or deplete GABA levels and, by contrast, GABA receptors can be upregulated by antidepressants.

The amino acids glutamate and glycine appear to be the major excitatory neurotransmitters in the central nervous system. Glutamate and glycine bind to sites associated with the *N*-methyl-D-aspartate (NMDA) receptor and, in excess, can have neurotoxic effects. The hippocampus has a high concentration of NMDA receptors; it is thus possible that glutamate in conjunction with hypercortisolemia mediate the neurocognitive effects of chronic stress. There is emerging evidence that drugs that antagonize NMDA receptors have antidepressant effects.

The binding of a neurotransmitter and postsynaptic receptor triggers a cascade of chemical processes that include the second messenger systems. Receptors interact with the intracellular environment via guanine nucleotide-binding proteins (G proteins). The G proteins, in turn, connect to various intracellular enzymes and effectors (e.g., adenylate cyclase, phospholipase C, and phosphodiesterase) that stimulate the formation of second messengers, such as cyclic nucleotide [e.g., cyclic adenosine monophosphate (cAMP) and cyclic guanine monophosphate (cGMP)], phosphatidylinositols (e.g., inositol triphosphate and diacylglycerol), and calcium-calmodulin. These second messengers regulate the function of neuronal membrane ion channels, neurotransmitter synthesis and release, and protein kinase activity. Protein kinase, for example, catalyzes phosphorylation, an anergy-liberating process involved in synthesis and degradation of neuroreceptors, ion channels, G proteins, and DNA transcription and messenger-RNA translation factors that regulate gene expression. Recent studies have reported abnormalities in platelet adenylate cyclase activity, phosphoinositide hydrolysis, intracellular calcium metabolism, and G-protein function in depressive disorders. Moreover, antidepressant medications may initiate a series of intracellular reactions that “turn down” synthesis of corticotropin-releasing hormone and monoamine receptors and “turn on” peptides such as neuronal growth factors. There is also increasing evidence that mood-stabilizing drugs (e.g., lithium) act upon G proteins or other second messengers.

Alterations of Hormonal Regulation

Cortical-Hypothalamic-Pituitary-Adrenal Cortical Activity Elevated glucocorticoid activity is a hallmark of the mammalian stress response. Evidence of increased cortisol secretion is apparent in 20 to 40 percent of depressed outpatients and 40 to 60 percent of depressed inpatients. Rates are highest among older patients, particularly those with highly recurrent or psychotic depressive disorders. Hypercortisolism is thus one of the most common correlates of melancholic depressions.

A variety of methods can be used to study elevated cortical-hypothalamic-pituitary-adrenal cortical activity: excretion of urinary free cortisol, 24-hour (or shorter time segments) intravenous collections of glucocorticoid plasma cortisol levels, salivary cortisol levels, and tests of the integrity of feedback inhibition. Methods of testing feedback inhibition usually involve administration of the potent synthetic glucocorticoid dexamethasone, which in 0.5-, 1-, or 2-mg doses normally suppresses cortical-hypothalamic-pituitary-adrenal cortical axis activity for 24 hours. Impaired feedback inhibition is reflected by nonsuppression of cortisol secretion at 8 AM the following morning or subsequent escape from suppression at 4 PM or 11 PM. A more recent development is the pairing of dexamethasone suppression with an infusion of corticotropin-releasing hormone. The sensitivity and specificity of these various tests of feedback inhibition are not sufficient for use and adrenocortical hyperactivity is observed in many other psychiatric disorders, albeit usually at a lower prevalence. Nonsuppression usually implicates a premature loss of inhibitory hippocampal glucocorticoid receptors, which also may account for the age dependence of cortisol nonsuppression. Hypercortisolemia associated with early trauma also may permanently decrease synthesis of glucocorticoid receptors or actually lead to atrophy of these vulnerable neurons.

Hypersecretion of cortisol and dexamethasone nonsuppression are imperfectly correlated (about 60 percent concordance). Elevated cortical-hypothalamic-pituitary-adrenal cortical activity in depression is typically not associated with the physical stigmata of Cushing's disease, but it is sufficient to induce a reversible cortical atrophy and is implicated in the genesis of neurocognitive disturbances. Starvation and protracted sleep deprivation also can induce hypercortisolism. Patients with increased cortical-hypothalamic-pituitary-adrenal cortical activity are typically less responsive to attention placebo and psychosocial treatments. However, hypercortisolism does typically resolve with effective treatment and, when persistent, conveys a high risk of relapse. This is presumed to be a consequence of incomplete resolution of the depressive episode at the level of the brain. Dexamethasone and the cortisol synthesis inhibitor ketoconazole (Nizoral Ò) are sometimes used to externally suppress the hypothalamic-pituitary-adrenocortical axis of hypercortisolemic patients with more refractory depressive disorders.

Beyond failure of feedback inhibition, a deficit of 5-HT activity and an increase in norepinephrine or acetylcholine activity have been shown to increase cortical-hypothalmic-pituitary-adrenal cortical activity.

Thyroid Axis Activity About 5 to 10 percent of people evaluated for depression have previously undetected or subclinical thyroid dysfunction, as reflected by an elevated basal thyroid-stimulating hormone (TSH) concentration or an increased TSH response to a 500-µg infusion of the hypothalamic neuropeptide thyrotropin-releasing hormone (TRH). Such abnormalities are often associated with elevated antithyroid antibody levels and, unless corrected with thyroid hormone replacement therapy, may compromise response to treatment. These findings are especially relevant to women with rapid-cycling bipolar disorder.

More commonly, depressed patients receiving a TRH challenge test show a blunted TSH response. This abnormality, which may be state-independent, has been associated with a heightened relapse risk following pharmacotherapy or ECT. The TSH response may represent pituitary downregulation consequent to a prolonged elevation of TRH secretion. In turn, increased TRH secretion could result from a homeostatic response intended to enhance noradrenergic neurotransmission. Some researchers further speculate that the therapeutic benefit of liothyronine (Cytomel) augmentation therapy is the result of correction of this failed homeostatic response.

Growth Hormone Growth hormone secretion from the anterior pituitary is stimulated by norepinephrine and dopamine and inhibited by CRH and somatostatin, a hypothalamic neuropeptide. Somatostatin also inhibits CRH secretion. Secretion of growth hormone follows a 24-hour circadian rhythm, with a characteristic secretory surge during the first few hours of sleep. The most consistent finding in depression is a blunted growth hormone response to clonidine, an a_2 receptor agonist. The onset of sleep and nonselective adrenergic agonists such as desipramine also elicit a blunted growth hormone response.

Somatostatin Although the hypothalamus has the highest concentrations of somatostatin, significant concentrations are also found in the amygdala, hippocampus, nucleus accumbens, prefrontal cortex, and locus ceruleus. In addition to inhibition of growth hormone and release of corticotropin-releasing hormone, somatostatin inhibits GABA, adrenocorticotropic hormone (ACTH) and thyroid-stimulating hormone. Somatostatin levels are lower in the cerebrospinal fluid of people with depression as compared to those with schizophrenia or normals, and increased levels have been observed in mania.

Prolactin Prolactin release from the pituitary is stimulated by serotonin and inhibited by dopamine. Most studies have not found significant abnormalities of basal or circadian prolactin secretion in depression, although a blunted prolactin response to various serotonin agonists has been frequently reported. This response is less likely to be abnormal in premenopausal women, suggesting that estrogen has a moderating effect.

Alterations of Sleep Neurophysiology People prone to depression tend to have a premature loss of deep, slow (delta) wave sleep, and an early onset of the first episode of rapid eye movement (REM) sleep (Fig. 14.4-4). Results of family and twin studies suggest that these related abnormalities are at least partly heritable. Consistent with the expected behavior of a heritable trait, reduced REM latency and deficits of slow-wave sleep typically persist following recovery from a depressive episode. A blunted growth hormone response following sleep onset or administration of adrenergic agonists is correlated with a slow-wave sleep deficit and shows similar state-independent or trait-like behavior.

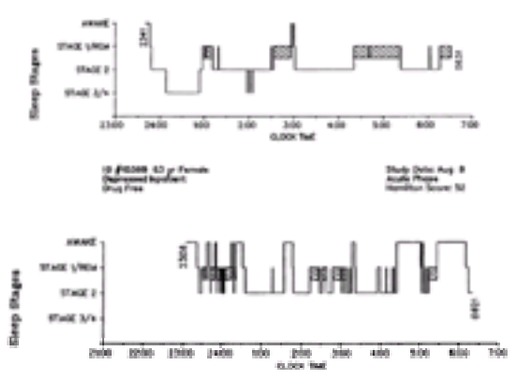

FIGURE 14.4-4 The all night electroencephalographic (EEG) sleep profiles of a healthy young woman and a 63-year-old woman with melancholia. (Reprinted with permission from Thase ME, Howland: Biological Processes in Depression: An Updated Review and Integration. In *Handbook of Depression*, ed 2, EE Beckham, WR Leber, editors. Guilford, New York, 1995.)

More severe depressions are associated with age-dependent decreases in sleep maintenance (i.e., the capacity to sleep without awakenings) and an increase in the phasic intensity of REM sleep, particularly during the first several REM periods. These changes correlate with clinical measures of severity of depression and tend to normalize during times of remission. Other state-dependent abnormalities are hypercortisolemia, dexamethasone nonsuppression, and elevated levels of peripheral catecholamine metabolites.

A deficit of slow-wave sleep and reduced REM latency can be induced and may be caused by a decrease in 5-HT neurotransmission or an increase in central cholinergic activity. Serotoninergic neurons from the dorsal raphe-nuclei project to cholinergic cells in the pons to tonically inhibit REM sleep. During non-REM (NREM) sleep, these cholinergic neurons are inactive. L-tryptophan depletion results in an increase in REM time and a decrease in REM latency.

Serotoninergic neurons projecting rostrally to the thalamus and prefrontal cortex also mediate slow-wave activity, as do drugs that antagonize 5-HT_2 receptors. Low CSF concentrations of 5-HIAA is correlated with diminished slow-wave sleep, an effect mimicked by acute serotonin depletion.

Prefrontal cortical metabolism is normally decreased during nREM sleep, a time of physical and metabolic rest. By contrast, REM sleep is normally associated with an increase in glucose metabolism in the limbic system. In depression there is relatively increased prefrontal glucose metabolism during nREM sleep, corresponding to the diminution of restorative slow wave sleep. REM sleep is associated with an even greater increase in limbic glucose utilization.

The sleep profiles of younger, hypersomnolent patients can be remarkably normal, particularly if laboratory routines do not permit an extended morning sleep period. Such patients may actually have increased slow-wave sleep and an increase in REM time associated with a greater total sleep time. Reduced REM latency, however, has been reported in juvenile depressives by at least one group of investigators.

The combination of reduced REM latency, increased REM density, and decreased sleep maintenance identifies about 40 percent of depressed outpatients, 80 percent of depressed inpatients, and 10 percent of age-matched normal controls. These sleep abnormalities also have been reported in a subset of dysthymic disorder patients. Sleep studies are too expensive and inconvenient to be used routinely for diagnostic purposes in depression and, like dexamethasone nonsuppression, false-positive cases are common in other psychiatric disorders. Nevertheless, current data indicate that patients manifesting this constellation of disturbances are less responsive to psychotherapies and may benefit preferentially from pharmacotherapy. It remains to be seen if those normal individuals with false-positive studies have an increased vulnerability to future episodes of depression. Successful nonpharmacological treatment of the depressive episode results in normalization of this profile in about 50 percent of cases. Pharmacotherapy with most antidepressant agents has an overcorrective effect characterized by prolongation of REM latency and suppression of REM sleep; such medications have variable effects on sleep maintenance. REM suppression may reflect activation of postsynaptic 5-HT_{1A} receptors or enhanced norepinephrine neurotransmission. Both desipramine (Norpramin) and the SSRIs for example, produce a rapid REM suppression in normal patients as well as in patients with depression. The efficacy of antidepressant medications that do not suppress REM sleep, such as nefazodone (Serzone), and bupropion (Wellbutrin) in patients with pathologically increased REM sleep suggests that these formulations may not apply to all depressions.

Alterations of Circadian Rhythms In addition to sleep disturbances, depressed patients often show a blunting of circadian rhythms of cortisol secretion, growth hormone secretion, and body temperature. These changes were originally thought to represent a phase advance of the sleep-wake cycle, although stronger evidence now suggests that circadian rhythms may be disorganized by heightened nocturnal arousal. Increased CRH, increased somatostatin, hypercortisolemia, and decreased 5-HT could all be implicated in this process. By contrast, in some cases of depressive disorders with seasonal (winter) pattern there is evidence of a phase delay of the sleep-wake cycle in relation to the nocturnal onset of melatonin secretion. The role of melatonin in the pathophysiology of mood disorders remains

unclear.

Brain Structure and Function

Structural Lesions Computed axial tomography and magnetic resonance imaging scans provide sensitive, noninvasive methods to assess the brain, including cortical and subcortical tracts, as well as white matter lesions. The most consistent abnormality observed in the depressive disorders is increased frequency of abnormal hyperintensities in subcortical regions, especially the periventricular area, basal ganglia, and thalamus (Fig. 14.4-5). More common in bipolar I disorder and among the elderly, these hyperintensities appear to reflect the deleterious neurodegenerative effects of recurrent mood episodes. Ventricular enlargement, cortical atrophy, and sulcal widening also have been reported in patients with mood disorders as compared to normal controls. In addition to age and illness duration, structural abnormalities are associated with increased illness severity, bipolar status, and increased cortisol levels. Some depressed patients also may have reduced caudate nucleus volumes, suggesting a defect in the mesocorticolimbic system. Cerebrovascular factors, including strong, often involve subcortical frontal and basal ganglia structures, and appear particularly relevant to late-life depression.

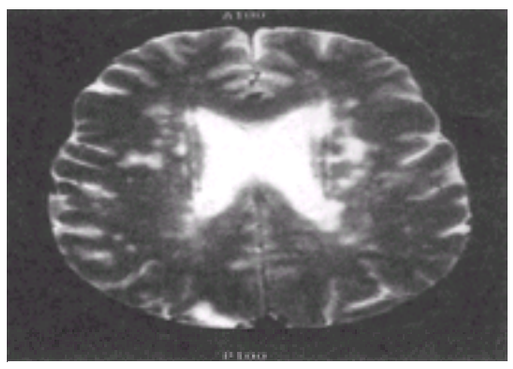

FIGURE 14.4-5 This magnetic resonance imaging (MRI) scan of a patient with late onset major depressive disorder illustrates extensive periventricular hyperintensities associated with diffuse cerebrovascular disease.

Cerebral Metabolic Alterations Positron emission tomography (PET) scanning is currently the most powerful method for visualizing brain metabolism during rest and various states of activation. Normal sadness is associated with an increase in cerebral blood flow to the thalamus and medial prefrontal cortex. This appears to be a nonspecific change associated with diverse emotional responses. More specific activation is seen in the left amygdala, hippocampal formation, and parahippocampal gyrus. Sadness generated by one's own thoughts (as opposed to a video scenario) also is associated with a relative increase in cerebral blood flow to the anterior insular cortex, as is anticipatory anxiety.

Direct activation of limbic structures by intravenous infusions of procaine hydrochloride also has been studied in normal controls. Such activation is characterized by reliable, bilateral increases in cerebral blood flow in the amygdala, parahippocampal gyri, insula, and anterior cingulate cortex. These changes are associated with a wide range of emotions, ranging from euphoria to severe anxiety.

The most widely replicated PET finding in depression is decreased anterior brain metabolism, which is generally more pronounced on the left side. This abnormality appears to be state dependent and has been observed in both depressive and bipolar disorders (Fig. 14.4-6), as well as in depression associated with obsessive-compulsive disorder. There is a reversal of hypofrontality following shifts from depression into hypomania, such that there are greater left-hemisphere reductions in depression compared to greater right-hemisphere reductions in mania.

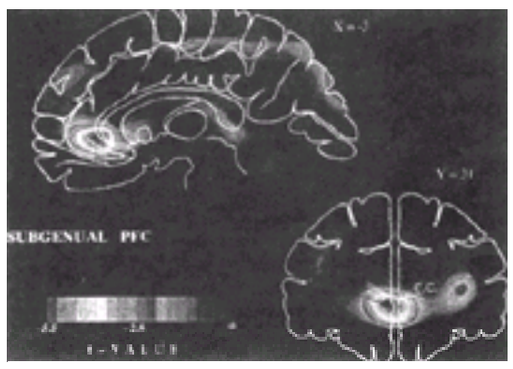

FIGURE 14.4-6 Composite coronal and sagittal sections of positron emission tomography (PET) scans show areas where cerebral glucose metabolism is decreased in depressed patients relative to matched health controls. (Reprinted with permission from Drevets WC: Nature 386:824–827, 1997. Ó 1997 MacMillan Magazine Limited.)

Other studies have observed more specific reductions of reduced cerebral blood flow and metabolism in the dopaminergically innervated tracts of the mesocortical and mesolimbic systems in depression. There is evidence that antidepressant agents at least partially normalize some of these changes.

In addition to a global reduction of anterior cerebral metabolism, increased glucose metabolism has been observed in several limbic regions. The best evidence of this abnormality comes from studies of patients with relatively severe recurrent depression and a family history of mood disorder (Fig. 14.4-7). This abnormality was found to be reversible with effective pharmacotherapy, but persistent when recently remitted patients were studied again when they were off medication. During episodes of depression, increased glucose metabolism is correlated with intrusive ruminations. If truly state-independent, such amygdalar hypermetabolism could represent the emotional “amplifier” that helps to distort the signal of relatively minor stressors in vulnerable people.

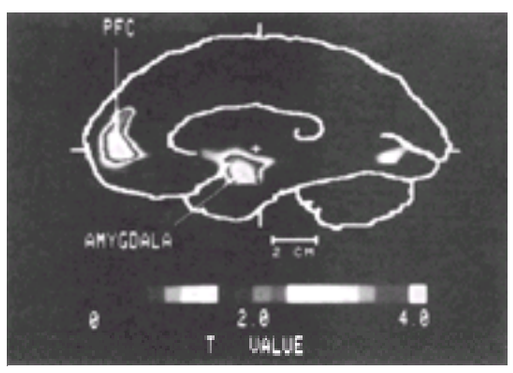

FIGURE 14.4-7 A lateral composite positron emission tomogram (PET) illustrating increased blood flow to the amygdala of patients with pure familial depressive disease as compared to healthy controls. (Reprinted with permission from Drevets WC: Exploring the Functional Anatomy of Depressive Disorder—Part I. In *Masters in Psychiatry*, Cliggott Communications, 1994.)

Magnetic resonance spectroscopy has recently been used to study brain phosphorus metabolism in mood disorders. These studies focus on phosphorus metabolites because they reflect metabolic activity of several second messengers, such as cAMP, cyclic guanine monophosphate, and phosphatidylinositol. An asymmetrical abnormality of phosphorus metabolism has been observed in the frontal lobes of patients with bipolar disorder compared to normal controls, as well as the left frontal lobe and basal ganglia of patients with depression.

IMMUNOLOGICAL DISTURBANCE

Depressive disorders are associated with several immunological abnormalities, including decreased lymphocyte proliferation in response to mitogens and other forms of impaired cellular immunity. These lymphocytes produce neuromodulators such as corticotropin-releasing factor and cytokines, which are peptides known as *interleukins.* There appears to be an association with clinical severity, hypercortisolism, and immune dysfunction and the cytokine interleukin-1 may induce gene activity for flucocorticoid synthesis. The precise clinical relevance of these findings requires further investigation.

SEX DIFFERENCES

There is no compelling evidence that a single, sex-related factor accounts for the increased risk of depression in women. Certainly, alterations of sex hormones or hypothalamic gonadotropins in depression have not been documented consistently. Prior to menopause, estrogen and its metabolites may actually “protect” depressed women from developing hypercortisolemia. Although probably not a specific causal factor in depression, menopause may thus represent a point of transition from less severe depressions characterized by reverse vegetative symptoms to melancholia. There are, however, a multitude of risk factors that may contribute to the “gender gap,” including greater risk of early sexual abuse and current spousal abuse, higher rates of thyroid disease, oral contraceptive use, and premenstrual or postpartum-onset mood disorders.

Alternatively, gender differences in emotional expressivity may interact with sociocultural factors and the texture of modern life to create the increased risk of depression for women. Conversely, use of external coping strategies and greater traditional social role expectations to achieve competence outside of the home (and the resultant economic power) may provide men relatively greater protection against depression. Gender differences in rates of depression are not well documented in nonindustrialized cultures and, in the United States, no differences in men's and women's rates of depression were found in the old-order Amish of Pennsylvania.

FUTURE DIRECTIONS

Major depressive disorder is associated with a myriad of neurobiological disturbances, perhaps as varied as the range of effective treatments and clinical presentations. Broadly viewed as traits (either inherited or acquired) or states (abnormalities only apparent during illness), these disturbances begin to show some psychobiological coherence. State-dependent abnormalities, for example, tend to coaggregate in patients with more severe syndromes and, especially past ages 40 to 50, are associated with the more classic endogenous or melancholic manifestations. These changes include increased phasic REM sleep, poor sleep maintenance, hypercortisolism, impaired cellular immunity, global reductions of anterior cerebral blood flow and glucose metabolism, elevated peripheral noradrenergic metabolites, and possibly increased glucose metabolism in the left amygdala. Such changes suggest, almost without exception, the consequences of an exaggerated and sustained stress response. Once manifest in this fashion, the depressive episode tends to be longer, more disabling, more prone to relapse, and more likely to benefit from pharmacotherapy or ECT.

Trait-like abnormalities include reduced slow-wave sleep, reduced REM latency, blunted nocturnal growth hormone response, and various indicators of decreased serotonin neurotransmission. Heritability of these abnormalities is inferred from family studies and other at-risk paradigms. These abnormalities are associated with an early age of onset and perhaps with increased vulnerability to recurrent illness. They may also increase the likelihood of state-dependent biological changes during depressive episodes, probably by reflecting impairments in the ability to dampen or lower stress responses.

Examples of more persistent but “acquired” abnormalities may include global and focal changes, cortical atrophy, hypertrophy of the adrenal cortex, periventricular hyperintensities, and alterations in CRH synthesis. Blunted response of thyroid-stimulating hormone to an infusion of thyrotropin-releasing hormone and dexamethasone nonsuppression may represent “hybrids,” in that these abnormalities can be slow to normalize and, when persistent after remission, convey a high risk of relapse.

Although specific genes have not yet been identified, vulnerability to mood disorders is heritable for some people. This type of heritability is most likely polygenetic and, in all likelihood, will be best understood through models that include gene-environment interactions. Nevertheless, increased heritability is associated with an earlier age of onset, greater comorbidity, increased risk of recurrent illness, and an increased likelihood of hypomanic or manic episodes.

Two of the more heritable forms of depression, early-onset chronic depression and bipolar depression, are commonly nonmelancholic in clinical presentation and relatively less likely to manifest state-dependent neurobiological disturbances. Both different genetic vulnerabilities and age-dependent changes in the brain's response to depression might explain this apparent paradox. Hypersomnolence and hyperphagia may thus reflect an episodic yet age-dependent homeostatic response to enhance serotoninergic dysfunction. In contrast, the sharp rise of mania post-pubescently may be related to maturational effects of catecholaminergic systems in the brain.

Aging and an accumulating risk of recurrent episodes are inextricably connected, although the diseases of aging that ravage brain function definitely increase the risk of depression, and these syndromes often prove to be resistant to treatment. The late-onset form of depression associated with periventricular hyperintensities also illustrates a more subtle interplay between vascular disease, brain damage, and mood disorder.

Ultimately, depression remains the most human of the Axis I disorders, partly because everyone can relate to sadness, grief, and the heartbreak of lost love and partly because the cognitive world of animals subjected to prolonged, inescapable stress is inaccessible. Even if their mental equivalents of “Why did this happen to me?” “Why bother—nothing I try will help?” and “I wish I was dead” could be identified, however, the incidence, prevalence, disability, and tragedy of depression in humans cannot be generalized to rodents or primates. Strong, sustaining affective bonds and an enduring sense of self-worth and competence are all-important and assaults on these fundamental aspects of human well-being are so frequent that many individuals succumb to depression. Some individuals are more vulnerable than others, and the association between severe depression and numerous, reproducible changes in brain function are well documented. Understanding the mechanisms of adaptation and brain dysfunction that predispose, initiate, distort, and maintain depressive disorders represents our best hope to prevent and relieve the misery and suffering of tens of millions of people.

SUGGESTED CROSS-REFERENCES

Monoamine neurotransmitters are discussed in Section 1.4, and the contributions of the neural sciences in general are the focus of the other sections of Chapter 1. Biological therapies are covered in Chapter 31.

14.5 MOOD DISORDERS: PSYCHODYNAMIC ASPECTS

GLEN O. GABBARD, M.D.

A contemporary psychodynamic approach to mood disorders takes into account the strong biological underpinnings of these disorders. The domain of meanings is central to psychodynamic thought. Even when psychiatric illnesses can be traced to alternations in neurotransmitters, the symptomatology may acquire specific meanings for the patient. Moreover, psychosocial stressors and interpersonal events appear to trigger certain neurophysiological and neurochemical changes in the brain that significantly alter the balance of neurotransmitters. In other words, the development of an episode of depression or mania is generally regarded as a final common pathway of a complex mixture of psychosocial, genetic, and biological influences.

Clinically significant depression has long been linked to psychosocial stressors, such as the loss of a spouse. In addition, the loss of a parent before age 11 places adults at a higher than usual risk of depression. Some investigators have linked early childhood losses or separations to changes in neuronal receptor sites in the brain. This mechanism, known as kindling, is postulated to work in the following manner. Environmental stressors in childhood (e.g., loss or separation) so sensitize the receptor sites that relatively minor stressors in later life may suffice to trigger an episode of affective disorder. Chronic stress and deprivation of environmental origin may produce alterations in the catecholaminergic system in response to stimulation from the corticotrophin-releasing hormone–adrenocorticotropic hormone (ACTH) axis.

Primate studies have lent some support to the hypothesis that psychosocial influences have permanent effects on neurophysiological factors. Infant squirrel monkeys who are separated from their mothers experience long-lasting and, in some cases, permanent neurobiological changes. The changes include lasting alterations in the sensitivity of noradrenergic receptors, changes in hypothalamic serotonin secretion, and persistently elevated plasma cortisol concentrations. The sensitivity and number of brain opioid receptors are also significantly affected by repeated separation. Some changes are reversible if the infant monkeys are reunited with their mothers or siblings; other changes are not. Moreover, the separations appear to be more or less damaging during certain developmental periods, possibly because of the correlation with myelinization in the nervous system.

Although depression was once divided into endogenous and reactive subgroups, recent research has rendered these distinctions obsolete. Most depression is triggered by stressors, although at times relatively mild to an outside observer, and all depression involves endogenous biochemical factors. In this regard, every case of depression and mania can be regarded as having both a psychosocial and a biological dimension. Similarly, most depressions, except those of extreme severity, respond equally well to psychotherapy and medication.

One of the most sophisticated efforts to define the relative contributions of psychological vulnerability, genetics, and environmental stressors in major depressive disorder was a prediction study involving female twins. Multiple assessments of 680 female-female twin pairs of known zygosity were made over time, and the findings allowed the investigators to develop an etiological model to predict major depressive episodes. One of the most influential predictors was the presence of recent stressful events. Genetic factors were also important in predicting depression. Two other factors, neuroticism and interpersonal relations, also played substantial etiological roles. Neuroticism seemed to contribute in part by reducing the level of social support for an individual. Interpersonal dimensions of social support, recent difficulties, and parental warmth were all involved in predicting a major depressive episode.

Kenneth Kendler and his colleagues expanded on their twin study by examining information about stressful life events and the onset of major depressive episodes in a population base sample of 1082 female-female twin pairs. They interviewed members of the sample on two different occasions separated by a mean time of 17.3 months. They again found that stressful events significantly predicted onset of major depression in the month of occurrence. The most severe stressors included death of a close relative, serious marital problems, assault, and divorce or breakup. Genetic liability also had a significant impact on the risk of onset of depression. In individuals at lowest genetic risk (i.e., monozygotic twins with an unaffected cotwin), the probability of having a major depression in a particular month was 0.5 percent if unexposed to a severe life event. However, if the individual did experience such an event, the probability went up to 6.2 percent.

An even more dramatic difference was found by looking at individuals at the highest genetic risk (i.e., monozygotic twins with an affected cotwin). In these cases, the probability of having a major depression in a particular month was only 1.1 percent if no stressor was involved. However, if these individuals were exposed to a severe event, their risk of having a depressive episode skyrocketed to 14.6 percent.

The investigators described the best model for the joint effect of genetic liability and stressful life events on the onset of major depression as follows: genetic factors influence the risk of onset of major depression, at least in part, by altering the sensitivity of individuals to the depression-inducing effect of stressful life events. They emphasized that an individual's genetic endowment is not static. It interacts with the environment and reacts to psychosocial stressors.

One factor not captured by research using large samples is the role of the meaning of a particular stressor. What may seem a relatively mild psychological stressor may have conscious or unconscious meanings to an individual patient that greatly magnify its impact. In examining research on the role of stressful events in the course of unipolar and bipolar disorders, Constance Hammen concluded, “The field has reached considerable consensus that it is not the mere occurrence of a negative life event but rather the person's interpretation of the meaning of the event and its significance in the context of its occurrence.” In a longitudinal study of the link between depressive reactions and stressors, Hammen and her colleagues found that stressors whose content matched the patient's area of self-definition were particularly likely to precipitate depressive episodes. In other words, in someone whose sense of self is partly defined by social connectedness, loss of significant interpersonal contacts may precipitate a depressive episode. On the other hand, someone whose self-worth is linked to achievement and efficacy might be more likely to have a depressive episode in response to a perceived failure in the workplace.

Psychodynamic theories of etiology have accumulated over years of clinical experience. These psychodynamic theories must be viewed within a broad dialogue with the neuroscientific data regarding brain changes in affective disorders. The following theories may also be regarded as psychodynamic themes that emerge in the treatment of depressed patients and may assist the clinician in understanding the patient's inner experience.

PSYCHODYNAMIC THEORIES OF DEPRESSION

Anger Turned Inward A common finding in depressed patients is profound self-depreciation. Sigmund Freud, in his classic 1917 paper “Mourning and Melancholia,” attributed that self-reproach to anger turned inward, which he related to object loss, which may or may not be real. A fantasied loss may suffice to trigger a severe depression. Moreover, the patient may actually be unaware of any specific feelings of loss, since the fantasied loss may be entirely unconscious.

Freud drew an analogy between serious melancholic states and normal grief. Both may be time limited, but Freud cited two principal differences. In cases of grief, there is an actual object loss in external reality; in depression the lost object is more likely to be emotional than real. The second difference is that persons with depression experience profound loss of self-esteem, but the self-regard of persons engaged in a mourning process is not diminished.

The observational differences between grief and depression were pivotal in Freud's theory. He reasoned that one way of dealing with the loss of a beloved person is to become like the person. Freud defined that process as *introjection*, a defense mechanism central to the psychodynamics of depression, in which the patient internalizes the lost object so that it becomes an internal presence. Freud later noted that introjection is the only way that the ego can give up a valued and loved object.

Because depressed persons perceive the departed love object as having abandoned them, feelings of hatred and anger are intermingled with feelings of love. Freud

suggested that ambivalence involving the coexistence of love and hate is instrumental in the psychodynamics of depression. As a result of introjecting the lost object, the negative part of the depressed patient's ambivalence—the hatred and anger—is directed inward and results in the pathognomonic picture of self-reproach. In that manner a suicidal act may have the unconscious meaning of murder.

Karl Abraham, one of Freud's early colleagues, shared Freud's view of depression but also extended and elaborated it. Abraham viewed the process of introjection as a defense mechanism that takes two forms. First, he thought that the introjection of the original love object is the basis for building one's ego-ideal, so that the role of the conscience is eventually taken over by the introjected object. In that conceptualization much pathological self-criticism is seen as emanating from the introjected love object. In the second form of introjection, more in keeping with Freud's idea, the content of self-reproach is merciless criticism directed at the object. In other words, Abraham viewed the two processes of introjection as instrumental in creating the superego. Abraham also linked depression to early fixations at the anal and the oral levels of psychosexual development. He viewed oral sadistic tendencies as the primary source of self-punishment in depressed patients, and he inferred that inadequate mothering during the oral stage of development was involved.

The psychodynamic understanding of depression defined by Freud and expanded by Abraham is known as the classical view of depression. That theory involves four key points: (1) disturbances in the infant-mother relationship during the oral phase (the first 12 to 18 months of life) predispose to subsequent vulnerability to depression; (2) depression can be linked to real or imagined object loss; (3) introjection of the departed object is a defense mechanism invoked to deal with the distress connected with the object loss; and (4) because the lost object is regarded with a mixture of love and hate, feelings of anger are directed inward at the self.

Depressive Position Although Melanie Klein understood depression as involving the expression of aggression toward loved ones, much as Freud did, the developmental theory on which her view was based is quite different from Freudian theory. During the first year of life, Klein believed, the infant progresses from the paranoid-schizoid position to the depressive position. In the first few months of life, according to Klein, the infant projects highly destructive fantasies into its mother and then becomes terrified of the mother as a sadistic persecutor. That terrifying “bad” mother is kept separate from the loving, nurturing “good” mother through the defense mechanism of splitting. In that manner the infant's blissful feeding experience remains uncontaminated and undisturbed by persecutory fears of attack by the “bad” mother. In the course of normal development, according to Klein, the positive and negative images of the mother are integrated into a more ambivalent view. In other words, the infant recognizes that the “bad” mother it fears and hates is the same mother as the “good” mother it loves and adores. The recognition that one can hurt loved ones is the essence of the depressive position.

Klein connected clinical depression with an inability to successfully negotiate the depressive position of childhood. She regarded depressed persons as fixated or stuck at a developmental level in which they are extraordinarily concerned that loved good objects have been destroyed by the greed and destructiveness they have directed at them. In the absence of those good objects, depressed persons feel persecuted by the hated bad objects. In short, Klein's view was that depressed patients are longing or pining for the lost love objects while being persecuted by bad objects. In that theoretical framework the feelings of self-depreciation are linked to the fear that one's good parents have been transformed into violent persecutors as a result of one's own destructive tendencies. Also, the bad internal objects are internalized into the superego, which then makes sadistic demands on the patient. Hence, in the kleinian view, the self-reproaches experienced by depressed patients are directed against the self and internal impulses, rather than toward an introjected object, as in Freud's view.

Tension Between Ideals and Reality Whereas most psychodynamic theories of depression incorporate the superego as a significant part of the conceptual understanding, Edward Bibring viewed depression as tension arising from within the ego itself, rather than between the ego and the superego. According to Bibring, the ego has three highly invested narcissistic aspirations—to be good and loving, to be superior or strong, and to be loved and worthy. Those ideals are held up as standards of conduct. Depression sets in when a person becomes aware of the discrepancy between those ideals and reality. Helplessness and powerlessness result from the feeling that one cannot measure up to such high standards. Any blow to the self-esteem or any frustration of the strivings toward those aspirations precipitates depression. Bibring's theory, unlike Freud's and Klein's, does not regard aggression as playing a primary role in depression. The depressed person may ultimately experience anger turned inward, resulting from the awareness of helplessness; however, such expressions of aggression are secondary, rather than primary. The essence of depression, in Bibring's view, is a primary affective state arising within the ego and is based on the tension between what one would like to be and what one is.

Ego as Victim of Superego Edith Jacobson compared the state of depression to a situation in which the ego is a powerless, helpless child, victimized by the superego, which becomes the equivalent of a sadistic and powerful mother who takes delight in torturing the child. Like Freud, Jacobson assumed that depressed persons have identified with ambivalently regarded lost love objects. The self is experienced as identified with the negative aspects of the object, and ultimately the sadistic qualities of the lost love object are transformed into the cruel superego. Hence, depressed persons feel that they are at the mercy of a sadistic internal tormentor that is unrelenting in its victimization. Jacobson also noted that the boundary between self and object may disappear, resulting in a fusion of the bad self with the bad object.

Dominant Other Silvano Arieti studied the psychodynamic underpinnings of depression in severely ill patients who were unresponsive to most somatic treatments. He observed a common psychological theme in those patients that involved living for someone else, rather than for themselves. He referred to the person for whom depressed patients live as the dominant other. In most cases the dominant other is the spouse or a parent, but Arieti also noted that sometimes a principle, an ideal, or an organization serves a similar psychodynamic function. In such cases he referred to the entity as the dominant ideology or the dominant goal.

Depression often sets in when patients realize that the person for whom they have been living is never going to respond in a manner that will meet their expectations. The goal of their lives is regarded as unattainable, and a profound feeling of helplessness sets in. In Arieti's conceptualization of depression, he stressed a marked rigidity in the thinking of depressed persons, so that any alternative to living for the dominant other or the dominant ideology is viewed as unacceptable and even unthinkable. Depressed patients feel locked into an inflexible perspective on how they should live their lives and how gratification or fulfillment can be obtained. Even though they are depressed because living for someone or something other than themselves has been a failure, they nevertheless feel paralyzed and unable to shift their approach to life. If the dominant other will not respond to them in the way they have longed for, they feel that life is worthless, and that rigidity is often involved in a decision that suicide is the only alternative.

A 19-year-old college student consulted a psychiatrist after one semester in school. He told the psychiatrist that he was depressed and discouraged with college and with himself. College was not what he had expected, and he had not performed up to his expectations. He was seriously questioning whether he should return for the second semester, and he had a sense of hopelessness about changing his feelings. Suicidal thoughts had occasionally crossed his mind, although he was not planning to act on them. His sleep was disturbed by awakening in the middle of the night and ruminating about what he should do. He felt a significant diminution in his energy level, and he commented that things he used to find enjoyable no longer gave him pleasure.

The patient attended a prestigious college on the West Coast, but he indicated that he had actually wanted to get into Harvard. His application to Harvard had resulted in his being placed on the waiting list, but he had not been accepted. The psychiatrist he consulted commented that the college he had chosen to attend was certainly highly regarded. The patient responded, “It's not Harvard.” When the psychiatrist asked the patient how he had done academically during the first semester, the patient appeared embarrassed and replied, “I only got a 3.25 grade-point average—one A and three Bs.” The psychiatrist asked him why he seemed embarrassed to reveal such a solid academic record. The patient explained that he had wanted to make the dean's list but that he had fallen short of it, since the list required a 3.5 grade-point average.

The psychiatrist asked the patient if he hoped to be in a different situation after one semester of college. The patient's answer revealed that he had an extraordinarily high internal expectation of himself. He had wanted to be “a star,” a straight-A student at Harvard. He explained that his father had gone to Harvard, and he hoped that, by being a standout there, he would finally achieve the praise and recognition from his father that he had always longed for but had never received. His father seemed disappointed that his son had not been accepted at Harvard, and the patient was convinced that his father was ashamed of him for not making the dean's list.

The above case example illustrates the psychodynamic theories of both Arieti and Bibring. The patient was living his life for a dominant other—his father. He tried to perform beyond his abilities to extract an approving and loving response from his father that was never forthcoming. That longed-for response was rigidly construed as the only thing that mattered in life. Even though he was succeeding at a highly competitive college, his success did not make him feel good about himself. Moreover, the patient's depression can also be linked to his awareness of the disparity between his idealized expectations of himself and the reality of his situation, as described by Bibring. Being a straight-A student at Harvard was his aspiration; the reality was that he was a B + student at a college that did not measure up to Harvard.

The vignette also reflects two other key elements in the psychodynamic etiology of depression. First, in accord with the psychoanalytic notion of multiple causation,

more than one psychodynamic theory may be pertinent in understanding an individual patient's depression. Clearly, both the dominant other and the tension between ideals and realities were significant determinants in causing the patient's depression. Second, the precipitating factors that produce depression do not have to be catastrophic events involving obvious external disasters. To a casual observer the college student had no apparent reason to be depressed, since he was performing successfully at a highly regarded college. Nonetheless, the intrapsychic meaning of his academic performance was such that the patient felt hopeless and despairing as a result. In assessing the psychodynamic factors in depression, clinicians must always attend to idiosyncratic personal meanings of events to understand fully the effects they have on the patient. Otherwise, clinicians run the risk of responding in the same unempathic manner that often characterizes the responses of family members. In the absence of objective evidence of any disastrous events in the depressed person's life, loved ones often react by saying: “You have no reason to be depressed. Everything is going so well in your life.”

Selfobject Failure The ego and the superego do not figure in Heinz Kohut's conceptualization of depression. Kohut's theory, known as self psychology, rests on the assumption that the developing self has specific needs that must be met by parents to give the child a positive sense of self-esteem and self-cohesion and that similar responses are required from others throughout the course of the life cycle. He referred to those needs as mirroring, twinship, and idealization. The *mirroring* responses required by the self are equated with the gleam in the mother's eye when the child exhibitionistically shows off for her. Admiration, validation, and affirmation are responses that are included in the category of mirroring. *Twinship* responses refer to the child's need to be like others. A small boy who is outside playing with his toy lawn mower while his father is mowing the lawn is meeting important psychological needs in asserting his commonality with his father. Finally, the need for *idealization* is an important aspect of the development of the self. Children who grow up with parents they can respect and idealize develop healthy standards of conduct and morality.

Kohut referred to those three needs collectively as selfobject needs. In other words, the responses demanded from others are required by the self, and the needs of the object as a separate person are not taken into account. The other person serves as an object who meets the needs of the self. *Selfobject needs* essentially refer to certain functions that persons in the environment provide rather than to those persons themselves. Kohut felt that selfobject responses continue to be needed throughout life and are as necessary for emotional health as oxygen is for physical health. Within that conceptual framework, depression involves the failure of selfobjects in the environment to provide the self of the depressed person with mirroring, twinship, or idealizing responses necessary for the self to feel whole and sustained. The massive loss of self-esteem seen in depression is regarded by Kohut and the self psychologists as a serious disruption of the self-selfobject connection or bond.

Depression as Affect and Compromise Formation Some contemporary ego psychologists believe that depression is not truly a psychiatric disorder or illness. Instead, depression is regarded as an affect reflecting conflict and compromise formation. Charles Brenner, the principal architect of that view, suggested that concern about such childhood calamities as object loss, loss of love, castration, and punishment are associated with two kinds of unpleasure. One form of unpleasure is anxiety, which involves an anticipated calamity or danger. The other form of unpleasure, depressive affect, involves a calamity that has already happened. That theory of depressive affect differs sharply from the classical views of Freud and Abraham. Brenner pointed out that depression is not always related to object loss or to oral wishes. He also asserted that identification with a lost object is found in some depressed persons but not in all and that anger turned inward is a result of depression, rather than a cause. Depressive affect, in Brenner's view, can be linked to any of the childhood calamities, rather than uniquely to object loss. People can experience depressive affect because they feel unloved, because they feel castrated, or because they feel punished in a variety of ways. Depressive affect is a normal and universal part of the human condition.

A critical feature in Brenner's formulation is the idea of compromise formation, in which a symptom is viewed as simultaneously expressing an unconscious wish or drive and a defense against that wish or drive. A particular compromise formation may be more or less successful in eradicating depressive affect in the same manner as it may succeed to varying degrees in dealing with anxiety. A dog phobia, for example, is a symptomatic compromise formation that succeeds in eliminating anxiety as long as dogs are avoided. Similarly, certain forms of compromise formation may eradicate depressive affect while others do not.

The central point of Brenner's psychodynamic theory is that depressive affect is a universal feature in every pathological conflict, whether it is apparent on the surface or buried in the depths of the compromise formation. Depressive affect is a universal factor in all cases of psychiatric illness. From that standpoint, Brenner believed that classifying certain forms of mental illness as depression simply because depressive affect is part of the conscious symptoms does not make sense. The conscious experience of depression provides information about the efficacy and the nature of a patient's defensive maneuvers and compromise formations, in Brenner's view, but it does not reveal much about the underlying causes of the patient's illness.

Early Trauma and Deprivation Several investigators have noted that consistent, loving, nurturant parental involvement appears to have some value in preventing the development of depression. Conversely, separation from parents early in life or the actual loss of a parent may predispose one to depression. Edith Zetzel observed that adverse experiences in the formative years of childhood, particularly those involving separation and loss, make it difficult for children to tolerate depressive affects without resorting to primitive defensive operations. If caretakers fail to assist children in identifying and tolerating painful feelings that result from an adverse life experience, the child will grow up with inadequate coping mechanisms. That impaired adaptation may contribute to the subsequent development of depression.

Empirical research has provided some corroboration for the view that early deprivation is relevant to the cause of depression. René Spitz demonstrated that infants separated from their mothers during the second 6 months of life have overt signs of depression. In some cases the infants in Spitz's studies wasted away and died in response to the separation. Margaret Mahler and her colleagues, who studied the interactions between normal and abnormal mother-infant pairs, found that children's emotional dependence on their parents is instrumental in the development of their capacity to grieve and mourn. That capacity, in turn, influences children's feelings of self-esteem and helplessness. Although the development of depression may involve genetic and constitutional factors, as well as environmental stressors, most theorists agree that the early relationship between child and parent plays a significant role in causing depression.

One elegantly designed study documented an increased risk for major depressive disorder in those women who had experienced maternal or paternal separation in childhood or adolescence. A prospective study from the United Kingdom found that women with a history of childhood abuse or neglect are twice as likely to have negative relationships and low self-esteem in adulthood. Those abused or neglected women who have these negative relationships and low self-esteem in adulthood are then ten times more likely to experience depression. One of the clinical implications of this finding is that exploration of the impact of childhood trauma or neglect may be crucial in the psychodynamic therapy of depressed patients.

These empirical findings suggest a stress-diathesis model for mood disorders. In other words, a genetic substrate might serve to diminish monoamine levels in synapses or to increase reactivity of the hypothalamic-pituitary-adrenal axis to stress. Corticotropin-releasing factor (CRF), which induces the pituitary to secrete ACTH, is consistently elevated in the cerebrospinal fluid of depressed patients when compared with normal controls. When the brains of laboratory animals are given additional CRF, they have exhibited behavior similar to depression in humans. In keeping with the stress-diathesis model, some investigators have postulated that if there is no serious stress on the individual, the genetically determined threshold is not necessarily sufficient to induce depression. However, experiences of neglect or abuse in childhood may activate the stress response and induce elevated activity in CRF-containing neurons, which are known to be stress responsive and to be excessively active in depressed people. These cells can become supersensitive in certain individuals and then react dramatically to even mild stressors.

Premorbid Personality Factors A comprehensive psychodynamic understanding of depression must include premorbid personality factors in the equation. All persons may become depressed, given sufficient environmental stress, but certain personality types or traits appear to dispose one to depression. For example, the harsh, perfectionistic superego characteristic of persons with obsessive-compulsive personality disorder may lead them to feel that they are always falling short of their own excessive expectations of themselves. That intrapsychic constellation may be critical in the development of a major depressive episode. Similarly, Axis II personality disorders involving dependent yearnings for care—such as dependent, histrionic, and borderline personality disorders—may also be more vulnerable to depression. Personality disorders that use projection and other externalizing defense mechanisms, such as antisocial and paranoid personality disorders, are less likely to decompensate into depression. No particular premorbid personality type has been associated with the development of bipolar disorder.

Evidence is accumulating that an Axis II diagnosis of a personality disorder may complicate the course and treatment of depression. Depressed patients with personality disorders generally have poorer outcomes in the area of social functioning than those without personality disorders. Furthermore, residual depressive symptoms are more likely to present in recovering depressed patients with an Axis II diagnosis. Psychoanalytic clinicians have observed that personality factors frequently serve to maintain a depressed state once it has occurred. In clinical practice the complicating factors of a comorbid personality disorder diagnosis are quite common. One study found that 42 percent of persons with major depressive disorder and 51 percent of patients with dysthymic disorder have an accompanying Axis II diagnosis.

In an 18-year follow-up study of 89 depressed patients, the investigators found that the personality measure of neuroticism led to poorer outcomes in patients with melancholia. Similarly, an examination of the National Institute of Mental Health (NIMH) Treatment of Depression Collaborative Research Project data found that patients with personality disorders who were also depressed had poorer outcomes in social functioning and a much greater likelihood of residual depressive

symptoms than those who did not have personality disorders. In a third study 76 depressed outpatients were treated with interpersonal psychotherapy. The only significant predictor of time to remission was the degree of personality pathology. Even though patients with the most-severe personality disorders, borderline and antisocial, were excluded from the study, those who had other Axis II conditions responded more slowly to psychotherapy or not at all.

Characterological Depression Many patients encountered in clinical practice report feelings of depression even though they lack symptoms of a well-defined Axis I disorder, such as major depressive episode. Many of those patients have a primary diagnosis of a personality disorder on Axis II and experience characterological depression, a feeling of pervasive loneliness or emptiness associated with the perception that others are not meeting one's emotional needs. They can be distinguished from patients with an Axis I diagnosis of major depressive episode by the absence of vegetative symptoms (e.g., psychomotor retardation, loss of libido, diminished appetite, lack of energy, and sleep disturbance) and by the presence of certain qualitative features of their complaint of depression. Loneliness, emptiness, and boredom are often chronic complaints in characterological depression but are much less common in Axis I illnesses. In addition, a conscious sense of rage at not having their needs met may be present. The patients often describe childhood experiences in which they felt deprived of appropriate emotional nurturance from their patients. As a result, they continue to seek parental substitutes in adult life.

Characterological depression is differentiated from Axis II personality disorders by the fact that it is an affective state occurring within the context of certain personality disorders, rather than a constellation of traits forming an overarching personality type.

A 29-year-old woman came to psychotherapy complaining that she was “empty” inside and “needed to be filled up” by a positive experience with a psychotherapist. She said that, while she was growing up, her mother never had time for her and that her mother loved her two sisters more than her. The patient had had a series of romantic relationships with men, but she never felt that she was getting the kind of attention and love that she needed from any of them. The men often ended the relationship because they felt that she was too demanding and that they could not possibly meet all her needs. Her last therapist had “given up” on her because he, too, felt that he was unable to be of help to her. The patient also indicated that she had called her previous therapist almost every night because she would begin to feel lonely and need his reassurance that he still cared. She feared that she had turned off her therapist by being too demanding. She also described several angry outbursts directed at him when he would not talk with her for lengthy periods of time on the phone during the evening. She wondered if her outbursts made him hate her.

The patient had taken four different antidepressive medications with no improvement. She did not meet the diagnostic criteria for an Axis I dysthymic disorder or major depressive episode. However, she did have characteristics in keeping with two different Axis II diagnoses dependent personality disorder and borderline personality disorder.

Other Clinical Entities In addition to the existence of characterological depression and the presence of other Axis II diagnoses, another clinical entity gaining increased acceptance is depressive personality disorder. In Appendix B of the fourth edition of *Diagnostic and Statistical Manuel of Mental Disorders* (DSM-IV) the criteria for the disorder emphasize a constellation of personality traits, while the criteria for dysthymia focus on somatic symptoms. These traits include a mood dominated by unhappiness, dejection, and gloominess; a self-concept centered on worthlessness and low self-esteem; a proneness to feel guilt or remorse; a tendency to blame and criticize oneself; a negativistic and judgmental stance toward others; a pessimistic attitude; and a tendency to worry and to brood. Although this diagnostic entity has a long-standing psychoanalytic tradition, there has been controversy regarding whether or not it is truly distinct from dysthymic disorder. Data are emerging suggesting that the distinction between the two is valid and clinically useful. In a study of 54 patients with early onset long-standing mild depressive features, Katherine Phillips and her collaborators identified 30 subjects with and 24 without depressive personality disorder. Sixty-three percent of the subjects with depressive personality disorder did not have dysthymic disorder, while 60 percent did not have current major depressive disorder. The depressive personality disorder patients were more likely than the comparison group to have another personality disorder, but 40 percent of them had no such disorder. Those who were comorbid for another personality disorder tended to have anxious or Cluster C personality disorder, suggesting that defenses and conflicts at a neurotic level were most prominent, in keeping with the psychoanalytic conceptualization of depressive personality disorder. Finally, the duration of psychotherapy was significantly longer for subjects who had depressive personality disorder when compared to those who did not. Antidepressant drugs may be combined with psychotherapy in the treatment of characterological depression.

Clinicians must remember that depression spans the entire spectrum of pathology and health. In addition to being a discrete psychiatric disorder, depression refers to an emotional state that can occur in normal persons at certain times as well as in persons with characterological or psychotic conditions. Moreover, simply because the patient does not have sufficient symptoms to be given an Axis I diagnosis of a mood disorder does not mean that the depression is benign. In one study, employees with minor forms of depression that did not meet Axis I criteria had 51 percent more disability days than did persons with a diagnosis of major depressive episode.

PSYCHODYNAMIC PSYCHOTHERAPY

Although brief psychodynamic psychotherapy has been shown in meta-analyses to be no better or worse than other forms of psychotherapy, there are few controlled trials of the modality with depressed patients. Even more problematic is the fact that few of the trials that exist have been carried out by advocates of the technique who actively practice it. In most studies brief dynamic therapy was used on a comparison or control group to contrast with the different psychotherapies that the investigators favored. Most studies testing brief dynamic therapy were also done in a group format, even though individual therapy is much more widely practiced by psychodynamic clinicians. A number of the trials involving brief dynamic therapy, in which the investigators favored other therapies, found it significantly less effective than the other interventions.

More recently, well-designed studies show promising results from brief dynamic therapy. In an investigation of depressed caregivers of elderly family members, random assignment was made to one of two treatment cells: brief psychodynamic therapy or cognitive-behavioral therapy. After 20 sessions, 71 percent of the caregivers were no longer clinically depressed. Overall, no differences were found between the two treatment groups. Symptom-oriented measures suggested that those who had been caregivers for more than 3.5 years improved more with cognitive-behavioral therapy, whereas those who had been caregivers for shorter periods showed more improvement from brief psychodynamic therapy.

In the British study known as the second Sheffield Psychotherapy Project, similar findings were obtained in a randomized, controlled trial. Some 120 depressed patients were assigned to either 8 or 16 sessions of cognitive-behavioral therapy or psychodynamic-interpersonal therapy. Both treatments were found equally effective, and their effects equally rapid. Patients with only mild or moderate depression had the same outcome whether they were treated with 8 or 16 weeks of therapy. However, significantly better outcomes were noted in the severely depressed group when 16 weeks of therapy were provided, whether cognitive-behavioral or psychodynamic-interpersonal. At 1-year follow-up no overall differences were found in outcome or maintenance of gains between those receiving the two types of therapy. However, longer periods of therapy appeared to be associated with better long-term outcomes, particularly in the case of psychodynamic-interpersonal therapy.

Systematic controlled studies using randomized assignment are not available for extended psychodynamic psychotherapy and psychoanalysis. Most therapists would agree that these modalities are not indicated as exclusive treatment for patients in the acute phase of major depressive disorder. However, a subgroup of patients who do not respond to medication or brief psychotherapy may benefit from more-extended psychodynamic exploration. Sidney Blatt and his associates reanalyzed the data from the NIMH Treatment of Depression Collaborative Research Project and found that highly perfectionistic and self-critical patients did not respond well to any of the treatment cells, which included 16 weeks of cognitive therapy, 16 weeks of interpersonal therapy, 16 weeks of imipramine (Tofranil) plus clinical management, and 16 weeks of placebo plus clinical management. In two other naturalistic follow-along studies of extended psychotherapy on such patients, self-critical and perfectionistic traits appeared to respond well to intensive psychoanalytic psychotherapy. Hence a subgroup of depressed patients may be particularly well suited to more-extended psychoanalytic therapy. Depressed patients with significant Axis II pathology may also respond poorly to brief therapies or medication and require intensive psychotherapy over a long time. However, no data from controlled trials are available to confirm this clinical impression.

In any depressed patient, certain psychodynamic principles may be useful, no matter which treatment modality is selected. For example, the American Psychiatric Association practice guidelines for depression suggest that psychotherapeutic management should be part of every treatment for depression. Psychodynamic concepts such as therapeutic alliance, transference, resistance, and countertransference apply to all patients, regardless of the type of treatment. The role of the therapeutic alliance may be particularly important in terms of outcome in both psychotherapy and pharmacotherapy. A team of investigators led by Janice Krupnick looked at 225 cases of depressed patients in the NIMH Treatment of Depression Collaborative Research Program. Clinical raters scored videotapes made of the treatments in all four cells. When outcomes were assessed on these cases, the therapeutic alliance was found to significantly affect clinical outcomes of both psychotherapies, placebo treatment, and the imipramine group. In fact, the patient contribution to the therapeutic alliance accounted for 21 percent of the outcome variance on standardized outcome measures, with more of the variance in outcome attributed to alliance than to the treatment method itself. Among the four cells,

none showed significant group differences in terms of the relationship between therapeutic alliance and outcome. Hence attention to the psychotherapeutic relationship is of central importance in all treatment of depression.

Sydney Blatt has suggested that the psychodynamic psychotherapeutic approach must be tailored to the underlying type of depression. His research has delineated two distinct categories of depressed patients: anaclitic and introjective. *Anaclitic depression* is characterized by feelings of helplessness, loneliness, and weakness related to chronic fears of being abandoned and unprotected. These individuals have longings to be nurtured, protected, and loved. They have a vulnerability to having interpersonal relationships disrupted. These types of patients require a therapy that emphasizes the therapeutic relationship rather than interpretation or insight.

By contrast, *introjective depression* is characterized by feelings of unworthiness, failure, guilt, and inferiority. These individuals are also highly self-critical and suffer from a chronic fear of criticism and disapproval from others. They are highly perfectionistic and competitive and are often driven to achieve in work and school. They have a characteristic vulnerability to disruptions of a positive and effective sense of self, and their depression is manifested primarily by dysphoric feelings of guilt, worthlessness, failure, and by a sense that one's autonomy and control have been lost. Interpretive interventions that provide insight seem to be more helpful with this category of depressed patients.

MANIA

Almost all researchers who have studied bipolar disorders have concluded that psychosocial interventions may be crucial in concert with pharmacotherapy for the prevention of relapse. Relapse rates as high as 60 percent over a period of 2 years have been reported, even when maintenance therapy on lithium carbonate (Eskalith) has achieved adequate plasma concentrations. Work status deteriorates in about two-thirds of patients, while social function deteriorates in one-half of patients. In addition, there is a 45 percent separation or divorce rate, compared with 18 percent in controls. In fact, the average 25-year-old female patient can expect to lose nearly 9 years of life, 14 years of effective major activity (work or school), and 12 years of normal health.

A psychodynamic understanding can be extraordinarily helpful in identifying the nature of stressors likely to precipitate episodes. In one 2-year study of 61 outpatients, patients with the highest levels of stress had a 4.53 times greater risk of relapse than patients without stress. In a 10-year follow-up study, two different groups of treatment failures were identified in a cohort of patients with bipolar disorder. One group of patients relapsed because the treating psychiatrist had failed to increase the lithium dosage in response to increased physiological activation before the onset of a manic episode. In the other group of treatment failures, psychological issues that were clearly involved in precipitating manic episodes had not been given appropriate attention by the responsible psychiatrists, and manic episodes had resulted from the stress of those psychosocial factors.

In one study investigators examined both individual differences in stress reactivity and psychological characteristics of a group of 58 patients with bipolar disorders followed for at least 1 year. The stress level predicted relapse, but personality variables, particularly introversion and obsessionality, were also significant predictors. Hence a psychodynamic perspective on the bipolar disorder patient may help both in identifying psychological and environmental stressors and in dealing with characterological issues that may complicate the treatment. There is an increasing recognition that with refined diagnostic methods, a high degree of comorbidity may exist between bipolar disorders and Axis II disorders. In a study of 66 outpatients with a Research Diagnostic Criteria diagnosis of hypomania and a lifetime diagnosis of bipolar disorder, each patient was interviewed during the hypomanic episode and after recovery. Knowledgeable informants were also interviewed at both times. The researchers found that hypomania was associated with higher levels of maladaptive personality traits than the euthymic state, but even when euthymic, 50 percent of the cohort had at least one personality disorder. They also found that the alleged decrease in maladaptive personality traits following recovery was much greater in the reports by patients than in those by informants.

Some of these characterological features of the personality disorder may contribute to compliance problems with medications designed to stabilize mood. They also may alienate family members who then become more critical and more distant, producing an increased risk of relapse. Often these character traits may require individual dynamic psychotherapy in which they can be addressed in the transference-countertransference dimensions of the treatment.

Even in bipolar disorder patients without a personality disorder, compliance is a major problem. At least half of bipolar disorder patients stop taking medication at least once in the course of their illness. Frederick Goodwin and Kay Jamison found that the most important reasons for noncompliance listed by patients were dislike of having medication control their moods, dislike of the idea of having a chronic illness, aversion to feeling depressed, and dislike of adverse effects. The combination of medication and individual psychotherapy is required for comprehensive treatment and optimal compliance.

Patients with bipolar disorder have been studied from the perspective of ongoing psychoanalysis and psychoanalytic psychotherapy, and those clinical investigations have revealed specific psychodynamic factors at work in the onset of manic episodes. In one series of patients, unconscious sexual urges and fantasies seemed to overpower ego defense mechanisms, leading to a clinical picture of hypersexuality and other symptoms of mania. Increasing the lithium dosage decreased the sexual behavior and reinstituted the ego defense mechanisms present before the manic episode. In the course of continued psychotherapeutic or psychoanalytic treatment, the patients became consciously aware of their unconscious sexual desires and of the defenses elicited to deal with those desires. This conscious awareness enabled the patients to identify early warning signals of increased sexual impulses, so that future manic episodes could be avoided by increasing their lithium dosage.

These studies reflect how a psychodynamic understanding of patients with bipolar disorder may be crucial to the effective treatment of the disorder. Most manic patients cannot make use of psychotherapy interventions in the midst of a full-blown manic episode because the essence of mania is a denial of psychological problems. However, after the patient has become euthymic as a result of pharmacological stabilization, psychotherapeutic interventions may have value both in preventing subsequent episodes and in dealing with the feelings of shame and guilt associated with embarrassing behavior that took place during the manic episode.

Psychodynamic Theories of Mania The psychodynamic understanding of mania is usefully applied to clinical instances of hypomania because the differences between the two entities are quantitative, rather than qualitative. Just as mania and depression have been linked from a neurophysiological standpoint, they are similarly connected from a psychodynamic perspective.

Karl Abraham Most theories of mania view manic episodes as defensive against underlying depression. Abraham, for example, believed that manic episodes may reflect an inability to tolerate childhood depression in reaction to a developmental tragedy, such as the loss of a parent. The manic state, in Abraham's view, is understood as a way of removing the shackles of a tyrannical superego by merging the ego and the superego. Self-criticism is then replaced by euphoric self-satisfaction.

Bertram Lewin Lewin regarded the hypomanic patient's ego as a purified pleasure ego. The defense mechanism of denial is appropriated by the ego to disregard unpleasant perceptions and affects as well as distressing psychic realities that may result in self-punishment or self-criticism.

Melanie Klein Klein also viewed mania and hypomania as defensive reactions to depression, but she linked the mechanism to the depressive position, rather than to an overriding of the superego. The essence of the depressive position is intense anxiety that one's own aggression has resulted in the destruction of important love objects, such as parents. In Klein's own words, “Persecution (by ‘bad' objects) and the characteristic defenses against it, on the one hand, and pining for the loved (‘good') object, on the other, constitute the depressive position.” She thought that manic defenses are necessary both to control and to master the dangerous bad objects and to restore and to save the loved good objects.

Manic defenses include omnipotence, denial, idealization, and contempt. Omnipotence serves to deny the need for good objects, to delude oneself into feelings of self-containment and grandiosity, and to help one feel insulated and protected from assault by internal persecutors. Idealization and denial work together so that idealization of self and others serves to deny any destructiveness or aggression in relationships. The euphoric disposition of the manic or hypomanic patient reflects the tendency to gloss over any unpleasant aspects of reality and to treat everything with a sense of humor and a striking disregard for the tragic dimensions of reality, even if the situation is tragic. Idealization, however, may rapidly give way to contempt, which is also linked to denial because it is a way of disregarding the importance of love objects and, therefore, denying the concern that damage has been done to them and reparation is needed. Moreover, the manic patient can then minimize any distressing feelings of sorrow or regret that may arise in connection with concerns about having destroyed love objects.

Klein also observed that a wish to triumph over parents is often an integral part of the manic defensive posture. She noted that a frequent childhood fantasy is to reverse the child-parent relationship and that the fantasy produces feelings of guilt and anxieties of a depressive nature related to the wish to destroy and replace the parents. Feelings of depression may develop after a job promotion or other professional success because the person's unconscious wish to triumph over and to

surpass one's parents has been fulfilled.

The kleinian conceptualization of mania as defensive against feelings of depression is useful in understanding the phenomenon of dysphoria in manic patients when depression breaks through a manic episode, requiring a resurgence of manic denial. This formulation is also useful in understanding the commonly observed phenomenon of elation after the death of a loved one.

> A patient received a phone call that informed him of his mother's death. Rather than feeling grief-stricken or shocked, be noted a sense of expansiveness and power. As he discussed the odd reaction with his psychotherapist, he was able to recognize that the high feeling he experienced was related to a sense that he was finally liberated from feelings of slavish dependence on a tyrannical mother.

Other Theories Other views of mania include Bibring's conceptualization that manic elation is essentially a compensatory reaction secondary to severe depression or an unconscious fulfillment of a person's narcissistic aspirations to be loved, worthy, superior, and virtually flawless. Jacobson understood mania as a transformation of the sadistic superego figure from a punitive tormentor into a loving and forgiving object who is thoroughly idealized. This dramatically altered superego is then projected into persons in the outside world with whom the manic patient establishes idealized relationships that are free from any negative characteristics, such as hatred and anger.

OTHER PSYCHOLOGICAL THEORIES

Adolf Meyer Meyer viewed depression as a person's reaction to a distressing life experience, such as a financial setback, the loss of a job, the death of a loved one, or a serious physical illness. He believed that depression must always be understood in the context of the patient's life history, as an event with psychic causality.

Karen Horney Horney believed that children raised by rejecting and unloving parents are prone to feelings of insecurity and loneliness. In her view, children need to be loved but fear criticism and rejection, which make them susceptible to feelings of depression and helplessness.

Sandor Rado Rado linked depression to a profound feeling of helplessness. He believed that anhedonia, the inability to experience pleasure, is a central phenomenon in depression that develops when persons are not aware of their capacities or cannot provide feelings of emotional self-gratification. Rado connected severe depression with a punitive superego that punishes the patient for unconscious hostility toward a deceased loved one.

John Bowlby Bowlby saw depression from an ethological perspective that emphasized disturbances of the mother-infant attachment bond. He believed that separation of infants from mothers (or other caregivers) early in life leads to feelings of depression and hopelessness that may in some cases continue throughout the life cycle.

Harry Stack Sullivan Although Sullivan concentrated his efforts more on schizophrenia than on mood disorders, his interpersonal perspective applies to both. He thought that adverse interactions between persons and their psychosocial environments were critical to the development of depression.

Cognitive-Behavioral Theory According to the theory developed by Aaron Beck, depression results from specific cognitive distortions present in persons prone to depression. Those distortions, referred to as *depressogenic schemata*, are cognitive templates that perceive both internal and external data in ways that are altered by early experiences. These schemata are associated with four systematic errors in logic: overgeneralization, magnification of negative events with a simultaneous minimization of positive events, arbitrary inference, and selective abstraction.

Learned Helplessness The learned helplessness theory of depression connects depressive phenomena to the experience of uncontrollable events. For example, when dogs in a laboratory were exposed to electrical shocks from which they could not escape, they showed behaviors that differentiated them from dogs who had not been exposed to such uncontrollable events. After exposure to the shocks, they would not cross a barrier to stop the flow of electric shock when put in a new learning situation. According to the learned helplessness theory, the dogs learned that outcomes were independent of responses, so they had both cognitive motivational deficit (i.e., they would not attempt to escape the shock) and emotional deficit (indicating a decreased reactivity to the shock). In the reformulated view of learned helplessness as applied to human depression, internal causal explanations are thought to produce a loss of self-esteem after adverse external events. Behaviorists who subscribe to the theory stress that improvement of depression is contingent on the patient's learning a sense of control and mastery of the environment.

Psychodynamic Treatment Clinicians who combine pharmacotherapy with a mood stabilizer and individual dynamic therapy focus to a large extent on preventing relapse through greater medication compliance, through detailed understanding of problematic stressors, and through careful examination of relationship difficulties, some of which may relate to Axis II psychopathology. Several major psychodynamic themes are often present in bipolar patients, all of which may be relevant at one time or another in the ongoing treatment of the condition. Denial of illness is one of the major defensive postures encountered with these patients. Many argue that their manic or hypomanic symptoms are not part of an illness but rather a reflection of who they really are. Hence when their collaboration is enlisted in a medication regimen or other component of the treatment plan, they frequently deny having a problem that requires treatment. Patients with bipolar illness are notoriously lacking in insight. In one study of 28 manic patients treated on an inpatient unit, insight was measured at admission and discharge. Even when all other symptoms of mania had improved or remitted, insight remained notably absent. The investigators concluded that poor insight is a prominent characteristic of a bipolar disorder regardless of illness phase.

Often related to denial is another psychodynamic theme—splitting or psychic discontinuity. Many bipolar I disorder patients continue to deny the significance of their prior manic episodes when they are euthymic. They may claim that the behavior was simply a result of being exhausted and not taking care of themselves. They also assert that nothing like that will ever happen again. This involves a form of splitting the self-representation so that the self involved in a manic episode is considered entirely disconnected from the self in the euthymic phase. The discontinuity between the different versions of the self may be regarded with bland denial or indifference.

> A 35-year-old dentist was admitted to an inpatient unit with pressured speech, flight of ideas, and extreme hyperactivity. He had been engaging in extensive sexual activity in the days preceding the admission, and he had been spending all of his savings on a variety of outlandish investment schemes. When he finally arrived on the hospital unit, he was singing and dancing around the lounge area to such an extent that he had to be placed in the seclusion room to try to settle him down long enough to conduct a psychiatric interview. The female psychiatric resident who was on call entered the seclusion room with her attending psychiatrist. The patient abruptly stopped his singing and said, “I have a plan.” He then pointed to the female resident and said, “I'll screw her, and you watch.” The patient was told that his plan was not tenable and that he needed to take medication. With considerable coaxing, he finally agreed to take lithium and an antipsychotic agent.
>
> Seven days later his manic episode had subsided. He was calm, polite, and generally socially appropriate. A teaching conference for residents was held in which the patient was interviewed. The attending psychiatrist asked him about his reasons for hospitalization and the nature of his problems. He went on at some length about how he was experiencing “burnout” on his job because people were always telling dentists their problems. He continued to say that he had gotten rather tired and found his job less than fulfilling. He also said that his marriage was troubled because of his long work hours. The impression he created was that of a hardworking professional who was suffering mild stress as a result of occupational difficulties. At no time did he mention anything to the group of residents attending the conference that reflected his bizarre behavior associated with his recent manic episode.
>
> The attending psychiatrist interviewing the patient finally interrupted him and said that he wondered why he was not bringing up any of the behaviors that had brought him into the hospital 7 nights ago, such as singing and dancing, spending vast sums of money on unwise investments, staying up all night, and engaging in extensive sexual activity. The patient stared at the interviewer blandly and said, “Oh, that? Well, that's not a problem now.”
>
> This vignette clearly illustrates how the manic self and the euthymic self are maintained in separate compartments so that no continuity of the self is apparent.

This form of compartmentalization is a major contributor to compliance difficulties. If patients can maintain this kind of discontinuity, they can deny the need for medication or even vulnerability to a subsequent episode. The clinician needs to assemble the self-fragments into a continuous narrative of the patient's life so that maintenance treatment becomes more compelling. Tape recording manic episodes (with the patients' permission) and then playing the recordings back to patients

when they are in a euthymic state may be a useful technique.

Another reason for this form of splitting is a wish to avoid the work of mourning and grief that becomes necessary when the manic self and the euthymic self are connected. There may be mourning of the healthy premorbid self, which seems to be forever gone. Also, following a manic episode, patients may become acutely aware of their own destructiveness and feel intense remorse about the harm they have caused others during the manic phase. Splitting it off and denying its significance spares them the pain of this awareness. If the therapist can gently confront them with this defensive maneuver, they can then acknowledge the harm they have done and attempt to make reparation.

Another relevant psychodynamic theme is ego-syntonic attachment to hypomania. Many patients insist that they are more creative, more full of life, and more engaging when they are in a hypomanic or manic episode. They do not want to comply with their mood-stabilizer medication because they feel it interferes with their creativity and their enjoyment of life. Helping them to see that their behaviors clearly had a negative impact on others may help them deal with the attachment and make it more ego dystonic.

Lithium or other mood stabilizers may take on special meanings to bipolar patients. These agents may come to represent something that is taken away from them. If they comply, they have to resign themselves to no longer experiencing the euphoria of their manic periods, and their denial of their illness is challenged. Maintenance medication may have the meaning of having a severe mental illness that requires lifelong treatment. Integrating this notion into their sense of self also requires the work of mourning. Clinicians must always keep in mind that there is a psychological function of mania that runs in parallel with the biological alteration of the brain—namely, manic denial serves to defend against depression and loss. Medication may also have the meaning of identification with specific family members who have had bipolar illness. To take the medication may unconsciously mean that the course of their illness will be the same as their relative's.

The cornerstone of the psychotherapeutic strategy with bipolar disorder patients is to build a therapeutic alliance. Arguing with the patient about whether or not a bipolar disorder is a correct diagnosis is of little value. Psychotherapeutic exploration, empathy, and education are generally more effective. Creation of a mood chart that helps the patient track highs and lows may also be helpful. Transference tends to shift from idealization to devaluation, often in parallel with shifts in mood. The therapist must also be wary of countertransference acting out in response to anger and frustration with the patient's refusal to cooperate with the treatment plan.

Most clinicians now treating bipolar disorders consider the combination of psychotherapy and pharmacotherapy essential.

Jamison, who wrote a vivid personal account of her struggles with bipolar illness, described it as follows:

Ineffably, psychotherapy heals. It makes some sense of the confusion, reins in the terrifying thoughts and feelings, returns some control and hope and possibility of learning from it all.... No pill can help me deal with the problem of not wanting to take pills; likewise, no amount of psychotherapy alone can prevent my manias and depressions. I need both.

CHAPTER 14. MOOD DISORDERS

14.6 MOOD DISORDERS: CLINICAL FEATURES

HAGOP S. AKISKAL, M.D.

HETEROGENEITY OF MOOD DISORDERS

Terminology Mood disorders are characterized by pervasive dysregulation of mood and psychomotor activity and by related biorhythmic and cognitive disturbances. The rubric of “affective disorder,” which in some European classifications also subsumes morbid anxiety states, is increasingly being replaced by the nosologically more delimited concept of “mood disorder.” Thus *mood disorder* is now the preferred term in both the World Health Organization's (WHO's) 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) and the American Psychiatric Association's (APA's) fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). Official mood disorder categories in current use include bipolar disorders (with manic or hypomanic, depressive, or mixed episodes) and major depressive disorders and their respective attenuated variants known as cyclothymic and dysthymic disorders. Conditions that in earlier editions of these manuals were categorized as “endogenous depression,” “involutional melancholia,” and “psychotic depressive reaction” have been incorporated into major depressive disorder, whereas “depressive neurosis” has been largely absorbed by dysthymic disorder. Although the neurotic-endogenous distinction has been officially deleted, the term “melancholic features” is now used to qualify major depressive disorders in which biological concomitants predominate. While both the American and international classifications recognize the common occurrence of mixed anxiety-depressions, whether they should be classified with mood disorders or with anxiety disorders remains unresolved. It is equally uncertain how to classify the classic neurasthenic conditions, which have recently reemerged and overlap to some extent with the so-called chronic fatigue syndrome.

Destigmatization The reshuffling and reclassification of various affective conditions into the mood disorders chapter of the third edition of DSM (DSM-III) and DSM-IV has, on balance, considerably broadened their boundaries. This change reflects, in part, new developments in pharmacotherapy that have resulted in considerable alleviation of suffering for persons whose illnesses fall short of and sometimes beyond the boundaries of classic mood disorders. As a result, many persons with recurrent mood disorders who would have been disabled can now lead productive lives. Such gratifying results have, in turn, helped to destigmatize this group of disorders. Destigmatization has been further facilitated by published self-revelations of famous persons with depressive and bipolar disorders.

Spectrum of Mood Disorders As often happens when new therapeutic interventions prove successful, the past two decades have witnessed an increased readiness to diagnose mood disorders and their variants. These developments should not be dismissed as mere therapeutic fad, however. External validating strategies, such as familial-genetic studies and prospective follow-up, can now be used to buttress the broadened concept of mood disorders. New research comparing monozygotic and dizygotic twins has demonstrated that the genetic propensity to mood disorders embraces entities that extend beyond endogenous depression (melancholia in DSM-IV) to subsume a larger variety of depressions, including some encountered in persons in the community who have never received psychiatric treatment. Although such data might seem counterintuitive to those who would restrict depression to a core primary biological disease, they suggest that the constitutional predisposition for affective dysregulation occurs in as many as one of every three persons. That ratio is similar to the proportion of those who progress to a full depressive syndrome following bereavement, of rhesus monkeys developing depressive-like behavior following a separation paradigm, and of dogs who develop learned helplessness after inescapable shock. The fact that these rates are considerably higher than one observes in clinical populations suggests that many subjects possess protective factors against major depressive episodes; alternatively, the data suggest that other factors determine which person with emotional distress will become a clinical case. A great deal might therefore be revealed about the nature of pathological affective processes through study of self-limiting affective conditions on the border of mood disorders.

The suffering and dysfunction resulting from mood disorders are among the most common reasons for consulting psychiatrists and other physicians. In fully developed cases, all activity stops—including creative powers—and life is grim and in total disarray (as portrayed in Dürer's masterpiece, Fig. 14.6-1).

FIGURE 14.6-1 *Melancholia* (1514) by Albrecht Dürer.

All great physicians of the past, beginning with Hippocrates, have devoted considerable space in their general medical texts to the clinical characterization of melancholic and manic states, as well as alternations in the same patient. Greco-Roman medicine recognized a broad spectrum of affective disturbances, ranging from the relatively mild temperamental variants (represented in the official nosology by dysthymic and cyclothymic disorders) to their severest forms (including what today is considered mood disorder with mood-congruent and mood-incongruent psychotic features). The ancients also recognized the intimate relation of morbid states of fear to melancholia. Furthermore, they noted that melancholia and certain physical diseases shared seasonal incidence and described the common occurrence of alcohol indulgence, especially in those prone to mania.

Boundaries The boundaries between temperament (personality) and mood disorder, grief and melancholia, anxiety and depressive states, depressive and bipolar disorders, mood-congruent and mood-incongruent psychotic features, and other (schizophrenic) psychotic conditions remain unresolved. Mood disorders have long been known to be highly comorbid with alcohol use and somatic disease; these trends continue today, with the addition of substance use disorders.

AFFECTS, MOODS, TEMPERAMENTS, AND MORBID MOOD STATES

Ethological Considerations *Affects* and *moods* refer to different aspects of emotion. Affect is communicated through facial expression, vocal inflection, gestures, and posture and (according to current ethological research) is intended to move human beings and other primates to appraise whether a person is satisfied, distressed, disgusted, or in danger. Thus joy, sadness, anger, and fear are basic affects that serve a communicative function in primates as well as many other mammalian species.

Affects tend to be short-lived expressions, reflecting momentary emotional contingencies. Moods convey sustained emotions; their more-enduring nature means that

they are experienced long enough to be felt inwardly. Moods are also manifested in subtle ways, and their accurate assessment often requires empathic understanding by the interviewer. The words that subjects use to describe their inner emotions may or may not coincide with the technical terms used by researchers or clinicians and often vary from one culture to another. Furthermore, the inward emotion and the prevailing affective tone may be discordant. This conflict could be due to deliberate simulation (i.e., the subject does not wish to reveal his or her inner emotion) or it could result from a pathological lesion or process that has altered the emotions and their neural substrates. Thus, evaluating moods and affective expression requires considerable clinical experience.

Sadness and Joy The normal emotions of sadness and joy are part of everyday life and should be differentiated from major depressive disorder and mania. Sadness, or normal depression, is a universal human response to defeat, disappointment, or other adversities. The response may be adaptive, in an evolutionary sense, by permitting withdrawal to conserve inner resources, or it might signal the need for support from significant others. Transient depressive periods also occur as reactions to certain holidays or anniversaries, as well as during the premenstrual phase and the first week postpartum. Termed, respectively, “holiday blues,” “anniversary reactions,” “premenstrual tension disorder” and “maternity blues,” they are not psychopathological per se, but those predisposed to mood disorder may develop clinical depression during such times.

Premenstrual Dysphoric Mood Changes In view of the higher prevalence of depressive disorders in women, premenstrual affective changes—dysphoria, tension, irritability, hostility, and labile mood—have received both clinical and research attention. The attempt to establish a specific premenstrual dysphoric disorder has neglected the not uncommon occurrence of premenstrual eutonia, increased energy, and sexual drive. The not uncommon occurrence of these positive emotions, along with the labile mixed affective manifestations, tend to point toward a “bipolar” phenomenon. Although women with severe premenstrual complaints appear to have higher rates of lifetime major mood disorders, a recent twin study found that genetic and environmental factors contributing to premenstrual depression and major depressive disorders are largely distinct. Furthermore, events such as migraine, epileptic attacks, and panic states may, in some instances, be associated with the premenstrual phase. The foregoing considerations suggest the hypothesis that premenstrual psychobiological changes exacerbate different neuropsychiatric disorders to which women are otherwise predisposed. Whether the exaggerated premenstrual variability in emotional equilibrium constitutes a variant of mood disorder must await more definitive studies.

Grief Normal bereavement or grief, considered the prototype of reactive depression, occurs in response to significant separations and losses such as death, divorce, romantic disappointment, leaving familiar environments, forced emigration, or civilian catastrophes. DSM-IV tends to limit the concept of normal grief to loss due to death. However, the work of Elie Karam and colleagues showed that losses associated with the civil war in Lebanon served as potent forces in depression formation. In addition to depressed affect appropriate to the loss, bereavement reactions are characterized by the prominence of sympathetic arousal and restlessness, believed to represent (from an evolutionary perspective) physiological and behavioral mechanisms to facilitate the search for the lost object. Like other adversities, bereavement and loss do not generally seem to cause depressive disorder, except in those predisposed to mood disorder.

Elation The positive emotion of elation is popularly linked to success and achievement. However, paradoxical depressions may also follow such positive events, possibly because of the increased responsibilities that often have to be faced alone. Elation is conceptualized psychodynamically as a defense against depression or as a denial of the pain of loss, as exemplified by the so-called maniacal grief, a rare form of bereavement reaction in which elated hyperactivity may replace the expected grief.

Other pseudomanic states include the brief energetic and unusually lucid periods encountered in dying patients or in those who need to take superhuman action in the face of unusual duress, both of which have been conceptualized as “flight into health.” In predisposed persons such reactions might be the prelude to a genuine manic episode. Sleep deprivation, which commonly accompanies major stressors, might represent one of the intermediary mechanisms between stressor and adverse clinical outcome.

Affective Temperaments Another mediating factor between normal and pathological moods is temperament. Most persons have a characteristic pattern of basal affective oscillations that defines their temperament. For instance, some are easily moved to tears by sad or happy circumstances, whereas others tend to remain placid. Normally oscillations in affective tone are relatively minor, tend to resonate with day-to-day events, and do not interfere with functioning. Some exhibit greater variability of emotional responses whereby, with no obvious provocation, the person alternates between normal mood and sadness or elation, or both. Temperaments tend to cluster into basic types, four of which are of the greatest relevance to mood disorders. The depressive temperament, in which the person easily swings into the sad direction, occurs in 3 to 6 percent of the general population; the hyperthymic temperament, in which the person is naturally inclined toward cheerful moods has been reported in 4 to 8 percent and the cyclothymic temperament swinging between cheerful and sad moods characterizes 4 to 6 percent of young adults. All three types have an early insidious onset and tend to persist throughout adult life. An irritable-explosive type occurs in 2 to 3 percent of young subjects and tends to attenuate by middle age.

An examination of the traits associated with these temperaments can provide the rationale for Ernst Kretschmer's hypothesis about the social functions they served. Thus, the person with a depressive temperament is hard working, dependable, and suitable for jobs that require long periods of devotion to meticulous detail (Table 14.6-1). Such persons shoulder the burdens of existence without experiencing its pleasures. A person with the hyperthymic temperament, endowed with high levels of energy, extroversion, and humor (Table 14.6-1), will assume leadership positions in society or excel in the performing arts or entertainment. In talented persons the cyclothymic temperament, which alternates between sadness and elation, could provide the inspiration and the intensity needed for composing music, painting, or writing poetry. One with the irritable temperament, probably a variant of the cyclothymic type, might be best suited for a military career or even revolutionary action. The danger with such temperaments is that they could swing too far in one or the other direction, or in both directions (i.e., major depressive, manic, or mixed episodes). Use of such substances as alcohol, caffeine, and other stimulants might further destabilize affective regulation in persons with those attributes. Some adolescent girls with the irritable temperament might develop the extreme emotional disequilibrium that in contemporary psychiatry is considered borderline personality disorder.

Depressive	Hyperthymic
Gloomy, incapable of fun, complaining	Cheerful and exuberant
Humorless	Articulate and jocular
Pessimistic, and given to brooding	Overoptimistic and carefree
Guilt-prone, low self-esteem, and preoccupied with inadequacy or failure	Overconfident, self-assured, boastful, and grandiose
Introverted with restricted social life	Extroverted and people seeking
Sluggish, living a life out of action	High energy level, full of plans
Few but constant interests	Versatile with broad interests
Passive	Overinvolved and meddlesome
Reliable, dependable, and devoted	Uninhibited and stimulus seeking

Table 14.6-1 Attributes, Assets and Liabilities of Depressive and Hyperthymic Temperaments

Morbid Mood States Mood disorders represent abnormal or extreme variations of mood and associated manifestations and are characterized by the following features.

Pathological Mood Change Pathological moods are distinguished from heir normal counterparts by being out of proportion to any concurrent stressor or situation; being unresponsive to reassurance; being sustained for weeks, months, and sometimes years; and having a pervasive effect on the person, such that judgment is seriously influenced by the mood.

Endoreactive Moods Depression and mania are diagnosed, respectively, when sadness or elation is overly intense and continues beyond the expected impact of a stressful life event. Indeed the morbid mood might arise without apparent or significant life stress. The pathological process in mood disorders is thus partly defined by the ease with which an intense emotional state is released and especially by its tendency to persist autonomously even when the offending stressor is no longer operative. Rather than being endogenous (i.e., occurring in the absence of precipitants), mood disorders are best conceptualized as endoreactive (i.e., once released, they tend to persist autonomously). The homeostatic dyscontrol of mood, which is part of a more pervasive mood dysregulation, resists reversal to the habitual baseline affective tone. DSM-IV, which tends to disparage theory and adhere to a descriptive level of operationalization, gives insufficient weight to this fundamental

characteristic of mood disorders.

Recurrence In a more descriptive vein, what sets mood disorders apart from their normal emotional counterparts is the clustering of signs and symptoms into discrete syndromes that typically recur on an episodic basis or pursue an intermittent, subthreshold course over the span of many years, if not a lifetime. Cyclic course and in some cases regular recurrence, or periodicity, are other signs of mood dysregulation particularly relevant to bipolar disorder.

Impairment Normative reactions to adversity and stress, including biological stress, typically consist of transient admixtures of anxiety and dysphoria that are best captured under the DSM-IV rubric of adjustment disorder with mixed emotional features. That is, the self-limiting reactions are best qualified broadly as normal affective states that produce little, if any, impairment in the main areas of functioning.

Although anxiety, irritability, and anger do occur in various types of mood disorders, pathologically sustained mood states of depression and elation characterize those disorders. Morbid mood states (mood disorders) then consist of protracted emotional reactions that deepen or escalate, respectively, into clinical depression or mania, with a tendency to recur or evolve into unremitting chronicity in 15 to 20 percent of cases. The contribution of temperamental peculiarities to such outcomes should be apparent. The impaired functioning characteristic of mood disorders is thus based on a combination of factors, including severity, autonomy, recurrence, and chronicity of the clinical features.

To recapitulate, dysregulation in mood disorders can take different forms. It could be expressed as a single severe episode that persists autonomously for many months and sometimes years or it might recur with episodes of varying severity, years apart or in rapid succession, with or without interepisodic remission. In general, the earlier the age at onset, the more likely are recurrences, especially those of bipolar nature. Thus, depending on the course of the illness, impairment could be state dependent and occur during an episode or it could extend into the interepisodic period. According to National Institute of Mental Health (NIMH) estimates, on average, a woman with bipolar disorder spends 12 years in florid episodes (often hospitalized), loses 14 years from a productive career and motherhood, and has her life curtailed by 9 years.

Recent observations have also revealed another pattern of impairment. In dysthymic and cyclothymic disorders, which represent an intensification of temperamental instability, impairment is not due to the severity of the mood disturbance per se, but to the cumulative impact of the dysregulation beginning in the juvenile or early adult years and continuing unabated or intermittently over long periods; hence the frequent confusion with character pathology. Here the impairment is more subtle but nonetheless pervasive. Persons with cyclothymic disorder tend to be dilettantes, whereas those with dysthymic disorder often lead morose and colorless lives.

PSYCHOPATHOLOGY

Depressive Syndrome Like other illnesses, depressive disorder clusters into signs and symptoms that constitute what DSM-IV and ICD-10 term major depressive episode (Tables 14.6-2). These criteria attempt to set an operational threshold for depressive disorder based on a specified number of items and their temporal patterns. The diagnosis of clinical depression cannot be accomplished by a checklist: The DSM-IV diagnostic criteria for major depressive disorder provide only a general guide. Only after an in-depth phenomenological approach can a clinician ascertain diagnosis of a depressive disorder. Disturbances in all four spheres (mood, psychomotor activity, cognitive, and vegetative) should be ordinarily present for a definitive diagnosis of major depressive disorder, although that is not specified in DSM-IV.

Table 14.6-2 DSM-IV Criteria for Major Depressive Episode

Mood Disturbances Mood change, usually considered the sine qua non of morbid depression, appears in a variety of disturbances, including (1) painful arousal, (2) hypersensitivity to unpleasant events, (3) insensitivity to pleasant events, (4) insensitivity to unpleasant events, (5) reduced anticipatory pleasure, (6) anhedonia or reduced consummatory pleasure, (7) affective blunting, and (8) apathy. The phenomenology and psychometric properties of this broad range of mood disturbances are under investigation at the Salpêtrière Hospital in Paris. Our focus here is primarily on painfully aroused mood (depression) and diminished capacity for pleasure (anhedonia), two mood disturbances given selective weight in DSM-IV and ICD-10.

DEPRESSED MOOD The term “depressed mood” refers to negative affective arousal, variously described as depressed, anguished, mournful, irritable, or anxious. These terms tend to trivialize a morbidly painful emotion, typically experienced as worse than the severest physical pain. Thus depressed mood has a somatic quality that in the extreme is indescribably painful. Even when not so severe, depressive suffering is qualitatively distinct from its neurotic counterparts, taking the form of groundless apprehensions with severe inner turmoil and torment. This description is particularly apt for middle-aged and elderly persons, who were once considered to be suffering from “involutional melancholia.” The sustained nature of the mood permits no respite, although it tends to lift somewhat in the evening. Suicide may represent an attempt to find deliverance from such unrelenting psychic torment; death can be experienced as comforting (Fig. 14.6-2).

FIGURE 14.6-2 *Death Giving Comfort* by Kaethe Kollwitz (1867–1945).

Patients with a milder form of the malady typically seen in primary care settings might deny experiencing mournful moods and instead complain of physical agony from headache (Fig. 14.6-3), epigastric pain, precordial distress, and so on, in the absence of any evidence of diagnosable physical illness. Such conditions have been described as “depressio sine depressione,” or “masked depression.” In such cases, commonly observed in older patients, the physician should corroborate the presence of mood disturbance by the depressed affect in the patient's facial expression, voice, and overall appearance.

FIGURE 14.6-3 *Headache* by Honoré Daumier (1808–1879).

ANHEDONIA AND LOSS OF INTEREST Paradoxically, the heightened perception of pain in many persons with depressive disorder is accompanied by an inability to experience normal emotions. Patients exhibiting the disturbance may lose the capacity to cry, a deficit that is reversed as the depression is lifting.

In evaluating anhedonia inquiring whether the patient has lost the sense of pleasure is not enough; the clinician must document that the patient has actually given up previously enjoyed pastimes. When mild, anhedonia evidences with decreased interest in life. Later, patients complain that they have lost all interest in things. This is best illustrated by William Shakespeare in Hamlet's disgust: “How weary, stale, flat, and unprofitable seem to me all the uses of the world” (Act I, Scene II). In the extreme, patients lose their feelings for their children or spouses, who once were a source of joy. Thus the hedonic deficit in clinical depression might represent a special instance of a more pervasive inability to experience emotions.

Patients with severe depression may complain of being emotionally cut off from others and experience depersonalization and a world that seems strange to them (derealization). The impact of the loss of emotional resonance can be so pervasive that patients may denounce values and beliefs that had previously given meaning to their lives. For instance, members of the clergy might present with the complaint that they no longer believe in the Church, that they have lost God. The inability of the person with depressive disorder to experience normal emotions (commonly observed among young depressed patients) differs from the schizophrenic patient's flat affect in that the loss of emotions is itself experienced as painful; that is, the patient suffers immensely from the inability to experience emotions.

Psychomotor Disturbances In depression psychomotor changes consist of abnormalities in the motor expression of mental and emotional activity. In severe cases, these changes manifest in specific facial features (Fig. 14.6-4).

FIGURE 14.6-4 The Swiss neuropsychiatrist Otto Veraguth described a peculiar triangle-shaped fold in the nasal corner of the upper eyelid. The fold, often associated with depression, is referred to as Veraguth's fold. The photograph illustrates this physiognomic feature in a 50-year-old man during a major depressive episode. Veraguth's fold may also be seen in persons who are not clinically depressed, usually while they are harboring a mild depressive affect. Distinct changes in the tone of the corrugator and zygomatic facial muscles accompany depression, as shown on electromyograms. (Courtesy of Heinz E. Lehmann, M.D.)

PSYCHOMOTOR AGITATION Although agitation (pressured speech, restlessness, hand wringing, and hair pulling) is the more readily observed abnormality, it appears to be less specific to the illness than retardation (slowing of psychomotor activity). Psychophysiological studies have documented that such slowing often coexists with agitation.

PSYCHOMOTOR RETARDATION Underlying many of the deficits seen in clinical depression, some authorities believe psychomotor retardation to be the core, or primary, pathology in mood disorders. Morbid depression—what patients describe as being “down”—can be understood in terms of moderate-to-extreme psychomotor slowing. The patient experiences inertia, being unable to act physically and mentally. Recent brain imaging research that has revealed subcortical (extrapyramidal system) disturbances in mood disorders tends to support the centrality of psychomotor dysfunction in these disorders.

Long neglected in psychopathological research, psychomotor retardation, can be measured with precision. The Salpêtrière Retardation Scale developed by Daniel Widlöcher and colleagues places special emphasis on the following disturbances: (1) paucity of spontaneous movements; (2) slumped posture with downcast gaze (Fig. 14.6-5); (3) overwhelming fatigue (patients complain that everything is an effort”); (4) reduced flow and amplitude of speech and increased latency of responses, often giving rise to monosyllabic speech; (5) a subjective feeling that time is passing slowly or has stopped; (6) poor concentration and forgetfulness; (7) painful rumination—thinking that dwells on a few (usually unpleasant) topics; and (8) indecisiveness, or an inability to make simple decisions.

FIGURE 14.6-5 A 38-year-old woman during a state of deep retarded depression **(A)** and 2 months later, after recovery **(B).** Note the turned-down corners of her mouth, her stooped posture, her drab clothing, and her hairdo during the depressed episode. (Courtesy of Heinz E. Lehmann, M.D.)

DSM-IV places greater emphasis on the more easily observable objective or physical aspects of retardation. For the patient, however, the subjective sense of slowing is as pervasive and disabling. This more psychological dimension of retardation is most reliably elicited from depressed persons with good verbal skills.

Ms. A, a 34-year-old literature professor, presented to a mood clinic with the following complaint: “I am in a daze, confused, disoriented, staring. My thoughts do not flow, my mind is arrested... I seem to lack any sense of direction, purpose...I have such an inertia, I cannot assert myself. I cannot fight, I have no will.”

Less linguistically sophisticated patients would simply complain of an inability to perform household chores or difficulty in concentrating on their studies. Such psychomotor deficits in turn underlie depressed patients' diminished efficiency or their inability to work.

PSEUDODEMENTIA The slowing of mental functions can be so pronounced in elderly persons that they experience memory difficulties, disorientation, and confusion.

STUPOR Psychomotor slowing in young persons is sometimes so extreme that patients might slide into a stupor, unable to participate even in such basic biological functions as feeding themselves. Such an episode is often the precursor of bipolar disorder, which later declares itself in a manic episode. Today depressive disorder is diagnosed in its earlier stages, and subtle stupor is much more likely to be encountered clinically.

A 20-year-old male college student seen in the emergency room spoke of “being stuck—as if I have fallen into a black hole and can't get out.” Further evaluation revealed that the patient was metaphorically describing his total loss of initiative and drive and was engulfed by the disease process. A clinician without the requisite phenomenological training, might consider such a patient bizarre and perhaps even psychotic. Yet the patient responded dramatically to fluoxetine (Prozac) and in 2 weeks was back in school.

Cognitive Disturbances The cognitive view of depression considers negative evaluations of the self, the world, and the future (the negative triad) central to understanding depressed mood and behavior, but it is equally likely that the depressed mood colors perceptions of the self and others or that disturbed psychomotor activity leads to negative self-evaluations. Therefore, instead of being considered causal, the cognitive triad in depression is best approached empirically as a psychopathological manifestation of depression. Those faulty thinking patterns are clinically expressed as (1) ideas of deprivation and loss; (2) low self-esteem and self-confidence; (3) self-reproach and pathological guilt; (4) helplessness, hopelessness, and pessimism; and (5) recurrent thoughts of death and suicide.

The essential characteristic of depressive thinking is that the sufferer views everything in an extremely negative light. The self-accusations are typically unjustified or are blown out of proportion, as in the case of a middle-aged woman who was tormented by guilt because as a child she had not repaid 5 cents she had borrowed from a classmate. Some of the thoughts may verge on the delusional. For instance, an internationally renowned scientist complained that he was “nothing.” Self-evaluations that indicate an extremely low image of self might nonetheless reflect an accurate perception of one's impairment from psychomotor retardation.

MOOD-CONGRUENT PSYCHOTIC FEATURES In depressive disorder with psychotic features (Table 14.6-3), negative thinking acquires grossly delusional proportions and is maintained with such conviction that the thoughts are not amenable to change by evidence to the contrary. According to Kurt Schneider, delusional thinking in depression derives from humankind's four basic insecurities, those regarding health, financial status, moral worth, and relationship to others. Thus, severely depressed patients may have delusions of worthlessness and sinfulness, reference, and persecution: They believe they are being singled out for their past mistakes and that everyone is aware of their errors. Persecutory ideation in depression is often prosecutory in that it derives from the belief that the person deserves punishment for such transgressions. A severely depressed man may feel so incompetent in all areas of functioning, including the sexual sphere, that he may suspect his wife of having an affair (delusion of infidelity).

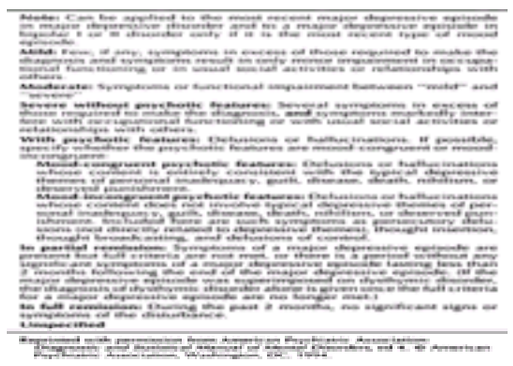

Table 14.6-3 DSM-IV Criteria for Severity/Psychotic/Remission Specifiers for Current (or Most Recent) Major Depressive Episode

Other depressed persons believe that they have mismanaged their finances and their children will starve (delusions of poverty) or that they harbor an occult illness, such as cancer or the acquired immune deficiency syndrome (AIDS) (delusions of ill health) or that parts of their bodies are missing (nihilistic delusions). In more severe illness the patient might feel that the world has changed and that calamity and destruction await everyone. In rare instances a parent with such delusions might kill his or her young children to save them from moral or physical decay and then commit suicide. Finally, a minority of depressed persons have fleeting auditory or visual hallucinations with extremely unpleasant content along the lines of their delusions (e.g., hearing accusatory voices or seeing themselves in coffins or graveyards). All of these psychotic experiences are genuine affective delusions or hallucinations. They are mood congruent in the sense that they are phenomenologically understandable in light of the prevailing pathological mood.

MOOD-INCONGRUENT PSYCHOTIC FEATURES Sometimes so-called first-rank or schneiderian-type symptoms can arise in the setting of a major depressive episode.

A 42-year-old civil servant said she was so paralyzed by depression that she felt that she had no personal initiative and volition left; she believed some malignant force had taken over her actions, and it would comment on every action that she would undertake. The patient recovered fully with thymoleptic medication. There is no reason to believe that in this patient the feelings of somatic passivity and running commentary indicated a schizophrenic process.

Thus, with proper phenomenological probing, certain classes of apparently mood-incongruent psychotic experiences listed in DSM-IV can be understood as arising from the pathological mood and the profound changes in psychomotor activity that accompany them. (In other instances, the clinician must seek a history of alcohol or substance use disorder or withdrawal as a putative explanation for mood incongruence in psychotic depression.) In brief, incidental schneiderian first-rank symptoms should not distract from the diagnosis of an affective disorder if otherwise typical signs and symptoms are present.

HOPELESSNESS AND SUICIDE Given that most, if not all, clinically depressed patients find themselves locked in the private hell of their negative thoughts, it is not surprising that up to 15 percent of untreated or inadequately treated patients give up hope of ever recovering and kill themselves. The suicide attempt is not, however, undertaken in the depth of melancholia. One severely depressed patient asked if she had any suicide plans, replied, “Doctor, I don't exist—I am already dead.”

Thus the risk of suicide is less pronounced during acute severe depression. Emil Kraepelin observed that it is when psychomotor activity is improving, and yet mood and thinking are still dark, that the patient is most likely to muster the requisite energy to commit the suicidal act. Hopelessness on mental status evaluation in a patient recovering from depression should alert the clinician to the possibility of such an outcome.

There is no basis for the common belief that inquiring about suicide provokes such behavior. On the contrary, patients are often relieved that the physician appreciates the magnitude of their suffering. Suicidal ideation is commonly expressed indirectly (e.g., in a wish not to wake up or to die from a malignant disease). Some depressed persons are tormented with suicidal obsessions and are constantly resisting unwanted urges or impulses to destroy themselves. Others might yield to such urges passively (e.g., by careless driving or by walking into high-speed traffic). A third group harbors elaborate plans, carefully preparing a will and taking out insurance. Deliberate planning indicates a very high suicidal risk. The foregoing examples are not exhaustive; they are meant to remind clinicians in charge of depressed patients to be always alert to the possibility of suicide.

Vegetative Disturbances The Greeks considered depression a somatic illness and ascribed it to black bile; hence the term “melancholia.” The mood change in

depressive disorder is accompanied by measurable alterations of biorhythms that implicate midbrain dysfunction. Once the changes occur, they tend to be independent of the environment throughout much of the episode, and as a consequence, they do not respond to interpersonal feedback of a pleasant and upbeat nature. The biological concomitants of melancholia include profound reductions in appetite, sleep, and sexual functioning as well as alterations in other circadian rhythms, especially matinal worsening of mood and psychomotor performances. These disturbances are central to the DSM-IV concept of melancholia (Table 14.6-4), a form of depression in which such biological concomitants predominate. A smaller subgroup of depressed persons exhibits a reversal of the vegetative and circadian functions, with increases in appetite and sleep—and sometimes in sexual functioning—and an evening worsening of mood; in this atypical pattern (Table 14.6-5), patients characteristically exhibit mood reactivity and sensitivity to rejection.

Specify if:
With melancholic features (can be applied to *major depressive* episodes occurring in major depressive disorder, bipolar I disorder or bipolar II disorder only if it is the most recent type of mood episode)

A. Either of the following, occurring during the most severe period of the current episode:
   (1) loss of pleasure in all, or almost all, activities.
   (2) lack of reactivity to usually pleasurable stimuli (does not feel much better, even temporarily, when something good happens)

B. Three (or more) of the following:
   (1) distinct quality of depressed mood (i.e., the depressed mood is perceived as distinctly different from the kind of feeling experienced after the death of a loved one)
   (2) the depression is regularly worse in the morning
   (3) early morning awakening (at least 2 hours before usual time of awakening)
   (4) marked psychomotor retardation or agitation
   (5) significant anorexia or weight loss
   (6) excessive or inappropriate guilt

Table 14.6-4 DSM-IV Criteria for Melancholic Features Specifiers

Specify if:
With atypical features (can be applied when these features predominate during the most recent 2 weeks of a major depressive episode in major depressive disorder or in bipolar I or bipolar II disorder when the major depressive episode is the most recent type of mood episode, or when these features predominate during the most recent 2 years of dysthymic disorder)

A. Mood reactivity (i.e., mood brightens in response to actual or potential positive events).

B. Two (or more) of the following features, present for most of the time, for at least 2 weeks:
   (1) significant weight gain or increase in appetite
   (2) hypersomnia
   (3) leaden paralysis (i.e., heavy, leaden feelings in arms or legs)
   (4) long-standing pattern of interpersonal rejection sensitivity (not limited to episodes of mood disturbance) resulting in significant social or occupational impairment

C. Criteria are not met with melancholic features or with catatonic features during the same episode.

Table 14.6-5 DSM-IV Criteria for Atypical Features Specifier

ANOREXIA AND WEIGHT LOSS The most reliable somatic indicators of depressive disorder include anorexia and weight loss. In addition to the presumed hypothalamic disturbance of depression, anorexia might be secondary to blunted olfactory or taste sensations or a decreased enjoyment of food, or (rarely) it might result from a delusional belief that the food has been poisoned.

If weight loss is severe, especially after the age of 40, the psychiatrist should first use appropriate medical consultation to rule out the likelihood of an occult malignancy. Inanition, especially in elderly persons, can lead to malnutrition and electrolyte disturbances that represent medical emergencies.

WEIGHT GAIN Overeating, decreased activity, or both may result in weight gain. In middle-aged patients it may aggravate preexisting diabetes mellitus, hypertension, or coronary artery disease. In younger patients, especially women, weight problems may conform to a bulimic pattern that is sometimes the expression of the depressive phase of a bipolar disorder with infrequent hypomanic periods (bipolar II disorder).

INSOMNIA Sleep disturbance, a cardinal sign of depression, often is characterized by multiple awakenings, especially in the early hours of the morning, rather than by difficulty falling asleep. The light sleep of a depressed person, in part a reflection of the painful arousal of the disorder, tends to prolong the depressive agony over 24 hours. Thus, deep stages of sleep (3 and 4) are either decreased or deficient. The attempt to overcome the problem by drinking alcohol may initially succeed but ultimately aggravates the sleep patterns and insomnia. This is also true for sedative-hypnotic agents, which are often prescribed by the busy general practitioner who has not spent enough time diagnosing the depressive condition. Although sedatives (including alcohol) effectively reduce the number of awakenings in the short term, they are not effective in the long run because they further diminish stage 3 and stage 4 sleep. They are not antidepressants, and they tend to prolong the depression.

HYPERSOMNIA Young depressed patients, especially those with bipolar tendencies, often exhibit excessive sleep and have difficulty getting up in the morning.

Kevin, a 15-year-old boy, was referred to a sleep center to rule out narcolepsy. His main complaints were fatigue, boredom, and a need to sleep all the time. Although he had always started the day somewhat slowly, he now could not get out of bed to go to school. That alarmed his mother, prompting sleep consultation. Formerly a B student, he had been failing most of his courses in the 6 months before referral. Psychological counseling, predicated on the premise that his family's recent move from another city had led to Kevin's isolation, had not been beneficial. Extensive neurological and general medical workup had also proven negative. He slept 12 to 15 hours a day but denied cataplexy, sleep paralysis, and hypnagogic hallucinations. During psychiatric interview he denied being depressed but admitted that he had lost interest in everything except his dog. He had no drive, participated in no activities, and had gained 30 pounds in 6 months. He believed he was “brain damaged” and wondered whether it was worth living like that. The question of suicide disturbed him as it was contrary to his religious beliefs. These findings led to the prescription of desipramine (Norpramin) in a dosage that was gradually increased to 200 mg a day over 3 weeks. Not only did desipramine reverse the presenting complaints, but it also pushed him to the brink of a manic episode.

The affective nature of the disorder in such patients is often unrecognized, and their behavior is attributed to “laziness.” The vignette also illustrates the emergence of manic behavior during antidepressant treatment. Such shifts in polarity are common in major depressive disorder and necessitate revising the diagnosis to a bipolar disorder (contrary to the admonitions of DSM-IV).

CIRCADIAN DYSREGULATION Many circadian functions, such as temperature regulation and cortisol rhythms, are disrupted in major depressive disorder. Disturbances of sleep rhythms, however, have received the greatest research focus. These include deficits in stage 4 or delta sleep, as well as more intense rapid eye movement (REM) activity in the first third of the night. More specific to depressive disorders—and whether suffering from insomnia or hypersomnia—nearly two-thirds of patients exhibit a marked shortening of REM latency, the period from the onset of sleep to the first REM period. This abnormality is observed throughout the depressive episode and may also be seen during relatively euthymic periods in persons with recurrent depression. The occurrence of short REM latency in the younger “well” relatives of the affectively ill suggests that neurophysiological abnormalities might precede the overt psychopathological manifestations of the illness; upon closer scrutiny, these well relatives will often be found to meet criteria for subthreshold mood conditions such as dysthymic disorder, intermittent depression or labile temperament.

Few data exist on the consistency of sleep electroencephalographic (EEG) abnormalities in patients from episode to episode. However, clinical experience suggests that a patient observed over time (even during the same episode) may exhibit insomnia and morning worsening of mood and activity during one period of the disorder and hypersomnia extending to late morning hours during another period. In either case, persons with depressive disorder are characteristically tired in the morning, which means that even prolonged sleep is not refreshing for them. The propensity to exhibit such divergent patterns of sleep disturbance is more likely in bipolar disorders. Patients with major depressive disorder tend to exhibit insomnia more stereotypically episode after episode; despite extreme fatigue, they rarely oversleep. Such fatigue coexisting with negative affective arousal is even more exhausting.

SEASONALITY Another classic biorhythmic disturbance in mood disorders is seasonal (especially autumn-winter) accentuation or precipitation of depression. Most of those patients experience increased energy and activation, if not frank hypomania, in the spring. In the fall and winter, they complain of fatigue, tend to crave sugars, and overeat and oversleep. The hypersomnia in some of these patients is associated with delayed (rather than short) REM latencies. These data suggest dysregulation of circadian rhythms in depressive disorders rather than mere phase advance. Although autumnal-winter depression has received the greatest attention, there also exist summer depressions; the former appear related to reduction of daylight (photoperiods), and the latter to increased temperature. The DSM-IV criteria for seasonal pattern specifiers are listed in Table 14.6-6.

Specify if:
With seasonal pattern (can be applied to the pattern of major depressive episodes in bipolar I disorder, bipolar II disorder, or major depressive disorder, recurrent)

A. There has been a regular temporal relationship between the onset of major depressive episodes in bipolar I or bipolar II disorder or major depressive disorder, recurrent, and a particular time of the year (e.g., regular appearance of the major depressive episode in the fall or winter)
Note: Do not include cases in which there is an obvious effect of seasonal-related psychosocial stressors (e.g., regularly being unemployed every winter).

B. Full remissions (or a change from depression to mania or hypomania) also occur at a characteristic time of the year (e.g., depression disappears in the spring).

C. In the last 2 years, two major depressive episodes have occurred that demonstrate the temporal seasonal relationships defined in criteria A and B, and no nonseasonal major depressive episodes have occurred during that same period.

D. Seasonal major depressive episodes (as described above) substantially outnumber any nonseasonal major depressive episodes that may have occurred over the individual's lifetime.

Table 14.6-6 DSM-IV Criteria for Seasonal Pattern Specifier

SEXUAL DYSFUNCTION Decreased sexual desire is seen in both depressed men and women. In addition, some women experience temporary interruption of their menses. Depressed women are typically unresponsive to lovemaking or are disinclined to participate in it, a situation that could lead to marital conflict. Psychotherapists might mistakenly ascribe the depression to the marital conflict and devote unnecessarily zealous psychotherapeutic attention to conjugal issues. Decreased or lost libido in men often results in erectile failure, which may prompt endocrinological or urological consultation. Again, depression may be ascribed to the sexual dysfunction rather than the reverse, and definitive treatment may be delayed by the physician's focus on the sexual complaint. Tragically, some men with depressive disorder have been subjected to permanent penile implants before receiving more definitive treatment for their depression. This is less likely to occur in the sildenafil (Viagra) era, but even treatment with such agents would not necessarily resolve the impotence in clinically depressed patients without competent treatment of the mood disorder.

A small subgroup of persons with depressive disorder may exhibit increased sexual drive or activity of a “compulsive” nature. These patients tend to have other atypical features as well; hence the increased sexual drive can be considered the “fifth reverse vegetative sign” (after evening or morning worsening of mood, initial insomnia, hypersomnia, and weight gain). In these depressed persons, increased sexual drive may indicate a mixed episode of bipolar disorder. Further scrutiny in such cases will often reveal a premorbid cyclothymic or hyperthymic temperament.

Manic Syndrome As with clinical depression, the psychopathology of mania (Table 14.6-7) can be conveniently discussed under mood, psychomotor, circadian, and cognitive disturbances. The clinical features of mania are generally the opposite of those of depression. Thus, instead of lowered mood, thinking, activity, and self-esteem, there is elevated mood, a rush of ideas, psychomotor acceleration, and grandiosity. Despite those contrasts, the two disorders share such symptoms as irritability, anger, insomnia, and agitation. Actually, an excess of such symptoms of escalating intensity suggests a mixed phase or mixed episode (Table 14.6-8) of mania and depression occurring simultaneously. Manic and mixed episodes represent the hallmark of what was once termed manic-depressive psychosis and is currently termed bipolar I disorder.

A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood, lasting at least 1 week (or any duration if hospitalization is necessary).

B. During the period of mood disturbance, three (or more) of the following symptoms have persisted (four if the mood is only irritable) and have been present to a significant degree:
(1) inflated self-esteem or grandiosity
(2) decreased need for sleep (e.g., feels rested after only 3 hours of sleep)
(3) more talkative than usual or pressure to keep talking
(4) flight of ideas or subjective experience that thoughts are racing
(5) distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli)
(6) increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation
(7) excessive involvement in pleasurable activities that have a high potential for painful consequences (e.g., engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments)

C. The symptoms do not meet criteria for a mixed episode.

D. The mood disturbance is sufficiently severe to cause marked impairment in occupational functioning or in usual social activities or relationships with others, or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features.

E. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication, or other treatment) or a general medical condition (e.g., hyperthyroidism).

Note: Manic-like episodes that are clearly caused by somatic antidepressant treatment (e.g., medication, electroconvulsive therapy, light therapy) should not count toward a diagnosis of bipolar I disorder.

Table 14.6-7 DSM-IV Criteria for Manic Episode

A. The criteria are met both for a manic episode and for a major depressive episode (except for duration) nearly every day during at least a 1-week period.

B. The mood disturbance is sufficiently severe to cause marked impairment in occupational functioning or in usual social activities or relationships with others, or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features.

C. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication, or other treatment) or a general medical condition (e.g., hyperthyroidism).

Note: Mixed-like episodes that are clearly caused by somatic antidepressant treatment (e.g., medication, electroconvulsive therapy, light therapy) should not count toward a diagnosis of bipolar I disorder.

Table 14.6-8 DSM-IV Criteria for Mixed Episode

Although milder mania (hypomania [Table 14.6-9]) can contribute to success in business, leadership roles, and the arts, recurrences of even mild manic symptomatology are typically disruptive. The elated mood tends to produce overoptimism concerning one's abilities, which coupled with the impulsivity characteristic of mania, often leads to disaster. Thus, accurate and early diagnosis is paramount.

A. A distinct period of persistently elevated, expansive, or irritable mood, lasting throughout 4 days, that is clearly different from the usual nondepressed mood.
B. During the period of mood disturbance, three (or more) of the following symptoms have persisted (four if the mood is only irritable) and have been present to a significant degree:
(1) inflated self-esteem or grandiosity
(2) decreased need for sleep (e.g., feels rested after only 3 hours of sleep)
(3) more talkative than usual or pressure to keep talking
(4) flight of ideas or subjective experience that thoughts are racing
(5) distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli)
(6) increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation
(7) excessive involvement in pleasurable activities that have a high potential for painful consequences (e.g., the person engages in unrestrained buying sprees, sexual indiscretions, or foolish business investments)
C. The episode is associated with an unequivocal change in functioning that is uncharacteristic of the person when not symptomatic.
D. The disturbance in mood and the change in functioning are observable by others.
E. The episode is not severe enough to cause marked impairment in social or occupational functioning, or to necessitate hospitalization, and there are no psychotic features.
F. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication, or other treatment) or a general medical condition (e.g., hyperthyroidism).
Note: Hypomanic-like episodes that are clearly precipitated by somatic antidepressant treatment (e.g., medication, electroconvulsive therapy, light therapy) should not count toward a diagnosis of bipolar II disorder.

Table 14.6-9 DSM-IV Criteria for Hypomanic Episode

Classic mania as formulated in the DSM-IV operationalization of manic episode (Table 14.6-7) is relatively easy to recognize. Misdiagnosis was once rampant in North American practice as clinicians confused severe mania with schizophrenia, and its milder variants with normality or with narcissistic and sociopathic personality disorders. Like the misdiagnosis of depressive conditions, such errors of clinical judgment are due to a lack of familiarity with the phenomenology of the classic illness. Again, DSM-IV criteria provide only a guideline. The actual diagnosis requires careful history and phenomenologic understanding. The manic patient lifts the observer's mood, makes the examiner smile and even laugh, and can often be irritating. The patient's speech is fast and may even appear “loose,” but it also can often be witty. Finally, the behavior is typically dramatic, expansive, and jesting. For the experienced clinician, the overall gestalt experienced in the presence of such patients is emotionally and qualitatively distinct from that of persons with schizophrenia or frontal lobe diseases; the latter conditions tend to leave the examiner “cold.” These considerations become clearer when the clinical observer systematically examines the psychopathology of mania in the areas of mood, behavior, and thinking.

Mood Disturbance Mood disturbance in mania represents a contrast to that observed in depression, but not entirely.

MOOD ELEVATION The mood in mania is classically one of elation, euphoria, and jubilation, typically associated with laughing, punning, and gesturing.

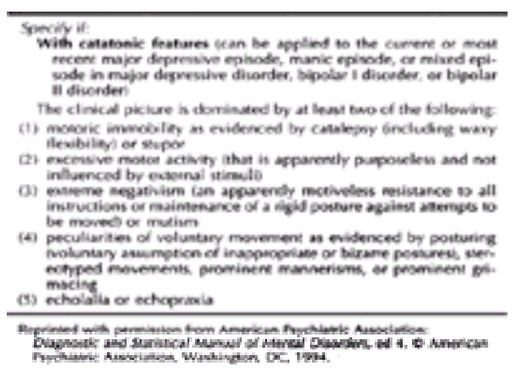
LABILITY AND IRRITABILITY The prevailing positive mood in mania is not stable, and momentary crying or bursting into tears is common. Also, the high is so excessive that many patients experience it as intense nervousness. When crossed, patients can become extremely irritable and hostile. Thus, lability and irritable hostility are as much features of the manic mood as is elation.

Psychomotor Acceleration Accelerated psychomotor activity, the hallmark of mania, is characterized by overabundant energy and activity and rapid, pressured speech. Subjectively, the patient experiences an unusual sense of physical well-being (eutonia).

FLIGHT OF IDEAS Thinking processes are accelerated, experienced as flight of ideas, and thinking and perception are unusually sharp. The patient may speak with such pressure that associations are difficult to follow; such clang associations are often based on rhyming or chance perceptions and can be lightning fast. The pressure to speak may continue despite development of hoarseness.

IMPULSIVE BEHAVIOR Manic patients are typically impulsive, disinhibited, and meddlesome. They are intrusive in their increased involvement with others, leading to friction with family members, friends, and colleagues. They are distractible and move quickly, not only from one thought to another, but also from one person to another, showing heightened interest in every new activity that strikes their fancy. They are indefatigable and engage in various activities in which they usually display poor social judgment. Examples include preaching or dancing in the street; abuse of long distance calling; buying new cars, hundreds of records, expensive jewelry, or other unnecessary items; paying the bills of total strangers in bars; giving away furniture; impulsive marriages; engaging in risky business ventures; gambling; and sudden trips. Such pursuits can lead to personal and financial ruin.

DELIRIOUS MANIA An extremely severe expression of mania (once known as “Bell's mania”), delirious mania involves frenzied physical activity that continues unabated and leads to a life-threatening medical emergency. This complication, the manic counterpart of stupor, is rare today. (There is no need to invoke here the concept of catatonic features as advocated by DSM-IV (Table 14.6-10). The DSM-IV position is terminologically confusing and phenomenologically imprecise).



Specify if:
With catatonic features (can be applied to the *current or most recent major depressive episode, manic episode, or mixed episode in major depressive disorder, bipolar I disorder, or bipolar II disorder*)
The clinical picture is dominated by at least two of the following:
(1) motoric immobility as evidenced by catalepsy (including waxy flexibility) or stupor
(2) excessive motor activity (that is apparently purposeless and not influenced by external stimuli)
(3) extreme negativism (an apparently motiveless resistance to all instructions or maintenance of a rigid posture against attempts to be moved) or mutism
(4) peculiarities of voluntary movement as evidenced by posturing (voluntary assumption of inappropriate or bizarre postures), stereotyped movements, prominent mannerisms, or prominent grimacing
(5) echolalia or echopraxia

Table 14.6-10 DSM-IV Criteria for Catatonic Features Specifier

Vegetative Disturbances Vegetative disturbances are more difficult to evaluate in mania than in depression.

HYPOSOMNIA The cardinal sign is decreased need for sleep—the patient sleeps only a few hours but feels energetic on awakening. Some patients may actually go sleepless for several days. This practice could lead to dangerous escalation of manic activity, which might continue despite signs of physical exhaustion.

INATTENTION TO NUTRITION There does not seem to be a clinically significant level of appetite disturbance as such, but weight loss may occur because of increased activity and neglect of nutritional needs.

SEXUAL EXCESSES The sexual appetite is typically increased and may lead to sexual indiscretion. Married women with previously unblemished sexual lives may associate with men below their social status. Men typically overindulge in alcohol, frequent bars, and squander their savings on prostitutes. The sexual misadventures of manic patients result in marital disasters and hence the multiple separations or divorces that are almost pathognomonic of the disorder. Such sexual impulsivity is even more problematic now, in view of the specter of AIDS.

Cognitive Distortions Manic thinking is overly positive, optimistic, and expansive.

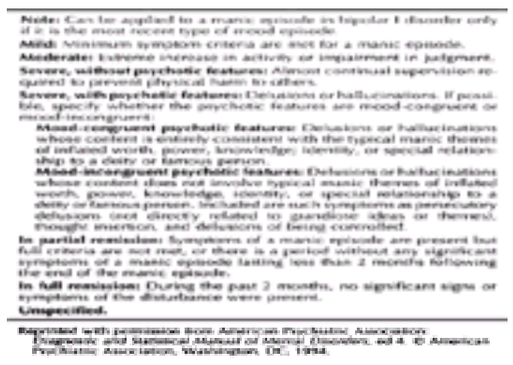
GRANDIOSITY, LACK OF INSIGHT, AND DELUSION FORMATION The patient exhibits inflated self-esteem and a grandiose sense of confidence and achievements. Behind that facade, however, may be a vague and painful recognition that the positive self-concepts do not represent reality. However, such insight (if present at all) is transient, and manic patients are notoriously refractory to self-examination and insight. Denial and lack of insight, cardinal psychological derangements of mania, are not listed in the DSM-IV criteria for manic episode or bipolar disorders. This is a serious omission because this lack of insight leads manic patients to engage in activities that harm themselves and their loved ones. It also explains, in part, their noncompliance with medication regimens during the manic phase. Finally, because of their lack of insight, mania nearly always reaches delusional proportions, including delusions of exceptional mental and physical fitness and exceptional talent; delusions of wealth, aristocratic ancestry, or other grandiose identity; delusions of assistance (i.e., well-placed persons or supernatural powers are assisting their endeavors); or delusions of reference and persecution, based on the belief that enemies are observing or following them out of jealousy at

their special abilities. At the height of mania patients may even see visions or hear voices congruent with their euphoric mood and grandiose self-image (e.g., they might see images of heaven or hear cherubs chanting songs to praise them). The denial characteristic of mania—and the frequently psychotic nature of episodes—means that clinicians must routinely obtain diagnostic information about past episodes from significant others. (Lack of insight also unfortunately means that hospitalization must usually be arranged on an involuntary basis).

MOOD-INCONGRUENT PSYCHOSIS Psychosis in the setting of mania and mixed manic episodes is typically mood congruent. The sense of physical well-being and mental alacrity is so extraordinary that it is understandable why manic patients believe that they possess superior powers or perhaps are great scientists or famous reformers. Moreover, their senses are so vivid that reality appears richer and more exotic, and can be easily transformed into a vision. Likewise, their thoughts are so rapid and vibrant that they feel they can hear them. Thus, certain first-rank schneiderian-type symptoms that have been traditionally considered mood incongruent can be understood phenomenologically to arise from the powerful mental experiences of mania.

A 37-year-old engineer, had experienced three manic episodes for which he had been hospitalized; all three episodes were preceded by several weeks of moderate psychomotor retardation. Although he had responded to lithium (Eskalith, Lithobid) each time, once outside the hospital he had been reluctant to take it and eventually refused to do so. Now that he was euthymic, following his third and most disruptive episode during which he had badly beaten his wife, he could more accurately explain how he felt when manic. Mania, he felt, was “like God implanted in him,” so he could serve as “testimony to man's communication with God.” He elaborated as follows: “Ordinary mortals will never, never understand the supreme manic state which I'm privileged to experience every few years. It is so vivid, so intense, so compelling. When I feel that way, there can be no other explanation: To be manic is, ultimately, to be God. God himself must be supermanic: I can feel it, when mania enters through my left brain like laser beams, transforming my sluggish thoughts, recharging them, galvanizing them. My thoughts acquire such momentum, they rush out of my head, to disseminate knowledge about the true nature of mania to psychiatrists and all others concerned. That's why I will never accept lithium again—to do so is to obstruct the divinity in me.” Although he was on the brink of divorce, he would not yield to his wife's plea to go back on lithium.

The vignette illustrates the possibility that even some of the most psychotic manifestations of mania represent explanatory delusions, the patient's attempt to make sense of the experience of mania. The DSM-IV criteria for severity/psychotic specifiers for manic and mixed episode (Table 14.6-11 and Table 14.6-12) are more concerned with operational rigor than with the phenomenological sophistication needed to understand such core manic experiences. (Many manic patients abuse alcohol and stimulants to enhance their mental state; mood incongruence can sometimes be explained on that basis).



Note: Can be applied to a manic episode in bipolar I disorder only if it is the most recent type of mood episode.

Mild: Minimum symptom criteria are met for a manic episode.

Moderate: Extreme increase in activity or impairment in judgment.

Severe, without psychotic features: Almost continual supervision required to prevent physical harm to others.

Severe, with psychotic features: Delusions or hallucinations. If possible, specify whether the psychotic features are mood-congruent or mood-incongruent:

Mood-congruent psychotic features: Delusions or hallucinations whose content is entirely consistent with the typical manic themes of inflated worth, power, knowledge, identity, or special relationship to a deity or famous person.

Mood-incongruent psychotic features: Delusions or hallucinations whose content does not involve typical manic themes of inflated worth, power, knowledge, identity, or special relationship to a deity or famous person. Included are such symptoms as persecutory delusion (not directly related to grandiose ideas or themes), thought insertion, and delusions of being controlled.

In partial remission: Symptoms of a manic episode are present but full criteria are not met, or there is a period without any significant symptoms of a manic episode lasting less than 2 months following the end of the manic episode.

In full remission: During the past 2 months, no significant signs or symptoms of the disturbance were present.

Unspecified.

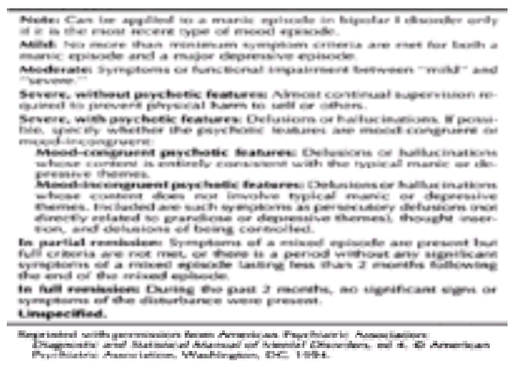
Table 14.6-11 DSM-IV Criteria for Severity/Psychotic/Remission Specifiers for Current (or Most Recent) Manic Episode



Note: Can be applied to a manic episode in bipolar I disorder only if it is the most recent type of mood episode.

Mild: No more than minimum symptom criteria are met for both a manic episode and a major depressive episode.

Moderate: Symptoms or functional impairment between "mild" and "severe."

Severe, without psychotic features: Almost continual supervision required to prevent physical harm to self or others.

Severe, with psychotic features: Delusions or hallucinations. If possible, specify whether the psychotic features are mood-congruent or mood-incongruent:

Mood-congruent psychotic features: Delusions or hallucinations whose content is entirely consistent with the typical manic or depressive themes.

Mood-incongruent psychotic features: Delusions or hallucinations whose content does not involve typical manic or depressive themes. Included are such symptoms as persecutory delusions (not directly related to grandiose or depressive themes), thought insertion, and delusions of being controlled.

In partial remission: Symptoms of a mixed episode are present but full criteria are not met, or there is a period without any significant symptoms of a mixed episode lasting less than 2 months following the end of the mixed episode.

In full remission: During the past 2 months, no significant signs or symptoms of the disturbance were present.

Unspecified.

Table 14.6-12 DSM-IV Criteria for Severity/Psychotic/Remission Specifiers for Current (or Most Recent) Mixed Episode

MANIA VERSUS HYPOMANIA Nonpsychotic and nondisruptive variants of mania are much more common and are recognized by DSM-IV as hypomanic episodes. Diagnostically, history of a partial manic syndrome is preferably obtained from significant others who have observed the patient; the experience is often pleasant, and the subject may either be unaware of it or tend to deny it. DSM-IV stipulates a minimum duration of 4 days for hypomania; however, the Memphis and Zurich studies found a modal duration of 2 days. Finally, although DSM-IV states that treatment-emergent hypomania in a depressed patient does not count toward a diagnosis of bipolarity, prospective observations show that nearly all such episodes are followed eventually by spontaneous hypomania (or mania).

DIAGNOSTIC CLASSIFICATION

P>The classification of mood disorders in DSM-IV subsumes a large variety of patients seen in private and public, ambulatory and inpatient settings. The main demarcation in that large clinical terrain is between bipolar and depressive (unipolar) disorders. Thus, bipolar disorders range from the classic manic and depressive episodes of psychotic intensity (bipolar I disorder) through recurrent major depressive episodes, alternating with hypomanic episodes (bipolar II disorder), and cyclothymic mood swings. Likewise, depressive disorders include those with psychotic severity, melancholia, atypical features, and dysthymic variants.

Major and specific attenuated subtypes are distinguished on the basis of severity and duration. In dysthymic and cyclothymic disorders a partial mood syndrome—consisting of such subthreshold features as subdepressive and hypomanic periods—is maintained, intermittently or continuously, for at least 2 years. Subdepressive periods dominate in dysthymia; in cyclothymia, they alternate with hypomania. The onset is typically in adolescence or childhood, and most persons with these diagnoses seen in young adulthood have had low-grade mood symptoms for 5 to 10 years. Major mood disorders, which generally begin much later in life, require the presence of either a full manic episode or a full depressive episode—sustained for at least 1 or 2 weeks, respectively—and an episodic course, typically permitting recovery or remission from episodes. DSM-IV recognizes that a significant minority of persons with major depressive disorders fails to achieve full symptomatic recovery and should thus be qualified as chronic or in partial remission. They are no longer considered dysthymic (the misleading convention in DSM-III).

Dichotomy or Continuum? Although, in the extreme, bipolar and depressive (unipolar) disorders can be discriminated clinically and therapeutically (Table 14.6-13), clinical observations testify to a vast overlap between those extremes. Thus the distinctions between the various affective subtypes are not as hard and fast as DSM-IV attempts to portray. For instance, full-blown bipolar disorder can be superimposed on cyclothymic disorder that tends to persist after the resolution of manic or major depressive episodes. Even more common is major depressive disorder complicating cyclothymic disorder, which should be reclassified as an important course variant of bipolar II disorder. Likewise, recent evidence indicates that dysthymic disorder may precede major depressive disorder in as many as a third of cases. Moreover, one in four persons with major depressive disorder subsequently develops hypomanic or manic episodes and so should be reclassified as having bipolar disorder. Finally, unexpected crossing from dysthymic disorder to hypomanic or manic episodes has also been described, suggesting that some forms of dysthymic disorder are subaffective precursors of bipolar disorder. Such observations are in line with Kraepelin's historic attempt to bring all mood disorders under one rubric. Epidemiological studies in the community have also shown much fluidity between various subthreshold and major mood disorders.

	Bipolar	Unipolar
History of mania or hypomania (definitional)	Yes	No
Temperament/ personality	Cyclothymic/ extroverted	Dysthymic/ introverted
Sex ratio	Equal	More women than men
Age of onset	Teens, 20s, and 30s	30s, 40s, 50s
Postpartum episodes	More common	Less common
Onset of episode	Often abrupt	More insidious
Number of episodes	Numerous	Fewer
Duration of episode	3 to 6 months	3 to 12 months
Psychomotor activity	Retardation > agitation	Agitation > retardation
Sleep	Hypersomnia > insomnia	Insomnia > hypersomnia
Family history		
Bipolar disorder	Yes	∆
Unipolar disorder	Yes	Yes
Alcoholism	∆	Yes
Pharmacological response		
Cyclic antidepressants	Induce hypomania-mania	∆
Lithium carbonate	Acute antidepressant effects	Ineffective

Table 14.6-13 Differentiating Characteristics of Bipolar and Unipolar Depressions

Heterogeneity undoubtedly exists among mood disorders; however, the foregoing observations suggest that much of the unipolar terrain might be “pseudo-unipolar” (i.e., soft bipolar). The clinical significance of these considerations lies in the fact that many DSM-IV subtypes of mood disorders are not pure entities, and considerable overlap and switches in polarity take place. They also provide some rationale, for instance, for why lithium (or lithium augmentation) may be effective in some apparently unipolar depressions; such patients do not experience spontaneous hypomanic episodes, but instead often exhibit a high baseline level of hyperthymic traits. Finally, several studies have shown that bipolar patients with cyclothymic premorbid adjustment and interepisodic adjustment are at considerable risk for antidepressant-induced rapid cycling, defined as a rapid succession of major episodes with few or no intervals of freedom.

Such considerations further testify to the wisdom of supplementing major mood diagnoses with temperamental attributes. DSM-IV only makes subtle or oblique hints concerning this, and instead provides the practitioner with an unwieldly, if not useless, array of episode and course specifiers. The DSM-IV criteria for longitudinal course specifiers are given in Table 14.6-14.

Specify if (can be applied to recurrent major depressive disorder or bipolar I or II disorder):

With full interepisode recovery: if full remission is attained between the two most recent mood episodes

Without full interepisode recovery: if full remission is not attained between the two most recent mood episodes

Table 14.6-14 DSM-IV Criteria for Longitudinal Course Specifiers

As Kraepelin illustrated in his monograph, course is best captured graphically. DSM-IV only provides examples of this for depressive disorders (Fig. 14.6-6) and limits itself to four patterns. Kraepelin, after diagramming 18 illustrative patterns for the entire spectrum of manic-depressive illness, declared that the illness pursued an indefinite number of courses.

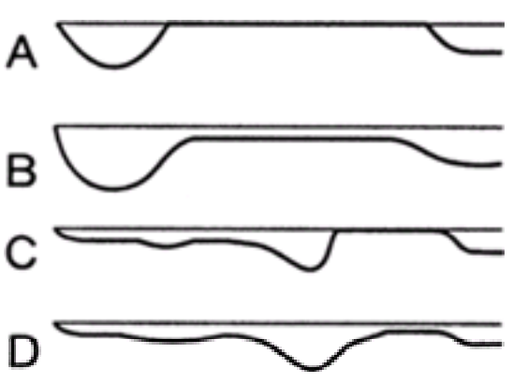

FIGURE 14.6-6 Graphs depicting prototypical courses. **A**, Course of major depressive disorder, recurrent, with no antecedent dysthymic disorder and a period of full remission between the episodes. This pattern predicts the best future prognosis. **B**, Course of major depressive disorder, recurrent, with no antecedent dysthymic disorder but with prominent symptoms persisting between the two most recent episodes (i.e., partial remission is attained). **C**, Rare pattern (present in fewer than 3 percent of persons with major depressive disorder) of major depressive disorder, recurrent with antecedent dysthymic disorder but with full interepisode recovery between the two most recent episodes. **D**, Course of major depressive disorder, recurrent, with antecedent dysthymic disorder and no period of full remission between the two most recent episodes. This pattern, commonly referred to as double depression, is seen in about 20 to 25 percent of persons with major depressive disorder. (Reprinted with permission from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, ed 4. Copyright, American Psychiatric Association, Washington, DC, 1994.)

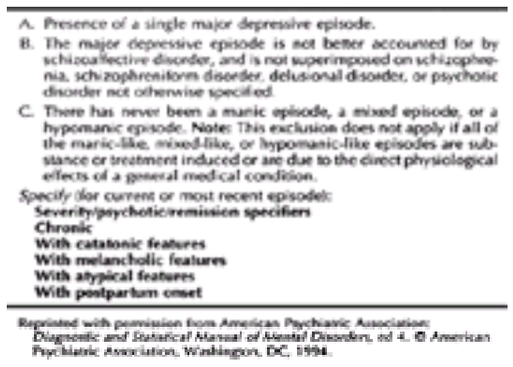
DEPRESSIVE DISORDERS

The broad category of depressive disorders includes major depressive disorder, dysthymic disorder, and depressive disorder not otherwise specified.

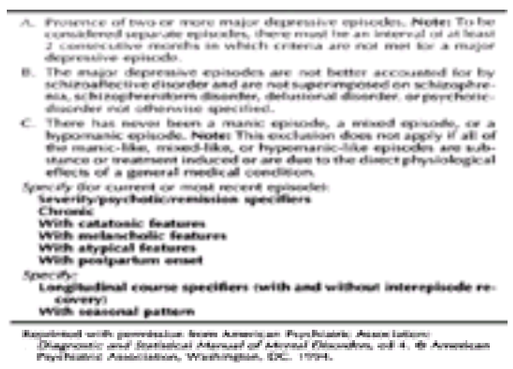
Major Depressive Disorder Episodes usually begin over a prodromal period of weeks to months. The DSM-IV diagnosis of major depressive disorder requires (1) dysphoric mood or decreased interest in usual activities and (2) at least four additional classic depressive signs and symptoms, (3) which must be sustained for at least 2 weeks, and (4) cannot be explained by another process known to cause depressive symptoms, such as normal bereavement, certain physical conditions commonly associated with depression, or another mental disorder. It can be single and, more commonly, recurrent. (Table 14.6-15 and Table 14.6-16).



A. Presence of a single major depressive episode.
B. The major depressive episode is not better accounted for by schizoaffective disorder, and is not superimposed on schizophrenia, schizophreniform disorder, delusional disorder, or psychotic disorder not otherwise specified.
C. There has never been a manic episode, a mixed episode, or a hypomanic episode. **Note:** This exclusion does not apply if all of the manic-like, mixed-like, or hypomanic-like episodes are substance or treatment induced or are due to the direct physiological effects of a general medical condition.

Specify (for current or most recent episode):
Severity/psychotic/remission specifiers
Chronic
With catatonic features
With melancholic features
With atypical features
With postpartum onset

Table 14.6-15 DSM-IV Diagnostic Criteria for Major Depressive Disorder, Single Episode



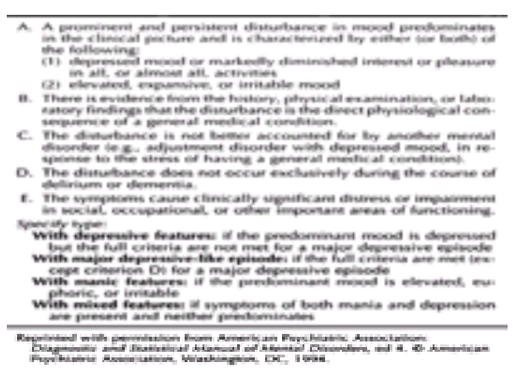
A. Presence of two or more major depressive episodes. **Note:** To be considered separate episodes, there must be an interval of at least 2 consecutive months in which criteria are not met for a major depressive episode.
B. The major depressive episodes are not better accounted for by schizoaffective disorder and are not superimposed on schizophrenia, schizophreniform disorder, delusional disorder, or psychotic disorder not otherwise specified.
C. There has never been a manic episode, a mixed episode, or a hypomanic episode. **Note:** This exclusion does not apply if all of the manic-like, mixed-like, or hypomanic-like episodes are substance or treatment induced or are due to the direct physiological effects of a general medical condition.

Specify (for current or most recent episode):
Severity/psychotic/remission specifiers
Chronic
With catatonic features
With melancholic features
With atypical features
With postpartum onset

Specify:
Longitudinal course specifiers (with and without interepisode recovery)
With seasonal pattern

Table 14.6-16 DSM-IV Diagnostic Criteria for Major Depressive Disorder, Recurrent

Comorbid Physical Disease Those considerations raise the question whether major depressive disorder should be limited to depressions of unknown etiology (i.e., those without documented physical causes). The DSM-IV approach has basically been that when the cause is known, the condition should be diagnosed as mood disorder due to a general medical condition (Table 14.6-17) which must be specified, or substance-induced mood disorder (Table 14.6-18). The problem with this approach is that many common medical factors historically associated with depression (e.g., use of certain antihypertensive agents) do not seem to be causative in the etiological sense, but rather are triggering agents in otherwise predisposed persons. This is analogous to the situation with life events, which no longer are used in making distinctions between reactive and endogenous subtypes of depression. A more troubling implication is that major depressive disorders without demonstrable physical disease are not medical or otherwise biological. More importantly there appears to be no reliable or valid way for a clinician to decide that a depressive condition is due to a specified medical condition. For this reason it is generally more practical to diagnose the depressive disorder on Axis I and specify the contributing physical condition on Axis III. In brief, the designation “due to a general medical condition” is both cumbersome and redundant. The author considers major depressive disorder to represent the final common pathway of multifactorial interacting factors—both physical and psychological—a syndrome that should be diagnosed irrespective of presumed cause.



A. A prominent and persistent disturbance in mood predominates in the clinical picture and is characterized by either (or both) of the following:
(1) depressed mood or markedly diminished interest or pleasure in all, or almost all, activities
(2) elevated, expansive, or irritable mood
B. There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct physiological consequence of a general medical condition.
C. The disturbance is not better accounted for by another mental disorder (e.g., adjustment disorder with depressed mood, in response to the stress of having a general medical condition).
D. The disturbance does not occur exclusively during the course of delirium or dementia.
E. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Specify type:
With depressive features: if the predominant mood is depressed but the full criteria are not met for a major depressive episode
With major depressive–like episode: if the full criteria are met (except criterion D) for a major depressive episode
With manic features: if the predominant mood is elevated, euphoric, or irritable
With mixed features: if symptoms of both mania and depression are present and neither predominates

Table 14.6-17 DSM-IV Diagnostic Criteria for Mood Disorder Due to a General Medical Condition

Table 14.6-18 DSM-IV Diagnostic Criteria for Substance-Induced Mood Disorder

Diagnostic Threshold Another question concerning the DSM-IV definition of major depressive disorders relates to the threshold at which a constellation of depressive features becomes a condition distinct from the ordinary blues. According to the current definition, a person who responds to a setback with lowered spirits and self-doubt, difficulty in sleeping and concentration, and decreased sexual interest for 14 days qualifies for a diagnosis of a major depressive disorder of mild intensity. Many clinicians would consider such a condition a relatively minor departure from normality, probably no more than an adjustment disorder. Obviously, criteria other than signs, symptoms, and duration are necessary to differentiate a depressive disorder from adjustment reactions to life situations. The presence of the following characteristics might assist in such a differentiation.

- By definition, a major depressive disorder should be incapacitating. Previously, much attention was paid to the interpersonal consequences of depression. Recent evidence indicates that measurable deficits in work performance are often early manifestations. Afflicted persons also do not benefit from taking leisure time, and hence prescribing vacations is futile.
- Depressive disorder is usually perceived as a break from a person's usual or premorbid self, which can be so striking that sufferers may feel as though they are losing their minds. The important point is that both the patient and significant others can usually relate the onset of the illness to a given month or quarter of a year, which is not true, for instance, for dysthymic disorder.
- Depressive disorder is often experienced by the sufferer as qualitatively distinct from grief or other understandable reactions to loss or adversity. William James

described it as follows:

There is a pitch of unhappiness so great that the goods of nature may be entirely forgotten, and all sentiment of their existence vanish from the mental field. For this extremity of passion to be reached, something more is needed than adversity; the individual must in his own person become the prey of pathological melancholy. Such sensitiveness and susceptibility of mental pain is a rare occurrence where the nervous constitution is entirely normal: one seldom finds it in a healthy subject even where he is the victim of the most atrocious cruelties of outward fortune; it is an active anguish, a sort of psychical neuraglia wholly unknown to healthy life.

Two additional features, when present, would further validate the diagnosis of major depressive disorder.

- History of past episodes.
- Consecutive-generation family history of mood disorder—especially when a large number of family members are afflicted with depression or mood disorder—is characteristic of clinical depression. For instance, one study that prospectively followed persons with minor or neurotic depression found that such pedigrees predicted the development of future major episodes. DSM-IV makes no provision for considering such familial factors in diagnostic decisions. In clinical practice these factors often strongly influence whether depression is taken seriously.

Single Episode and Recurrent Subtypes About a third of all major depressive episodes do not recur (Table 14.6-15). Such patients tend to be older and less likely to have a positive family history for mood disorders, and have a more protracted (1 to 2 years) course of the disorder. Patients with major depressive disorder, single episode should be distinguished from those experiencing their first episodes of major depressive disorder, recurrent (Table 14.6-16). The latter group tends to be younger, and the disorder is more likely to have been preceded by a depressive temperament or dysthymic disorder.

Research has established that recurrent major depressive disorders are more familial than their single-episode counterparts. The average length of episodes is 6 months, whereas the mean interval between episodes tends to vary (typically years). The mean number of major episodes over a lifetime, according to retrospective and prospective studies, is five to six, in contrast to an average of eight to nine major episodes in bipolar disorder.

Melancholic Features In DSM-III the neurotic-endogenous distinction was deleted. Neurotic depression was largely absorbed by dysthymic disorder and the major depressive disorders that complicate it; endogenous depression became “melancholic features,” a qualifying phrase for major depressive disorders in which anhedonia, guilt, and psychomotor-vegetative disturbances dominate the clinical picture (Table 14.6-4). DSM-IV retains these conventions.

Although the foregoing conventions have received much criticism, they are based on solid data from independent studies in the United States and Germany. Thus neurotic depression, defined as a reactive (i.e., precipitated) nonpsychotic depression of mild to moderate intensity with predominant anxiety and characterologic pathology, does not seem to constitute a distinct nosological entity. Although such a presentation is common in clinical practice, well-conducted studies in the United States and Europe have shown that the prospective follow-up course of those patients is heterogeneous, including melancholic and even psychotic depressions and, in some instances, bipolar transformation. The progression of a precipitated, relatively mild depression (reactive illness) to severe psychotic depression—or one with melancholic autonomy—during prospective observation suggests that so-called endogenous depressions may have their onset in milder depressions, that neurotic and psychotic depressions do not necessarily refer to distinct disorders but to disorders that differ in severity, and that the presence of precipitating stress carries little diagnostic weight in differentiating subtypes of depression (although the absence of such stress might be used to support a melancholic level of major depressive disorder).

At the heart of the concept of morbid depression is its autonomy from stresses that may have precipitated it and its general unresponsiveness to other environmental input. This is embodied in Donald Klein's concept of endogenomorphic depression, which could be precipitated and mild (endoreactive) while exhibiting disturbances of hedonic mechanisms refractory to current interpersonal contexts. Many authorities believe that such features dictate the need to use somatic approaches to reverse the maladaptive autonomy and restore response to interpersonal feedback; that is, psychotherapeutic approaches are deemed largely ineffective until the autonomy is somatically lysed.

Given the somatic connotation of the ancient concept of melancholia, the APA classification has officially adopted it as the preferred nosological term for the revised concept of endogeneity; hence the prominence of the vegetative and biorhythmic features accorded to it in both DSM-III and DSM-IV. However, the APA diagnostic schema risks confusing endogeneity with another classic concept of mood disorder, that of “involutional melancholia.”

Psychotic Features About 15 percent of major depressive disorders, usually from the rank of those with melancholic features, develop into delusional depressions. In young persons they tend to be retarded, even stuporous, and are best considered initial episodes of a bipolar disorder. More typically, psychotic depression that develops for the first time after the age of 50 often presents with severe agitation, delusional guilt, hypochondriacal preoccupations, early-morning awakening, and weight loss. The premorbid adjustment of such patients is classically characterized as “obsessoid.” Their mournful-anxious mood and agitation are autonomous, being refractory to psychological interventions, and they endure great psychic suffering. Except for the fact that generally one to two episodes occur in late-onset (so-called involutional) depressions, they represent a severe variant of DSM-IV melancholia. Kraepelin's postulation of a cerebrovascular basis for such cases makes the ventricular enlargement and white matter opacities reported in psychotic depressions of some interest. Their etiological specificity for persons with late-onset psychotic depression has been controversial, however, since younger (more bipolar) persons with psychotic depression exhibit similar findings. Brain imaging findings tend to be correlated with the neurocognitive deficits observed in psychotic depressions. Those features do not seem to define a distinct depressive subtype, but one of greater severity. Finally, despite attempts to suggest a neurochemical uniqueness based largely on the need for antipsychotic treatment in the acute phase of many of those patients, familial and other external validators have failed to support psychotic depression as a separate entity; hence the decision in DSM-IV to use psychotic features merely as a specifier for major depressive episode (Table 14.6-3). Emerging data, nonetheless, might eventually force a change in this convention. For instance, William Coryell and collaborators in the NIMH collaborative study of depression have shown psychotic depression to be the most consistent unipolar subtype across episodes. Alan Schatzberg's work, originally conducted at Harvard, likewise underscores the uniqueness of psychotic depression based on neuroendocrine and putative neurochemical considerations.

Chronic Depression The DSM-IV criteria for chronic specifier appear in Table 14.6-19. The clinical situation, however, is much more complex than these conventions. For instance, the symptom profile in chronic depressions usually displays low-grade intensity rather than severe syndromal chronicity. Severe depressive disorder in its psychotic forms is so agonizing that the sufferer is at risk of committing suicide before the disorder has a chance to become chronic. More commonly, the psychotic symptoms respond to medication or to electroconvulsive therapy (ECT), but residual depressive symptoms may linger for a long time. In other persons with chronic depressions the chronicity arises from more mundane (nonpsychotic) major depressive episodes, depressive residua following one or several clinical episodes that fail to remit fully. Instead of the customary remission within a year, the patients are ill for years. The level of depression varies, fluctuating between syndromal illness and milder symptoms. The patients often show a sense of resignation, generalized fear of an inability to cope, adherence to rigid routines, and inhibited communication.

Specify if:

Chronic (can be applied to the current or most recent major depressive episode in major depressive disorder and to a major depressive episode in bipolar I or II disorder only if it is the most recent type of mood episode)

Full criteria for a major depressive episode have been met continuously for at least the past 2 years

Table 14.6-19 DSM-IV Diagnostic Criteria for Chronic Specifier

Rather than exhibiting a frankly depressive mood, many persons with chronic depression suffer from deficits in their ability to enjoy leisure and display an attitude of

irritable moroseness. The leisure deficits and irritable humor tend to affect their conjugal lives: their marriages are typically in a state of chronic deadlock, leading neither to divorce nor to reconciliation. In other patients the residual phase is dominated by somatic features, such as sleep and other vegetative or autonomic irregularities. Thus, self-treatment with ethanol or iatrogenic benzodiazepine dependence is common. That these interpersonal, conjugal, and autonomic manifestations represent unresolved depression is shown by persistent sleep EEG (especially REM and delta phase) abnormalities that are indistinguishable from their acute counterparts.

Failure to recover from major depressive disorder is associated with increased familial loading for depression, disabled spouses, deaths of immediate family members, concurrent disabling medical disease, use of depressant pharmacologic agents, and excessive use of alcohol and sedative-hypnotic agents. Social support is often eroded in persons with residual depression, through either the death or illness of significant others. Therefore, a thorough medical evaluation and socially supportive interventions should be essential ingredients of the overall approach to those patients.

Interpersonal disturbances in such patients are usually secondary to the distortions produced by long-standing depression. Therefore, observed pathological characterological changes—clinging or hostile dependence, demandingness, touchiness, pessimism, and low self-esteem—are best considered as “postdepressive personality” changes. A dangerous stereotypical thinking holds that because a patient has not responded adequately to standard treatments (the illness has become chronic), the disorder must have a characterological substrate. The long duration of the disorder often leads the patient to identify with the failing functions of depression, producing the self-image of being a depressed person. This self-image itself represents a malignant cognitive manifestation of the depressive disorder and dictates vigorous treatment targeted at the mood disorder.

Dysthymic Disorder Dysthymic disorder (Table 14.6-20) is distinguished from chronic depressive disorder by the fact that it is not a sequel to well-defined major depressive episodes. Instead, in the most typical cases, patients complain that they have always been depressed. Thus, most cases are of early onset, beginning in childhood or adolescence and certainly by the time patients reach their 20s. A late-onset subtype, much less prevalent and not well characterized clinically, has been identified among middle-aged and geriatric populations, largely through epidemiological studies in the community.

Table 14.6-20 DSM-IV Diagnostic Criteria for Dysthymic Disorder

Although the dysthymic disorder category in DSM-IV can occur as a secondary complication of other psychiatric disorders, the core concept of dysthymic disorder refers to a subaffective disorder with (1) low-grade chronicity for at least 2 years, (2) insidious onset with origin often in childhood or adolescence, and (3) persistent or intermittent course. Although not part of the formal definition of dysthymic disorder, the family history is typically replete with both depressive and bipolar disorders, which is one of the more robust findings supporting its link to primary mood disorder.

Social Adjustment Dysthymic disorder is typically an ambulatory disorder compatible with relatively stable social functioning. However, the stability is precarious; recent data document that many patients invest whatever energy they have in work, leaving none for leisure and family or social activities, which results in marital friction. These empirical findings on the work orientation of persons with dysthymic disorder echo earlier formulations in the German and Japanese literature. For instance, Kraepelin described such persons as follows: “Life with its activity is a burden which they habitually bear with dutiful self-denial without being compensated by the pleasure(s) of existence.”

The dedication of persons with dysthymic disorder to work has been suggested to be an overcompensation and a defense against their battle with depressive disorganization and inertia. Nevertheless, Kretschmer suggested that such persons are the “backbone of society,” dedicating their lives to jobs that require dependability and great attention to detail. Epidemiological studies have demonstrated that some persons with protracted dysthymic complaints, extending over many years, have never experienced clear-cut depressive episodes. Some of them may seek outpatient counseling and psychotherapy for what some clinicians might consider “existential depression,” with feelings of being empty and lacking any joy in life outside their work. Such persons have been described as leading monocategorical existences. Others present clinically because their low-grade dysphoria has intensified into a major depression disorder.

Course An insidious onset of depression dating back to late childhood or the teens, preceding any superimposed major depressive episodes by years or even decades, represents the most typical developmental background of dysthymic disorder. A return to the low-grade depressive pattern is the rule following recovery from superimposed major depressive episodes, if any; hence the designation “double depression” as a prominent course pattern illustrated in DSM-IV for depressive illness (Fig. 14.6-6). This pattern, commonly seen in clinical practice, consists of the baseline dysthymic disorder fluctuating in and out of depressive episodes. The more prototypical patients with dysthymic disorder often complain of having been depressed since birth or of feeling depressed all the time. They seem, in the apt words of Kurt Schneider, to view themselves as belonging to an “aristocracy of suffering.” Such descriptions of chronic gloominess in the absence of more objective signs of depression earn such patients the label of “characterological depression.” The description is further reinforced by the fluctuating depressive picture that merges imperceptibly with the patient's habitual self and thus raises uncertainty as to whether dysthymic disorder belongs in Axis I or Axis II.

Clinical Picture The profile of dysthymic disorder overlaps with that of major depressive disorder but differs from it in that symptoms tend to outnumber signs (more subjective than objective depression). This means that marked disturbances in appetite and libido are uncharacteristic, and psychomotor agitation or retardation is not observed. This all translates into a depression with attenuated symptomatology. However, subtle endogenous features are not uncommonly observed: inertia, lethargy, and anhedonia that are characteristically worse in the morning. Because patients presenting clinically often fluctuate in and out of a major depression, the core DSM-IV criteria for dysthymic disorder tend to emphasize vegetative dysfunction, whereas the alternative criterion B for dysthymic disorder (Table 14.6-21) in a DSM-IV appendix lists cognitive symptoms.

B. Presence, while depressed, of three (or more) of the following:
(1) low self-esteem or self-confidence, or feelings of inadequacy
(2) feelings of pessimism, despair, or hopelessness
(3) generalized loss of interest or pleasure
(4) social withdrawal
(5) chronic fatigue or tiredness
(6) feelings of guilt, brooding about the past
(7) subjective feelings of irritability or excessive anger
(8) decreased activity, effectiveness, or productivity
(9) difficulty in thinking, reflected by poor concentration, poor memory, or indecisiveness

Table 14.6-21 DSM-IV Alternative Research Criterion B for Dysthymic Disorder

Although dysthymic disorder represents a more restricted concept than its parent, neurotic depression, it is still quite heterogeneous. Anxiety is not a necessary part of its clinical picture, yet dysthymic disorder is often diagnosed in patients with anxiety and neurotic disorders. That clinical situation is perhaps to be regarded as a secondary or “anxious dysthymia” or, in the framework of Peter Tyrer, as part of a “general neurotic syndrome.” For greater operational clarity it is best to restrict dysthymic disorder to a primary disorder, one that cannot be explained by another psychiatric disorder. The essential features of such primary dysthymic disorder include habitual gloom, brooding, lack of joy in life, and preoccupation with inadequacy. Dysthymic disorder then is best characterized as long-standing fluctuating low-grade depression, experienced as part of the habitual self and representing an accentuation of traits observed in the depressive temperament (Table 14.6-1). Dysthymia then can be viewed as a more symptomatic form of that temperament (introduced in a DSM-IV appendix as a depressive personality disorder). Sleep EEG data indicate that many persons with dysthymic disorder at baseline exhibit the sleep patterns of those with acute major depressive disorder, providing support for the constitutional nature of the disorder. Further evidence for that position comes from studies demonstrating high rates of familial affective disorder in dysthymic disorder, depressive temperament, or both.

The clinical picture of dysthymic disorder that emerges from the foregoing description is quite varied, with some patients proceeding to major depression, while others manifest the pathology largely at the personality level. The foregoing considerations suggest that a clinically satisfactory operationalization of dysthymia must include symptomatic, cognitive, and trait characteristics.

A 27-year-old, male, grade-school teacher presented with the chief complaint that life was a painful duty that had always lacked luster for him. He said he felt enveloped by a sense of gloom that was nearly always with him. Although he was respected by his peers, he felt “like a grotesque failure, a self-concept I have had since childhood.” He stated that he merely performed his responsibilities as a teacher and that he had never derived any pleasure from anything he had done in life. He said he had never had any romantic feelings; sexual activity, in which he had engaged with two different women, had involved pleasureless orgasm. He said he felt empty, going through life without any sense of direction, ambition, or passion, a realization that itself was tormenting. He had bought a pistol to put an end to what he called his “useless existence” but did not carry out suicide, believing that it would hurt his students and the small community in which he lived.

Dysthymic Variants Dysthymia is not uncommon in patients with chronically disabling physical disorders, particularly among elderly adults. Dysthymia-like clinically significant subthreshold depression lasting 6 or more months has also been described in neurological conditions, including stroke. According to a recent WHO conference, this condition aggravates the prognosis of the underlying neurological disease and, therefore, deserves pharmacotherapy. Ongoing studies should provide more explicit clinical recommendations on this topic.

Prospective studies on children have revealed an episodic course of dysthymia with remissions, exacerbations, and eventual complications by major depressive episodes, 15 to 20 percent of which might even progress to hypomanic, manic, or mixed episodes postpuberty. Persons with dysthymic disorder presenting clinically as adults tend to pursue a chronic unipolar course that may or may not be complicated by major depression. They rarely develop spontaneous hypomania or mania. However, when treated with antidepressants, some of them may develop brief hypomanic switches that typically disappear when the antidepressant dose is decreased. Although DSM-IV would not allow the occurrence of such switches in dysthymia, systematic clinical observation has verified their occurrence in as many as a third of dysthymic patients. In this special subgroup of persons with dysthymic disorder, the family histories are often positive for bipolar disorder. Such patients represent a clinical bridge between depressive disorder and bipolar II disorders.

Depressive Disorder Not Otherwise Specified The DSM-IV criteria for depressive disorder not otherwise specified, are presented in Table 14.6-22. What follows are descriptions of conditions that are commonly used in the epidemiological, clinical, or pharmacological literature but do not easily fit into the official nosology of depressive disorders. Some represent complex interweaving of depression with personality constructs. For instance, community studies have revealed a prevalent pattern of intermittent depressive manifestations with brief episodes, below the 2-week duration threshold for major depressive disorder. In so-called minor depressive disorder (Table 14.6-23), observed in primary care settings, the depression is subthreshold, milder than major depression and yet not protracted enough to be considered dysthymic. These varied manifestations of depression argue for a continuum model (Fig. 14.6-7) as originally envisaged by Kraepelin. Lewis Judd and collaborators at the University of California at San Diego have suggested that subthreshold depressive symptoms—without necessarily meeting the criterion for mood change—might actually represent the most common expressions of a depressive diathesis. From such a subsyndromal symptomatic depressive base, individuals predisposed to depressive illness are said to fluctuate in and out of the various DSM-IV and subthreshold subtypes of depressive disorders. This viewpoint is presently most cogent for subsyndromal symptomatic depression that follows major depressive disorder, a strong predictor of subsequent frequent relapse or chronic course. There is an important message for the clinician here: treat subsyndromal symptomatic depression residual to major depressive disorder.

The depressive disorder not otherwise specified category includes disorders with depressive features that do not meet the criteria for major depressive disorder, dysthymic disorder, adjustment disorder with depressed mood, or adjustment disorder with mixed anxiety and depressed mood. Sometimes depressive symptoms can present as part of an anxiety disorder not otherwise specified. Examples of depressive disorder not otherwise specified include:

1. Premenstrual dysphoric disorder: in most menstrual cycles during the past year, symptoms (e.g., markedly depressed mood, marked anxiety, marked affective lability, decreased interest in activities) regularly occurred during the last week of the luteal phase (and remitted within a few days of the onset of menses). These symptoms must be severe enough to markedly interfere with work, school, or usual activities and be entirely absent for at least 1 week postmenses.
2. Minor depressive disorder: episodes of at least 2 weeks of depressive symptoms but with fewer than the five items required for major depressive disorder.
3. Recurrent brief depressive disorder: depressive episodes lasting from 2 days up to 2 weeks, occurring at least once a month for 12 months (not associated with the menstrual cycle).
4. Postpsychotic depressive disorder of schizophrenia: a major depressive episode that occurs during the residual phase of schizophrenia.
5. A major depressive episode superimposed on delusional disorder, psychotic disorder not otherwise specified, or the active phase of schizophrenia.
6. Situations in which the clinician has concluded that a depressive disorder is present but is unable to determine whether it is primary, due to a general medical condition, or substance induced.

Table 14.6-22 DSM-IV Diagnostic Criteria for Depressive Disorder Not Otherwise Specified

Table 14.6-23 DSM-IV Research Criteria for Minor Depressive Disorder

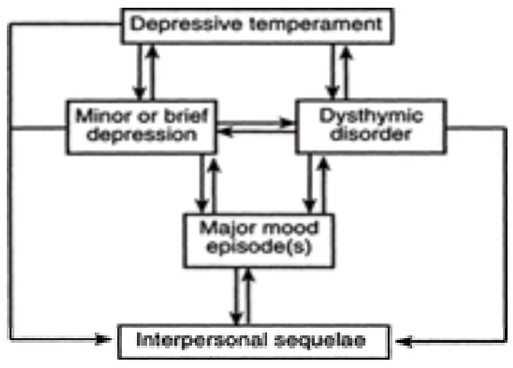

FIGURE 14.6-7 Relation of various depressive conditions supporting a spectrum concept. (Reprinted with permission from Akiskal HS: Dysthymia: Clinical and external validity. Acta Psychiatr Scand *89*(Suppl):19, 1994.)

Recurrent Brief Depressive Disorder Now in a DSM-IV appendix (Table 14.6-24), recurrent brief depressive disorder derives from British work on young adults with frequent suicide attempts and epidemiological studies conducted in a young adult cohort in Zurich. It is described as short-lived depressions that usually recur on a monthly basis but are not menstrually related. They could coexist with major depressive disorder and dysthymic disorder. Such patients are believed to be more prevalent in primary care than in psychiatric settings. Those seen in psychiatric settings are likely to be given Axis II diagnoses such as borderline personality disorder.

A. Criteria, except for duration, are met for a major depressive episode.
B. The depressive periods in criterion A last at least 2 days but less than 2 weeks.
C. The depressive periods occur at least once a month for 12 consecutive months and are not associated with the menstrual cycle.
D. The periods of depressed mood cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
E. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hypothyroidism).
F. There has never been a major depressive episode, and criteria are not met for dysthymic disorder.
G. There has never been a manic episode, a mixed episode, or a hypomanic episode, and criteria are not met for cyclothymic disorder. **Note:** This exclusion does not apply if all of the manic-, mixed-, or hypomanic-like episodes are substance or treatment induced.
H. The mood disturbance does not occur exclusively during schizophrenia, schizophreniform disorder, schizoaffective disorder, delusional disorder, or psychotic disorder not otherwise specified.

Table 14.6-24 DSM-IV Research Criteria for Recurrent Brief Depressive Disorder

The current nosological status of those patients is uncertain, but they testify to Kraepelin's observation that many transitional forms link the depressive temperament to affective episodes:

> A permanent gloomy stress in all the experiences of life usually perceptible already in youth, and may persist without essential change throughout the whole of life (or) there is actually an uninterrupted series of transitions to periodic melancholia in which the course is quite indefinite with irregular fluctuations and remissions.

Reactive Depression Classically, reactive depression is defined as resulting from a specific life event. In an ideal case the depression would not have occurred without the event (e.g., love loss) to which it is a reaction. It continues as long as the event is present, and it terminates with the reversal of the event (e.g., return of the lover). Depressions exhibiting all of those features are almost never seen in clinical practice. With interpersonal support most people can face life's reverses, which explains why reactive depression tends to be self-limiting. Hence, adjustment disorder is the more appropriate diagnosis for most cases of reactive depression.

Conceptually, however, one can envision chronically unsatisfactory life situations that might lead to chronic demoralization. However, such a condition, which could warrant the designation of chronic reactive depression, is a contradiction in terms. The question often raised is why a person would continue to stay in the situation. Sometimes psychodynamic authors invoke the concept of masochism to explain why certain persons cannot rid themselves of painful life situations, implying that they somehow contribute to their maintenance. Current thinking is that some of those presumed self-defeating traits are more situation specific than previously believed and might resolve with the elimination of the situation. So-called self-defeating features then are best considered psychodynamic mechanisms rather than indicators of a specific personality. At the present stage of knowledge, they do not deserve to be raised to the level of a nosological entity (hence, their disappearance from DSM-IV). Chronic adjustment disorder might describe the chronic demoralization observed among some individuals stuck in chronically unsatisfactory life situations. Many more might fulfill the criteria for dysthymia.

Neurasthenia A century-old term developed by the American neuropsychiatrist George Beard, neurasthenia refers to a more chronic stage of anxious-depressive symptomatology. The anxiety generated by overstimulation is so excessive that it is replaced by a chronic disposition to irritability, fatigue (especially mental fatigue), lethargy, and exhaustion. It is as if the sufferer's mind refuses to take on new stresses. The clinical picture described by Beard suggests that anxious manifestations were preeminent in his time. They included headache, scalp tenderness, backache, heavy limbs, vague neuralgias, yawning, dyspepsia, palpitations, sweating hands and feet, chills, flushing, sensitivity to weather changes, insomnia, nightmares, pantaphobia, asthenopia, and tinnitus.

Although the diagnosis of neurasthenia is now used more in China than in the rest of the world, the recent worldwide popularity of the concept of chronic fatigue syndrome attests to the clinical acumen of classic physicians. Despite much energy invested in finding a viral or immunological cause, current descriptions tend to suggest an anxiety or mood disorder basis for some (but not all) of those with the syndrome. However, what circumstances would lead anxiety or depression to manifest primarily in fatigue is as elusive as it was 100 years ago. Like many other patients presenting to primary care settings with somatic complaints, those with chronic fatigue tend to denounce psychiatric diagnoses as inadequate explanations for their ills.

Postpsychotic Depressive Disorder of Schizophrenia DSM-IV describes postpsychotic depressive disorder of schizophrenia as follows:

> The essential feature is a Major Depressive Episode that is superimposed on, and occurs only during, the residual phase of Schizophrenia. The residual phase of Schizophrenia follows the active phase (i.e., symptoms meeting Criterion A) of Schizophrenia. It is characterized by the persistence of negative symptoms or of active-phase symptoms that are in an attenuated form (e.g., odd beliefs, unusual perceptual experiences). The superimposed Major Depressive Episode must include depressed mood (i.e., loss of interest or pleasure cannot serve as an alternate for sad or depressed mood). Most typically, the Major Depressive Episode follows immediately after remission of the active-phase symptoms of the psychotic episode. Sometimes it may follow after a short or extended interval during which there are no psychotic symptoms. Mood symptoms due to the direct physiological effects of a drug of abuse, a medication, or a general medical condition are not counted toward postpsychotic depressive disorder of Schizophrenia.

According to DSM-IV, persons whose presentation meets those research criteria (Table 14.6-25) would be diagnosed as having depressive disorder not otherwise specified. As already pointed out, mood or depressive disorder not otherwise specified represents such a hodgepodge of clinical situations that the designation not otherwise specified is at best meaningless and at worst countertherapeutic. In all postpsychotic depressions, one must first exclude a missed bipolar diagnosis. Negative symptoms due to classic antipsychotics—especially depot phenothiazines and those due to the residium of schizophrenia once positive symptoms are brought under control—should be distinguished from the depressive episodes that complicate the course of schizophrenia in young, intelligent patients.

A. Criteria are met for a major depressive episode. **Note:** The major depressive episode must include criterion A1: depressed mood. Do not include symptoms that are better accounted for as medication side effects or negative symptoms of schizophrenia.
B. The major depressive episode is superimposed on and occurs only during the residual phase of schizophrenia.
C. The major depressive episode is not due to the direct physiological effects of a substance or a general medical condition.

Table 14.6-25 DSM-IV Research Criteria for Postpsychotic Depressive Disorder of Schizophrenia

BIPOLAR DISORDERS

Four bipolar disorders are included in DSM-IV: bipolar I disorder, bipolar II disorder, cyclothymic disorder, and bipolar disorder not otherwise specified.

Bipolar I Disorder Typically beginning in the teenage years, the 20s, or the 30s, the first episode could be manic, depressive, or mixed. One common mode of onset is mild retarded depression, or hypersomnia, for a few weeks or months, which then switches into a manic episode. Others begin with a severely psychotic manic episode with schizophreniform features; only when a more classic manic episode occurs is the affective nature of the disorder clarified. In a third group several depressive episodes take place before the first manic episode. A careful history taken from significant others often reveals dysthymic or cyclothymic traits that antedated the frank onset of manic episodes by several years.

According to DSM-IV, bipolar I disorder, single manic episode (Table 14.6-26) describes patients having a first episode of mania (most such patients eventually develop depressive episodes). The remaining subcategorization is used to specify the nature of the current or most recent episode in patients who have had recurrent mood episodes (Table 14.6-27, Table 14.6-28, Table 14.6-29, Table 14.6-30 and Table 14.6-31. For clinicians and researchers alike it is more meaningful to chart a patient's course in color over time—for example using red rectangles for manic, blue for depressive, and violet for mixed episodes, with hypomanic, dysthymic, and cyclothymic periods drawn in the appropriate colors on a smaller scale between the major episodes. Life events, biologic stressors, and treatment can be indicated by arrows on the time axis. This approach, originally championed by Kraepelin, is routinely used in mood clinics. Robert Post at the NIMH has developed this approach into systematic clinical science.

A. Presence of only one manic episode and no past major depressive episodes.
Note: Recurrence is defined as either a change in polarity from depression or an interval of at least 2 months without manic symptoms.
B. The manic episode is not better accounted for by schizoaffective disorder, and is not superimposed on schizophrenia, schizophreniform disorder, delusional disorder, or psychotic disorder not otherwise specified.

Specify if:
Mixed: if symptoms meet criteria for a mixed episode

Specify (for current or most recent episode):
Severity/psychotic/remission specifiers
With catatonic features
With postpartum onset

Table 14.6-26 DSM-IV Diagnostic Criteria for Bipolar I Disorder, Single Manic Episode

A. Currently (or most recently) in a manic episode.
B. There has previously been at least one major depressive episode, manic episode, or mixed episode.
C. The mood episodes in criteria A and B are not better accounted for by schizoaffective disorder and are not superimposed on schizophrenia, schizophreniform disorder, delusional disorder, or psychotic disorder not otherwise specified.

Specify (for current or most recent episode):
Severity/psychotic remission specifiers
With catatonic features
With postpartum onset

Specify:
Longitudinal course specifiers (with and without interepisode recovery)
With seasonal pattern (applies only to the pattern of major depressive episodes)
With rapid cycling

Table 14.6-27 DSM-IV Diagnostic Criteria for Bipolar I Disorder, Most Recent Episode Manic

A. Currently (or most recently) in a hypomanic episode.
B. There has previously been at least one manic episode or mixed episode.
C. The mood symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The mood episodes in criteria A and B are not better accounted for by schizoaffective disorder and are not superimposed on schizophrenia, schizophreniform disorder, delusional disorder, or psychotic disorder not otherwise specified.

Specify:
Longitudinal course specifiers (with and without interepisode recovery)
With seasonal pattern (applies only to the pattern of major depressive episodes)
With rapid cycling

Table 14.6-28 DSM-IV Diagnostic Criteria for Bipolar I Disorder, Most Recent Episode Hypomanic

A. Currently (or most recently) in a mixed episode.
B. There has previously been at least one major depressive episode, manic episode, or mixed episode.
C. The mood episodes in criteria A and B are not better accounted for by schizoaffective disorder and are not superimposed on schizophrenia, schizophreniform disorder, delusional disorder, or psychotic disorder not otherwise specified.

Specify (for current or most recent episode):
Severity/psychotic remission specifiers
With catatonic features
With postpartum onset

Specify:
Longitudinal course specifiers (with and without interepisode recovery)
With seasonal pattern (applies only to the pattern of major depressive episodes)
With rapid cycling

Table 14.6-29 DSM-IV Diagnostic Criteria for Bipolar I Disorder, Most Recent Episode Mixed

A. Currently (or most recently) in a major depressive episode.
B. There has previously been at least one manic episode or mixed episode.
C. The mood episodes in criteria A and B are not better accounted for by schizoaffective disorder and are not superimposed on schizophrenia, schizophreniform disorder, delusional disorder, or psychotic disorder not otherwise specified.

Specify (for current or most recent episode):
Severity/psychotic remission specifiers
Chronic
With catatonic features
With melancholic features

Table 14.6-30 DSM-IV Diagnostic Criteria for Bipolar I Disorder, Most Recent Episode Depressed

A. Criteria, except for duration, are currently (or most recently) met for a manic, a hypomanic, a mixed, or a major depressive episode.
B. There has previously been at least one manic episode or mixed episode.
C. The mood symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The mood symptoms in criteria A and B are not better accounted for by schizoaffective disorder and are not superimposed on schizophrenia, schizophreniform disorder, delusional disorder, or psychotic disorder not otherwise specified.
E. The mood symptoms in criteria A and B are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication, or other treatment) or a general medical condition (e.g., hyperthyroidism).

Specify:
Longitudinal course specifiers (with and without interepisode recovery)
With seasonal pattern (applies only to the pattern of major depressive episodes)
With rapid cycling

Table 14.6-31 DSM-IV Diagnostic Criteria for Bipolar I Disorder, Most Recent Episode Unspecified

On average, manic episodes predominate in youth, and depressive episodes in later years. Although the overall sex ratio is about one to one, men on average undergo more manic episodes and women experience more mixed and depressive episodes. Bipolar I disorder in children is not as rare as previously thought; however, most reported cases are in boys, and mixed-manic (dysphoric-explosive) presentations are the mode. Childhood-onset depression must also be considered a major risk for ultimate bipolar transformation. This is based on the following characteristics: (1) early age of onset; (2) even sex ratio; (3) prominence of irritability, labile moods, and explosive anger, suggesting mixed episodes; (4) questionable response to antidepressants, hypomanic switches, or both; (5) high recurrence rate after depression; and (6) familial affective loading. Mania can also first appear after age 65, though a diligent search often reveals a past mild, forgotten, or untreated depressive episode in earlier years.

Acute Mania Mania typically escalates over a period of 1 to 2 weeks; more-sudden onsets have also been described. The DSM-IV criteria (Table 14.6-7) stipulate (1) a distinct period that represents a break from premorbid functioning, (2) a duration of at least 1 week, (3) an elevated or irritable mood, (4) at least three to four classic manic signs and symptoms, and (5) the absence of any physical factors that could account for the clinical picture. The irritable mood in mania can deteriorate to cantankerous behavior, especially when the person is rebuffed. Such patients are among the most aggressive seen in the emergency room. Florid grandiose psychosis with paranoid features, a common presentation of mania, further contributes to the aggression. Alcohol use, observed in at least 50 percent of bipolar I patients (often during the manic phase), further disinhibits the patient and might lead to a dangerous frenzy. Such patients may attack loved ones and hurt them physically. So-called crimes of passion have been committed by patients harboring delusions of infidelity on the part of spouses or lovers, usually when under the influence of alcohol.

The genesis of delusional, hallucinatory, even first-rank, psychotic experiences in mania has been described. Recent research has documented that most types of formal thought disorders are common to both schizophrenic and mood psychoses; only poverty of speech content (vagueness) emerges as significantly more common in schizophrenia. Finally, posturing and negativism occur in mania (and, in the author's view, do not warrant the designation of catatonic features as advocated by DSM-IV). Although not specifically mentioned in the DSM-IV definition, confusion, even pseudodemented presentations, can occur in mania. Mania is most commonly expressed as a phase of bipolar type I disorder, which has strong genetic determinants. Available evidence does not permit separating recurrent mania without depressive episodes from that type as a distinct nosological entity.

Secondary Mania Although there is some suggestion that postpartum mania without depression is distinct from familial bipolar I disorder (in which depressive, manic, and especially mixed manic episodes occur in the postpartum period), the evidence for a distinct puerperal mania is not compelling at this time (hence the decision in DSM-IV to include the postpartum-onset specifier [see Table 13.4-3], rather than a separate mood disorder diagnosis). Mania without prior bipolarity can arise in the setting of such somatic illnesses as thyrotoxicosis, systemic lupus erythematosus or its treatment with steroids, rheumatic chorea, multiple sclerosis, Huntington's disease, cerebrovascular disorder, diencephalic and third ventricular tumors, head trauma, complex partial seizures, syphilis, and (most recently) AIDS. The family history is reportedly low in such cases, suggesting a relatively low genetic predisposition and thus a lower risk of recurrence. These patients do not easily fit into the DSM-IV category of mood disorder due to a general medical condition (Table 14.6-17) because most of the conditions appear to be cerebral. Such factors must always be diligently sought in manias of late life.

Less well defined forms of mania are the so-called reactive manias. Personal loss and bereavement are hypothesized to be triggering factors, and the reaction is conceptualized psychodynamically as a denial of loss. Although such explanations may be plausible in individual cases, no systematic data suggest that these patients differ in family history from persons with other manias. The same is generally true for depressed patients who switch to hypomania or mania after abuse of stimulant drugs, treatment with antidepressants, or sleep deprivation. In all of these situations a bipolar diathesis is usually manifest either in a family history of mania or in spontaneous excited episodes during prospective observation. First-onset manic episodes can also occur in persons who abruptly abstain from alcohol after one or more decades of chronic use and then develop classic bipolar I disorder.

Chronic Mania DSM-IV does not specifically address the diagnostic questions posed by the 5 percent of bipolar I patients who have a chronic manic course. These cases commonly represent deterioration of course dominated by recurrent manic episodes grafted on a hyperthymic baseline. Noncompliance with pharmacological treatment is the rule. Recurrent excitement is personally reinforcing, subjective distress is minimal, and insight is seriously impaired. Thus the patient sees no reason to adhere to treatment. Episodic or chronic alcohol abuse, prevalent in such patients, has been suggested as a contributory cause of the chronicity. Some authorities

further consider comorbid cerebral pathology responsible for nonrecovery (and increased mortality) from manic excitements occurring in late life.

Grandiose delusions (e.g., delusions of inventive genius or aristocratic birth) are not uncommon in chronic mania and may lead to the mistaken diagnosis of paranoid schizophrenia. Because of their social deterioration, Kraepelin subsumed such patients under the category “manic dementia.” Organic factors such as head trauma and chronic alcohol abuse may contribute to the deterioration. Nonschizoid premorbid adjustment, a family history of bipolar I disorder, and the absence of flagrant formal thought disorder can be marshaled in establishing the affective basis of these poor-prognosis manic states.

Bipolar Mixed Phase Momentary tearfulness and even depressed mood are commonly observed at the height of mania or during the transition from mania to retarded depression. These transient labile periods, which occur in most bipolar I disorder patients, must be contrasted with mixed episodes proper.

The latter, variously referred to as “mixed mania” or “dysphoric mania,” are characterized by dysphorically excited moods, irritability, anger, panic attacks, pressured speech, agitation, suicidal ideation, severe insomnia, grandiosity, and hypersexuality, as well as persecutory delusions and confusion. Severely psychotic mixed states that involved hallucinations and schneiderian symptoms risk being labeled “schizoaffective.” A correct diagnosis is mandatory because conventional antipsychotic drugs tend to exacerbate the depressive component and failure to use mood stabilizers can prolong the patient's misery.

New research data from mood centers worldwide on mixed mania suggest that dysphoric mania—mania and full-blown depression occurring simultaneously—is relatively uncommon. Two to four depressive symptoms from the list of depressed mood, helplessness, hopelessness, fatigue, anhedonia, guilt, and suicidal ideation, or impulses, or both, in the setting of a manic syndrome, appear to suffice for the diagnosis of mixed manic states, which occurs in 50 percent of patients with bipolar disorder sometime during their lives. Mixed states occur predominantly in females in whom mania is superimposed on a depressive temperament or a dysthymic baseline. These considerations suggest that the DSM-IV concept of mixed episode (Table 14.6-8) as a cross-sectional mixture of mania and depression is simplistic and phenomenologically naive. The emerging conceptualization of mixed mania is a manic state intruding upon long-term depressive traits.

Depressive Phase Psychomotor retardation, with or without hypersomnia, marks the uncomplicated depressive phase of bipolar I disorder. Onset and offset are often abrupt, though onset can also occur gradually over several weeks. Patients may recover into a free interval or switch directly into mania. Switching into an excited phase is particularly likely when antidepressants have been used. However, not all patients develop mania after antidepressant treatment of bipolar depression. Some develop a mixed agitated depression; indeed, patients may be stuck for many months in a severe depressive phase with some manic admixtures such as racing thoughts and sexual arousal. DSM-IV does not specifically recognize a mixed depressive phase with few manic symptoms occurring during full-blown depression. Such recognition is necessary because these patients don't need continued aggressive antidepressant therapy but mood stabilizers, ECT, or both.

Delusional and hallucinatory experiences are less common in the depressive phase of bipolar I disorder than in the manic and mixed manic phases. Stupor is the more common psychotic presentation of bipolar depression, particularly in adolescents and young adults. Pseudodemented organic presentations appear to be the counterpart of stupor in elderly adults.

Cyclothymic Disorder An attenuated bipolar disorder that typically begins insidiously before the age of 21, cyclothymic disorder is characterized in DSM-IV by frequent short cycles of subsyndromal depression and hypomania (Table 14.6-32). The author's research has revealed alternating patterns of moods, activity, and cognition (Table 14.6-33), which are more explicit than the DSM-IV criteria. The course of cyclothymia is continuous or intermittent, with infrequent periods of euthymia. Shifts in mood often lack adequate precipitants (e.g., sudden profound dejection with social withdrawal for a few days switching into cheerful, gregarious behavior). Circadian factors may account for some of the extremes of emotional lability, such as the person's going to sleep in good spirits and waking up early with suicidal urges. The mood changes of cyclothymia are best described as “endoreactive” in the sense that endogenous overreactivity seems to determine the sudden shifts in mood and behavior (e.g., falling in love with a person one has just met and as quickly falling out of love).

A. For at least 2 years, the presence of numerous periods with hypomanic symptoms and numerous periods with depressive symptoms that do not meet criteria for a major depressive episode.
Note: In children and adolescents, the duration must be at least 1 year.
B. During the above 2-year period (1 year in children and adolescents), the person has not been without the symptoms in criterion A for more than 2 months at a time.
C. No major depressive episode, manic episode, or mixed episode has been present during the first 2 years of the disturbance.
Note: After the initial 2 years (1 year in children and adolescents) of cyclothymic disorder, there may be superimposed manic or mixed episodes (in which case both bipolar I disorder and cyclothymic disorder may be diagnosed) or major depressive episodes (in which case both bipolar and cyclothymic disorder may be diagnosed).
D. The symptoms in criterion A are not better accounted for by schizoaffective disorder and are not superimposed on schizophrenia, schizophreniform disorder, delusional disorder, or psychotic disorder not otherwise specified.
E. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hyperthyroidism).
F. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Table 14.6-32 DSM-IV Diagnostic Criteria for Cyclothymic Disorder

Biphasic dysregulation characterized by abrupt endoreactive shifts from one phase to the other, each phase lasting for a few days at a time, with infrequent euthymia.

Behavioral manifestations:
- Introverted self-absorption versus uninhibited people-seeking
- Taciturn versus talkative
- Unexplained tearfulness versus buoyant jocularity
- Psychomotor inertia versus restless pursuit of activities

Subjective manifestations:
- Lethargy and somatic discomfort versus eutonia
- Dulling of senses versus keen perceptions
- Slow-witted versus sharpened thinking
- Shaky self-esteem alternating between low self-confidence and overconfidence
- Pessimistic brooding versus optimism and carefree attitudes

Updated from Akiskal HS, Khani M, Scott-Strauss A: Cyclothymic temperamental disorders. Psychiatr Clin North Am 2:527, 1979.

Table 14.6-33 Clinical Features of Cyclothymic Disorder

Mood swings in these ambulatory patients are overshadowed by the chaos that the swings produce in their personal lives. Repeated romantic breakups or marital failures are common because of interpersonal friction and episodic promiscuous behavior. Uneven performance at school and work is also common. Persons with cyclothymic disorder are dilettantes; they show great promise in many areas, but rarely bring any of their efforts to fruition. As a result, their lives are often a string of improvident activities. Geographical instability is a characteristic feature; easily attracted to a new locale job, or love partner, they soon lose interest and leave in dissatisfaction. Polysubstance abuse which occurs in as many as 50 percent of such persons, is often an attempt at self-treatment.

Bipolar II Disorder (and the Soft Bipolar Spectrum) Research conducted during the past three decades showed that between the extremes of classic manic-depressive illness defined by at least one acute manic episode (bipolar I disorder) and strictly defined major depressive disorder without any personal or family history of mania (pure unipolar disorder), exists an overlapping group of intermediary forms characterized by recurrent major depressive episodes and hypomania. Table 14.6-34 summarizes the author's observations in defining the clinical subtypes within this intermediary realm best described as “soft bipolarity.” The most accepted of the subtypes is bipolar II disorder (with spontaneous hypomania), elevated to the status of a nosological entity in DSM-IV (Table 14.6-35). Current data worldwide indicate that bipolar II disorder is actually more prevalent than bipolar I disorder. This certainly appears true in the outpatient setting, where 30 to 50 percent of persons with major depressive disorder have been reported to conform to the bipolar II pattern.

	Bipolar I:	At least one manic episode
Soft bipolar	Bipolar II:	Recurrent depressions with hypomania and cyclothymic disorder
Soft bipolar	Bipolar III: (pseudounipolar)	Recurrent depressions without spontaneous hypomania but often with hyperthymic temperament and bipolar family history
Unipolar depressions:		No evidence for hypomania, cyclothymic disorder, hyperthymic disorder, or bipolar family history

Table 14.6-34 Spectrum of Bipolar Disorders Compared With Unipolar Depression

A. Presence (or history) of one or more major depressive episodes.
B. Presence (or history) of at least one hypomanic episode.
C. There has never been a manic episode.
D. The mood symptoms in criteria A and B are not better accounted for by schizoaffective disorder, and are not superimposed on schizophrenia, schizophreniform disorder, delusional disorder, or psychotic disorder not otherwise specified.
E. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Specify current or most recent episode:
Hypomanic: if currently (or most recently) in a hypomanic episode
Depressed: if currently (or most recently) in a major depressive episode

Specify if the current or most recent major depressive episode only if it is the most recent type of mood episode:
Severity/psychotic/remission specifiers
Chronic
With catatonic features
With melancholic features
With atypical features
With postpartum onset

Specify:
Longitudinal course specifiers (with or without interepisode recovery)
With seasonal pattern (applies only to the pattern of major depressive episodes)
With rapid cycling

Table 14.6-35 DSM-IV Diagnostic Criteria for Bipolar II Disorder

The following self-description provided by a 34-year-old poet illustrates the pattern:

> I have known melancholy periods, lasting months at a time, when I would be literally paralyzed: All mental activity comes to a screeching halt, and I cannot even utter one word. I become so dysfunctional that I was once hospitalized. Although the paralysis creeps into me insidiously—often lasting months—it typically reverses within hours. I am suddenly alive and vibrant, I cannot turn off my brain neither during the day nor at night; I usually go on celebrating like this for many weeks, needing no more than few hours of slumber each day.

This vignette is nearly identical to the autobiographical description provided by the British poet William Cowper three centuries earlier:

> I have known many a lifeless and unhallowed hour ... long intervals of darkness interrupted by short returns of peace and joy ... For many succeeding weeks to rejoice day and night was all my employment. Too happy to sleep much, I thought it was lost time that was spent on slumber.

The hypomania at the end of depressive episodes in most bipolar II patients does not persist long; it is usually measured in days. The modal duration of hypomania found in Memphis and Zurich studies was 2 days. Another common form of bipolar II disorder is major depressive disorder superimposed on cyclothymic disorder, in which hypomania precedes and follows major depression, the entire interepisodic period characterized by cyclothymic mood instability. As a result, these are difficult bipolar II patients to manage in clinical practice.

Hypomania in bipolar II disorder can be defined as minimanic episodes occurring spontaneously. Bipolar II disorder—especially when major depressions are superimposed on cyclothymia—is thus best characterized as cyclical or “cyclothymic depression.”

The depressive episodes of patients with bipolar disorder often have admixtures (e.g., flight of ideas, increased drives and impulsivity in sexual and other domains). The phenomenon of lithium augmentation is perhaps best explained by the high prevalence of pseudounipolar depressions with subtle hypomania either during or following a depressive episode, as well as the mixed simultaneous presence of depressive and hypomanic symptoms. The latter are not as severe as dysphoric mixed states, but are refractory to antidepressants nonetheless.

Hypomania The common denominator of the soft spectrum of bipolar disorders is the occurrence of hypomania. Hypomania (Table 14.6-9) refers to a distinct period of at least a few days of mild elevation of mood, sharpened and positive thinking, and increased energy and activity levels, typically without the impairment characteristic of manic episodes. It is not merely a milder form of mania. Hypomania occurring as part of bipolar II disorder rarely progresses to manic psychosis; distractibility is uncommon in hypomania, and insight is relatively preserved. Hypomania is distinguished from mere happiness in that it tends to recur (happiness does not) and can sometimes be mobilized by antidepressants. In cyclothymic disorder it alternates with minidepressions; in hyperthymic temperament it constitutes the person's habitual baseline. These definitions then recognize three patterns of hypomania: brief episodes heralding the termination of a retarded depressive episode (bipolar II disorder), cyclic alternation with minidepressions (cyclothymic disorder), and an elevated baseline of high mood, activity, and cognition (hyperthymic or chronic hypomanic traits).

Because hypomania is experienced either as a rebound relief from depression or as pleasant, short-lived, ego-syntonic mood state, persons with bipolar II disorder rarely report it spontaneously. Skillful questioning is thus required to make the diagnosis of soft bipolar conditions; as in mania, collateral information from family members is crucial. In interviewing the patient the following probes have been found useful to elicit hypomania: “Have you had a distinct sustained high period (1) when your thinking and perceptions were unusually vivid or rapid, (2) your mood was so intense that you felt nervous, and (3) you were endowed with such energy that others could not keep up with you?” The hypomanic manifestations for hypomania in the DSM-IV scheme basically list the signs and symptoms of mania in criterion A and B for mania (Table 14.6-9) but require fewer items and shorter duration. Clinical and epidemiological studies in the United States and Europe have revealed a richer range of manifestations including an increase in cheerfulness and jocularity; gregariousness and people seeking; greater interest in sex; talkativeness, self-confidence, and optimism; and decreased inhibitions and sleep need. The clinician must ascertain that those experiences were not due to stimulant or alcohol withdrawal. Depressive and hypomanic periods are often not easily discerned because chronic caffeinism, stimulant abuse, or both complicate the depression. In such instances, diagnosis should be based on clinical observation for 1 month after detoxification.

When in doubt, direct clinical observation of hypomania—sometimes elicited by antidepressant pharmacotherapy—provides definitive evidence for the bipolar nature of the disorder. Unfortunately DSM-IV denies bipolar status to treatment-emergent hypomanic episodes. Follow-up studies in juvenile and young adults with pharmacological hypomania have demonstrated that nearly all such individuals progress to spontaneous hypomanic (or manic) episodes. Although DSM-IV stipulates a minimum duration of 4 days for hypomania, any recurrent hypomania coupled with major depression should count toward the diagnosis of bipolar II.

Seasonal Patterns Seasonality is observed in many cyclic depressions, often with autumn or winter anergic depression and energetic periods in the spring. This natural propensity explains why phototherapy may provoke mild hypomanic switches. Although not specifically identified by DSM-IV, seasonal depressions conform, in large measure, to the bipolar II or III pattern. Furthermore, preliminary evidence suggests that treatment with classic antidepressants disrupts the baseline seasonality, with the depressive phase appearing in the spring and summer. The changes antidepressants induce in seasonal depressions probably represent a special variant of the rapid-cycling phenomenon.

Temperament and Polarity of Episodes New systematic clinical observations have revealed that bipolar II disorder (characterized predominantly by depressive attacks) arises more often from a hyperthymic or cyclothymic baseline, whereas bipolar I disorder (defined by manic attacks) not uncommonly arises from the substrate of a depressive temperament. When the hyperthymic temperament occurs in bipolar I disorder, it is usually associated with a recurrent mania, which is an

uncommon bipolar course. A prospective 11-year NIMH study of major depressive disorder patients who switched to bipolar II disorder showed that “mood-labile” (cyclothymic) and “energetic-active” (hyperthymic) temperament traits were highly specific and reasonably sensitive predictors of such an outcome.

Bipolarity is conventionally defined by the alternation of manic (or hypomanic) and depressive episodes. The foregoing data on temperaments suggest hat a more fundamental characteristic of bipolarity is the reversal of temperament into its “opposite” episode (in the case of the bipolar II spectrum, from cyclothymia and hyperthymia to major depression). Such findings suggest that the intrusion of cyclothymic and hyperthymic traits into a depressive episode may underlie the instability of the bipolar II subtype and could partly explain why bipolar II depression often has mixed features. These considerations may have important implications for preventing recurrence. For instance, a prospective study of the onset of bipolar disorder in the offspring or sibs of adults with the disorder found that children with depressive onsets as their first episode (and which were usually treated with antidepressants) had significantly higher rates of recurrence than those with manic or mixed onsets (treated with lithium) during a 3-year prospective observation. It appears that temperamental instability in the depressive group might have predisposed them to the cycling effect of antidepressants.

Alcohol, Substance Abuse, and Suicide New evidence supports the high prevalence of alcohol and substance abuse in mood disorder subtypes, especially those with interepisodic cyclothymia and hyperthymia. The relation appears particularly strong in the teenage and early adult years, when the use of such substances often represents self-medication for the mood instability. It is not just self-treatment for selected symptoms associated with the down or up phases (e.g., alcohol to alleviate the insomnia and nervousness characteristic of both phases), it also augments certain desired ends (e.g., stimulants to enhance high-energy performance and sexual behavior associated with hypomania). How many display alcohol and substance abuse secondary to an underlying bipolar diathesis remains to be determined. But in view of findings suggesting a link between polysubstance abuse and suicide in adolescents with bipolar familial backgrounds, the use of mood stabilizers in these adolescents should be strongly considered. Although alcohol and stimulant use continues into adult years in a considerable number of bipolar disorder patients, such use is often unrelated to familial alcoholism, and frequently tends to dwindle during long-term follow-up, which supports the self-medication hypothesis. To complicate matters, in a substantial minority of cases, bipolar mood swings appear for the first time after abrupt cessation of long-term alcohol use; it is not uncommon for such mood swings to escalate into full-blown bipolar syndromes.

Rapid-Cycling Bipolar Disorder Rapid cycling is defined as the occurrence of at least four episodes—both retarded depression and hypomania (or mania)—a year (Table 14.6-36). Thus rapid cyclers are rarely free of affective symptoms and suffer serious vocational and interpersonal incapacitation. Lithium is often only modestly helpful to those patients, as are traditional antipsychotic agents; most antidepressants readily induce excited episodes and thus aggravate the rapid-cycling pattern. A balance among mood stabilizers, antipsychotic drugs, and antidepressants may be difficult to achieve. Many such patients require frequent hospitalization because they develop explosive excitement and precipitous descent into severe psychomotor inhibition. The disorder is a roller coaster nightmare for the patient, significant others, and the treating physician. Treating these patients is an art.

Specify if:

With rapid cycling (can be applied to bipolar I disorder or bipolar II disorder)

At least four episodes of a mood disturbance in the previous 12 months that meet criteria for a major depressive, manic, mixed, or hypomanic episode.

Note: Episodes are demarcated either by partial or full remission for at least 2 months or a switch to an episode of opposite polarity (e.g., major depressive episode to manic episode).

Table 14.6-36 DSM-IV Diagnostic Criteria for Rapid Cycling Specifier

As expected, rapid cycling commonly arises from a cyclothymic substrate, which means that most rapid cyclers have bipolar II disorder. Factors favoring its occurrence include (1) female gender; (2) borderline hypothyroidism; (3) menopause; (4) temporal lobe dysrhythmias; (5) alcohol, minor tranquilizer, stimulant, or caffeine abuse; and (6) long-term, aggressive use of antidepressant medications. Most clinically identified patients are bipolar II women in middle age or upper social classes. Rapid cycling is uncommon from a bipolar I base.

Leadership and Creativity Persons with hyperthymic temperament and soft bipolar conditions in general possess assets that permit them to assume leadership roles in business, the professions, civic life, and politics. Increased energy, sharp thinking, self-confidence and eloquence represent the virtues of an otherwise stormy life.

Creative achievement is relatively uncommon among those with the manic forms of the disorder, which is too severe and disorganizing to permit the necessary concentration and application. Notable artistic achievements are found among those with soft bipolar disorders, especially cyclothymic disorders. Psychosis, including severe bipolar swings, is generally incompatible with creativity. That conclusion, based on recent systematic studies, tends to refute the romantic tendency to idolize insanity as central to the creative process. As talent is the necessary ingredient of creativity, how might soft bipolarity contribute? The simplest hypothesis is that depression might provide insights into the human condition, and the activation associated with hypomania helps in producing the artistic work. A more profound interpretation suggests that the repeated self-doubt that comes with recurrent depression might be an important ingredient of creativity, because original artistic or scientific expression is often initially rejected, and the self-confidence that accompanies repeated bouts of hypomania can help in rehearsing such ideas or expressions until they are perfected. Finally, the tempestuous object relations associated with bipolarity in the parent's or the patient's life often create the unique biographical landmarks that might be immortalized in an artistic medium.

Bipolar Disorder Not Otherwise Specified The criteria for bipolar disorder not otherwise specified are listed in Table 14.6-37.

The bipolar disorder not otherwise specified category includes disorders with bipolar features that do not meet criteria for any specific bipolar disorder. Examples include:

1. Very rapid alternation (over days) between manic symptoms and depressive symptoms that do not meet minimal duration criteria for a manic episode or major depressive episode
2. Recurrent hypomanic episodes without intercurrent depressive symptoms
3. A manic or mixed episode superimposed on delusional disorder, residual schizophrenia, or psychotic disorder not otherwise specified
4. Situations in which the clinician has concluded that a bipolar disorder is present but is unable to determine whether it is primary, due to a general medical condition, or substance induced

Table 14.6-37 DSM-IV Diagnostic Criteria for Bipolar Disorder Not Otherwise Specified

Recurrent hypomanic episodes without intermittent depressions (example 2 in the DSM-IV criteria for bipolar disorder not otherwise specified are almost never observed clinically.

Recurrent Brief Hypomania Recurrent brief depressive disorder as a transitional form between dysthymia and major depression or brief hypomanic episodes often have been missed during evaluations performed by nonclinicians. Some patients who meet the Zurich description might therefore belong in the soft bipolar spectrum. Indeed, subsequent evaluation and analyses have revealed high rates of comorbidity between recurrent brief depression and brief hypomania. Thus, some recurrent brief depressive cases appear to be variants of bipolar disorder. The subtle bipolar nature of recurrent brief depressive disorder is clinically supported by the fact that

the very few such patients the author has encountered in his own practice did poorly with antidepressant monotherapy but benefited from mood stabilizers used alone or combined with antidepressants.

The recurrent hypomanic counterpart of recurrent brief depressive disorder is described under soft bipolar conditions. By DSM-IV criteria, it represents an instance of bipolar disorder not otherwise specified.

Hysteroid Dysphoria The category hysteroid dysphoria combines reverse vegetative signs with the following characteristics: (1) giddy responses to romantic opportunities and an avalanche of dysphoria (angry-depressive, even suicidal responses) upon romantic disappointment; (2) impaired anticipatory pleasure, yet the capability to respond with pleasure when such is provided by others (i.e., preservation of consummatory reward); (3) craving for chocolate and sweets, which contain phenylethylamine compounds and sugars believed to facilitate cellular and neuronal intake of the amino acid L-tryptophan, hypothetically leading to synthesis of endogenous antidepressants in the brain. The use of the epithet “hysteroid” was used to convey that the apparent character pathology was secondary to a biological disturbance in the substrates governing affect, drives, and reward. The intense, giddy, unstable life of the patient with hysteroid dysphoria suggests links to cyclothymic disorder or bipolar II disorder. This suggestion is further supported by the Columbia group's tendency to subsume those patients under atypical depressions (some of which, as indicated, have bipolar affinities). Like patients with bipolar depression, they respond preferentially to monoamine oxidase inhibitors (MAOIs). In brief, hysteroid dysphoria appears to be a variant of bipolar II with cyclothymic-irritable traits. Other variants of bipolar II disorder with hyperthymic-narcissistic traits are described under soft bipolar disorder and represent instances of bipolar disorder not otherwise specified.

Bipolar III Disorder In bipolar III disorder (which is not an official nosological term but can be subsumed under bipolar disorder not otherwise specified) evidence of bipolarity is softer, such as a single brief episode of an antidepressant-mobilized switch. In a related subgroup of cryptic bipolar disorders, strong evidence for familial bipolarity raises the possibility that some phenotypically “unipolar” depressed patients are nonetheless constitutionally bipolar; in such cases, history for hypomania occurring in discrete episodes is not obtained; instead the patient's habitual temperamental baseline is sunny, overenergetic, and overoptimistic (hyperthymic).

Depending on the threshold of traits used in determining the presence of hyperthymia, bipolar III patients may constitute 10 to 20 percent of those with major depressive disorder. Thus, many patients with so-called unipolar depression are actually “pseudounipolar.” The presence of marked narcissistic traits is a helpful clinical clue that a clinically depressed patient might belong to the group of those with hyperthymic depressions.

MOOD DISORDERS NOT OTHERWISE SPECIFIED

After all diagnostic information has been obtained, some depressed and bipolar or otherwise affective patients do not meet the specific criteria for the mood conditions described thus far. Mood disorders not otherwise specified is a statistical concept for filing purposes and not a clinical description. The author prefers to consider such cases as undiagnosed mood disorders rather than using the DSM-IV categories of depression disorder not otherwise specified, bipolar disorder not otherwise specified or mood disorder not otherwise specified.

What follows are descriptions of conditions that commonly appear in the psychiatric literature but do not easily fit into the official nosology of mood disorders. They represent hybrids between mood and anxiety disorders.

Mixed Anxiety-Depressive Disorder The inclusion of anxious depressive states in a DSM-IV appendix acknowledges the simultaneous occurrence of anxious (e.g., the threat loss represents) and depressive (e.g., the despair of loss) cognition in a person confronted with a major aversive life situation. The admixture implies that the psychopathology progresses from anxiety to depression, that the patient's mental state is still in flux, and that the ongoing dynamics partly explains the subacute or chronic nature of the disorder. Anxious depression serves to point to the common presence of anxiety in depressive states, especially its greater visibility when the depression is less prominent. Patients with the latter presentation are reportedly most prevalent in general medical settings. This should not come as a surprise, because depressive symptoms that motivate medical consultation commonly complicate generalized anxiety states with a subthreshold level of symptomatology. Some authorities argue that neurotic depressions arise as maladaptive responses to anxiety and on that basis suggest retaining the “neurotic depression” rubric. Recent preliminary genetic data indirectly support the contention that certain (unipolar) depressive and (generalized) anxiety states are related. However, more research is needed before such an entity can be unequivocally accepted as an official nosological category. The difficulty is that as currently defined, anxious depressions are heterogeneous. In patients refractory to anxiolytic or antidepressant treatment or both, practitioners must entertain the diagnosis of a complex bipolar II disorder with mixed features. Indeed, recent genetic investigations suggest that bipolar II disorder with panic attacks might represent a special form of bipolar disorder.

Atypical Depression Although a delimited version of atypical depression was incorporated into DSM-IV as “atypical features (Table 14.6-5) to qualify the cross-sectional picture of depressive disorders, this construct is much broader in the clinical research literature. Originally developed in England and currently under investigation at Columbia University in New York, atypical depression refers to fatigue superimposed on a history of somatic anxiety and phobias, together with reverse vegetative signs (mood worse in the evening, insomnia, tendency to oversleep and overeat). Sleep is disturbed in the first half of the night in many persons with atypical depressive disorder, so irritability, hypersomnolence, and daytime fatigue would be expected. The temperaments of these patients are characterized by inhibited-sensitive traits. The MAOIs and serotonergic antidepressants seem to show some specificity for such patients, which is the main reason that atypical depression is taken seriously.

Other research suggests that reverse vegetative signs can be classified as either (1) the anxious type just described or (2) a subtle bipolar subtype with protracted hyperphagic-hypersomnic-retarded dysthymic disorder with occasional brief extroverted hypomanic-type behavior, often elicited by antidepressants. Increasing evidence indicates considerable affinity between atypical depression and bipolar II and III disorders. Furthermore, many patients with dysthymic disorder exhibit atypical features at various times. Actually, atypical depression might be an artifact of the DSM-IV definition of hypomania of 4 or more days. Recent Italian research suggests that many patients with atypical depressive meet criteria for brief hypomania or cyclothymic disorder.

The categories of not otherwise specified in the DSM-IV mood disorders schema largely reflect inadequacies of the operational approach to capture patients whose symptomatology falls between or on the boundaries of more classic diagnoses.

DIFFERENTIAL DIAGNOSIS

A missed mood disorder diagnosis means that the disorder does not receive specific treatment, which has serious consequences. Many such persons drop out of school or college, lose their jobs, get divorced, or may commit suicide. Those with unexplained somatic symptoms are frequent users of the general health system. Others are unwell despite interminable psychotherapy. Some, treated with dopamine receptor antagonists develop tardive dyskinesia unnecessarily. As with other medical disorders for which specific treatments are available, accurate diagnosis and early treatment are within the purview of all physicians and mental health professionals. Psychiatrists, in particular, should develop the competence to detect the entire spectrum of mood disorders. Despite massive educational efforts, underdiagnosis and undertreatment of mood disorders remain serious problems worldwide.

Although much enthusiasm was generated a decade ago about the potential use of certain biologic markers (e.g., REM latency, dexamethasone (Decadron) suppression test, and the thyrotropin-releasing-hormone test) to corroborate the differentiation of mood disorder from adjacent disorders, no definitive progress justifies their routine use in clinical practice. Faced with unusual or confusing presentations, a systematic clinical approach is still the best method in differential diagnosis (1) to detail all clinical features of the current episode, (2) to elicit a history of more typical major mood episodes in the past, (3) to assess whether the presenting complaints recur periodically or cyclically, (4) to substantiate adequate social functioning between periods of illness, (5) to obtain a positive family history for classic mood disorder and to construct a family pedigree, and (6) to document a history of unequivocal therapeutic response to thymoleptic medication or ECT in either the patient or the family.

Using the foregoing validating approach, one can examine the affective links of many DSM-IV disorders currently listed under mood disorders not otherwise specified, as well as controversial nosological entities currently categorized as nonmood disorders. The latter include conduct disorders; borderline personality disorder; impulse-control disorders; polysubstance abuse; psychotic disorder not otherwise specified; pain disorder; hypochondriasis; hypoactive sexual desire disorder; circadian rhythm sleep disorder, delayed sleep phase type; bulimia nervosa; and adjustment disorder (with work inhibition). These conditions place special emphasis on selected affective features, such as disinhibited behavior, temperamentality, mood lability, vegetative disturbances, and psychomotor anergia. What follows is a systematic examination of the differential diagnosis of mood disorders with their more classic boundaries.

Alcohol and Substance Use Disorders The high comorbidity of alcohol and substance use disorders with mood disorders cannot be explained as merely the chance

occurrence of two prevalent disorders. Self-medication for mood disorders is insufficiently appreciated by both psychiatrists and other professionals who deal with addiction. Given the clinical dangers of missing an otherwise treatable disorder, mood disorder should be seriously considered as the primary diagnosis if marked affective manifestations persist or escalate after detoxification (e.g. 1 month). This consideration also pertains to cyclothymic disorder and dysthymic disorder, which appear particularly likely to invite self-medication. The clinical validating strategies listed above can further buttress a mood disorder diagnosis.

The DSM-IV category of substance-induced mood disorder (Table 14.6-18) is difficult to validate clinically because in the absence of an affective diathesis, detoxification should, in principle, rapidly clear affective disturbances in persons whose primary problem is that of substance abuse. In the author's view, a dual diagnosis of both a mood disorder and a substance use disorder is a more realistic clinical approach to this group of patients. Bipolarity, particularly bipolar II disorder, should be sought in the interface of mood and substance use disorders.

A 27-year-old married businessman employed in an international family venture owned by his father presented with a court-ordered request for psychiatric treatment. He had been found “bringing” cocaine across the U.S.-Mexican border and was briefly jailed. He had used stimulants since his late teens to enhance his already high level of energy. His family was rich, and he had no difficulty affording cocaine. During the previous year, he had needed more cocaine because of greater moodiness and fleeting suicidal ideation, which he linked to increasing tensions between him and his father: “My father was never satisfied with me and demanded greater and greater performance from me.” His arrest by police was a major embarrassment for him and his family and motivated his compliance with psychiatric hospitalization to detoxify him. He had not had cocaine for 10 days, exhibited marked lability of mood, and gradually sank into a severe hypersomnic-retarded depression of stuporous proportions. He was treated with tranylcypromine (Parnate) 20 mg twice a day, and within 10 days he switched into hypomania, his mind “exploding with creativity and confidence,” marked jocularity and witticisms that entertained other patients, and marked seductiveness toward the nurses. His wife recalled that the patient previously had had several such periods naturally (i.e., “off cocaine”), which had strained their marriage due to “brief sexual liaisons.” Reducing the tranylcypromine dosage by 50 percent did not eliminate the hypomanic behavior and lithium 900 mg a day was added. He has since been maintained on a combination of tranylcypromine and lithium for 4 years; he has not relapsed into cocaine use, and following few psychoeducational sessions involving father and spouse, relationships with family and spouse have been less tempestuous. (Since consultation was sought by the patient's 60-year-old mother, an attractive, sophisticated woman, who confessed that for years she had been engaging in “love relationships” with young artists, with apparently her husband's “silent consent”; since at least her mid-20s, she by history would meet the criteria for bipolar II, only treated “on the couch,” and both her sister and brother had received treatment for “alcohol excesses.”) Patient states that pharmacotherapy—which did require adjustment now and then—has helped in balancing the “rough edges” of his “high-nervous temperament” and his “periodic lapse into paralyzing fatigue states that occurred at stressful times.”

If clinicians had assumed that primarily due to cocaine withdrawal, they would have never treated the patient's bipolar II disorder. DSM-IV conventions in this regard unfortunately bias diagnosis in favor of substance use disorders and, more tragically, against the realistic chance of cure from substances.

There is emerging interest in treating dually diagnosed patients with mood stabilizers, especially anticonvulsants. The intention is to attenuate any withdrawal phenomena from substances of abuse, while treating any underlying or emerging soft bipolar disorders.

Personality Disorders The state dependency of most personality measures is well documented. Accordingly, as exhorted by DSM-IV, clinicians should refrain from using personality disorder labels in describing patients with active affective illness and should focus instead on competent treatment of the mood disorder. Even in those with chronic or subthreshold mood disorders, personality maladjustment is best considered postaffective, arising from the distortions and conflicts that affective disturbances produce in the life of the sufferer. The most problematic of the personality labels used in those with mood disorders is borderline personality disorder, usually applied to teenage and young adult females. The DSM-IV diagnostic criteria for the disorder indicate a liberal mélange of low-grade affective symptoms and behavior. Table 14.6-38 shows that the overlap between borderline personality and mood disorders is extensive, so that giving a “borderline” diagnosis to a person with mood disorder is redundant. Use of personality disorder diagnoses may lead to neglect of the mood disorder or perhaps half-hearted treatment of the mood disorder; failure to respond would then be blamed on the patient's “self-defeating character” or “resistance to getting well,” thus exculpating the clinician.

Familial:	High rates of mood disorder
Phenomenology:	Dysthymic disorder
	Cyclothymic disorder
	Bipolar II disorder
	Mixed state
Pharmacological response:	Worsening on tricyclic antidepressants
	Stabilization on anticonvulsants
Prospective course:	Major mood episodes
	Suicide

Summarized from Akiskal H, Chen S, Davis G, Puzantian V, Kashgarian M, Bolinger M: Borderline: An adjective in search of a noun. Clin Psychiatry 46: 41, 1985.

Table 14.6-38 Overlap of Borderline Personality Disorder and Mood Disorders

Although more-systematic research is needed on the complex interface of personality and mood disorders, clinically they are often inseparable. As with alcohol and substance use disorders, it is generally preferable to diagnose mood disorders at the expense of personality disorders, which should not be difficult to justify in most cases that satisfy the validating strategies outlined above. When features of personality and mood disorders coexist, it is good practice to defer Axis II diagnoses and embark upon competent treatment of the concurrent mood disorder. Although not all personality disturbances recede with the competent treatment of mood disorders, so many experienced clinicians have seen such disturbances melt away with the successful resolution of the mood disorder that erring in favor of mood disorders is justified.

A 19-year-old single woman presented with the chief complaint that “all men are bastards.” Since her early teens, with the onset of her menses, she had complained of extreme variability in her moods on a nearly daily basis; irritability with hostile outbursts was her main affect, though more protracted hypersomnic depressions with multiple overdoses and wrist slashings had led to at least three hospitalizations. She also suffered from migrainous headaches that, according to the mother, had motivated at least one of those overdoses. Despite her tempestuous and suicidal moods that led to these hospitalizations, she complained of “inner emptiness and a bottomless void.” She had used heroin, alcohol, and stimulants to overcome this troubling symptom. She also gave history of ice-cream craving and frequent purging. She was talented in English and wrote much-acclaimed papers on the American confessional poet, Anne Sexton. She said she was mentally disturbed because of a series of stepfathers who had all forced “oral rape” between the ages of 11 and 15. She subsequently gave herself sexually to any man she met in bars, no longer knowing whether she was a “prostitute” or a “nice little girl.” On two occasions she had inflicted cigarette burns on her vagina “to feel something.” She had also engaged in a “brief lesbian relationship” that ultimately left her “emptier” and guilt-ridden; nonetheless, she now believed that she should burn in hell, because she could not get rid of “obsessing” about the excitement of mutual cunnilingus with her much older female partner. The patient's mother, who owned an art gallery, had been married five times and gave history of unmistakable hypomanic episodes; a maternal uncle had died from alcohol-induced cirrhosis. The patient's father, a well-known lawyer known for his “temper and wit,” had committed suicide. The patient was given phenelzine (Nardil), eventually raised to 75 mg a day, at which point the mother described her as “the sweet daughter she was before age 13.” At her next premenstrual phase, patient developed insomnia, ran away from home at night, started “dancing like a go-go girl,” met an “incredibly handsome man” of 45 years (actually, a pornography shop owner) and got married. Lithium augmentation controlled this excited episode. After many dosage adjustments, she is maintained on a combination of lithium (900 mg a day) and divalproex (Depakote) (750 mg a day). The patient now attends college and has completed four semesters in art history. In addition to control of her irritable and suicidal moods, bulimic and migraine attacks have abated considerably. Her marriage has been annulled on the basis that she was not mentally competent at the time of the wedding. She is no longer promiscuous and now expresses fear of intimacy with men she is attracted to. She is receiving individual psychotherapy for this problem.

The author often hears the complaint that even when a mood disorder is diagnosed in a “borderline” patient, response to antidepressants is disappointing. The problem is that affective disorders in these patients usually conform to bipolar II disorder—often complicated by ultrarapid cycling—and many clinicians, including

some with biological orientation, may lack sufficient experience in the art of pharmacologically managing patients who markedly deviate from classic bipolar I disorder.

The interface of mood disorders and behavioral disturbances (conduct and attention-deficit/hyperactivity disturbances) in children is even more problematic than in adult psychiatry. Nonetheless, progress has occurred in clinically recognizing certain behavioral manifestations as possible signs of depression in juvenile subjects, including periodic marked decline in school performance; restlessness and pulling or rubbing hair, skin, or clothing; outbursts of complaining, shouting, or crying; and aggressive or antisocial acts (such as kicking the mother, shoplifting) out of character to the child; as well as other acute personality changes ranging from defiant attitudes to negativism and avoidant behavior. Examined carefully, children and pubescent youth with these characteristics often meet the specific criteria for the diagnosis of major depressive disorder or dysthymic disorder. However, most children do not complain of subjective dysphoria; instead, the clinician can observe the depressed affect in the child's facial expressions or overall demeanor. After much resistance, many child clinicians now accept the existence of childhood mood disorders.

Bipolar disorder in children, even in adolescents, is still grossly underdiagnosed at the expense of so-called externalizing disorders. Table 14.6-39 lists those and related conditions often confused with bipolar disorders in juvenile patients. Many children express bipolar disorder in explosive outbursts of irritable mood and behavior (i.e., as a mixed or dysphoric manic state); another pattern is intermittent hypomania and cyclothymia. Children with bipolar disorder are distinguished from those with so-called externalizing disorders by the fact that they are often, though not always, considered charming and likeable, yet overconfident or delusionally grandiose, and may exhibit age-inappropriate sexual behavior, such as lecherous advances toward adult women (e.g., their elementary school teachers): Moreover, they often get worse on stimulant medication. Correct diagnosis depends on the index of suspicion of a clinician who is convinced that bipolarity exists in juvenile subjects. Depression with first onset before age 18 has an extremely high rate of switching into both bipolar I and bipolar II disorders.

Total (N = 44)	Percent
Adjustment disorder	35
Conduct disorder	15
Attention-deficit/hyperactivity disorder	9
Mental retardation	6
Separation anxiety disorder	9
Overanxious disorder	11
Schizophrenia	15

Table 14.6-39 Misdiagnosis in the Affectively Ill Juvenile Kin of Adults With Bipolar Disorder

Normal Bereavement Bereaved persons exhibit many depressive symptoms during the first 1 to 2 years after their loss, so how can the 5 percent of bereaved persons who have progressed to a depressive disorder be identified?

- Grieving persons and their relatives perceive bereavement as a normal reaction, while those with depressive disorder often view themselves as sick and may actually believe they are losing their minds.
- Unlike the melancholic person, the grieving person reacts to the environment and tends to show a range of positive affects.
- Marked psychomotor retardation is not observed in normal grief.
- Although bereaved persons often feel guilty about not having done certain things that might have saved the life of the deceased loved one (guilt of omission), they typically do not experience guilt of commission.
- Delusions of worthlessness or sin and psychotic experiences in general point toward mood disorder.
- Active suicidal ideation is rare in grief but common in major depressive disorder.
- Mummification (i.e., keeping the belongings of the deceased person exactly as they were before his or her death) indicates serious psychopathology.
- Severe anniversary reactions should alert the clinician to the possibility of psychopathology.

In another form of bereavement depression, the sufferer simply pines away, unable to live without the departed person, usually a spouse. Although not necessarily pathological by the foregoing criteria, such persons do have a serious medical condition. Their immune function is often depressed, and their cardiovascular status is precarious. Death can ensue within a few months of that of a spouse, especially among elderly men. Such considerations (highlighted in the work of Sidney Zisook and his San Diego colleagues at the University of California) suggest that it would be clinically unwise to withhold antidepressants from many persons experiencing an intensely mournful form of grief.

A 75-year-old widow was brought by her daughter because of severe insomnia and total loss of interest in daily routines following her husband's death 1 year before. She had been agitated for the first 2 to 3 months and thereafter “sank into total inactivity—not wanting to get out of bed, not wanting to do anything, not wanting to go out.” According to her daughter, she was married at 21, had four children, and had been a housewife until her husband's death from a heart attack. Past psychiatric history was negative; premorbid adjustment had been characterized by compulsive traits. During the interview she was dressed in black, appeared moderately slowed, and sobbed intermittently, saying “I search everywhere for him ... I don't find him.” When asked about life, she said “everything I see is black.” Although she expressed no interest in food, she did not seem to have lost an appreciable amount of weight. Her dexamethasone suppression test result was 18 μg/dL. The patient declined psychiatric care, stating that she “preferred to join her husband rather than get well.” She was too religious to commit suicide but by refusing treatment she felt she would “pine away ... find relief in death and reunion.”

Anxiety Disorders Anxiety symptoms including panic attacks, morbid fears, and obsessions are common during depressive disorders, and depression is a common complication of anxiety states. Systematic British studies have shown that early-morning awakening, psychomotor retardation, self-reproach, hopelessness, and suicidal ideation are the strongest clinical markers of depression in that differential diagnosis. On follow-up of depressed patients, the manifestations tend to remit, whereas those with anxiety states continue to exhibit marked tension, phobias, panic attacks, vasomotor instability, feelings of unreality, and perceptual distortions as well as hypochondriacal ideas. A predominance of such anxiety features antedating the present disorder suggests the diagnosis of an anxiety disorder. Since anxiety disorders rarely first appear after the age of 40, late appearance of marked anxiety features strongly favors the diagnosis of melancholia. The clinical picture is often one of morbid groundless anxiety with somatization, hypochondriasis, and agitation. The depressive nature of the illness is further supported by a superior response to ECT.

Periodic monosymptomatic phobic and obsessional states exist that can be regarded as affective equivalents on the basis of a family history of mood disorders and their response to thymoleptic agents. Recent data from a large clinical series suggests that 15 percent of patients with obsessive-compulsive disorders develop unmistakable hypomanic symptoms; these patients are best considered to have bipolar II disorder and treated with lithium salts. Social phobias exist that usher in adolescent depression, even a bipolar disorder.

The psychopathological differentiation of anxiety and depressive states has not been entirely resolved. Cognitive factors may differentiate them best (Table 14.6-40). Although recurrent (especially retarded) major depressive disorder is a distinct disorder from anxiety states, at least some forms of depression may share a common diathesis with anxiety disorders, particularly generalized anxiety disorders. Before assigning patients to such a putative mixed anxiety-depressive group (not yet an official nosological entity), the clinician must note that anxiety that arises primarily during depressive episodes is best considered as epiphenomenal to depressive disorder. The same is generally true for anxiety symptoms that occur in a person with depressive disorder who is using alcohol or sedative-hypnotic or stimulant drugs. Finally, anxiety symptoms could be prominent features of mixed bipolar states as well as of complex partial seizures.

Anxiety	Depression
Hypervigilance	Psychomotor retardation
Severe tension and panic	Severe sadness
Perceived danger	Perceived loss
Phobic avoidance	Loss of interest—anhedonia
Doubt and uncertainty	Hopelessness—suicidal
Insecurity	Self-deprecation
Performance anxiety	Loss of libido
	Early-morning awakening
	Weight loss

Table 14.6-40 Unique Cross-Sectional Profiles of Clinical Anxiety and Depression

Physical Disease Somatic complaints are common in depressive disorders. Some, such as vegetative disturbances, represent the hypothalamic pathology that is believed to underlie a depressive disorder. Autonomic arousal, commonly associated with depression, could explain such symptoms as palpitations, sweating, and headache. In some instances the physical symptoms might reflect delusional experiences. The clinician must be vigilant about the likelihood that somatic complaints in depression can also reflect an underlying physical illness. Table 14.6-41 lists the most common medical conditions that have been associated with depression. When depressive symptoms occur in the setting of physical illness, it is not always easy to determine whether they constitute a genuine depressive disorder. Before diagnosing depression, psychiatrists must ensure that they are not dealing with pseudodepression: (1) functional loss due to physical illness; (2) vegetative signs, such as anorexia and weight loss, as manifestations of such an illness; (3) stress and demoralization secondary to the hospitalization; (4) pain and discomfort associated with the physical illness; and (5) medication adverse effects. On the other hand, nonpsychiatric physicians who manage such patients must consider the diagnosis of depression in the presence of persistent anhedonia; observed depressed mood with frequent crying; observed psychomotor retardation or agitation; indecisiveness; convictions of failure, worthlessness, or guilt; and suicidal ideation. The physician should also suspect clinical depression in all patients who refuse to participate in medical care.

Pharmacological	Steroidal contraceptives Reserpine; α-methyldopa Anticholinesterase insecticides Amphetamine or cocaine withdrawal Alcohol or sedative-hypnotic withdrawal Cimetidine; indomethacin Phenothiazine antipsychotic drugs Thallium; mercury Cycloserine Vincristine; vinblastine
Endocrine	Hyperthyroidism and hypothyroidism Hyperparathyroidism Hypopituitarism Addison's disease Cushing's disease Diabetes mellitus
Infectious	General paresis (tertiary syphilis) Toxoplasmosis Influenza; viral pneumonia Viral hepatitis Infectious mononucleosis AIDS
Collagen	Rheumatoid arthritis Lupus erythematosus
Nutritional	Pellagra Pernicious anemia
Neurological	Multiple sclerosis Parkinson's disease Head trauma Complex partial seizures Sleep apnea Cerebral tumors Cerebrovascular disorder
Neoplastic	Abdominal malignancies Disseminated carcinomatosis

Table 14.6-41 Pharmacological Factors and Physical Diseases Associated with Onset of Depression

Diagnosing depression in medically ill elderly patients can be particularly difficult. This task should be undertaken diligently because it was recently reported that (especially in those with cardiovascular disease) mortality is accelerated by depression. Depressed elderly adults often deny being “depressed” but complain of anxiety, fatigue, and worsening memory. Hypochondriacal symptoms and pain are common. Patients may exhibit extreme negativism and querulousness when invited to participate in medical procedures; others develop poor fluid and food intake out of proportion to their physical conditions.

Another important diagnostic problem at the interface of mood disorder and physical disease is the rare development of malignancy in patients with an established mood disorder. Patients who had responded well to a given antidepressant during previous episodes now have an unsatisfactory response to the same medication. Even a small dose may cause such alarming symptoms as agitation, dizziness, depersonalization, and illusions, which might indicate an occult malignancy, perhaps in the abdomen or the brain. The psychiatrist should always be vigilant about the development of life-threatening physical diseases in patients with preestablished depressive disorder.

> A 55-year-old woman had suffered from four previous episodes of severe depression that had responded to ECT or amitriptyline (Elavil) or both in her native city of Cairo, Egypt. She immigrated to the United States at age 43 and encountered several major stresses; including unfamiliarity with English, daughter dating a man of Japanese extraction, and a complicated series of operations for uterine prolapse. Then her husband confessed he had had an affair with a much younger woman. For months the patient had complained of intermittent fatigue and expressed anger toward her husband. Her ensuing fifth depressive episode appeared fully “understandable,” but her physician's prescription of 25 mg of amitriptyline resulted in dizzy spells that culminated in syncope. Paroxetine (Paxil) 10 mg did not fare any better. An extensive medical workup revealed a retroperitoneal lymphoma. She died 6 months later.

Stupor Although less common today, stupor still raises a diagnostic problem in differentiating between a mood disorder and somatic disease as well as other psychiatric disorders. Depressive stupor is relatively easy to distinguish from so-called hysterical mutism; in the latter, behavior is meaningfully directed to significant others in the patient's environment. The rubric of catatonic stupor is best reserved for a phase of schizophrenia; in such patients the schizophrenic origin of the catatonia might be apparent from the patient's history. Otherwise, most acute-onset stupors are probably of affective origin. The main differential diagnosis here is from organic stupor (due to drugs or acute intracranial events); the physical and neurological examination is not always decisive in such cases, and diagnosis depends on a high index of suspicion of possible somatic factors.

Depressive Pseudodementia The geriatric equivalent of semistupor in younger persons with depressive disorder, depressive pseudodementia is distinguished from primary degenerative dementia by its acute onset without prior cognitive disturbance; a personal or family history of past affective episodes; marked psychomotor retardation with reduced social interaction; self reproach; diurnal cognitive dysfunction (worse in the morning); subjective memory dysfunction in excess of objective findings; circumscribed memory deficits that can be reversed with proper coaching; and a tendency to improve with sleep deprivation.

Chronic Fatigue Syndrome Chronic fatigue syndrome is a complex differential diagnostic problem in view of the subtle immunological disturbances presumably associated with it. The following self-report by such a patient illustrates many of the uncertainties marking the present knowledge of the interface between the syndrome and mood disorders.

I am a 39-year-old, never-married woman, trained as a social worker, but currently on disability. I have experienced extreme lethargy and fatigue for many years. I have always felt foggy headed and had trouble thinking and concentrating. My complaint is of fatigue, not of depression. My body feels like lead and aches all over. My brain feels achy and sore. I feel much worse in the morning and I can't get out of bed; I feel better at night. I feel bad every day. I ache all over, as though someone had beaten me up. Exercise has been prescribed to me, but it makes me worse. Also, I am very sensitive to hot and cold. My sexual drive is low. I have a general feeling of anhedonia. As far back as I remember—in junior high school—I was always exhausted. I always complained about fatigue, not depression, because that has been the overwhelming problem. I feel the depression is secondary to the fatigue. In high school I was a compulsive overeater and I was bulimic for a few years, but it was never severe and I was only about 10 pounds overweight. In those days I would sleep 10 or 12 hours a night on the weekend and still feel exhausted; I could not get up for school on Monday. As an adolescent, I felt inferior. I couldn't make decisions, I didn't want to go to camp or leave home for long periods of time—I felt so insecure. Recently I had a sleep study done, which showed a short latency to stage REM sleep (49 minutes). I was diagnosed as having dysthymic disorder and began taking antidepressants. When I took tranylcypromine, it was the first time in my life that I felt like a normal person. I could play sports, I had a sex drive, I had energy, and I was able to think clearly. But the benefits lasted for barely 2 months. My response was equally short-lived to phenelzine, imipramine (Tofranil), selegiline (Eldepryl), and bupropion (Wellbutrin). I have not responded to serotonin-specific reuptake inhibitors (SSRIs) at all. I also wish to point out that I had never experienced high periods before I took antidepressants. My main problem has always been one of exhaustion. When I responded to medications, they worked very quickly (within a few days) and I felt great, but they all stopped working after a short time. The dose would be raised, and again I would feel better. Eventually, when I got to high doses, I either could not tolerate the high dose or the drug would no longer help. I have taken different combinations of drugs for 10 years and I haven't been able to feel well for more than 6 weeks at a time. Recently, I went to an immunologist. He said I have an abnormality in regulating antibody production and recommended gammaglobulin shots. They did not help. When I first started working, I always felt tired and foggy headed, so it was difficult to be sharp while at work. At times I would close the door to my office and put my head down. Working has become increasingly difficult for me. I had two great jobs, which I blew. As of last year I had to go on disability. I am desperate for relief, as my condition has drastically affected my life. Disability has been hard for me. I am single and have no other financial resources. I am very despondent, as I feel that my life is passing by without the hope of my ever really improving.

The foregoing clinical picture is compatible with a pseudounipolar or bipolar III disorder as described by the author. Some virologists and immunologists as well as some psychiatrists believe that abnormal substances circulate in the bloodstream supplying the brains of such patients. Industrial toxins have also been suggested.

While awaiting more definitive research on the etiology of chronic fatigue syndrome, the psychiatrist can cautiously consider certain patients for thymoleptic trials. That decision can be bolstered by the following considerations: the patient wakes up with fatigue and dread of facing the day; fatigue is part of a more generalized psychomotor inertia or lack of initiative; fatigue is associated with anhedonia, including sexual anhedonia; and fatigue coexists with anxious and pessimistic ruminations. Although none of the foregoing alone is pathognomonic for depression, in aggregate they point in that direction. The occurrence of hypomanic-like periods (as in the above vignette) further supports the link between some cases of chronic fatigue and mood disorder. Use of antidepressants without sedative effects, given in gradually increasing doses as tolerated, is a rational strategy; lithium and valproate, though not formally tested in such patients, are rational augmentation choices. Several recent neuroendocrine challenge studies suggest that some chronic fatigue patients might have a strong anxiety substrate and could be managed accordingly. This is not to say that chronic fatigue is largely a matter of missed affective diagnoses; yet it would be a pity to miss potentially treatable diagnoses. A family or past personal history of classic affective illness or episodes should strongly weigh in this direction. Obviously definitive data are lacking on the essential nature of chronic fatigue, and practitioners should be guided by their own clinical experience, while awaiting new research developments.

Schizophrenia Cross-sectionally, young patients with bipolar disorder might seem psychotic and disorganized and thus schizophrenic. Their thought processes are so rapid that they may seem loose, but, unlike those with schizophrenia, they display expansive and elated affect, which is often contagious. By contrast, the severely retarded bipolar depressive person, whose affect may superficially seem flat, almost never exhibits major fragmentation of thought. The clinician, therefore, should place greater emphasis on the pattern of symptoms than on individual symptoms in the differential diagnosis of mood and schizophrenic psychoses. No pathognomonic differentiating signs and symptoms exist. Differential diagnosis should be based on the overall clinical picture, phenomenology, family history, course, and associated features. Because the two groups of disorders entail radically different pharmacological treatments on a long-term basis, the differential diagnosis is of major clinical importance. Table 14.6-42 summarizes the author's clinical experience in the area and lists the most common pitfalls in diagnosis. In the past many bipolar patients, especially those with prominent manic features at onset, were labeled as having “acute schizophrenia” or “schizoaffective schizophrenia.” Such misdiagnoses (which typically led to long-term treatment with antipsychotic agents) has been costly in terms of tardive dyskinesia, vocational and social decline, and even suicide. For instance, some patients with postpsychotic depressive disorder of schizophrenia in the DSM-IV scheme (Table 14.6-25) have postmanic depressions that were treated with neuroleptic monotherapy without the benefit of more definitive thymoleptic agents.

Common pitfalls:
- Reliance on cross-sectional rather than longitudinal picture
- Incomplete interepisodic recovery equated with schizophrenic defect
- Equation of bizarreness with schizophrenic thought disorder
- Ascribing irritable and cantankerous mood to paranoid delusions
- Mistaking depressive anhedonia and depersonalization for schizophrenic emotional blunting
- Flight of ideas perceived as loose associations
- Lack of familiarity with the phenomenological approach in assessing affective delusions and hallucinations
- Heavy weight given to incidental schneiderian symptoms

Adapted from Akiskal HS, Puzantian VR: Psychotic forms of depression and mania. Psychiatr Clin North Am 2:419, 1979.

Table 14.6-42 Misdiagnosis of Mood Disorder as Schizophrenia

Modern treatments, which tend to keep many persons with schizophrenia out of the hospital, do not seem to prevent an overall downhill course. By contrast, the intermorbid periods in bipolar illness are relatively normal or even supernormal, yet over time some social impairment may result from the accumulation of divorces, financial catastrophes, and ruined careers. (Although rapid-cycling disorders, which have sharply risen during the past two decades, cause considerable social impairment, mood symptoms are so prominent that differentiation from schizophrenia is generally not difficult; also such patients usually display more classic bipolar phases before the rapid cycling).

Postpsychotic depressions in persons with established schizophrenia are sometimes due to inadequate control of schizophrenic symptomology. In other patients, especially more intelligent young schizophrenic patients, they reflect the experience of losing one's ego and sanity. It would be more meaningful to give such patients a diagnosis of both schizophrenia and a depressive disorder and treat the patient accordingly.

Schizoaffective Disorder As the above considerations suggest, depression in the setting of a schizophrenic disorder does not necessarily constitute a distinct nosological entity. The concept of schizoaffective (or cycloid) psychosis should be restricted to recurrent psychoses with full affective and schizophrenic symptoms occurring nearly simultaneously during each episode. This diagnosis should not be considered for a mood psychosis in which mood-incongruent psychotic features (e.g., schneiderian and bleulerian symptoms) can be explained on the basis of one of the following: (1) affective psychosis superimposed on mental retardation, giving rise to extremely hyperactive and bizarre manic behavior; (2) affective psychosis complicated by concurrent brain disease, substance abuse, or substance withdrawal, known to give rise to numerous schneiderian symptoms; or (3) mixed episodes of bipolar disorder (which are notorious for signs and symptoms of psychotic disorganization). Official diagnostic systems such as DSM-IV use the category of schizoaffective disorder broadly. Thus patients with clear-cut manic episodes receive a schizoaffective diagnosis if delusions or hallucinations occur in the interepisodic period, in the absence of prominent affective symptoms. Many psychotic symptoms in mood disorders are often explanatory (albeit delusional), whereby the patient tries to make sense of the core experiences of the affective illness. In patients with recurrent episodes, delusional thinking can be carried over into the interepisodic period. Such patients are thus delusional in the absence of prominent mood symptoms and technically (i.e., by research diagnostic or DSM-IV criteria) might be considered schizoaffective.

The author does not concur with that convention. Affective illness is typically a lifelong process, and limiting its features to discrete episodes is artificial. Although neuroleptic agents might be prescribed on an as needed basis to reduce the strong affective charge of those interepisodic delusions, they do not effectively eliminate the affect-laden experiences. Continued thymoleptic treatment (resorting to ECT, if necessary) and an empathic psychotherapeutic approach are more rewarding in

the long run.

A 29-year-old female college graduate, mother of two children and married to a bank president, had experienced several manic and retarded depressive episodes that had responded to lithium carbonate. She was referred to the author, because she had developed the delusion that she had been involved in an international plot. Careful probing revealed that the delusion represented further elaboration, in a rather fantastic fashion, of a grandiose delusion she had experienced during her last postpartum manic episode. She believed she had played an important role in uncovering the plot, thereby becoming a national hero. Nobody knew about it, she contended, as the affair was top secret. She further believed that she had saved her country from the international scheme and suspected that she was singled out for persecution by the perpetrators of the plot. At one point she had even entertained the idea that the plotters sent special radio communications to intercept and interrupt her thoughts. As is typical in such cases, she was on a heavy dosage of a lithium-antipsychotic combination. The consultation was requested because the primary mood symptoms were under control and yet she had not given up her grandiose delusion. She flippantly remarked that one must be “crazy” to believe in her involvement in an international plot, but she could not help but believe in it. Over several months, seen typically in 60-minute sessions weekly, the patient had developed sufficient trust that the author could gently challenge her beliefs.

She was in effect told that her self-professed role in the international scheme was highly implausible and that someone with her superior education and high social standing could not entertain a belief, to use her own words, “as crazy as that.” She eventually broke into tears, saying that everyone in her family was so accomplished and famous that to keep up with them, she had to be involved in something grand; in effect, the international scheme, she said, was her only claim to fame: “Nobody ever gives me credit for raising two kids, and throwing parties for my husband's business colleagues. My mother is a dean, my older brother holds high political office, my sister is a medical researcher with five discoveries to her credit [all true] and who am I? Nothing. Now, do you understand why I need to be a national hero?” As she alternated, over subsequent months, between such momentary flashes of insight and delusional denial, antipsychotic medication was gradually discontinued. Maintained on lithium, she now only makes passing reference to the grand scheme. She was encouraged to pursue her career goal toward a master's degree in library science.

The vignette illustrates how phenomenological understanding, rational pharmacotherapy, and practical psychotherapeutic or vocational guidance can be fruitfully combined in the approach to patients with psychotic mood disorders. At a more fundamental level it suggests that clinical diagnoses in psychiatry cannot be based entirely on operational criteria; one's opinion of patient's illnesses is not infrequently changed by their response to treatment.

In the author's view, DSM-IV represents something good (operationalization of diagnostic criteria) carried to extreme (arbitrary precision often divorced from clinical reality).

ICD-10

The ICD-10 criteria for mood disorders, which are used throughout the world, are listed in Table 14.6-43. Although these criteria derive in part from DSM-III-R, they are more flexible and clinician-friendly: they do not pretend to impose arbitrary precision on the clinical universe of psychiatry.

Table 14.6-43 ICD-10 Diagnostic Criteria for Mood [Affective] Disorders

SUGGESTED CROSS-REFERENCES

Diagnosis and psychiatry are discussed in Chapter 7, the clinical manifestations of psychiatric disorders are covered in Chapter 8, and the classification of mental disorders is presented in Chapter 9. Schizophrenia is the subject of Chapter 12. The somatic treatment of mood disorders is discussed in Section 14.7 and Section 14.8. Psychotherapy is covered in Section 14.9. Mood disorders and suicide in children are the topic of Chapter 45. Anxiety disorders are presented in Chapter 15, and mood disorders in geriatric psychiatry are discussed in Section 51.3d. Somatoform disorder including neurasthenia and chronic fatigue syndrome is covered in Chapter 16.

14.7 MOOD DISORDERS: TREATMENT OF DEPRESSION

A. JOHN RUSH, M.D.

Many available options now exist for treatment of mood disorders. Depressive disorders have enjoyed major therapeutic advances during the past decade, and the plethora of new options confronts clinicians with the problem of tailoring them to individual patients. Which strategies (types of treatment), applied in what order (strategic planning), and delivered by which methods (tactics) (e.g., dosage, duration) produce the best results for most patients in the shortest period of time? Specifying the objectives of each phase of treatment and careful, timely reappraisal of whether they are met, optimize patient outcomes.

Specific objectives of each treatment phase (i.e., acute, continuation, maintenance) provide a strategic map for managing these patients. For mood disorders, initial treatment objectives include (1) symptom remission (acute phase) and restoration of psychosocial functioning (acute and continuation phases), (2) prevention of a relapse (continuation phase), and (3) prevention of recurrences, or new episodes in patients with recurrent depressions (maintenance phase).

STRATEGIES

When initiating acute-phase treatment, practitioners decide where the patient should be treated (e.g., outpatient, day hospital, or inpatient). Treatment location is dictated by factors such as (1) the imminent risk of suicide, (2) the capacity of the patient to recognize and follow instructions or recommendations (adherence, psychosis), (3) the level of psychosocial resources, (4) the level of psychosocial stressors, and (5) the level of functional impairment.

Next, one chooses among the four common acute-phase treatments (medication, psychotherapy, the combination of medication and psychotherapy, or electroconvulsive therapy [ECT]). For some, light therapy alone or in combination with medications may also be an option.

In general, patients who respond to acute-phase medication (alone or combined with psychotherapy) receive continuation-phase medication at the same dosage. Continuation-phase ECT may be indicated for acute-phase ECT responders if continuation-phase medication does not prevent relapse or if prior medications have been ineffective, although the efficacy of this approach rests on open case series rather than randomized controlled trials of continuation-phase ECT.

While no randomized controlled trials of continuation-phase psychotherapy alone are available, a few open studies suggest that patients responding to acute-phase psychotherapy alone may further benefit from continuation-phase psychotherapy at less frequent intervals for the subsequent 6 to 8 months. The comparative efficacy of the combination of medication and formal psychotherapy during the continuation phase versus continuing medication only has not been investigated.

TACTICS

Tactics are devised to ensure an adequate treatment trial (e.g., adequate dosage and duration of treatment). Adequate implementation is required to determine whether any strategic choice was correct. Adherence is the most important tactical issue. Low adherence may be due to adverse effects, the conscious or unconscious meaning of taking medication, or the desire to leave treatment once improved (perhaps because of the shame and stigma that still surround psychiatric disorders).

A second key tactical issue is adequate evaluation of whether the objective (i.e., symptom remission) was met. Symptom severity may be gauged by careful interviewing or by use of a rating scale. For mood disorders, a serious difficulty is accepting a partial response in place of a full remission, a risk for any acute-phase treatment. A full remission carries a better prognosis and minimal residual symptoms.

STRATEGIC CHOICES

Medication The available antidepressants differ in their pharmacology, drug-drug interactions, and short- and long-term adverse effects. They do not differ in overall efficacy, speed of response, or long-term effectiveness. Substantial evidence shows that failure to tolerate or respond to one medication does not imply failure with other medications. In fact, a shift from one medication class to another carries 1 in 2 chance of response to both the initial medication and to the next medication if the first fails to provide a satisfactory response.

Psychotherapy Formal psychotherapy aims at particular objectives. General clinical management, part of any treatment, includes explaining the diagnosis, treatment plan, treatment objectives, anticipated treatment period, counseling, management of both adherence and adverse effects, and a regular assessment of whether or not the treatment objectives are being met. It may involve consulting both the patient and significant others.

The objectives of formal psychotherapy used alone to treat mood disorders are identical to those for medication: (1) symptom remission; (2) psychosocial restoration; and (3) prevention of relapse or recurrence. When used in combination with medication, psychotherapies can achieve such additional objectives as reducing the secondary psychosocial consequences of the disorder (e.g., marital discord, occupational difficulties) or increasing medication adherence.

Clinical management aims to increase adherence, but formal psychotherapy can also be beneficial. Individuals who may need more-formal adherence counseling include those with significant prior or current adherence difficulties and those with relatively fixed negative attitudes toward a clearly indicated treatment. Formal psychotherapy to address the psychosocial consequences of the disorder may include individual, family, couples, or occupational approaches. Evidence suggests that used in combination with medication to control symptoms, such treatments improve the targeted difficulty (e.g., marital counseling improves marriages).

Psychotherapy as monotherapy for symptom remission has shown greater efficacy than wait-listing controls in studies of less severely or chronically ill, nonpsychotic, depressed outpatients. In addition, while some evidence suggests that psychotherapy alone as a maintenance treatment has some benefit in prolonging the well interval, in general, when maintenance treatment is anticipated, medications (alone or combined with psychotherapy) are preferred, given the larger number of medication maintenance studies supporting efficacy.

Choosing Among Psychotherapies No established clinical predictors exist to guide selection of a psychotherapy. Cognitive therapy may be slightly less effective in those with more-dysfunctional attitudes, while interpersonal psychotherapy may be somewhat less effective in those with more-interpersonal problems. However, these predictors lack clinical utility. Time-limited therapies are usually preferred over time-unlimited therapies for symptom reduction because they have established efficacy (time-unlimited therapies do not) and because medication is an effective alternative if psychotherapy alone fails.

Some believe that reconstructive (time-unlimited) psychotherapies are more useful in the treatment of Axis II disorders, while reeducative therapies may be more useful with Axis I conditions. No evidence favors use of psychotherapy alone over medication when a concurrent Axis II disorder exists. On the other hand, psychotherapeutic tactics may benefit the medication management of depressed patients with Axis II conditions by ensuring adherence. Logically, psychotherapy, if

used alone, should be tried for a finite time period and outcome should be evaluated, just as with medication.

Declaration of psychotherapy failures is largely based on lack of efficacy, although a few patients discontinue treatment unilaterally. When to declare psychotherapy a failure is a complex problem. Some patients respond early, while others may take 8 to 10 weeks. The premature discontinuation rate may be higher in actual practice than it is in efficacy trials. Just as with medication, if a symptomatic patient inappropriately discontinues treatment, one should actively attempt to reengage them since the depression has not remitted and, consequently, the prognosis is poor.

What treatment should follow if psychotherapy alone is ineffective? Medication, given its established efficacy, is the next best logical step. The psychotherapy may be continued or discontinued when medication is begun. Whether a different form of psychotherapy would be effective if the initial psychotherapeutic approach has not been tested.

COMBINED TREATMENT

Medication and formal psychotherapy are often combined in practice, yet data from randomized controlled trials suggest that the combination does not predictably add to the symptom-reducing effects of either treatment alone, at least in less complex, chronically ill patients. Conversely, the combination may result in both symptom reduction and psychosocial restoration, which is an additional rationale for using the combined approach. There are basically three ways to develop a combined treatment: (1) initiate the combination as acute-phase treatment, (2) add formal psychotherapy to medication that has elicited a partial response (particularly when there are residual cognitive, psychological, or interpersonal symptoms or difficulties), or (3) add medication after a partial response to psychotherapy alone.

Using the combination of medication and formal psychotherapy at the outset of acute-phase treatment is called for if either (1) formal psychotherapy is used to increase adherence, while medications are used for symptom control or (2) if the targets of each treatment were somewhat distinct and both needed early remediation (e.g., medication for the depressive symptoms and psychotherapy for marital problems). In addition, clinical experience suggests that combination treatment may be preferable to either treatment alone with (1) a coexisting Axis II disorder, (2) a chronic and recurrent pattern with poor interepisode recovery, or (3) a patient who is discouraged and demoralized as well as clinically depressed.

Diagnosis and medication management must allow time for patients with little prior treatment to collaborate in the optimal use of medication. Thus, it is often simpler to initiate medication and clinical management and then determine whether formal psychotherapy is indicated either for complete symptomatic remission or to address psychosocial problems unrelieved by medication. For example, psychotherapy might be added after a partial medication response (e.g., persistence of cognitive and interpersonal difficulties).

When to add psychotherapy to medication is unclear. Evidence suggests that psychosocial and occupational improvements follow response. Thus, routine use of both treatments initially may not be necessary for psychosocial restoration. The need for adjunctive psychotherapy to redress psychosocial difficulties becomes clearer the longer symptom remission obtains and psychosocial problems persist. A history of long-standing psychosocial difficulties, even during remission of chronic depression, may suggest either beginning with combined treatment or adding psychotherapy shortly after symptoms are controlled with medication.

When combined treatment does not produce a full response, a switch of medication classes with continued psychotherapy is logically the next step, since evidence indicates that switching medication classes is effective.

ELECTROCONVULSIVE THERAPY

ECT is effective, even in patients who have failed to respond to one or more medications or combined treatment. It is effective in both psychotic and nonpsychotic forms of depression. Usually, 8 to 12 treatments are needed. Bilateral ECT is somewhat more effective than unilateral ECT, but it appears to have more cognitive adverse effects.

OTHER TREATMENTS

Light therapy has been most clearly evaluated in mood disorder with seasonal pattern, either as monotherapy or in combination with medication. Patients who respond do so within 2 to 4 weeks.

STRATEGIC ISSUES

Role of Diagnosis in Treatment Selection Maintenance medication effectively prevents recurrences of dysthymic disorder, complicated by recurrent major depressive episodes or not. Psychotic depression usually requires both an antidepressant and an antipsychotic agent. Alternatively, ECT is useful in psychotic depression, either as a first-line treatment or after medication has proven ineffective. For those with atypical features, strong evidence indicates that tricyclic drugs are less effective than the monoamine oxidase inhibitors (MAOIs). There is some suggestion of efficacy for the selective serotonin reuptake inhibitors (SSRIs) in atypical depression.

The concurrent presence of another disorder may also affect initial treatment selection. Presence of nonmood Axis I disorder favors use of medications with demonstrated efficacy in both the mood and nonmood disorder. For example, effective treatment of obsessive-compulsive disorder with depressive symptoms usually results in remission of the depression. Similar findings have been reported for anorexia nervosa and bulimia. When panic disorder co-occurs with major depressive disorder, medications with demonstrated efficacy in each condition are preferred (e.g., tricyclic drugs, SSRIs). In general, the nonmood disorder dictates the choice of treatment.

Concurrent substance abuse raises the possibility of a substance-induced mood disorder, which must be evaluated by history or after several weeks of abstinence, since abstinence results in remission of depressive symptoms in substance-induced mood disorders. If significant depressive symptoms continue, even with abstinence, an independent mood disorder is diagnosed and treated.

Axis II disorders frequently accompany mood disorders, but diagnosis of Axis II disorders remains tentative in the presence of a clinical depression. An Axis II disorder should not be mistaken for recurrent major depressive disorder with poor interepisode recovery, since the treatment objectives and strategies differ.

An Axis II disorder does not contraindicate treating the mood disorder, but its presence may prolong the time to acute-phase treatment response, interfere with adherence, or even preclude full symptomatic remission. In general, the presence of Axis II disorders suggests a less optimistic prognosis, because circumstantial evidence suggests that Axis II disorders are risk factors for subsequent relapse or recurrence.

Axis II disorders raise other tactical issues, such as adherence, establishing a therapeutic alliance, or long-term management. In addition, the response to either medication or time-limited psychotherapy is slower, less complete, or both in the presence of an Axis II disorder.

General medical conditions commonly accompany mood disorders and are established risk factors in their development. Recent evidence indicates that a major depressive episode is associated with increased morbidity or mortality of some associated general medical conditions.

Principles that apply to the treatment of depression without a general medical condition generally apply when these conditions are present. However, treatment strategies and tactics are more complex. The initial choice of treatment is influenced by prior response to antidepressant treatments, the relative medical safety of medications, and clinical judgment about whether psychotherapeutic methods might particularly benefit some of these patients. The tactical choice of medications is affected by drug interactions, the pharmacological profile of the compound, the general medical condition, and drug dosing requirements.

Complex, ongoing, stressful life events or social contextual issues (often profoundly disturbing to patients) should not influence whether or not medication is used. Often, patients in major depressive episodes whose symptoms are reduced by medication become less disabled from the mood disorder and are better able to manage these complex life circumstances. On the other hand, chronic, disturbing, life circumstances (e.g., chronic marital discord, spousal abuse) argue for stronger consideration of combined treatment, either initially or sequenced, to obtain both symptom remission and psychosocial restoration. Table 14.7-1 summarizes the

relation between clinical diagnoses and treatment selection.

Diagnosis	Treatment Recommendations
Major depressive disorder (mild- to-moderate severity)	Medication or time-limited, depression-targeted psychotherapies[a] No maintenance-phase treatment
Major depressive disorder, recurrent	Consider maintenance-phase treatment
Major depressive disorder with psychotic features	Antipsychotic plus antidepressant medication Electroconvulsive therapy
Major depressive disorder with melancholic or severe features	Medications essential
Depression with atypical features	Nortricyclic drugs preferred Monoamine oxidase inhibitors have established efficacy
Depression with seasonal pattern	Light therapy or medications
Dysthymic disorder	Medications, time-limited, depression-targeted psychotherapies, or their combination Consider maintenance-phase therapy
Complex[b] or chronic depressions	Medication plus psychotherapy[a]

[a] Interpersonal psychotherapy, cognitive therapy, or behavior therapy.
[b] Complex refers to depression co-occurring with other psychiatric conditions (e.g., anxiety disorders, Axis II conditions).
[c] Psychotherapy may aim at adherence enhancement, symptom reduction, relapse prevention, or psychosocial restoration.

Table 14.7-1 Relation of Diagnosis to Treatment Selection

Selecting Initial Treatment In general, about 45 to 60 percent of all outpatients with nonpsychotic major depressive disorder who begin treatment with medication, psychotherapy, or the combination respond. Consequently, roughly one-half of patients should anticipate a second treatment trial if the initial treatment selected is either intolerable or ineffective. Selection of the initial treatment depends on the chronicity of the condition, the history of recurrences (which predicts the likelihood of future recurrences), family history of illness, symptom severity, associated comorbid general medical or other psychiatric conditions, prior treatment responses to other acute-phase treatments, and patient preference. In general, the less severe, less chronic, and less complex the depression (i.e., less current comorbidity), the greater the role for patient preference, since evidence for selecting between time-limited, depression-targeted psychotherapy and medication is lacking. Furthermore, it is believed that the combination of medication and formal psychotherapy is less likely to be needed for milder, uncomplicated depressions.

Moderate-to-severe mood disorders with prominent chronicity or prior recurrences generally require maintenance treatment. Since medications are the maintenance treatments with established efficacy, medication treatment (alone or combined with psychotherapy) is recommended.

The evidence for the efficacy of medication alone in more-severe depressions is clear; psychotherapy alone is less well studied. Psychotherapy alone appears to be less predictably effective than medication in outpatients with endogenous or melancholic symptom features. Whether psychotherapy alone is effective in depressions with atypical symptom features is under study. However, the MAOIs and SSRIs have established efficacy in this group.

Selecting Second Treatment Options If the first treatment fails (e.g., due to intolerance or lack of efficacy), a strategic decision on the second treatment after the differential diagnosis (including occult general medical condition or substance abuse) has to be reconsidered.

For those receiving medication initially, dose adjustments, extending the trial period, switching to an alternative treatment (either medication or psychotherapy), or adding a second treatment to the initial one are common options. Factors recommending dose escalations are (1) no adverse effects, (2) a prior history consistent with rapid drug metabolism, or (3) low therapeutic blood concentrations. However, blood concentrations of newer-generation medications are related to outcome although they are for desipramine (Norpramin, Pertofrane), imipramine (Tofranil), and nortriptyline (Pamelor). Extending the initial trial is indicated if (1) it has been less than 6 weeks, (2) there is a partial response by 6 weeks, or (3) prior medication trials were unsuccessful and shorter than 6 weeks.

Likewise, partial response to psychotherapy by week 6 argues for extending the trial period. Nonresponse by 8 weeks often predicts an ultimate poor response. Extending a trial of light therapy beyond 3 weeks in nonresponders has not been evaluated. Clinical experience suggests that extending ECT beyond 10 trials with complete nonresponse is unlikely in most cases to elicit a subsequent response, although careful studies are lacking.

The choice to switch from the initial single treatment to a new single treatment (as opposed to adding a second treatment) depends on the philosophy guiding the clinician, the patient's prior treatment history, and other clinical issues. The best-documented augmentation strategies involve inexpensive medicines (e.g., lithium or thyroid hormones) and response, if it occurs, is often within 2 weeks. Conversely, a switching strategy sometimes involves a washout period (e.g., switching from fluoxetine [Prozac] to an MAOI) for safety reasons as well as the need to wait longer than 2 weeks for a full effect. Alternatively, how long to continue augmentation is not clear, and lithium augmentation entails some expense and inconvenience (i.e., blood concentration monitoring).

If the initial trial is the patient's first treatment and other clinical or economic reasons favor monotherapy, switching rather than augmenting is preferred. On the other hand, augmentation strategies, particularly the use of two different medications, seem effective in patients who have failed one or more well-conducted single medication trials. Thus, switching might be preferable for those with only one or two prior treatment attempts, while augmentation is preferable for those who have failed several single-treatment trials. Recent reviews indicate that if the initial medication is ineffective or cannot be tolerated, it is reasonable to switch medication classes. In psychiatric settings, augmentation may be preferable, since more psychiatric patients have failed several adequate prior single treatments.

The value of augmenting medication with psychotherapy is not well evaluated. Many clinicians believe that if the residual symptoms after a partial response to medication are largely cognitive or psychological, either augmentation with psychotherapy or prolonging the initial medication trial are preferred to switching medications or augmenting with another medication, based on the assumption that these symptoms represent residual psychosocial sequelae. On the other hand, if anhedonia persists after an initial medication trial, switching or augmentation with another medication rather than psychotherapy is often preferred since such symptoms suggest ongoing limbic/paralimbic system dysfunction. However, these suggestions are largely based on clinical experience rather than scientific evidence.

TACTICAL ISSUES

The strategic choices of treatment focus on selection of the initial therapy, or for those who fail the initial therapy, the selection of a second treatment option. Implementation of these strategies requires (1) careful attention to adherence, (2) careful evaluation of outcome, (3) proper dosing and duration of the trial, and (4) timely declaration of treatment failure.

Adherence Treatment adherence is increased if patients understand anticipated objectives and common strategies, if fewer daily doses are required (e.g., once-a-day versus three-times-a-day dosing), and no personality disorder is present. Evidence also suggests more-frequent early visits (e.g., weekly versus monthly) improve adherence. Whether other current psychiatric conditions affect adherence is unclear; it is not related to gender, educational level, or socioeconomic status. The best predictor of future adherence is prior adherence.

Thus, general clinical management of medication treatment should include discussions with patients (and, potentially, significant others) about the objectives of treatment, anticipated treatment period, and adherence obstacles. It is best to anticipate and identify obstacles to adherence prior to prescribing medication or initiating psychotherapy and to make adherence checks a routine part of each visit.

Initially, visits should be frequent enough to ensure adherence and permit timely intervention for adverse effects. Several brief telephone contacts during the initial weeks of treatment help adherence by reassuring patients, ensuring that adverse effects are avoided, countering demoralization and pessimism that impairs adherence, and providing information to overcome short-term concentration and recall problems that are part of depressive episodes.

Choosing Among Medications If medication (alone or in combination with psychotherapy) is part of the first step, the practitioner must select from a variety of available compounds. Medications differ in their short- and long-term adverse effects and spectrum of action but not in overall efficacy or speed of response. If maintenance medication is anticipated, long-term adverse effects are more important than short-term effects in selection (e.g., tertiary tricyclic drugs are associated with greater weight gain than SSRIs over the long run).

Table 14.7-2 lists commonly used antidepressant agents presently available in the United States and groups them on the basis of their presumed mechanisms of action (e.g., presynaptic or postsynaptic activity). However, as basic neuroscientific knowledge expands, further actions will likely be discovered. For example, the

number of serotonin receptor types has increased faster than our understanding of their physiological roles. Further, the actions of some (e.g., venlafaxine [Effexor]) are affected by the dosages used or levels attained in the central nervous system (CNS). Venlafaxine exerts proportionally more serotonin than norepinephrine reuptake blockade at lower dosages than at higher dosages.

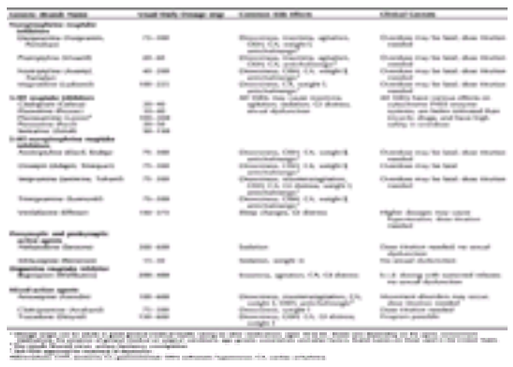

Table 14.7-2 Antidepressant Medications*

Table 14.8-2 lacks two commonly used drug combination treatments (lithium plus antidepressants and liothyronine [Cytomel] augmentation of tricyclic drugs). A Table 14.8-2 provides selected clinical caveats. This list is not exhaustive. Drug-drug interactions, at either the neuronal level (pharmacodynamics) or at the level of absorption, metabolism, and excretion (pharmacokinetics) affect selection of agents, their dosing, and ultimately the risk-benefit equation for individual patients. Patients should be advised what adverse effects to anticipate and encouraged to report them as early as possible. Management of adverse effects may include lowering the dosage, switching medications, or treating the adverse effects with an additional medication.

The MAOIs (tranylcypromine [Parnate] and phenelzine [Nardil]) still have a role in the treatment of depression, the depressed phase of bipolar disorders, and in depressions unresponsive to other treatments. However, because of the necessity of regulating diet (Table 14.7-3) and evaluating concomitant medications (Table 14.7-4), the MAOIs are not used as first-line drugs.

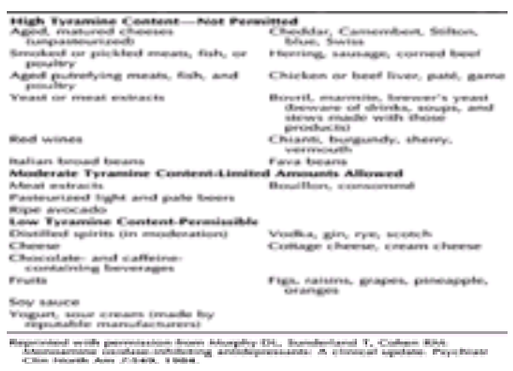

Table 14.7-3 MAOI Dietary Restrictions

Table 14.7-4 MAOI Drug Incompatibilities

Among the tricyclic medications, the secondary amines (desipramine or nortriptyline) have fewer adverse effects than the tertiary amines. Since nortriptyline has a well-established therapeutic window, drug concentration monitoring can ensure that patients who need minimal medication exposure obtain a therapeutic concentration. Conversely, the upper limit of the nortriptyline window may be a disadvantage when deciding to switch or augment treatments, as the blood concentrations may be used to declare a nonresponse.

Choosing more-sedating antidepressants (e.g., amitriptyline [Elavil, Endep]) for more-anxious depressed patients, or more-activating agents (e.g., desipramine) for those more psychomotor retarded is not based on evidence of differential efficacy. However, some clinicians believe that such choices based on adverse-effect profiles increase adherence in the initial weeks of treatment. That is, patients with marked insomnia and anxiety obtain some immediate relief from these associated symptoms before the full antidepressant effect of the drug appears and thus are more likely to comply with acute-phase treatment. These clinical observations are not supported by empirical data, however. In fact, attrition associated with paroxetine (Paxil) or fluoxetine (less-sedating drugs) is lower in acute-phase treatment than that with imipramine or amitriptyline (more-sedating drugs). In addition, the longer-term cost of a possibly beneficial short-term adverse effect advantage must be considered. For example, initially sedating antidepressants often continue to be sedating in the longer run, which may lead patients to prematurely discontinue continuation or maintenance phase treatment, thus increasing the risk of relapse or recurrence.

Some practitioners combine adjunctive medications (e.g., hypnotics or anxiolytics) with antidepressants to provide more immediate symptom relief either routinely from the outset or when the need for such adjunctive medications arises in an individual patient. Adjunctive medications used briefly to cover adverse effects to which most patients ultimately adapt can be useful. Conversely, discontinuing adjunctive medications can result in some return of symptoms or adverse effects to which the patient has not adapted.

Several disadvantages are associated with the routine use of adjunctive medications: (1) the potential risk, inconvenience and expense of unnecessary medications (i.e., many patients may not require them); (2) difficulty identifying the cause of medication intolerance or adverse effects (e.g., an allergic rash) when treatment with an antidepressant and an adjunctive medication is begun at the same time; (3) difficulty in judging response to the antidepressant medication alone if adjunctive medication addresses critical symptoms used to gauge the success of acute-phase treatment, (discontinuing the adjunctive medication to see if the apparent response holds on the antidepressant alone may unnecessarily increase the number of visits or delay a timely revision in the treatment plan); and (4) adjunctive medications may cover adverse effects that if observed would lead to either a dose reduction or to switching treatments. For example, a sedative-hypnotic agent used in conjunction with an SSRI may inappropriately delay a strategic decision to either decrease the dosage or switch to an alternative agent.

In addition to adverse effects, medication choice is affected by prior history of response, cross-sectional symptom features, patient preference, dosing convenience (which affects adherence), drug interactions (if patients are, or will be, taking other medications), current general medical conditions (making one adverse-effect profile preferred over another), and a family history of response. A patient's prior treatment history is important because prior response typically predicts current response. In addition, a documented failure on a properly conducted trial of a particular antidepressant class (e.g., SSRIs, tricyclics, or MAOIs) suggests choosing an agent from an alternative class. Switching classes for those who fail on one class appears to be associated with roughly a 50 percent response rate with the second class of drugs.

History of a first-degree relative responding to a tricyclic drug or an MAOI is associated with a better response to the same class of agents in the patient. Whether family history of response predicts response to the newer antidepressant compounds is not known.

Dosage and Duration Tactical issues surrounding medication use include dosing steps, drug metabolism, pharmacokinetics, drug interactions, and adverse effects. The tricyclic drugs typically are initially given at low dosages and increased to the maximally tolerated dosage or (in the case of nortriptyline) until a therapeutic concentration is obtained. Gradual dose escalations are important to ensure adherence and avoid severe initial adverse effects. Thus, the tricyclic drugs require visits roughly once a week for outpatients as dosages are adjusted. Tricyclic blood concentration monitoring may reduce dosage adjustment time. Dosing is less complicated for the SSRIs than for the tricyclic drugs; fewer dose increments are needed, and the proper dosage is attained earlier because of their better adverse-effect profiles. Some newer agents (e.g., SSRIs, bupropion [Wellbutrin]) need fewer dosage adjustments, but with others (e.g., venlafaxine and nefazodone [Serzone]), raising the dosage increases the likelihood of response, so several adjustments are often helpful.

Safety in overdose is an issue, especially early in treatment. Thus, a 1-week prescription is recommended (without refills) so patients return for frequent medication visits when adverse effects and dosage levels are managed. Tricyclic drugs account for a greater percent of completed suicides than the newer agents, which are far safer in overdose.

Evaluation of Outcome The objective of acute-phase treatment (medication, psychotherapy, their combination, or ECT) is symptom remission, not just symptom reduction. Partial response is associated with a stormier prognosis. Thus, careful interviewing for criterion symptoms at each visit is essential. Self-reported or clinician-rated instruments can facilitate this assessment. Often the patient is slower to recognize the early therapeutic effect of the treatment than the clinician. Thus, a clinician-rated scale may be preferred to a self-reported instrument.

Timely Declaration of Treatment Failures Growing evidence indicates that acute phase medication trials should last 6 (and preferably 8) weeks to determine the full extent of symptom reduction attainable, although most (but not all) patients who ultimately respond fully show at least a partial response by weeks 3 or 4 if the dose is adequate during the initial weeks of treatment. Clinical impression and recent reports suggest that no response by 3 to 4 weeks (e.g., <25 percent reduction in symptoms) indicates that a treatment change is needed (i.e., a few patients respond over the next several weeks), assuming an adequate dosage in the initial 3 to 4 weeks.

Each treatment step should be applied optimally (e.g., dosage and duration) to determine its effectiveness. There is a clinically important tension involved in evaluating the initial treatment—providing sufficient treatment for a long enough time to determine whether it is effective, while at the same time not prolonging (or overdosing) ultimately ineffective treatment.

Medication dosage obviously affects clinical outcome and adverse effect burden. Some patients metabolize certain drugs more rapidly or more slowly than others. Slow metabolizers, especially for the more anticholinergic tricyclic drugs, encounter adverse effects earlier in treatment or at lower dosages. High blood concentrations may cause arrythmias, seizures, or delirium. Fast metabolizers may exhibit virtually no adverse effects or benefits, even with rather large dosages. However, adverse effects, especially for desipramine and nortriptyline, do not predict blood concentrations. Indeed, orthostatic hypotension can occur even with low blood concentrations. Such cases argue for the value of a therapeutic blood concentration to determine dosing strategies, especially when tricyclic drugs are used in medically fragile patients.

Patients may not respond to a medication because (1) they cannot tolerate the adverse effects, even with a good clinical response; (2) an idiosyncratic adverse event occurs; or (3) the clinical response is not adequate. Idiosyncratic or serious adverse effects (e.g. seizures, allergic reactions), while rare, are most likely to be encountered in the first several weeks of treatment and often occur with dosage escalation or as medication concentrations rise to a steady-state level. Some of these adverse effects are dose dependent (e.g., sedation) and can be reduced by decreasing the dosage or slowing the rate of escalation. Moderate adverse effects, when encountered, argue for holding the dosage constant and allowing time for physiological adaptation, which often reduces adverse effects. Some adverse effects are less dose dependent (e.g., orthostatic hypotension), and tolerance to them is less likely. In these cases, gradual dosage escalation is less useful, and a change in treatment is often indicated.

Lack of efficacy is the most common reason for medication failure, but this cannot be fully gauged until patients have had several weeks of treatment at adequate dosages (4 to 6 weeks). Thus, careful evaluation of symptoms during acute-phase treatment (whether formally conducted with a rating scale or informally by assessing each criterion symptom of the mood disorder) is a useful gauge of the adequacy of medication response.

CONTINUATION TREATMENT

Continuation treatment typically lasts 4 to 9 months. In theory, the duration depends on an estimate of when the episode would have remitted spontaneously. Thus, patients with longer prior episodes (e.g., 9 to 15 months) who have had only 2 months of a current depression, for example, would be candidates for 5 to 11 months of continuation treatment, assuming that acute treatment lasted 2 months. Follow-up studies of those with psychotic depressions 1 year after acute-phase treatment indicate a poorer prognosis than for nonpsychotic depression. Thus, continuation-phase treatment for psychotic depressions should be longer.

Continuation-phase medication treatment should end with a gradual taper of medication and careful symptom assessment during, and for several months following, discontinuation. When medication is used alone or in combination with formal psychotherapy for acute-phase treatment, continuation medication treatment is recommended, because early medication discontinuation is associated with a higher relapse rate than later discontinuation. Whenever clinically feasible, continuation medication should be at the dosage used during acute-phase treatment. This recommendation is based on evidence from maintenance trials using lower-dosage tricyclic drugs, which suggested a higher recurrence rate than was obtained with full-dosage treatment.

Psychotherapy may be added to continuation-phase medication if psychosocial residua do not remit with medication alone. Whether to continue psychotherapy following response to acute-phase combined treatment is unclear and is entirely a matter of clinical judgment at this time. Continuation-phase psychotherapy alone (after acute-phase response to psychotherapy alone), has only indirect evidence of efficacy.

MAINTENANCE TREATMENT

Strategic Issues Maintenance treatment aims at preventing new episodes (recurrences). It is appropriate for recurrent (but not for single episode) major depressive disorder. Maintenance medication treatment has been found effective in virtually all studies to date. Strong evidence indicates that those with three or more episodes should receive maintenance-phase treatment, and indeed even at 5 years, maintenance medication has prophylactic efficacy.

Whether those with only two major depressive episodes should receive maintenance treatment is less clear. Information that helps with this decision includes poor recovery between the two episodes, presence of two episodes within the last 3 years, or a positive family history for depression or bipolar disorder; any of these factors increase the likelihood of recurrence. However, clinicians and patients must decide collaboratively whether to initiate maintenance treatment or provide more-diligent monitoring with no treatment until a need is established by the development of a new episode. If a new episode develops when the patient is free of treatment, early intervention shortens the length of the new episode.

Tactical Issues An important issue in both continuation and maintenance treatment is symptom breakthrough, which may be modest and time-limited, requiring only minor shifts in the treatment plan (e.g., dosage adjustment, reassurance). On the other hand, if symptom breakthrough is profound or prolonged or does not respond to dosage adjustment and reassurance, it must be treated. No randomized controlled trials have addressed this issue. Perhaps the simplest approach is to augment the current medication with an additional one (e.g., lithium, thyroid hormone, or another antidepressant). If this strategy is effective, then the augmenting medication may be discontinued after a time, to determine whether it is necessary over the longer term. If the augmenting medication fails, then a switch in treatment to another

medication may be needed.

Symptom breakthrough could also be remediated by psychotherapy, but this option has not been formally studied. Perhaps psychotherapy is indicated if the symptoms were caused by disturbed interpersonal relationships or life events (e.g., divorce or unemployment).

Another tactical problem encountered in both continuation and maintenance treatment is the management of the depression when intercurrent general medical illnesses requiring medication, surgery, or pregnancy occur. For patients who need a “window in time” for surgery or pregnancy, medication discontinuation should be gradual. Pregnancy lasts for a prolonged period and given the evidence for the efficacy of interpersonal therapy alone as a maintenance treatment, psychotherapy without medication may provide an extended drug-free period. The development of other general medical illnesses and the need for nonpsychotropic medications during continuation or maintenance treatment is not uncommon. These circumstances need to be managed with consideration of the pharmacokinetics and drug interactions between the psychotropic and nonpsychotropic agents.

When to discontinue maintenance medication treatment is unclear. As noted above, a recently completed study in patients with highly recurrent depressions (more than three episodes) indicates the efficacy of maintenance treatment continues for at least 5 years. Some patients may require very prolonged (e.g., a decade) or even lifetime maintenance medication treatment. Discontinuation requires careful monitoring, because the first 6 months following discontinuation appear to be a particular risk period for recurrences.

PATIENT PREFERENCE

Patients should become more informed about depressive disorders and their treatment. Even so, some patients are adamantly opposed to medication, while others are equally opposed to psychotherapy. Patient preference can play a greater role when evidence does not strongly support a specific choice. While patients may exercise their first preference initially, a contingency plan should be developed early in the management of the patient in case a second treatment trial is needed. Therefore, it might be wise to plan at the outset for at least two short-term treatment trials, to avoid inappropriate discouragement and consequent premature attrition if the initial treatment fails to provide full remission. Treatment tactics to optimize outcome include attention to adherence, careful titration of medication to attain maximal benefit with minimal adverse effects, and careful symptom evaluation to ensure that remission, not just improvement, has occurred. Establishing explicit goals and following a stepwise plan to attain them can help both practitioners and patients obtain the best outcomes.

14.8 MOOD DISORDERS: TREATMENT OF BIPOLAR DISORDERS

ROBERT M. POST, M.D.

Treatment of the mood disorders has reached a new level of sophistication based on a variety of advances. The descriptive and diagnostic aspects of bipolar disorders are now explicitly spelled out, recognizing that it is almost always recurrent with potential for severe morbidity and even mortality. There is increasing recognition that bipolar affective disorders have a prominent genetic component interacting with environmental events, and neurobiological alterations have been documented with biochemical assays and functional brain imaging. Thus, different treatment approaches are recognized as a function of type, severity, and course and as in other branches of medicine require the utmost clinical management skills.

Convergent with this increased knowledge about the classification, course, and mechanisms underlying acute episodes and their recurrences is an expanding array of effective psycho- and pharmacotherapeutic modalities and related somatic treatments. Whereas single drugs in one or two classes were available for the treatment of bipolar disorders several decades ago, multiple therapeutic modalities now exist, often including many agents within each class. Thus, the physician must be aware of the nuances in approach to the patient with acute and recurrent mood disorder, so that treatment can be optimized from the outset and the impact of the illness on patients and families minimized.

A growing consensus surrounds a series of new treatment principles. Early recognition and intervention in an acute episode may not only save the patient months of pain and suffering, but also may be life saving. More-careful assessment of the efficacy of an agent at early and regular intervals and early revision of the treatment modality if no improvement is shown are recognized guidelines. This is the case for somatic treatments and also for targeted psychotherapeutic approaches using cognitive, behavioral, and interpersonal therapies.

A substantial body of evidence indicates the efficacy of long-term prophylactic treatments in the management of the recurrent affective disorders. Moreover, earlier institution of long-term prophylaxis is critical to the patient with recurrent mood disorders; it will affect the morbidity of the illness and likely also its subsequent course and treatment responsiveness. Consensus is growing that a patient with a positive family history and a first episode of bipolar disorder is a candidate for continuation therapy after resolution of that episode and for long-term prophylaxis. These factors have dramatically changed the physician's approach to the patient with an acute episode of a mood disorder. The illness should be approached with the same respect accorded the early diagnosis and treatment of a malignancy. Delayed or inadequate treatment may be associated with considerable acute and long-term morbidity from both the illness and its secondary consequences. Thus, it appears appropriate to reconceptualize the recurrent mood disorders not as illusory mental phenomena that can be modified by the patient's will, but as a serious and potentially life-threatening medical illness that has clearly defined mood, cognitive, motor, somatic, and neurobiological concomitants.

Bipolar I disorder occurs in approximately 1 percent of the population, which translates into 2.5 million people in the United States alone. It is estimated that the average woman with onset of bipolar illness at age 25 will lose 14 years of effective lifetime functioning through her illness. Bipolar II disorder and bipolar disorder not otherwise specified may each account for another 1 percent or more. Fifteen to 20 percent of patients with bipolar illness commit suicide. It is against this backdrop of a recurrent, potentially disabling, medical illness that diagnostic and long-term treatment approaches should be conceptualized.

HISTORY

Over the course of this century a revolution has occurred in the treatment of bipolar disorders. In the first half of the century no adequate treatment was available; in the second half, lithium (Eskalith) emerged as a wonder drug for short-term and prophylactic management of the disorder. However, oscillations in the assessment of lithium's safety, efficacy, and utility have persisted. The drug was initially abandoned as unsafe until its concentration could be adequately monitored in blood, which virtually eliminated its most serious and potentially lethal cardiovascular and central nervous system (CNS) toxicities. However, concerns about long-term renal complications have not entirely dissipated after the kidney scare of the 1980s.

There is also greater recognition of lithium's efficacy limitations. As with penicillin, these limitations do not imply that lithium no longer works, but that the spectrum of therapeutic efficacy is narrower. More than 50 percent of patients do not show adequate response to lithium even with adjunctive antidepressant and neuroleptic treatment and using conservative criteria for clinical response (e.g., one episode of illness in a 2-year follow-up).

In the middle of the century electroconvulsive therapy (ECT) emerged as the most effective approach to treating acute episodes. Antipsychotics rapidly became a mainstay of treatment for both mania and psychosis. In the 1960s the first-generation monamine oxidase inhibitors (MAOIs) and tricyclic drugs were introduced and widely used in conjunction with lithium. Now, selective serotonin reuptake inhibitors (SSRIs), bupropion (Wellbutrin), venlafaxine (Effexor), mirtazapine (Remeron), and monoamine oxidase (MAO) type A selective modalities are available. Similarly, the phenothiazine, butyrophenone, and thiothixine antipsychotic classes have given way to the serotonin-dopamine antagonists (atypical antipsychotics), such as clozapine (Clozaril) and risperidone (Risperdal); olanzapine (Zyprexa); quetiapine (Seroquel); and sertindole (Serlect). These new agents include drugs with novel structures and mechanisms of action and more benign adverse effect profiles than the original agents.

This new range of psychopharmacological agents raises a series of important issues for the clinician, particularly when these agents must be chosen on the basis of an inadequate literature on relative efficacy or clinical and biological markers of responsiveness. There is a consensus that with the exception of ECT, no antidepressant modality is more effective or more rapid in onset than another. Thus, the choice of agents is typically based on their adverse effect profile and clinical lore regarding syndromal selectivity of response.

Fortunately, as the limitations of lithium as a mood stabilizer have been increasingly recognized, a variety of other treatment modalities have become available, particularly the anticonvulsants carbamazepine (Tegretol); valproate (Depakene); divalproex (Depakote); as well as the calcium channel inhibitors. Other promising anticonvulsants are being explored as possible third-generation mood stabilizers, including lamotrigine (Lamictal), and possibly gabapentin (Neurontin), and topiramate (Topamax). However, as with targeting therapeutic modalities to specific patients in the depressive disorders, the data are not yet adequate to choose among the accepted mood stabilizers or establish how to use them in combination, which has been increasingly necessary in recurrent bipolar disorders.

Thus, the clinician often has to resort to educated guesses and systematic and sequential clinical trials in individual patients to delineate optimal responsivity (Table 14.8-1). Even with the availability of many new treatments, episodes of illness can often emerge through otherwise partially successful pharmacoprophylaxis and necessitate adjunctive measures. The role of complex combination therapies is well recognized in many branches of medicine and is indispensable in the approach to tuberculosis, acquired immune deficiency syndrome (AIDS), congestive heart failure, or cancer chemotherapy. Systematic research of combination therapies has lagged markedly behind clinical practice, and clinicians are often left to their own devices, without the aid of controlled studies in the literature to guide the optimal

algorithm for approaching the patient who is refractory to standard treatment interventions.

Table 14.8-1 Steps in the Treatment Algorithm of the Bipolar Patient

IMPEDIMENTS TO SHORT- AND LONG-TERM TREATMENT

Although the bipolar disorders are eminently treatable, illness-related variables complicate diagnosis, accessibility to treatment, and the ability of the patient to follow through with treatment. It is estimated that as many as 40 percent of bipolar I disorder patients in community surveys are not in treatment.

Depressed patients often do not recognize that their symptoms are related to a medical illness, and the symptoms themselves (e.g., motor retardation, a sense of inertia, and hopelessness) may preclude the patient's seeking treatment. Thus, the patient's family, acquaintances, and physician may have to actively encourage the patient to initiate treatment.

Treatment must be conducted against the backdrop of the patient's distorted depressive cognitions (e.g., hopelessness, and view of the untreatability of the illness), which must be explained as symptoms of the illness that are not consistent with optimism of treatment response on the basis of the literature and the physician's knowledge base. The therapist's empirical basis for hope of recovery needs to be conveyed to the patient without the promise of immediate results, so that the expected lags in response are not further misinterpreted as a confirmation of the patient's worst fears. Moreover, each phase of the treatment needs continual review in relation to the potential for suicide.

There are major impediments to effective treatment of manic patients. In the early stages of hypomania, the sense of well-being and increased productivity may lead the patient to ignore more severe aspects of the illness, including irritability, argumentativeness, insomnia, poor judgment, and engaging in sexual and other high-risk behaviors without appropriate appreciation of the consequences. These deleterious activities may severely affect the patient's social structure, marriage, and employment. Early recognition that these symptoms and the denial of illness (anosognosia) are components of the illness itself may be crucial to instituting appropriate treatment and preventing escalation to destructive and full-blown manic episodes.

Again, family participation is crucial in both the diagnostic evaluation and the ongoing treatment. The family can assist in overcoming illness denial and thought disorder associated with hypomania and mania, which can be as problematic to receiving adequate treatment as the hopelessness and suicidality of the depression.

Therefore, therapeutic activism, engagement of the family, and early and aggressive treatment of both manic and depressive syndromes are of paramount importance. Individual patients and their families should receive initial and ongoing informational support regarding the medical aspects of the illness, its potential course, and response to treatment, with the long-term goals of increasing compliance, “medicalizing”, and destigmatizing the illness. Destigmatization may become a crucial issue later in therapy when recommendations for long-term prophylaxis may elicit society's negative attitudes toward taking maintenance medications for psychiatric indications (in contrast to most other types of medicine). Conceptualizing the recurrent mood disorders as medical illnesses deserving the same attention, care, and long-term respect as disorders of other organ systems and may help the patient and family accept appropriate long-term treatment options.

A variety of societal, attitudinal, and illness-related variables may interfere with appropriate help-seeking and maintenance behavior in the various treatment phases, including initiation of acute care, continuation treatment, and long-term prophylaxis. During each of these phases patients and their families should be helped to evaluate the medical data and the potential impact of the illness on the patient. Do not introduce all of these variables at the beginning; approach them sequentially in each phase as appropriate. For example, it may be better to discuss the importance of continuation and long-term prophylactic therapy after patients have begun to show an antimanic or antidepressant response, rather than raise this issue with acutely ill patients and possibly frighten them from pursuing further treatment.

Early discussion of long-term prophylaxis—with graphic, statistical, and both written and verbal presentation of the data to the patient and family—may be critical for achieving an optimal outcome. Even in an illness such as juvenile diabetes, where it is unequivocally demonstrated that the patient cannot survive without adequate insulin treatment, many adolescents nevertheless directly or indirectly test the need for insulin and suffer periods of marked hyperglycemia, often requiring hospitalization. In a parallel fashion, patients with bipolar disorder are likely to be tempted to discontinue treatment, especially when the data regarding the morbid or lethal consequences are less well delineated. Nevertheless, the treating clinician must provide the patients and their families with the now overwhelming data showing the high likelihood of a recurrence in a relatively short period of time in patients with one or more prior episodes and the ability of a variety of agents to prevent recurrences of both manic and depressive episodes.

In bipolar disorders the high likelihood of relapse (50 percent in the first 5 months following lithium discontinuation and 80 to 90 percent within the first year and a half) is now also widely recognized and should be explained to the patient. In addition, it has always been assumed that patients who experience a relapse will be readily treatable once their former therapeutic modality has been reinstituted. Most investigators have observed lithium-discontinuation-induced refractoriness in which a small percentage of patients who discontinue successful prophylactic treatment and experience a relapse fail to respond when the treatment is reinstituted. In other instances, patients may not respond as rapidly as they did initially or require increased adjunctive neuroleptic medication.

Many studies report that lithium is less effective in patients who have had more than three or four prior episodes than in those whose prophylaxis is initiated earlier in the illness course. Thus, not only should the potential morbidity and mortality of an episode itself be factored into the decision-making process for long-term prophylaxis, but also the possibility that new episodes could affect the subsequent course of the illness and its pharmacological responsivity.

PSYCHIATRIC HISTORY

A thorough medical history and examination are important, given the many syndromes that mimic both manic and depressive syndromes. The older patient with late-onset illness, in particular, should be approached with the possibility of an associated medical cause, and attention should be paid to obvious or subtle hallmarks of associated pathology. The physician should be alert to symptoms indicating CNS neuropathology, underlying endocrinopathy, or other associated medical illness. Although physicians should aggressively explore these themes with patient and family, they should remember—and even directly tell the patient—that all of the somatic and vegetative symptoms reported are consistent with, and most likely indicate, typical primary affective illness.

The earliest parts of the history can be used to uncover diagnostic clues and to educate the patient about the types of symptoms that are typical of the disorder, are associated with its natural course of spontaneous exacerbation and remission of episodes, and are likely to respond to somatic and pharmacological intervention. The medical history and examination should also seek evidence of cardiac, renal, or thyroid abnormalities that may help guide subsequent treatment choices.

The physician should cover each psychological and somatic symptom category associated with depression while simultaneously educating the patient, providing target symptoms for future assessment of the efficacy of psychological and pharmacological intervention, and constructing the framework for longitudinal monitoring of the patient. The symptoms that are typical for a given patient are likely to be involved in a future episode, and thus they provide an early warning system for illness detection and institution of additional treatment.

A detailed family history of medical and psychiatric illness is also crucial to the initial diagnostic assessment of the patient. Graphic construction of a formal family tree is recommended, with each first-degree relative specifically inquired about for their potential diagnosis, course of illness, and response to therapy (Fig. 14.8-1), since these may help guide the choice of therapies for the patient. A positive family history of bipolar illness may further support the recommendation of long-term prophylaxis after the emergence of the first manic episode.

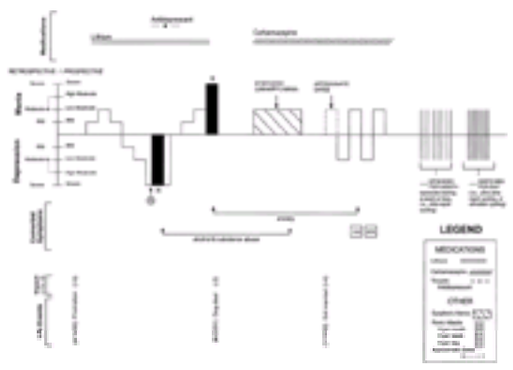

FIGURE 14.8-1 Schema for graphing the course of mood disorders: Retrospective and prospective.

A bipolar disorder family history, especially one with bilineal loading for mood disorder, should markedly raise suspicion of a juvenile- or adolescent-onset bipolar disorder, even if its presentation is less than typical. The clinician should recognize that even in an adult-onset bipolar disorder, the passing of a decade between affective symptom onset meeting diagnostic thresholds and the initiation of treatment is not uncommon. Moreover, in the prepubertal child, a bipolar disorder may present differently from the classic adult picture (Fig. 14.8-2). Instead of showing discrete episodes that easily meet the durational criteria of the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV), there may be a pattern of tantrums, mood lability, irritability, and marked and rapid fluctuations in mood and behavior. Hypersexuality and grandiosity (if not frank delusions), high-risk behaviors, sleep disturbance, extremes of anger or aggression, or expressions of suicidal ideas may be particular clues that one is dealing with more than attention-deficit/hyperactivity disorder in the hyperactive and inattentive child. Moreover, prepubertal onset of a psychotic depression may herald the beginning of bipolar illness, since a 30 percent switch rate into mania upon treatment with antidepressants has been reported. Similarly, bipolar disorders may present atypically in adolescence, either with extremes of mood lability or with more psychotic and schizophreniform features. In prepubertal children and adolescents, antidepressants may exacerbate the illness, and mood stabilizers, often in combination, are frequently required.

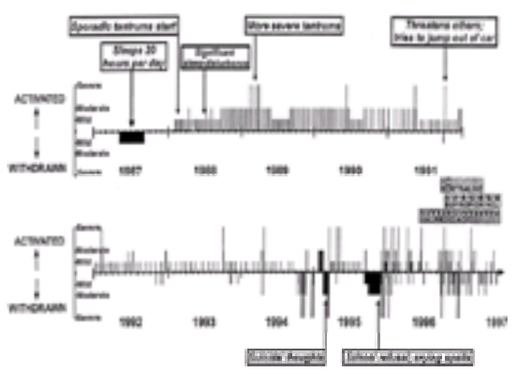

FIGURE 14.8-2 Kiddie Life Chart (K-LCM) of a 10-year-old child with affective dysfunction from the first year of life.

Graphing the Course of Illness The author suggests developing a graphic representation of the patient's prior depressive and manic episodes (Fig. 14.8-3). This graph will form a basis for evaluating the efficacy of previous treatments and assessing current and future prescription. A formal graphic representation of the patient's longitudinal course of illness is useful for several reasons: (1) it provides a clear picture of the earlier illness course, which appears to be the best predictor of the future episode pattern; (2) it clarifies prior and future medication responsiveness; (3) it helps medicalize the patient's history and management, as well as facilitate the recognition of low-level manic symptoms, and (4) it encourages the patient's collaboration and thus may enhance the doctor-patient relationship, making the patient an active partner rather than a passive participant.

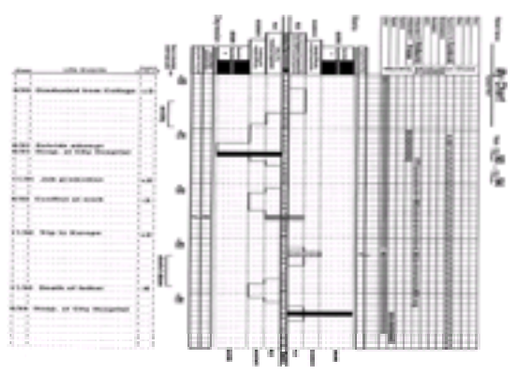

FIGURE 14.8-3 National Institute of Mental Health (NIMH)-life chart method (LCM) self ratings—retrospective.

If a number of past episode recurrences are uncovered in the history, such a graph may also help in the subsequent long-term approach to the illness and in the patient's compliance with prescribed regimens. Moreover, the author has found that this process often uncovers important psychosocial events and possible precipitants of the illness, as well as unique characteristics of the illness, such as cycle characteristics, illness rhythmicity or lack thereof, seasonal variation, relation to anniversaries, and other longitudinal treatment response patterns (such as tolerance or cycle acceleration) not easily uncovered without systematic, graphic representation of the illness. Carefully examining the periods of increased vulnerability to illness provides a template for future treatment intensification or augmentation of therapeutic modalities as appropriate.

With a little practice, the course of an illness can easily be graphically depicted. The author suggests that this be done as part of the initial intake session and be the primary mode of recording a patient's history, even preferable to an extensive written account intended for later conversion to a graph. In this way, both the patient and the physician are immediately and systematically focused on the longitudinal course of the illness and its variation over time, rather than having this focus develop later or possibly be completely sidetracked by attention to acute symptoms. The graphic approach and its associated temporal landmarks can also facilitate recall of important events, dates, and episodes that would otherwise be obscured or forgotten. Typically in this process, supposed first-episode patients will often uncover multiple prior minor or major episodes.

Levels of Severity Physicians can devise their own ways of plotting the course of illness or adopt a system like the one the author and his colleagues have used

successfully over the past decade, that is, graphing three levels (mild, moderate, and severe) of mania or depression on the basis of the degree of associated symptom-driven functional incapacity, which can be most readily assessed retrospectively, on the National Institute of Mental Health NIMH–life chart method (NIMH-LCM) (Fig. 14.8-3).

At the mild level, the patient or family notes a distinct change in the patient's mood, with no notable impairment in the patient's social, educational, or employment roles. This state is readily recognized by depressed patients and may represent the dysthymic baseline from which more severe episodes erupt (i.e., double depression). However, hypomanic patients may deny this mild state, so additional information and input from family members and relatives is important. This observation also reemphasizes the utility of a nonpsychoanalytic approach to the patient's diagnosis and treatment, including the participation and support of family members from the outset. This may be of value both in gaining historical information, and in managing potential suicidality of depression and denial of the adverse consequences of hypomania and mania.

Hypomanic signs and symptoms representing distinct periods of increased energy, productivity, and creativity and decreased need for sleep should be sought directly, and not raised in a negative fashion. These milder periods may be easier to explore after the more severe phases of a patient's illness have been detected and the characteristics of their early presentation agreed upon.

Moderate levels of depression and mania that represent phases with distinct functional impairment are graphed at the next level. Patients can continue their social or employment responsibilities, but only with obvious difficulties, such as absences from work or not being able to perform some routine social tasks. In prospective forms of the NIMH-LCM, moderate dysfunction has been divided into low and high categories, representing some and much dysfunction in usual roles, respectively (Fig. 14.8-4). The manic patient may reveal these levels of dysfunction more easily if asked whether coworkers, friends, or family members are commenting or complaining about the patient's behavior or directing them to seek help.

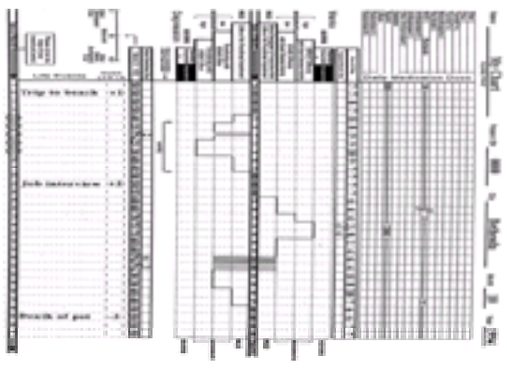

FIGURE 14.8-4 NIMH-LCM self ratings—prospective.

In severe impairment patients are functionally incapacitated and unable to perform their usual roles. Hospitalizations can be coded by shading in the severe manic or depressive episode on the graph. A past episode whose precise timing is unknown or unavailable can be graphed and coded with broken or dotted lines.

For prepubertal onsets a Kiddie-LCM is available that allows graphic depiction of symptom-driven dysfunction whether or not these often highly disturbed and dysfunctional children meet the artificial durational criteria intended for classical adult presentations. Such documentation may be crucial to a child's receiving adequate pharmacological intervention, which is often withheld because of diagnostic controversy and the attendant fears of using medications in children. Professional and societal attitudes and stigma would appear to be highly relevant here, as there is less concern about medications in children with epilepsy, rheumatoid arthritis, infections, malignancies, asthma, and many other medical illnesses with typical or atypical early onsets. Not only is childhood- and adolescent-onset bipolar illness prognostically more disabling than the adult variety in some long-term outcome studies, but the illness also puts the child at increased risk for alcohol and other substance abuse and for other potentially deleterious high-risk behaviors. Moreover, adolescent suicide is one of the fastest growing categories of early mortality.

Psychopharmacological Interventions The history of prior psychopharmacological interventions should be plotted directly above the episodes on this retrospective template of mood fluctuation as illustrated in Figure 14.8-1 of the life-chart schema and in the case example in Figure 14.8-5. When graphed in this fashion, the efficacy of earlier treatments is often more precisely categorized and reclassified. On careful reexamination, a treatment previously deemed ineffective may have partially decreased the frequency or severity of prior episodes. If so, one may now want to consider supplementing this partially effective treatment rather than abandoning it. Previous psychotherapeutic interventions should also be noted, so that their impact on the illness and patient satisfaction can be assessed. As illustrated in Figure 14.8-1 and Figure 14.8-3, important psychosocial events (e.g., significant anniversaries, suicide attempts) and notes about adverse effects (e.g., dosage, reasons for discontinuation of medications) can be entered below the mood graph.

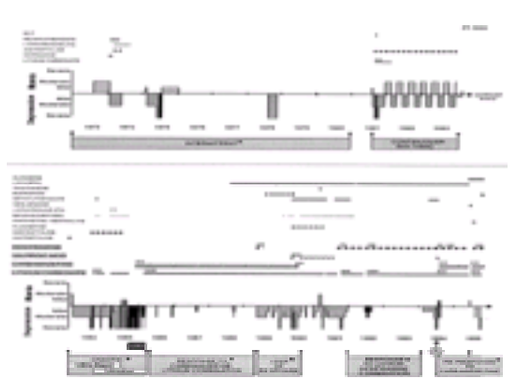

FIGURE 14.8-5 Phases of illness evolution and treatment response in a woman with bipolar II disorder.

Descriptive Symptoms The anamnestic account of specific symptoms and their associated dysfunction also provides the basis for following clinical improvement during an acute episode and during future possible episodes. In particular, one should try to determine the best descriptors and early predictors of an individual patient's episode. For some patients it may be impaired sleep with early morning awakening; for others it may be an inability to concentrate. Still others may experience decreased energy or increased agitation, isolation, anxiety, appetite, or weight gain. The sequential ebbing of symptomatology during a treated episode may also help delineate the need for continued augmentation treatment or reciprocally yield clues to the earliest symptoms of a recurrence. Should these or other residual symptoms break through during prophylaxis or emerge while tapering medication, they can be used to indicate roughening and the need for renewed, more aggressive management of a potential episode.

Similarly, clinicians should contract with their patients in advance about specific symptoms that may herald depressive or manic episodes and require additional monitoring and intervention. Early signs of the emergence of the patients' typical symptoms—such as increased energy or religiosity or decreased sleep—that may be welcomed, may actually presage more consequential manic symptoms. Attention to these early warning signs while insight is still preserved and denial manageable may save patients and their families from a more prolonged or catastrophic episode. A specific contract such as “call if you should have two nights with less than 5 hours of sleep” is often more helpful than a more general suggestion to call if needed.

Prospective Charting For the bipolar patient with several episodes, the author suggests that some elements of this life chart process be continued prospectively, preferably on a daily basis. This can be accomplished quite easily in a number of ways, including having the patient keep a nightly calendar and write a number on a

visual analog scale from 0 (worst ever felt) to 50 (normal or balanced) to 100 (most energized or manic ever). Following discussion with the clinician, this score can be converted to life-charted episodes based on functional incapacity.

In this fashion or with a more complete daily prospective mood chart such as the NIMH-LCM-p patients can track their mood fluctuations in a systematic manner that is unobtrusive and takes only seconds to complete. Pocket life charts and computer graphics packages are now available. Mood rating, like self-assessment of urine glucose concentration by the diabetic patient, may provide an important measure of how well the patient's illness is responding to a given treatment modality, and its dosage adverse-to-effect efficacy ratios and titration. The morbidity and mortality of the mood disorders can be as severe as those of many medical illnesses for which a great deal more attention is paid to the longitudinal and systematic monitoring of fluctuations in symptomatology, biochemistry, and underlying pathology. Patients should be encouraged to help in this life-chart process if they are amenable to it. The completed retrospective and ongoing prospective charts may also help in any future transfers of medical care, orientation of hospital staff, or consultation request should the patient move or suffer future episodes requiring review and revision of treatment.

Subjective and Objective Differences Finally, asking patients to make a calendar, rate their moods (with a specific number on the 100-mm line), and assess illness-driven functional incapacity, may have other secondary benefits. Patients can become better attuned to possible subjective versus objective differences in illness assessment. Some depressed patients can detect mood changes and adverse effects before therapist observation, but many bipolar depressed patients can show remarkable improvement in major aspects of their symptomatology, including sleep, appetite, energy, spontaneity, and sociability, without any subjective sense of mood improvement. If patients do not recognize that their depression is improving despite objective signs, it may lead to further therapeutic pessimism and also may increase the possibility of suicide, as they now may have more energy to carry out such a plan. Moreover, return to previous optimal social and occupational function may lag even further behind objective and subjective appreciation of symptomatic improvement, so that the patient requires additional support, encouragement, and possible retraining during this time frame.

TIME FRAME OF EDUCATION

Although a hopeful perspective about the treatability of a patient's episode should be maintained, a series of drug trials may be needed before the best treatment regimen is found. Evaluation of an acute antidepressant treatment response often requires 3 to 6 weeks, and a given agent's lack of efficacy should be treated as additional information about the patient's illness rather than an indication that the illness is not responsive. Several recent studies in unipolar depression suggest that a lack of some improvement after 4 weeks is a very poor prognostic sign for eventual response with further continuation into 5 and 6 weeks.

Thus, augmentation approaches, in particular, should be triggered at these early times rather than after several months, particularly if high doses or adequate blood concentrations of a given compound have been achieved. In the treatment of acute mania, in which response is typically more rapid (days to weeks), one should consider additional and alternative approaches if improvement is not observed over much shorter periods (days to a week). At the outset of treatment the availability of different effective treatments, with many drugs in each class, should be brought to the patient's attention. This puts possible treatment sequences in their proper perspective and emphasizes that a lack of response to, or an intolerance of, one drug does not portend an ultimate negative therapeutic outcome.

These points should be reemphasized throughout the entire therapeutic process, particularly in light of the different time frames available to the therapist and the patient. The therapist is aware of the many treatment alternatives and the extended treatment course sometimes required to achieve optimal efficacy. The patient (and perhaps even the family) may be overwhelmed by a sense of immediacy and desperation about the current mood-disordered state. Particularly for the depressed patient, this feeling of pain and hopelessness can too easily overtake the realities of the situation and increase the risk of suicide before a positive treatment outcome is achieved.

Reassurance without overpromising immediate therapeutic effects thus appears to be an important part of the treatment. A similar but inverse process may be required for the manic patient, who also may see only the immediate time frame and not the longer-term perspective. The therapist should encourage and help supply the ego for the longer-term view in both of these cases. Thus, supportive, interpersonal, cognitive, and behavioral approaches to the psychopharmacotherapy of the mood disorder may be essential. Patients should also be counseled not to make important long-term decisions on the basis of a distorted view of themselves and their future during an acute depressive or manic episode.

Stressing the time needed to evaluate a given treatment may help maintain the patients' and families' morale and help obtain an adequate informed consent while avoiding malpractice litigation. In this regard, the patient must be told the possible adverse effects of each drug treatment, so that these effects are expected and not seen as dangerously unpredictable, or conversely, they can be recognized as something that merits closer attention, a call to the physician, or an extra visit when indicated.

HOSPITALIZATION

The decision to hospitalize severely depressed or manic patients depends on a variety of clinical and (disappointingly) economic issues. Hospitalization is often indicated for the acutely suicidal patient and may also be considered for the patient with associated medical problems or one who needs close management and monitoring of complicated or novel psychopharmacological regimens. For the knowledgeable patient and supportive family, one or more of a series of psychopharmacological approaches can often be accomplished on an outpatient basis, particularly if there is close coordination between the patient and physician regarding dosage, titration, adverse effects, and indicators of improvement. Despite many of the largely societal criticisms of the modern use of ECT, this modality should be given a higher priority when treating patients with extreme suicidality, associated medical illnesses, difficult adverse reactions to routine psychopharmacological agents, or other medical emergency situations (such as malignant catatonia or hyperthermia) that demand the most rapid treatment response available. For the recurrent manic patient who has refused voluntary hospitalization at the height of an episode or might be likely to do so, obtaining informed consent in advance (during a well interval) for future involuntary hospitalization and pharmacological treatment may avoid many cumbersome practical and medicolegal difficulties should another manic episode requiring hospitalization occur.

PSYCHOTHERAPY AND PHARMACOTHERAPY

Depression is a serious, potentially life-threatening medical illness, and patients and their families deserve much support. Combining psychosocial and pharmacological approaches is important for most because of their potential mutual interaction and support in the context of ongoing pharmacotherapy.

Cognitive-behavioral therapy may enhance medication compliance and provide support for the patient in the interval before psychopharmacological interventions are successful, especially if several agents are required before an effective regimen is found. Moreover, stress and other psychosocial issues may be involved in the onset and recurrence of some depressions and manias and may be indicators for more aggressive pharmacological management.

Frequent meetings with the patient may also help in assessing response to pharmacotherapy and suicide risk. In a depressed patient with severe pain and suffering, frequent meetings may facilitate the fastest maximal application of pharmacological leverage; regimens can be revised as quickly as possible (days to a week in mania, and several weeks in depression) if improvement is not forthcoming. Combined treatment may also be helpful in instances of partial response to monotherapy, a protracted episode, poor interepisode recovery of function, an associated personality disorder, or the presence of acute psychosocial stressors.

NEUROTRANSMITTER THEORIES

Because most of the effective treatments for mood disorders were discovered by serendipity, pharmacological agents have propelled theoretical formulations rather than vice versa. Neurotransmitter theories of the basis of depression have included serotonergic, noradrenergic, cholinergic, dopaminergic, g-aminobutyric acid GABAergic, and, most recently, glutamatergic, each based on presumed mechanisms of effective pharmacotherapeutic interventions. For example, finding that several drugs that acutely potentiated catecholamines and indolamines were antidepressants and that reserpine (which depleted these neurotransmitters) could exacerbate depression and treat mania led to the amine hypotheses of deficiencies in depression and excesses in mania.

Relatively selective manipulations of each of several different neurotransmitter systems (serotonin, noradrenergic, and dopaminergic) now seem to be associated with antidepressant effects (Table 14.8-2 and Table 14.8-3), which raises a critical psychopharmacological question, whether an individual may respond to one type of treatment with a postulated mechanism of action targeting one neurotransmitter system, but not to another (Fig. 14.8-5). In the absence of definitive studies of this question, one is tempted to recommend the sequential use of drugs that act differently within or among classes of agents (e.g., changing from a relatively more

serotonergic to a relatively more noradrenergic tricyclic reuptake inhibitor or from a tricyclic drug to an MAOI to lithium). Few validated clinical or biological markers of response to given treatment agents exist, so one must move through the various treatments or adjuncts for the refractory patient until an effective one is found, largely through trial and error. An MAOI trial should be considered for a patient who has failed to respond to multiple previous antidepressants, as response rates remain 50 to 60 percent with this agent. A similar strategy of using agents with different mechanisms of action sequentially or concurrently in mania may also be warranted (Table 14.8-4 and Table 14.8-5).

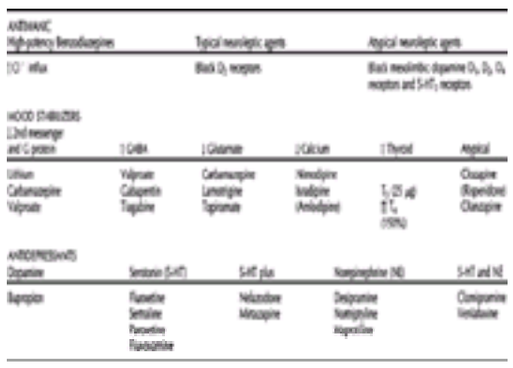

Table 14.8-2 Targets of Action of Antidepressants and Mood Stabilizers

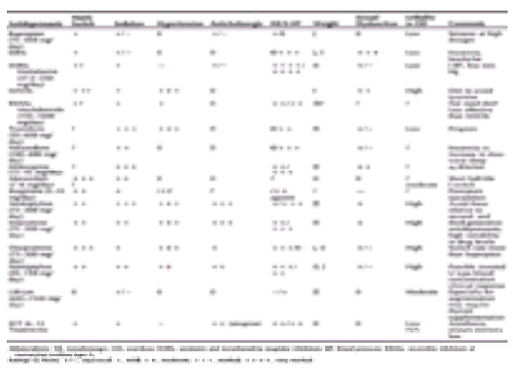

Table 14.8-3 Adverse Effects of Biological Treatments Used to Treat Depression in Bipolar Disorder Patients

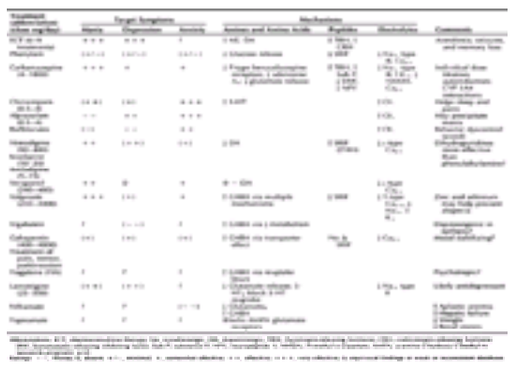

Table 14.8-4 Putative Psychotropic and Mechanistic Effects of the Anticonvulsants

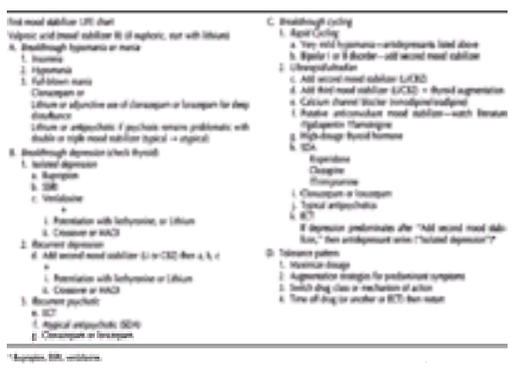

Table 14.8-5 Algorithm for Augmentation and Switching Strategies, Treatment of Bipolar Disorder, Manic Phase, Dysphoric Type

Since 1 month must elapse between treatment with serotonin-active compounds and an MAOI, a transition may be achieved with bupropion, a noradrenergic-selective agent, lithium, or an anticonvulsant. With increasing levels of refractoriness, one should reevaluate the diagnosis (especially with a careful assessment of possible physical, psychological, or drug abuse comorbidity) and consider consultation, psychotherapy revision, as well as more complex combination treatment approaches.

Lithium, valproate, and carbamazepine each alter dopamine and noradrenergic function and upregulate g-aminobutyric acid (GABA) type B ($GABA_B$) receptors in the hippocampus (Fig. 14.8-6). They also target G protein systems, decrease protein kinase C activity, and inhibit calcium influx through the glutamate *N*-methyl-D-aspartate (NMDA) receptor. Lithium and valproate increase myristoylated alanine-rich C kinase substrate (MARCKS) and activator protein–1 (AP-1) binding, as well as messenger ribonucleic acid (mRNA) levels for BCL-2, and brain-derived neurotrophic factor, the latter two of which may be involved in the prevention of apoptosis. GABAergic effects are enhanced by valproate and gabapentin, whereas topiramate, carbamazepine, and lamotrigine decrease excitatory amino acid release or function in part via blockade of sodium ion channels.

FIGURE 14.8-6 Common and different mechanism of mood stabilizers. PI, phosphoinositol; AC, adenylate cyclase; IMPase, inositol monophosphatase; PLC, phospholipase C; cAMP, cyclic adenosine monophosphate; NPY, neuropeptide y; ACh, acetylcholine; DA, dopaminergic; Ne, noradrenergic; PKC, protein kinase C; $A1_R$, adenosine A1 receptors; T_4, thyroxine; CRE, cyclic response element; CBZ, carbamazepine; TRH, thyrotropin-releasing hormone; CREB, cyclic response element binding protein; VPA, valproate; SRIF, somatostatin; t.o., turnover.

TREATMENT OF ACUTE MANIA

Lithium Lithium has been the paradigmatic treatment for acute and prophylactic treatment of mania. In comparative studies with antipsychotic agents, it yields better overall improvement in most aspects of manic symptomatology, including psychomotor activity, grandiosity, manic thought disorder, insomnia, and irritability. However, the onset of antimanic action with lithium can be rather slow (Fig. 14.8-7), even with aggressive dosing; thus acutely deteriorating aggressive or psychotic manic patients may require supplementation of lithium in the early phases of treatment. Until recently, this was traditionally accomplished with the typical neuroleptic drugs, including the phenothiazines, thiothixines, or butyrophenones such as haloperidol (Haldol). Because of the rapidly growing evidence for the parallel acute antimanic efficacy of the mood-stabilizing anticonvulsants carbamazepine (Fig. 14.8-7) and valproic acid, it is suggested that these alternative agents or the more recently available atypical serotonin dopamine antagonists be used as initial supplements rather than in place of the conventional antipsychotics for a variety of reasons related to their adverse effect profiles and the risk of tardive dyskinesia.

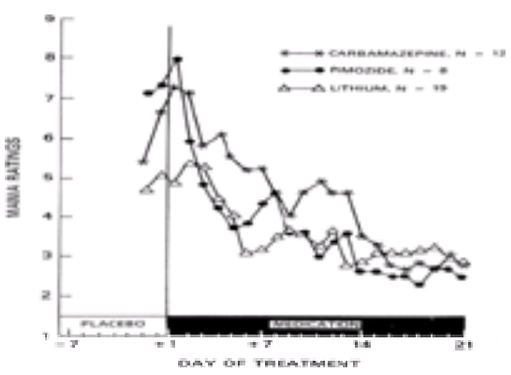

FIGURE 14.8-7 The time course of onset of antimanic response to blind administration of carbamazepine in 12 patients is compared with other similarly diagnosed and rated patients treated with pimozide (*N* = 8) or lithium (*N* = 19).

Double-blind controlled evaluations in many different laboratories have indicated that the onset of antimanic efficacy with carbamazepine is as rapid, or almost as rapid, as it is with traditional antipsychotic drugs, including chlorpromazine (Thorazine), thioridazine (Mellaril), haloperidol, and pimozide (Orap) (Fig. 14.8-7). As of 1998 19 double-blind studies of carbamazepine in acute mania indicated clinical efficacy. Fewer controlled studies have been performed with valproate, but they represent the largest placebo-controlled studies of both lithium and valproate, and they also indicate acute antimanic efficacy. Because initial acute antimanic response may be a guide to subsequent prophylaxis (the major focus of therapeutics of bipolar illness), the author also encourages the investigation of an individual's acute response to these anticonvulsant agents as adjuncts. Antipsychotic agents can always be used later in the sequence if dictated by a lack of clinical response to the mood stabilizers and the adjunctive high-potency benzodiazepines.

Lithium Response The typical clinical profile of the manic patient most responsive to lithium carbonate is one with a classic presentation and euphoric mania, rather than severe or dysphoric mania with paranoid or destructive trends; a pattern of mania followed by a depression and then a well interval rather than a pattern of depression, mania, well interval or continuous cycling; a history of fewer prior episodes and no rapid cycling (i.e., four episodes a year); a positive family history of primary mood disorder in first-degree relatives; and a lack of substance abuse and other comorbidities such as panic disorder. These characteristics can make the difference between a 70 and a 30 percent response rate (Fig. 14.8-8).

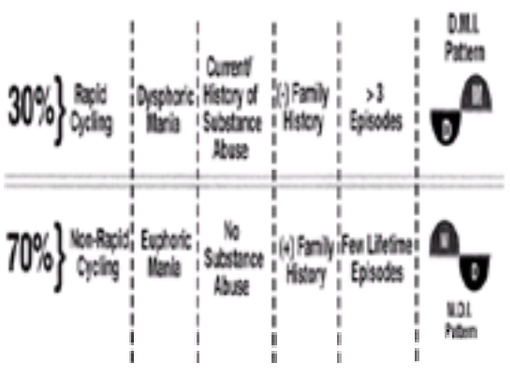

FIGURE 14.8-8 Variable lithium-response rate based on bipolar disorder subtype. D.M.I., depression, mania, well interval; M.D.I., mania, depression, well interval.

Lithium doses should be administered to achieve concentrations in serum between 0.6 and 1.2 mEq per liter. Although a high-dose strategy is advocated by some investigators (concentrations of 1.5 or above), the author has not seen many patients who fail to respond at more typical lithium blood concentrations and respond well when pushed to higher levels that are associated with greater side effects. Dose-limiting adverse effects may include gastrointestinal disturbances (particularly diarrhea) as well as neuropsychiatric syndromes including tremor, subjective sense of cognitive slowing, confusion, and myoclonic twitches. Concentrations of lithium in blood achieved at a given dosage may increase further if the patient switches from mania to depression, leading to greater adverse effects. For the inadequate responder to lithium at levels associated with few side effects, the author recommends potentiation with other agents, rather than discontinuing lithium and requiring a new agent to treat any additional withdrawal emergent symptoms.

The most recent and largest placebo-controlled study of lithium indicated that only 50 percent of patients achieved a 50 percent or greater improvement by 3 weeks. Those with a prior anecdotal history of lithium nonresponse by self-report were particularly at risk for nonresponse in this controlled study. However, even in the responsive group, many symptoms remained at the end of 3 weeks. Thus, even without the increased pressures from managed care for rapid discharge from the hospital, most full-blown manic patients require adjunctive treatment to achieve a timely and adequate antimanic response. A broad range of such options are now

available (Table 14.8-6).

Table 14.8-6 Speculative Differential Approaches to Bipolar Disorder Subtypes

Valproic Acid Typical dosages of valproic acid are 750 to 2000 mg a day, achieving blood concentrations between 50 and 120 μg/mL. Rapid oral loading with divalproex using 15 to 20 mg/kg from day 1 of treatment, has been well tolerated and associated with a rapid onset of response. Blood concentrations above 45 μg/mL have also been associated with earlier response. In several case series, patients with more-typical manic syndromes and fewer schizoaffective symptoms appeared to show a high frequency of response. In contrast to lithium, those with a history of lithium nonresponse, dysphoric mania, or rapid cycling are not less likely to respond to valproate (Table 14.8-6).

Carbamazepine Several preliminary studies have suggested that some of the variables associated with a poor response to or intolerance of lithium may be associated with a good antimanic response to carbamazepine. Thus, the drug may be considered for lithium-nonresponsive manic patients (Fig. 14.8-5).

Typical dosages of carbamazepine to treat mania have ranged between 600 and 1800 mg per day associated with blood concentrations between 4 and 12 μg/mL. However, within this dosage and blood-concentration range, there does not appear to be a clear relation to the degree of clinical response across patients. For an individual patient, however, clinical response and adverse effects are likely dose related. Dosage administration with this anticonvulsant must be individualized, as there is wide variability in the dosage and blood concentration at which adverse effects occur. Increasing the dosage to achieve a clinical effect and titrating the increases against the emergence of adverse effects is the appropriate strategy for such wide individual variability. After several weeks carbamazepine induces hepatic enzymes that lower its levels and may require additional upward dose titration.

Carbamazepine and valproic acid have been used in combination to treat epilepsy, but only preliminary evidence for the efficacy of this combination in acute and prophylactic management of the refractory bipolar patient is available. Valproate may increase concentrations of carbamazepine and its active 10,11-epoxide metabolite, indicating a need for lower carbamazepine dosage when both drugs are used in combination. Typical adverse effects of carbamazepine and other antimanic drugs are listed in Table 14.8-7.

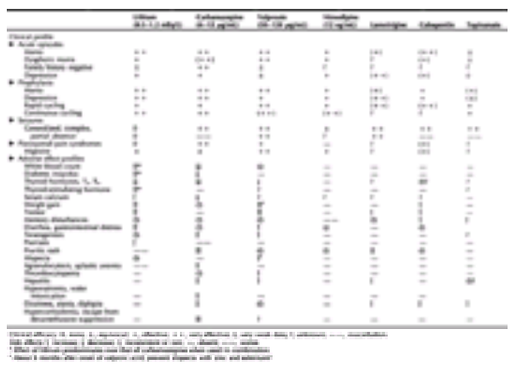

Table 14.8-7 Comparative Clinical and Adverse-Effect Profiles of Lithium, Nimodipine, and the Putative Mood-Stabilizing Anticonvulsants (Preliminary Clinical Impressions)

Clonazepam and Lorazepam The high-potency benzodiazepine anticonvulsants studied in acute mania include clonazepam (Klonopin) and lorazepam (Ativan). Both appear effective and are widely used for adjunctive treatment of acute manic insomnia, agitation, aggression, and dysphoria as well as panic. As noted above, the benign adverse-effect profiles of these agents render them ideal adjuncts to lithium, carbamazepine, or valproate and preferable to the dopamine receptor antagonists (typical antipsychotics) for first-line augmentation. The sedating effects of clonazepam may be problematic in some outpatients, but this property of the drug may be used for bedtime medication for severely insomniac manic patients.

Both of these two high-potency benzodiazepines work rather selectively at the central-type benzodiazepine receptor; in contrast, carbamazepine is not active at this receptor and appears to act at the so-called peripheral-type benzodiazepine receptor (Table 14.8-4). Classic central-type benzodiazepine receptors modulate GABA receptors that facilitate chloride influx and neuronal inhibition (Fig. 14.8-9). In contrast, the peripheral-type benzodiazepine receptor appears to be more closely associated with mitochondrial neurosteroid biosynthesis and calcium channels. These findings are noteworthy in regard to possible differential psychotropic responsiveness between these two classes of anticonvulsants.

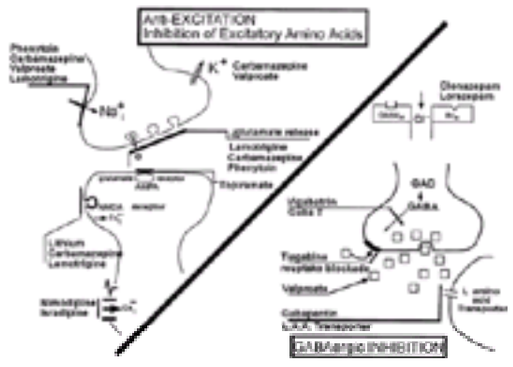

FIGURE 14.8-9 Dual targets of mood stabilizers. Bz_R, benzodiazepine type R receptors, AMPA, a-amino-3-hydroxy-5-methyl-4-isoxazole propionate; GAD, glutamic acid decarboxylase; L.A.A., L amino acids.

Dopamine Receptor Antagonists Studies indicate that short-term use of conventional antipsychotics (Table 14.8-8) in the treatment of mania results in unintended and often unneeded persistence of antipsychotic use 6 months or more after the acute episode. Such intermittent to chronic maintenance treatment with traditional neuroleptic drugs should be avoided, if possible, since bipolar disorder patients are reported to be at high risk for tardive dyskinesia (20 to 40 percent of those

exposed), equal to or greater than that of patients with schizophrenia.

Table 14.8-8 Antipsychotic Drug Use in Mania

Thus, the author recommends exploring potential mood-stabilizing alternatives to lithium (e.g., valproate and carbamazepine), short-term adjuncts (e.g., clonazepine or lorazepam), or serotonin-dopamine antagonists before using dopamine receptor antagonists in bipolar disorder. Intermittent neuroleptic drug use, rather than being a protective factor may actually increase the risk of tardive dyskinesia, according to both clinical and preclinical studies.

The strategy of rapid tranquilization with suprathreshold doses of antipsychotic agents should be avoided. Many double-blind evaluations of this strategy in acutely psychotic schizophrenia patients and one trial in manic patients have shown that the high-dosage strategy (40 to 60 mg a day of haloperidol) is no more efficacious than traditional dosage regimens (10 mg a day) and is associated with greater adverse effects. Particularly for extremely manic patients, the use of heroic antipsychotic dosages to decrease psychomotor activation may not be justifiable considering the added risk of ordinary toxicities, the risk for neuroleptic malignant syndrome, and the sporadic reports of reversible and irreversible organic impairments when used in conjunction with lithium.

Serotonin-Dopamine Antagonists The availability of new atypical antipsychotics with their presumed equal efficacy but superior adverse effect profiles (Table 14.8-9 and Table 14.8-10) may change the algorithm for the treatment of acute mania. A minority of patients appear to require antipsychotics for short- and long-term mood stabilization. Not only can the typical neuroleptic drugs predispose to a variety of acute extrapyramidal effects and long-term tardive dyskinesia, they can also exacerbate the depressive phases of bipolar illness, increasing the frequency or duration of depression or both. These potential liabilities should lead one to use the newer atypical neuroleptic agents if additional antipsychotic treatment is required.

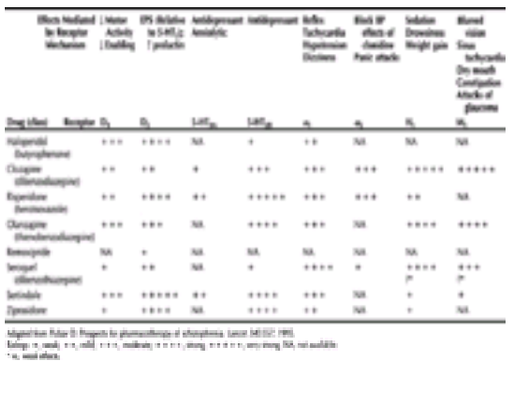

Table 14.8-9 Receptor Activities of Atypical Antipsychotics Relative to Haloperidol

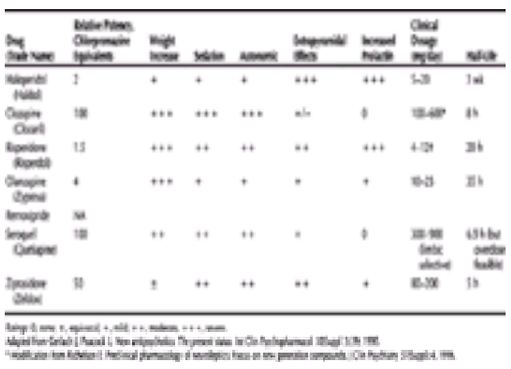

Table 14.8-10 Clinical Profiles of the Atypical Antipsychotics Relative to Haloperidol

Clozapine appears to be particularly efficacious in refractory bipolar I disorder characterized by either dysphoric mania or rapid cycling. Its efficacy in bipolar disorders equals or betters that in schizoaffective disorder and schizophrenia as well. However, it has considerable liabilities: inconvenience, cost, and risk of agranulocytosis, which requires weekly blood monitoring. Olanzapine has a biochemical profile similar to that of clozapine, and preliminary evidence suggests that this newly approved agent will assume a similar role in the treatment of refractory bipolar disorder patients. Initial trials of olanzapine in acute mania yielded positive results, and the drug appears to be generally well tolerated, except for substantial weight gain in some patients.

The use of low dosages of risperidone appears promising, although there are several case reports of depressed patients switching into mania when treated with high dosages of this agent. Low dosages are associated with increased prolactin, and dosages over 8 mg a day are associated with both extrapyramidal effects and weight gain.

Other atypical agents should be watched for their spectrum of efficacy in acute mania and prophylaxis, as they may have beneficial profiles in the treatment of mania such as relative lack of sedation (olanzapine and sertindole); lack of prolactin increases (clozapine, quetiapine, and sertindole); fewer anticholinergic adverse effects (seroquel and sertindole); and less weight gain (ziprasidone). The possible antidepressant aspects of these putative mood stabilizers, perhaps related to their positive effects in the negative symptoms of schizophrenia, also deserve close scrutiny. Table 14.8-9 and Table 14.8-10 summarize preliminary data on the mechanisms of action, adverse effects, and potential efficacies of the serotonin-dopamine antagonist.

A potentially unique approach to the dopamine system might be attained with the tricyclic drug trimipramine (Surmontil). This long-approved antidepressant had an unknown mechanism of action, since it was not a potent reuptake blocker of any of the amine systems. It was recently shown to be a moderately potent antagonist of type 2 dopamine (D_2) and D_4 receptors, somewhat similar to clozapine. It has also been reported in open studies to be effective in monotherapy for acute schizophrenic episodes and psychotic depression. Therefore, in light of its D_2 and D_4 blocking properties as well as its efficacy as an antidepressant, some have ecommended using trimipramine in bipolar patients with refractory rapid cycling depressions.

L-Type Calcium Channel Inhibitors A series of preliminary reports suggest that the calcium channel inhibitor verapamil (Calan, Isoptin) has acute antimanic efficacy.

Whereas a number of controlled studies suggest the antimanic utility of verapamil, several recent studies suggest the superiority of lithium. Moreover, one randomized study in acute depression indicated that verapamil is no more effective than placebo and less effective than routine antidepressant treatment. These data led to a search for a more effective calcium channel blocker that might have better spectrum of antidepressant and prophylactic effects than verapamil.

Several groups chose to study the dihydropyridine L-type calcium channel inhibitor nimodipine (Nimotop) because of its (1) ability to penetrate the CNS, (2) relative lack of tolerance development in the treatment of migraine (in contrast to many other calcium channel inhibitors, (3) better profile in many types of animal seizure models than verapamil, and (4) greater ability to block cocaine-induced hyperactivity and associated dopamine overflow. One study reported that 10 of the first 30 evaluable treatment-refractory patients had a clinically relevant response to nimodipine, including patients with rapid and ultradian cycling frequencies (Fig. 14.8-10 and Fig. 14.8-11). Responsivity was confirmed and reconfirmed in some of these patients in a double-blind, off-on-off-on design. Almost all of these patients needed their regimens further supplemented with another agent such as lithium or carbamazepine for a more complete response, however. Carbamazepine augmentation of nimodipine was effective (moderate or marked response on the Clinical Global Impression Scale) in only 5 of 14 patients treated with the combination.

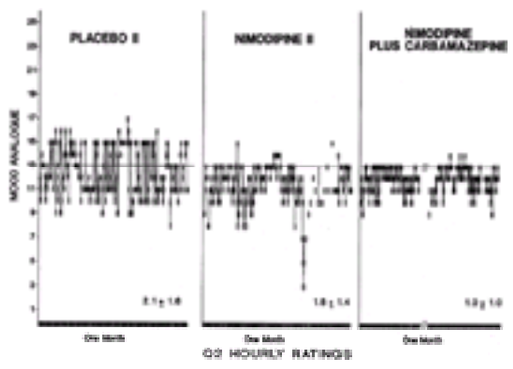

FIGURE 14.8-10 Efficacy of Nimodipine plus carbamazepine combination in a bipolar II female with ultradian cycling.

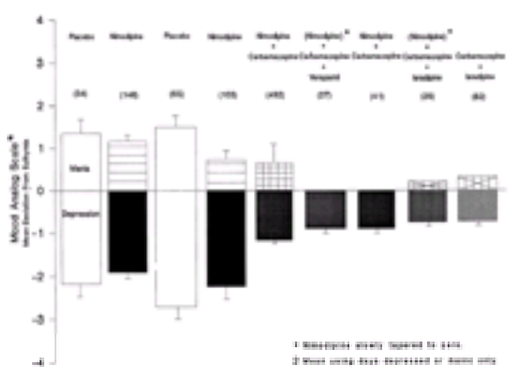

FIGURE 14.8-11 Nurse ratings of the efficacy of dihyropyridine L-type calcium channel inhibitors in a woman with bipolar II disorder.

Of considerable interest were several patients who clearly responded to either monotherapy or combination therapy with nimodipine and transitioned from nimodipine on a double-blind basis to maximally tolerated doses of verapamil, without maintaining response (Fig. 14.8-11). They later either reresponded to nimodipine or to another dihydropyridine L-type calcium channel inhibitor such as isradapine (Dynacirc) further confirming the initial responsivity to this drug class but also suggesting that responsivity might be better conferred by the dihydropyridine subtype of L-type calcium channel inhibitor (with the binding site deep inside the calcium channel) than the phenylalkylamine verapamil (which blocks at the outside of the channel) (Fig. 14.8-10).

Although there is some evidence that patients with extremely rapid cycling fluctuations within a 24-hour period (ultra-ultra rapid cycling) are among those who respond best to the dihydropyridines, the question of whether this subgroup is selectively targeted remains open. Depressed patients with the more classical pattern of global and frontal hypometabolism on positron emission tomography (PET) were among those who responded best to nimodipine. In contrast, those with a hyperactive metabolic pattern were more likely to respond to carbamazepine. Much work remains to define the precise role of the calcium channel blockers in the treatment of bipolar refractory depression (Table 14.8-5 and Table 14.8-6).

Lamotrigine A series of preliminary reports and two controlled trials suggest that lamotrigine, the newly approved anticonvulsant for add-on therapy, has antidepressant and possibly mood-stabilizing properties. In an open study 67 patients were studied usually with the drug as an adjunct to previously ineffective treatment regimens; 27 of 39 (69 percent) who presented in the depressed phase and 19 of 25 (76 percent) in the manic phase showed moderate-to-marked improvement.

A randomized, double-blind study at the NIMH found a significantly greater incidence of good response to blind lamotrigine monotherapy (17 of the first 3 patients [52 percent] than to (9 of 33 gabapentin [27 percent]) or placebo (7 of 32 [22 percent] placebo ($P < .05$). Many patients with refractory depression profiles were among those who showed a good response. Patients with bipolar I disorder depression showed a non-significantly better response than those with bipolar disorder II or a depressive disorder. Another large multicenter study indicated that both 50 and 200 mg a day of lamotrigine were superior to placebo in a 7-week trial in depressed bipolar I disorder patients.

Lamotrigine treatment should be initiated slowly in monotherapy with one 25-mg pill for the first 2 weeks and then 50 mg for 2 weeks, with slow increases thereafter to avoid a moderately high incidence of rash. The rate of increase should be halved if patients are on a regimen including valproate, which can markedly increase lamotrigine blood concentrations and the propensity for rash and more serious dermatologic complications. Conversely, carbamazepine decreases lamotrigine concentrations by approximately 50 percent, and one can start with higher dosages.

The precise anticonvulsant or psychotropic mechanisms of action of lamotrigine remain to be delineated. However, lamotrigine, like valproate, is a broad-spectrum anticonvulsant, effective not only in complex partial and generalized seizures, but also in absence and atonic seizures, in contrast to carbamazepine, which can exacerbate absence seizures. This is important because recent studies have suggested that carbamazepine, lamotrigine, and phenytoin have highly similar properties in the blockade of type 2 sodium channels and consequent inhibition of release of excitatory amino acids such as aspartate and glutamate (Fig. 14.8-9 and Fig. 14.8-12). However, the differential clinical profiles of these drugs in epilepsy and the preliminary evidence that lamotrigine may be effective in some patients who respond inadequately to carbamazepine suggest that lamotrigine has additional mechanisms not shared by carbamazepine. Recent evidence suggests that lamotrigine affects different types of calcium channels (N-type and P-type) and blocks serotonin reuptake and is active at serotonin (5-hydroxytryptamine [5-HT]) type 3 ($5\text{-}HT_3$) receptors, but the high concentrations at which these serotonergic effects are observed suggest that they are not clinically relevant. Preliminary data suggest that depressed patients with the more classical topographic pattern of frontal hypoperfusion on PET studies are likely to respond to lamotrigine.

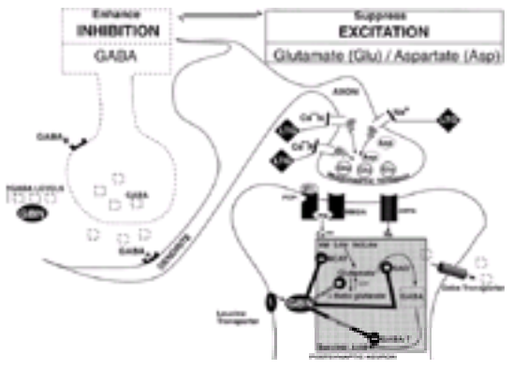

FIGURE 14.8-12 Targets of action of lamotrigine (LTG) and gabapentin (GBN). AMPA, a-amino-3-hydroxy-5-methyl-4-isoxalone propionate; GAD, glutamic acid decarboxylase; GDH, glutamate dehydrogenase; PCP, phencyclidine.

Gabapentin Open adjunctive studies indicate that gabapentin, a newly approved anticonvulsant for adjunctive therapy may also have some mood-stabilizing effects in bipolar patients. The drug appears to have positive effects on sleep and anxiety. However, two double-blind studies of monotherapy, one in acute mania and the other in refractory affectively ill patients showed no benefit over placebo. Whether gabapentin's prominent effects on the L–amino acid transport mechanism (Fig. 14.8-9) and resulting increases in brain GABA concentrations (Fig. 14.8-11) are related to its anticonvulsant or putative psychotropic properties remains to be determined.

Topiramate A recently approved add-on agent for treatment of refractory epilepsy, topiramate, is just beginning to be studied in bipolar disorders (Table 14.8-7). Preliminary uncontrolled data suggest it may have mood-stabilizing properties in rapid-cycling patients, with better antimanic than antidepressant effects. A major asset of topiramate is its positive effect of weight loss in contrast to lithium, valproate, gabapentin, many antidepressants, and most antipsychotic drugs. As a carbonic acid inhibitor it has a 1 percent risk of renal calculi (virtually all occurred in males); the calculi are made of calcium and respond well to emergency lithotripsy. Cognitive slowing and difficulty with word finding, may appear with rapid dosage escalation or in combination therapy. Topiramate is a selective inhibitor of glutamate a-amino-3-hydroxy-5-methyl-4-isoxalone-propionate (AMPA) receptors (Fig. 14.8-9) that also has GABAergic actions and blocks sodium ion channels.

Other Anticonvulsants The clinical utility of other GABA-active anticonvulsants, such as the GABA reuptake inhibitor tiagabine (the transamine inhibitor g-vinyl GABA (vigabatrin [Sabril]) and the agonist progabide (all remain to be further explored, as does the older anticonvulsant phenytoin (Dilantin). Acetazolamide (Diamox) has been reported to be effective for atypical psychoses associated with dreamy, confusional states as well as those occurring premenstrually or in the puerperium. Whether this profile is shared by other carbonic acid inhibitors such as topiramate remains to be determined.

Electroconvulsive Therapy Older clinical observations and recent controlled clinical trials continue to document the efficacy of ECT in acute mania. Bilateral treatments appear to be required; unilateral, nondominant treatments have been reported to be ineffective or to exacerbate manic symptoms in some studies. In light of the many effective pharmacological treatments noted above, and the utility of using the assessment of their acute antimanic efficacy as a surrogate marker for putative efficacy in long-term prophylaxis, ECT may be reserved for the very rare refractory manic patient or one with medical complications, as well as extreme exhaustion (lethal catatonia) or malignant hyperthermia (Table 14.8-6). Antimanic effects of a brief course of repeated transcranial magnetic stimulation (rTMS) of the brain at 20 Hz over the right but not left frontal cortex or 1 Hz rTMS bifrontally have been observed; whether this well-tolerated nonconvulsive strategy will eventually have a role in clinical therapeutics remains open.

OTHER THEORETICAL AND MECHANISTIC CONSIDERATIONS

Antiadrenergic Drugs A series of other nonanticonvulsant compounds with some neurotransmitter selectivity has been reported to be efficacious in treating mania. Clonidine (Catapres) an a_2-adrenergic agonist, is used to treat hypertension. It acutely inhibits the firing of the noradrenergic locus coeruleus and has been reported to show short-term antimanic efficacy in some (but not all) controlled trials. Response in the first few days of treatment may not be associated with an ultimate long-term response, however. Another agent that inhibits noradrenergic function is the b-adrenergic receptor antagonist propranolol (Inderal). Because very high dosages of either the dextrorotatory or levorotatory of this agent isomer form have been effective, it is questionable whether the b-antagonist properties or the membrane-stabilizing effects of this drug account for its short-term antimanic efficacy.

Cholinomimetics One open study reported that high dosages of choline (3 to 8 grams per day) possess antimanic and anticycling effects in refractory bipolar patients. Intravenous administration of the indirect cholinergic agonist physostigmine (Antilirium) has been demonstrated to have an almost immediate antimanic effect. Physostigmine inhibits acetylcholine esterase function, making more acetylcholine available at the synapse. Although this strategy can rapidly decrease manic symptomatology, it also has a rapid half-life and can be associated with rather marked increases in dysphoria and other adverse effects, such that its long-term utility is doubtful. The success of attempts to increase cholinergic function in the long term through other methods (e.g., lecithin, deanol, or direct acetylcholine agonists) has not been adequately delineated.

Overview of Antimanic Agents The ability to achieve rapid antimanic effects with intravenous physostigmine (an acetylcholinesterase inhibitor) suggests that given appropriate pharmacological intervention and pharmacokinetics, there is no theoretical reason why an acute antimanic response cannot be achieved extremely rapidly, even though most antimanic treatments have a moderate delay in onset. Manipulations of a variety of neurotransmitter systems (inhibition of nonadrenergic and dopaminergic and potentiation of the cholinergic, benzodiazepine, GABA, and perhaps serotonergic systems) all can induce antimanic effects. The antipsychotic agents block dopamine receptors; clonidine and propranolol appear to decrease a- and b-noradrenergic function, respectively. Reserpine (Diupres) which depletes catecholamines and indoleamines, has also been reported to have antipsychotic and antimanic effects.

As noted in Table 14.8-2 and Table 14.8-3, awareness of the multiple neurotransmitter approaches to the treatment of mania may be clinically useful in both changing and combining treatments that target different systems in nonresponsive patients. Alterations in endogenous neuropeptide function also have been postulated in mania. Although manipulations of opioids or cholecystokinin have not yielded consistent results in psychotic schizophrenia patients, isolated reports that thyrotropin-releasing hormone (TRH) or calcitonin were successful in treating excited psychotic states, including mania, deserve replication. The potential efficacy of peptide interventions in mania is mentioned because peptides could represent the next generation of antimanic treatments, particularly in light of the evidence of peptide neurotransmitters coexisting in neurons with more classical neurotransmitter substances that have been indirectly linked to the manic syndromes and the early reports of the antidepressant effects of a substance P antagonist.

Preliminary evidence indicates that the L-type calcium channel inhibitors that inhibit calcium influx through voltage-dependent channels may be effective in treating acute mania. New data indicate that lithium, carbamazepine, lamotrigine, and valproate all block calcium cation (Ca_{2+}) influx through the glutamate NMDA receptor (Fig. 14.8-9), which raises the theoretical rationale of using different mechanisms of blockade of Ca_{2+} influx for more effective or complete effects in refractory patients. Multiple studies of platelets and lymphocytes of bipolar disorder patients indicate increased baseline levels of, or serotonin- or thrombin-stimulated rise in, intracellular calcium.

A new approach examining common effects of chronic lithium and valproate has revealed inhibition of protein kinase C as a putative target for antimanic effects. This idea of H. Manji received preliminary support from the observations of rapid-onset acute antimanic effects in six of nine patients treated with the protein kinase C inhibitor tamoxifen (Nolvadex).

Many of the principles of treating unipolar depression are applicable to the treatment of depression in bipolar disorders, but the critical role of concomitant treatment with mood stabilizers and targeting the symptoms most characteristic of bipolar disorder depression—such as its atypicality, and reverse vegetative symptoms of hypersomnia, increased appetite, weight, lethargy, and psychomotor retardation—require emphasis. Antidepressant drugs that are particularly useful in bipolar disorder patients are listed in Table 14.8-2.

MAINTENANCE TREATMENT OF BIPOLAR DISORDERS

Lithium Prophylaxis Lithium originally appeared to be effective in some 70 to 80 percent of bipolar disorder patients, but current estimates suggest that even with adjunctive use of antidepressants and antipsychotics, a response rate of 40 percent or less in many lithium clinics is more accurate (Fig. 14.8-13).

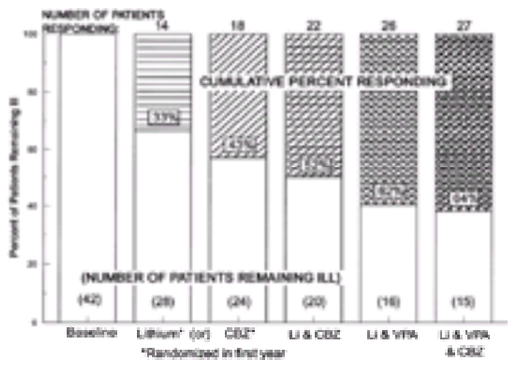

FIGURE 14.8-13 Cumulative response and failure rates on mood-stabilizing regimens. CBZ, carbamazepine; VPA, valproate.

Although initial studies indicated the need for blood concentrations between 0.8 and 1.2 mEq per liter, some series have suggested that concentrations of 0.5 to 0.8 mEq per liter might be effective in maintenance treatment. However, a recent controlled study indicated that the lower levels of adverse effects are achieved at a cost; the relapse rate with a low lithium concentration range (0.4 to 0.6 mg/L) is three times that at higher concentrations (0.8 to 1.0 mg/L). Monitoring of trough levels (performed in the early morning with the AM dose withheld) at 1- to 2-month intervals (or more frequently if the patient's course is unstable) is recommended. A 1-year controlled study reported that the greater the lithium-induced decreases in plasma free thyroxine (T_4) concentration, (but not lithium blood levels) the greater the severity of depression and cycling.

Because of the substantial data on long-term efficacy and prevention of suicide with lithium treatment, preventive treatment should be considered after one or two manic episodes and after a single severe episode of mania, particularly if there is a positive family history of bipolar disorder. The development of a life chart, so that the frequency, severity, and interval between episodes can be accurately assessed, may also assist in arriving at the decision for prophylaxis. If previous episodes were severe—socially incapacitating and requiring hospitalization—or associated with extremely adverse events for the patient and family, one would be more likely to consider prophylaxis earlier rather than later, despite moderately long well intervals between episodes. These factors should be discussed with the patient during a euthymic interval so that the appropriate risk-benefit ratios can be weighed carefully with adequate informed consent. Data from numerous studies indicate that greater numbers of prior episodes (more than three or four) are associated with a poor response to lithium prophylaxis, so delayed prophylaxis may have negative consequences not only for the increased morbidity during these recurrences, but also for ultimate treatment response. Whether greater numbers of prior episodes also predispose to the development of tolerance (Fig. 14.8-14) or lithium discontinuation-induced refractoriness (Fig. 14.8-15) remains to be studied.

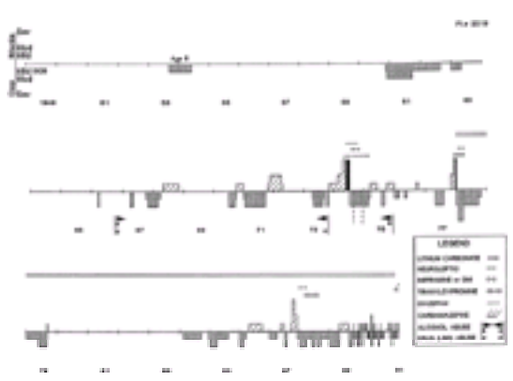

FIGURE 14.8-14 Development of refractoriness to lithium in the course of malignant progression of mood disorder. DMI, desipramine; LSD, lysergic acid diethylamide; DOB, date of birth.

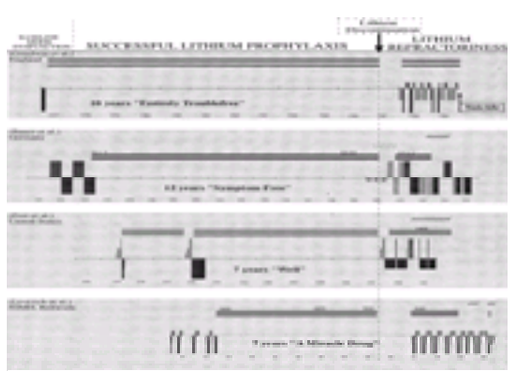

FIGURE 14.8-15 Lithium discontinuation–induced refractory illness.

Carbamazepine and Other Mood Stabilizers One alternative to traditional unimodal antidepressants for depressive breakthroughs is the addition of first-generation anticonvulsant mood stabilizers such as carbamazepine or valproate, or putative second-generation anticonvulsants such as lamotrigine (Table 14.8-11). Although the controlled evidence concerning the efficacy of carbamazepine used as monotherapy for primary depression is inadequate those findings taken with the more substantial emerging literature on the efficacy of carbamazepine prophylaxis for both manic and depressive episodes, raise the priority of using this agent to supplement lithium in depressive breakthroughs, particularly those of the rapid-cycling variety. Although only one-third of refractory depressed patients responded in one study, the responders tended to be the patients with greater initial severity of depression and clearer prior histories of discrete episodes rather than chronic depression.

Table 14.8-11 Drugs in the Prevention of Manic Depressive Episodes and Cycling

When antidepressant response to carbamazepine was observed, it tended to occur with the typical lag observed with other agents, so that only minor improvement was noted in the first and second weeks of treatment, but considerable improvement was observed after the third and fourth weeks. Surprisingly, the degree of antidepressant response was correlated with the degree of decrease in T_4 and free T_4. An abnormal EEG or increased psychosensory symptoms did not predict an acute response to carbamazepine in one series, but did in another when carbamazepine was used for augmentation, and a 53 percent response was observed compared with an even higher rate for lithium augmentation.

More than a dozen controlled studies support the comparative efficacy of carbamazepine and lithium in the prophylaxis of both manic and depressive episodes. One study reported lower antimanic effects of carbamazepine than with lithium as did another study in patients with classic euphoric mania. However, the latter study indicated a better response to carbamazepine in those with atypical presentations (i.e., dysphoric mania, schizoaffective disorder, rapid cycling and comorbidities).

In a small series of patients who responded inadequately to carbamazepine alone, one half showed a rapid onset of antidepressant effect with lithium augmentation. Thus, the combination of carbamazepine and lithium appears to help a substantial subgroup of otherwise refractory patients (Fig. 14.8-5). In one randomized study in bipolar outpatients with a high incidence of rapid cycling, response rates were under 25 percent with either lithium or carbamazepine monotherapy for 1 year, even when adjunctive antidepressants and antipsychotic drugs were allowed, but over 50 percent with both drugs in combination (Fig. 14.8-16). Thus, one might consider combination mood stabilizer treatment from the outset in this rapid-cycling subgroup.

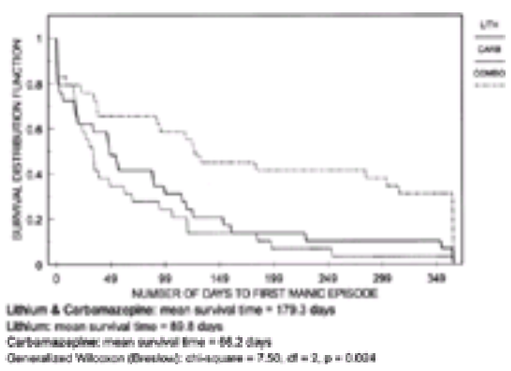

FIGURE 14.8-16 Mean survival time to first manic episode is longer on the combination of lithium and carbamazepine than with either lithium and carbamazepine alone (*N* = 29).

Carbamazepine has been reported effective in some patients failing multiple traditional antidepressant trials, especially in those with a history of head trauma or EEG abnormalities, in one series. As noted for refractory bipolar disorder patients discussed below, the anticonvulsants carbamazepine and valproate may be used in combination with unimodal antidepressants, and the role of these and other combination treatments for the refractory depressed patient deserves much further systematic research to provide adequate statistical and sequence-ordering guidance for the clinician.

Valproic Acid In many open series, valproic acid alone or in addition to lithium has been reported to be successful in the long-term treatment of a substantial subgroup of previously lithium- or carbamazepine-refractory patients. The acute antidepressant efficacy of valproic acid is much less well delineated than its antimanic efficacy, and the utility of this treatment for an acute depressive episode remains to be further elucidated. Nonetheless, the combination of lithium and valproate offers another excellent option in the long-term management of bipolar patients who do not respond to lithium alone. A response to one anticonvulsant may not predict a response to another, and positive long-term effects of valproic acid plus lithium have been noted in patients who did not respond to lithium or carbamazepine prophylaxis (Fig. 14.8-17 and Fig. 14.8-18).

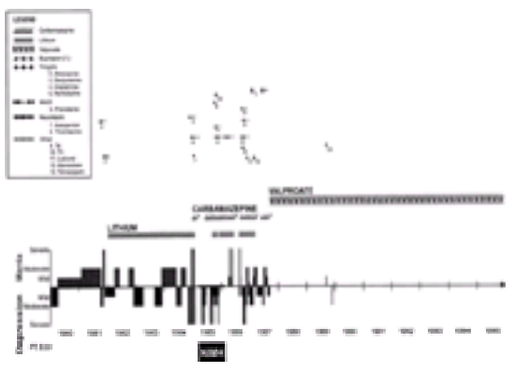

FIGURE 14.8-17 Prophylactic response to valproate in a nonresponder to lithium and carbamazepine.

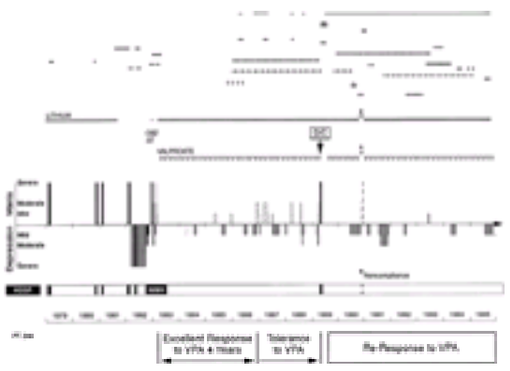

FIGURE 14.8-18 Tolerance and reresponse to the prophylactic effects of valproate (VPA). CBZ, carbamazepine; D/C, discontinuation.

Lamotrigine A series of open studies suggests the possibility of mood stabilizer effects of lamotrigine, in many instances in those not responsive to conventional treatments. One double-blind, controlled study of short-term prophylaxis in ultrarapid-cycling patients revealed significant antidepressant and antimanic effects over those of either gabapentin or placebo. These data, taken with the large controlled trial of lamotrigine in bipolar I disorder depression suggest that the addition of lamotrigine to lithium or another mood stabilizer is an alternative option to the addition of a unimodal antidepressant. Response rates of 60 to 70 percent were observed in open studies when lamotrigine was used adjunctively.

Calcium Channel Inhibitors The few uncontrolled studies of calcium channel inhibitors suggest their promise as prophylactic treatments, but they may be less effective for depressive breakthroughs than for manias. One study reported better prophylactic efficacy of 1 year of the combination of lithium and nimodipine compared with 1 year of either drug alone. Further controlled studies of prophylaxis are sorely needed. Although data are limited to just one double-blind series at the NIMH, in the several patients crossed over blindly from one L-type calcium channel inhibitors to another, agents in the dihydropyridine class (nimodipine and isradapine) had better antidepressant and mood-stabilizing effects than the phenylalkylamine verapamil (Fig. 14.8-10 and Fig. 14.8-11).

Gabapentin Gabapentin may show positive effects on mood, anxiety, and sleep in 30 to 40 percent of refractory bipolar disorder patients, but much higher rates of response are reported in open studies when gabapentin is used as add-on treatment. The mood-stabilizing anticonvulsants (carbamazepine, valproate, lamotrigine, and gabapentin) certainly also deserve more consideration for a patient's profound sleep disturbance, with or without associated posttraumatic stress disorder, especially if the patient has comorbid alcoholism or bipolar disorder depression and benzodiazepines are to be avoided.

Thyroid Although thyroid potentiation similar to that observed in unipolar depression can be attempted, treatment with dosages above suppressive doses should be approached with caution. Several investigators found associated medical toxicities with high-dosage thyroid treatment and inadequate maintenance of long-term prophylaxis unless other routine agents were used concurrently. Thus liothyronine (Cytomel), the levoratatory isomer of triiodothyronine (T_3), is recommended for short-term augmentation strategies because of its short half-life, and levothyroxine (Levoxyl, Synthroid) the levorotatory isomer of T_4 is recommended by some as more appropriate for long-term maintenance during prophylaxis. As noted above, addition of liothyronine to levothyroxine has been reported to benefit nonresponders.

Hypermetabolic Dosages of Levothyroxine Recent data indicate that high-dosage levothyroxine treatment— μg a day targeted toward achieving a free thyroxin index 150 percent of normal—may be helpful as an adjunctive treatment in rapid-cycling patients. Another report further suggests that this high-dosage augmentation strategy may benefit patients with persistent refractory depression. The data indicating improvement in both manic and depressive phases with hypermetabolic levothyroxine augmenting strategies speaks to the potential importance of this modality for bipolar disorders. However, systematic long-term trials must be conducted, and the issue of whether some patients lose responsivity to such thyroid augmentation strategies with the development of tolerance requires further exploration.

Serotonin-Dopamine Antagonists Given their short-term antimanic and longer-term antipsychotic effects against the positive and negative symptoms of schizophrenia, the serotonin-dopamine antagonists are becoming increasingly important in prophylaxis of mood and schizoaffective disorders. Their better profile of acceptability (Table 14.8-8) and safety than the conventional antipsychotics impels their use instead of these conventional antipsychotics even before adequate data on long-term efficacy become available.

POTENTIAL CORRELATES OF RESPONSE TO THE MOOD STABILIZERS

From a clinical and theoretical perspective it would be valuable to know whether the efficacy of carbamazepine, valproate, or the other putative mood-stabilizing anticonvulsants is related to their ability to stabilize neural excitability in temporal lobe and limbic structures (independent of whether or not a seizure disorder underlies the mood disorder) (Fig. 14.8-8 and Fig. 14.8-19). Only a minimum of evidence is available indicating that carbamazepine, for example, acts via its effects on temporal lobe or limbic substrates. However, the approximate rank ordering of carbamazepine, valproate, and phenytoin according to their degree of limbic selectivity is roughly related to their psychotropic efficacy and provides at least indirect support for the limbic hypothesis.

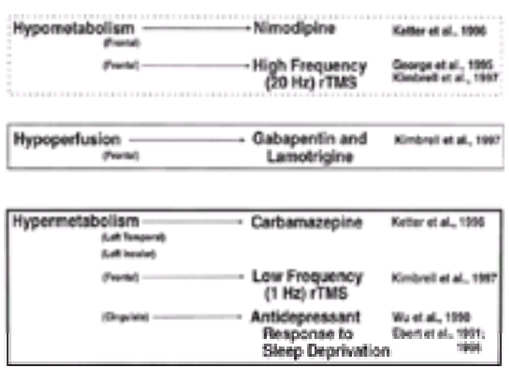

FIGURE 14.8-19 Preliminary predictors of clinical response—functional brain imaging. rTMS, repeated transcraneal magnetic stimulation.

An indirect marker of limbic dysfunction—degree of psychosensory symptoms—is not related to carbamazepine response in primary affective disorder, although others disagree. Recent PET data, however, suggest that patients with initial baseline hypermetabolism, particularly in the left insula, are among those who respond best to carbamazepine, whereas those with a pattern of baseline frontal hypometabolism respond best to nimodipine. These preliminary data are among the first to provide suggestive evidence that increased metabolism in mesiotemporal structures could be associated with the therapeutic response to carbamazepine. Patients with relative hypoperfusion at baseline show normalization upon successful treatment with lamotrigine or gabapentin, whereas nonresponders tend to be closer to normal at baseline and decrease significantly with treatment with these agents. Some preliminary data also link baseline hypometabolism with response to high-frequency rTMS, which normalizes this pattern. Those with relative hypermetabolism at baseline respond to low-frequency (1 Hz) rTMS in association with normalization of this pattern. Although not clinically useful at present, one can only hope that replication and extension of these studies will assist in better matching individual treatments to individual patients.

A number of studies suggest an equally good response to valproate in dysphoric compared to euphoric mania, in contrast to the relatively poor response to lithium in the dysphoric subtype. One small study suggested that carbamazepine responders tended to be more dysphoric at baseline than nonresponders.

P>More than 15 studies have reported a relatively poor response to lithium in rapid-cycling patients; only 2 studies have reported a good response, and 4 have reported no differential response. The relation of carbamazepine response to rapid cycling is less clear. In one acute mania study and several prophylaxis studies, a high response percentage was observed in rapid-cycling patients. However, when rapid-cycling patients were compared with non-rapid-cycling patients in two studies, both found a higher prophylactic response rate to carbamazepine in non-rapid-cycling patients. Data from Japan are revealing in that the 53 percent response rate to carbamazepine in patients with a history of rapid cycling (compared with 76 percent in those without) is still substantially higher than the 30 percent response rate observed for lithium in patients with a history of rapid cycling (compared with 64 percent in those without such a history).

Taken together, these data suggest that rapid cycling is a poor prognostic indicator for both carbamazepine and lithium treatment, although some patients with rapid cycling respond positively to carbamazepine. NIMH data suggest the potential utility of treatment of rapid-cycling patients on the combination of lithium and carbamazepine from the outset (with its 53 percent response rate) in light of the poor response to either monotherapy in these patients (28 percent response to lithium and 19 percent response to carbamazepine).

Rapid cycling and prediction of response to valproate is less well studied, but initial indications from a large double-blind collaborative study are that the short-term antimanic response is robust in these individuals, which agrees with other data from open studies indicating an excellent acute and prophylactic response in several large cohorts of rapid-cycling patients treated with either monotherapy or combination treatment. However, one study reported that an accelerating course of illness was a poor prognosis factor for predicting valproate response. Initiating treatment with valproate (Fig. 14.8-17) or lithium and valproate in rapid-cycling or dysphoric manic patients from the outset may thus be a particularly useful alternative to lithium and carbamazepine for this subgroup.

Some evidence suggests that a negative family history of mood disorders may be associated with a good response to carbamazepine; seven of eight studies reported that a positive family history of affective illness in first-degree relatives is associated with a positive response to lithium. These data, in conjunction with clinical case reports illustrating that patients with evidence of delirium, dementia, and other cognitive disorders show a relatively poor response to lithium, a high potential for toxicity, and a potentially good response to the anticonvulsants carbamazepine or valproate, suggest that the familial genetic subtype of mood disorders may be more responsive to lithium than the subtype mediated through other nonhereditary pathophysiological mechanisms, which may be better targeted with the mood-stabilizing anticonvulsants. These possible mechanisms include neuronal and environmental insult related to birth trauma, infection, secondary mood disorder, and substance

abuse. Further study of this issue is clearly required.

The mood-stabilizing anticonvulsants (carbamazepine, valproate, and possibly lamotrigine and gabapentin) certainly also deserve higher consideration for a patient's profound sleep disturbance (with or without associated posttraumatic stress disorder), especially if the patient has a comorbid alcohol use disorder or a bipolar disorder, and benzodiazepines are to be avoided.

RELATIVE ADVERSE-EFFECT PROFILES OF LITHIUM AND THE MOOD-STABILIZER ANTICONVULSANTS

Since only a modicum of data suggests clinical or biological predictors of response to the mood stabilizers (Fig. 14.8-8 and Fig. 14.8-19), adverse effect profiles and tolerability in long-term prophylaxis (Table 14.8-7) as well as mechanisms of action (Table 14.8-4, Fig. 14.8-6 and Fig. 14.8-9) become potential selection factors.

The general profile of lithium-induced side effects has proven to be relatively benign in the long-term maintenance treatment of bipolar patients. However, several of lithium's more prominent adverse effects deserve comment, as do the relative comparisons with and among the mood-stabilizing anticonvulsants.

Thyroid Function Lithium clearly can impair thyroid function by several different mechanisms; it has even been used to treat hyperthyroidism. Lithium uniformly lowers T_3 and T_4 concentrations in the plasma and, in some patients, increases thyroid-stimulating hormone (TSH). TSH concentrations above normal can be taken to indicate that the hypothalamic-pituitary-axis is working overtime to maintain normal levels of thyroid hormones. Lower free T_4 concentrations during lithium prophylaxis in one study were associated with more-severe depression and more-rapid mood fluctuation. Thus, one might consider thyroid replacement with levothyroxine when levels of TSH are elevated, even when thyroid hormone indexes are still within their normal lower limits. Occasional checks of thyroid function at 6-month to 1-year intervals are wise, as is an earlier check if there is a breakthrough of depressive symptomatology during otherwise adequate lithium maintenance treatment. In these instances, treatment of underlying hypothyroidism can help alleviate a depression that is linked to this hormonal deficit. Whereas levothyroxine is generally used for suppression of TSH and replacement, anecdotal evidence suggests that addition of liothyronine to the levothyroxine replacement may help some patients with refractory depression or cycling.

Carbamazepine tends to decrease T_4, free T_4, and T_3 concentrations (as does lithium), and in combination, the decreases are additive. During carbamazepine treatment there is a negligible incidence of clinical hypothyroidism or above-normal increases in TSH. Consequently, thyroid supplementation of carbamazepine is rarely needed. When the two drugs are used in combination, however, the lithium effect on TSH may override that of carbamazepine, and the patient may then require thyroid supplementation.

Renal Function By the late 1980s the fear regarding the possible high incidence of long-term adverse consequences of lithium on the kidneys had largely dissipated. Original reports of severe nephrotoxicity and pathology with elevated creatinine and low clearance originally attributed to lithium were, in part, related to the absence of an age-matched control group of psychiatric patients not treated with lithium. Thus, although lithium rather consistently impairs vasopressin function at the level of adenylate cyclase and often produces a syndrome of diabetes insipidus, it is less consistently associated with other evidence of renal toxicity, although isolated case reports persist. Preliminary data suggest that less renal toxicity may occur in patients using single nighttime dosing (producing higher peaks, but lower nadirs) than occurs with conventional dosing regimens. Single nighttime dosing may also facilitate compliance.

Current practice suggests that frequent monitoring of renal function during lithium treatment is not generally indicated; however, baseline measures of renal function including creatinine clearance should be obtained before beginning lithium treatment in patients with a history of some renal alterations. Patients must have adequate fluid intake to maintain an appropriate fluid and electrolyte balance because of the induction of diabetes insipidus syndrome related to the blockade of antidiuretic hormone actions. Several patients have been reported in whom high levels of lithium during intoxication were associated with irreversible cerebellar toxicity. Thus lithium levels, fluid and electrolyte status, or both, should be monitored closely during periods of febrile illness, decreased fluid intake, or greater-than-ordinary fluid loss (e.g., during extreme athletic stress or during gastrointestinal illnesses with vomiting or diarrhea).

Amiloride (Midamor) (5 to 10 mg) has been useful in the treatment of lithium-induced diabetes insipidus. If diuretics (furosemide [Lasix] or thiazides) are used, lower dosages of lithium are indicated because these agents will increase lithium concentrations.

Because carbamazepine appears to act as a vasopressin agonist either directly or by potentiating vasopressin effects at the receptor, it will not suffice to reverse lithium-induced diabetes insipidus, which occurs by an action of lithium below the receptor level at the adenylate cyclase second-messenger system. Demeclocycline (Declomycin) and doxycycline (Vibramycin) may counter the hyponatremic effects of carbamazepine, as may lithium. The hyponatremic effects of the ketoderivative oxcarbazepine may be more prominent than those of carbamazepine. To the extent that the minor cognitive impairments of lithium are in part related to its ability to impair vasopressin function in the brain, these data suggest that not only would carbamazepine be less likely to cause this adverse effect, but also during combination treatment, the adverse effects of lithium might override those of carbamazepine.

Carbamazepine tends to induce a benign hypocalcemia that is generally not associated with bone demineralization. In contrast, lithium often produces a transient increase in serum calcium concentration.

Tremor Tremor can be problematic for a small but substantial percentage of patients treated with lithium. The tremor is frequently exacerbated by social stress. When the tremor persists at doses near the lower end of the therapeutic range or at the minimum doses necessary for therapeutic efficacy, attempts can be made to treat it symptomatically. Some investigators find that 10 to 40 mg of the b-blocker propranolol in divided daily doses may reduce lithium tremor. Relief may occur within 30 minutes and may last from 4 to 6 hours. Valproate also has dose-related tremorogenic effects. Gabapentin, in contrast, has been used to treat essential tremor. The dihydropyridine L-type calcium channel inhibitors may provide a nontremorogenic adjunct or alternative to lithium.

Gastrointestinal Effects Gastrointestinal adverse effects (diarrhea and indigestion) can also be problematic for many patients on lithium and valproate but may be attenuated by reducing the dose or giving it at mealtimes (for indigestion). Antidiarrheal agents should be restricted to short-term treatment. The calcium channel blockers (which may be constipating) may substitute for lithium or partially counter its adverse effects when used in combination. Histamine type 2 receptor (H_2) inhibitors may help counter valproate's gastrointestinal adverse effects.

Cognitive Effects Patients may express concern about the effects of lithium on their memory, spontaneity, or creativity. Although some impairment can be objectively delineated in some, but not all, types of detailed neuropsychological testing, most patients either do not experience this effect or do not find it unduly impairing. In fact, productivity and creativity may, overall, be enhanced during lithium treatment, because it prevents unproductive manic and depressive phases. Although no adequate approach to the subjective cognitive effects of lithium has been demonstrated (other than reducing the dose), associated causes for cognitive impairment must be ruled out, including possible hypothyroidism or an inadequately treated coexistent depression. Donepezil (Aricept) has been reported helpful in isolated case reports and deserves further exploration and study.

Many so-called drug-related adverse effects are also evident during placebo treatment phases and thus appear to be more closely associated with illness-related variables than with a particular psychopharmacological treatment. This perspective on lithium maintenance treatment clearly needs to be explored with the patient to avoid premature discontinuation of treatment or noncompliance. Carbamazepine and valproate are noted for their benign cognitive side effects in the epilepsies and may be better tolerated than lithium in some instances, although they, too, can be associated with subjective complaints and word-finding difficulties. Lamotrigine does not appear to have lithium's occasional liability of stabilizing mood slightly below baseline, and some patients may be stabilized at a mood or energy level slightly over baseline (i.e., above 50 millimeters on the mood analogue scale). Topiramate clearly causes cognitive motor slowing, speech, or word-finding difficulties in a small percentage of patients, particularly with high initial doses, rapid upward titration or in combination therapy. Valproate has been associated with a reversible organic brain syndrome with EEG slowing and a dementia-like presentation in isolated patients with epilepsy.

Weight Gain Lithium-induced weight gain can be a vexing problem for a moderate percentage of patients, and in one study was a correlate of better mood-stabilizing response. Thyroid indexes should be rechecked, and the patient reminded not to use calorie-containing beverages when maintaining the necessary increased fluid intake associated with diabetes insipidus.

Weight gain can also be problematic with valproate. Whether this is a correlate or causal link in the reported occurrence of polycystic ovary syndrome in epileptic patients taking valproate remains for further study.

Like most dopamine receptor antagonists (with the possible exception of molindone [Moban]), the serotonin-dopamine antagonists are also associated with weight gain; clozapine, olanzapine, and risperidone are particularly problematic for some patients. One should watch for replication of one anecdotal report of the antidiabetic drug troglitazone (Rezulin) which helped to cause substantial weight loss in a patient who gained considerable weight on olanzapine. Topiramate has a strong tendency to help with weight loss, apparently by both decreasing carbohydrate craving and possibly increasing metabolism as well. Early clinical vignettes suggest it may help overcome lithium or valproate weight increases when used in combination with them. Carbamazepine and gabapentin are less problematic, and, L-type calcium channel inhibitors are relatively weight neutral. Patients lost about 2 pounds in 6 weeks on lamotrigine in one controlled study, compared with a gain of about 2 pounds on gabapentin.

Headache Many mood stabilizers, such as lithium, valproate, and the L-type calcium channel inhibitors are reported to be effective in migraine prophylaxis. Carbamazepine increases substance P concentrations and sensitivity and may treat cluster headaches but can exacerbate migraine. Lamotrigine, with its weak serotonin reuptake effects, may either ameliorate or exacerbate headaches. Lamotrigine and gabapentin have apparent antipain long-term effects in some syndromes.

Rash Lithium may precipitate or exacerbate psoriasis and acne. Lamotrigine treatment must be started extremely slowly to help avoid the otherwise high incidence of rash (10 percent); some estimates suggest that 1 in 500 patients progresses to severe, potentially lethal extremes of Stevens-Johnson or Lyell's syndromes. Risk factors, in addition to rate of titration, include use with valproate (requiring a halving of the lamotrigine dose) and a history of multiple or severe rash on other medications.

Carbamazepine may also produce a common pruritic rash (10 to 15 percent), but severe deterioration to Stevens-Johnson syndrome may be less common than during lamotrigine treatment. Nonetheless, in most instances, carbamazepine treatment should be discontinued with the onset of a rash. However, when patients respond to carbamazepine and other effective treatments are not available, prednisone has reportedly suppressed uncomplicated carbamazepine-induced rashes (i.e., those without evidence of systemic involvement with fever or lymphadenopathy) in a very high percentage of patients. Whether a similar strategy would be effective for lamotrigine remains unstudied.

Hepatitis Valproate has been associated with reports of severe hepatitis in the neurological literature; most of the fatalities have been in children under the age of 2 years, particularly those on polytherapy. Few serious hepatic adverse effects have been reported in adult psychiatric patients on valproic acid, but liver function might be monitored periodically when using this agent, and patients should be warned to report symptoms that might be referable to hepatitis such as fever, right upper quadrant pain, malaise, nausea, anorexia, Coca-Cola–colored urine, and jaundice. Benign elevation of liver function test (LFT) results to two or three times normal are not uncommon in patients taking valproate, carbamazepine, and other anticonvulsants, and LFTs can be followed without drug discontinuation. Zinc and selenium supplements are recommended with valproate, since they are reported anecdotally to decrease the incidence of hepatitis, pancreatitis, and alopecia. Rare cases of carbamazepine-induced hepatitis have been reported, but routine monitoring for this adverse effect does not appear to be indicated. Since lithium and gabapentin are excreted by the kidney, they have no liability in those with evidence of liver pathology or toxicity.

Hematological Effects The side-effect profile of carbamazepine tends to be quite different from that of lithium or valproate (Table 14.8-7). Whenever lithium and carbamazepine act on a common target system, the effects of lithium tend to override those of carbamazepine. In other instances this is a clinical disadvantage, except for the ability of lithium to increase the white count (via increases in colony stimulating factor) which will override the white count-suppressing effects of carbamazepine (via decreasing colony-stimulating factor), and may thus be clinically useful. However, lithium is effective in this regard only against carbamazepine's benign suppression of the white count, and its effects are doubtful if there is evidence of more problematic interference by carbamazepine in hematological function manifest in other cell lines, such as platelets or red cells (RBCs), indicating a possible pancytopenic or aplastic process. The risk of agranulocytosis or aplastic anemia in patients taking carbamazepine has been estimated to be from 1 in 10,000 to 1 in 100,000. If there are normal levels of other blood elements (platelets and RBCs), potentiation with lithium will likely reverse the benign white-count suppression of carbamazepine. Valproate has been associated with thrombocytopenia; the potential impact of lithium on this syndrome has not been reported.

Teratogenic Effects Cardiac (Ebstein's) anomalies of great vessels have been reported to occur with a higher frequency than expected in patients treated with lithium during pregnancy, although recent studies suggest the risk may not be much greater than that in the general population. Thus, the previous prohibition against use of lithium during pregnancy is being reevaluated. In some instances in which the discontinuation of lithium treatment would put the mother at high risk for a severe depression or mania, continuing lithium treatment may be appropriate, especially with increased ability for fetal monitoring.

An increased risk (several percent) of spina bifida has been reported for valproate (which may be dose-related) as well as a slightly smaller risk for carbamazepine, and use of these agents should be avoided in pregnancy if possible. Folate supplements should be used. Persisting biochemical alterations have been found in some animal studies of fetal exposure to typical antipsychotics but have not been assessed systematically in human follow-up studies. Few data are available for lamotrigine and gabapentin, but no specific teratogenic effects have been described. Topiramate causes some bone deformity in animals, but the risk for humans has not been systematically evaluated. ECT may have the lowest risk to the fetus among the somatic treatments, but the effect of maternal seizures has also not been systematically evaluated. The calcium channel blockers have a benign record for fetal abnormalities, and these agents remain among the better candidates for continuation of a putative mood stabilizer during pregnancy. As needed, short-term augmentation with minimal dosages of antipsychotics or high-potency benzodiazepines may be tolerated.

Approaches to Adverse Effects: Dosage Reduction, Adjunctive, Alternative Treatment Dosage reduction may be a first maneuver in treating a variety of lithium-induced problems (tremor, weight gain, thirst, urinary frequency, diarrhea, or psychomotor slowing). If these lower dosages are not adequate for prophylaxis, combination or alternative treatment, especially with carbamazepine or a dihydropyridine calcium channel adverse blocker (which have different side-effect profiles), or other putative mood stabilizers such as valproate may be indicated (Fig. 14.8-5). The renal clearance of lithium appears to decrease with age, so that a lower dose may be necessary and adequate in the older patient on lithium maintenance.

TREATMENT OF BREAKTHROUGH DEPRESSIVE EPISODES DURING LITHIUM AND OTHER MOOD-STABILIZER PROPHYLAXIS

Antidepressant Augmentation Approaches to a depression in an untreated bipolar patient or during an episode emerging during lithium prophylaxis differs from that in a unipolar depressive disorder patient, and few antidepressants have been systematically evaluated in bipolar disorders. The author emphasizes possible choices of agents based on adverse-effect profiles (Table 14.8-3), the differential presenting symptom clusters and comorbid syndromes (Fig. 14.8-20), and mechanisms of action (Table 14.8-2). However, a strong empirical database for these recommendations is lacking. Moreover, given the necessity for protracted clinical trials (of many weeks) to evaluate the clinical efficacy of each individual drug, attempting to potentiate a specific drug treatment once adequate dosages or blood concentration have been reached is recommended before switching treatment modalities. Thus, thyroid or lithium potentiation deserves emphasis in the treatment sequence before multiple trials with single alternative agents. Figure 14.8-21 illustrates a possible treatment algorithm for a depressed patient with a bipolar disorder.

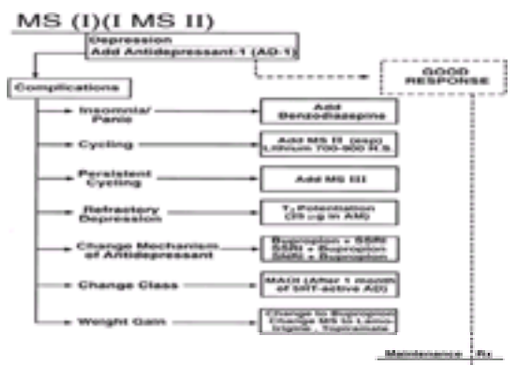

FIGURE 14.8-20 Algorithm for treating bipolar depression and treatment complications. MS I, first mood stabilizer; MS II second mood stabilizer

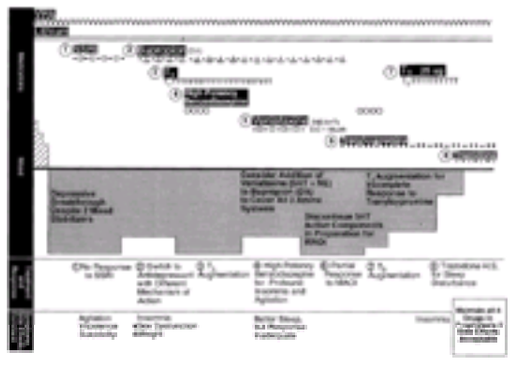

FIGURE 14.8-21 Possible sequential algorithm for the bipolar disorder patient with refractory depression. DA, dopaminergic; NE, noradrenergic.

Potentiation of the Antidepressant Given the long time frame that may be required to evaluate the adequacy of an antidepressant response, antidepressant potentiation should be considered in either the first or second antidepressant trial before switching antidepressants, even to a new category of agents. Thus, when a patient appears to be at either maximally tolerated dosages (or adequate blood concentration of the drug) and has not responded adequately, one might consider adding thyroid hormones or lithium (Table 14.8-5, Fig. 14.8-20).

A sizable but mixed literature exists regarding the efficacy of thyroid potentiation in converting (20 to 50 percent) antidepressant nonresponders to responders. This effect appears to be independent of initial clinical thyroid status or any evidence of hypothyroidism. A response to the addition of liothyronine (25 to 37.5 μg per day in the morning) may occur within days and usually occurs within the first week or two of treatment. Therefore, if there is no response in this time frame, the clinical trial of liothyronine potentiation can be exchanged for other options. Adverse effects are very unusual but could include tachycardia, hypertension, anxiety, or flushing.

A second option is potentiation with lithium. An extensive literature, particularly in unipolar depressions, reveals that addition of lithium carbonate to a variety of antidepressant modalities, including tricyclic drugs, heterocyclic drugs, MAOI, or even carbamazepine, often yields clinical improvement (40 to 60 percent). Response may begin within 24 to 48 hours but may be slower in onset and stretch over 1 to 3 weeks. Dosages of lithium slightly below those conventionally used for monotherapy are generally effective (i.e., 750 to 900 mg in a single dose at bedtime may suffice to reach a target of 0.75 mg/L, which is the concentration reported to be needed for potentiation in unipolar depression). When used in this fashion, the adverse-effect profile of lithium appears quite benign. Lithium potentiation may be effective for all subtypes of depression.

New data suggest that concurrent treatment of acute depression with lithium and antidepressants from the outset also results in more rapid response than with an antidepressant alone. Thus, for the untreated bipolar disorder patient presenting with a depressive episode, the combination of an antidepressant and a mood stabilizer such as lithium is highly recommended. The initial reports of estrogen potentiation of antidepressant response do not appear as promising as those of either thyroid or lithium potentiation but may be considered for postmenopausal women.

Shifting Antidepressant Classes: MAOIs One might consider shifting treatment from one type of antidepressant to another if unacceptable adverse effects appear before adequate blood concentrations or a clinical response has been achieved. If adequate dosages and blood concentrations have been achieved without antidepressant effect, one may switch to a drug with a different biochemical profile within the same class or to a different class, such as an MAOI, but only after a 2- to 4-week period off agents with high potency in blocking serotonin reuptake (Table 14.8-5, Fig. 14.8-20). Problems with orthostatic hypotension may become more prominent in the second and third weeks of MAOI treatment. Salt loading, pressure stockings, and fludrocortisone (Florinef) or the peripherally acting a $_1$ agonist midodrine may prove effective in the treatment of MAOI-induced hypotension. MAOIs can be given in single morning doses or in divided doses. If marked insomnia occurs, nighttime doses of trazadone (Desyrel) have been recommended by some authorities. Bouts of daytime drowsiness and sedation may also become a problem. One might attempt to titrate the dosage against adverse effects, as variations in dosage or timing may be helpful.

The necessity of restricting substances that release tyramine or catecholamines and can produce hypertensive crises during MAOI treatment should be emphasized to the patient. These crises may be clinically manifested as explosive headaches, flushing, palpitations, perspiration, and nausea. Immediate treatment with a slow infusion of phentolamine (Regitine) (5 mg intravenously) in an emergency room is recommended. Most authorities suggest that the patient carry a 10-mg nifedipine (Adalat, Procardia) capsule with them that they could use sublingually or bite and swallow in the event of a presumptive hypertensive crisis.

Although tricyclic and heterocyclic drugs, SSRIs, serotonin-noradrenaline reuptake inhibitors (SNRIs), and MAOIs are central treatments for the unipolar depressed patient, there is reason for caution in their use for the bipolar patient. Some but not all studies have reported an increased incidence of switches into hypomania or mania during tricyclic or MAOI therapy, higher than expected for the patient's natural course of illness, particularly in previous rapid cyclers (Fig. 14.8-22). Whether this increased incidence of switching or cycle acceleration is sufficient to avoid the initial use of antidepressants in favor of mood stabilizers remains controversial. Thus, a shorter depression may occur at the cost of the more rapid onset of the following manic episode, whereas withdrawal of tricyclic drugs and MAOIs has also been shown to slow this cycle acceleration in a small number of patients.

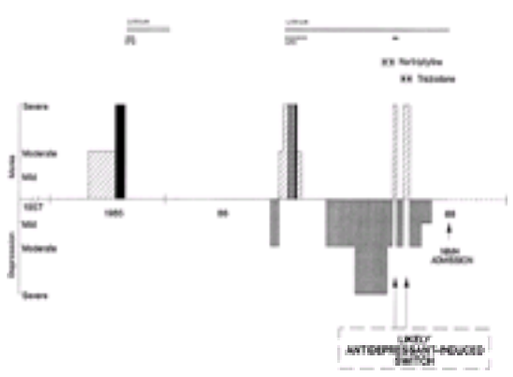

FIGURE 14.8-22 Antidepressant-induced mania in a male patient with bipolar I disorder. CPZ, chlorpromazine.

Uncontrolled observations suggest that tricyclic antidepressants and related compounds may be implicated in the development of continuous cycling phases (i.e., successive episodes without a well interval) (Fig. 14.8-23). This phase of the illness becomes difficult to treat and tends to be relatively lithium refractory. Anecdotal evidence and one double-blind, randomized study indicate that bupropion may not be associated with the same switching tendency as the tricyclic antidepressant desipramine (Norpramine). SSRIs may be less involved in the switch phenomenon and in cycle induction than the tricyclic drugs, but this too requires further investigation, since the commencement of rapid or continuous cycling coincident with the use of SSRIs has been observed anecdotally.

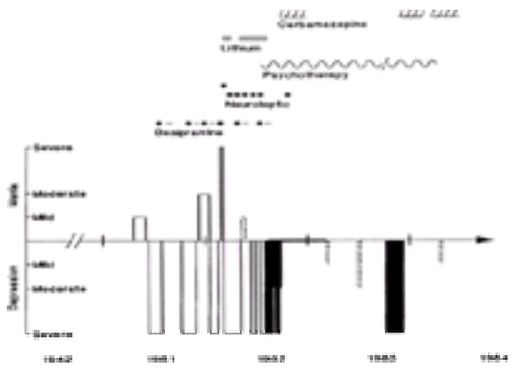

FIGURE 14.8-23 Life chart of a patient rated likely to have had antidepressant-induced cycle acceleration. *Solid black shading* indicates patient was hospitalized.

Once a switch has been observed with an MAOI, reexposure to even a different MAOI may also lead to an earlier onset of a switch, as observed in one controlled study, perhaps reflecting a sensitization phenomenon. Naturalistic data, however, raise questions about whether antidepressant-induced switches occur on each exposure to these drugs. Moreover, it is unclear whether a drug-induced switch appears only in those predestined to have spontaneous switches or whether this occurrence actually predisposes the patient to develop further spontaneous manic episodes. Women and those with rapid cycling may be at higher risk for tricyclic-induced switching or cycle acceleration.

Adding a Second Mood Stabilizer The unimodal antidepressants should be used cautiously and in conjunction with mood stabilizers for bipolar disorder depressive episodes, and particularly if there is a prior history of drug-induced switches, other options should be considered. There is much to recommend adding a second or even a third mood stabilizer (lithium, lamotrigine, carbamazepine, valproate, or a dihydropyridine L-type calcium channel inhibitor) in the rapidly (or ultrarapidly or ultradian) cycling depressed bipolar disorder patient prior to the use of a unimodal antidepressant (Table 14.8-5, Fig. 14.8-24).

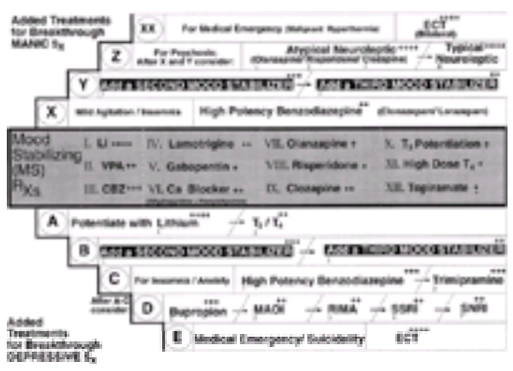

FIGURE 14.8-24 Treatment algorithm for bipolar disorder patients with rapid and ultrarapid cycling. VPA, valproate; CBZ, carbamazepine.

If unimodal antidepressants are used for a bipolar disorder depression, clinical lore suggested that they should be tapered and discontinued as soon as possible, to avoid the potential for drug-induced switches and cycle acceleration, especially since lithium may not be able to prevent these phenomena. However, maintenance therapy with bupropion and lithium has been reported to be effective in rapid-cycling patients, and use of unimodal antidepressants in conjunction with the new putative mood stabilizers deserves study. Several case reports suggest that alprazolam (Xanax) may, like the tricyclic drugs, also induce switches into hypomania and mania (even in unpredisposed patients) and this high-potency benzodiazepine should be avoided in favor of the long half-life compounds clonazepam and lorazepam, which do not appear to share the proclivity of the triazolobenzodiazepine compounds for the induction of mania. These high-potency benzodiazepines may be useful adjuncts to the mood stabilizers; however, the rare patient may experience these classical benzodiazepines as mood destabilizing or even depressogenic.

Some evidence suggests that the MAOIs, in general, may be less prone than tricyclic drugs to induce switches. The MAOIs should be given relatively greater consideration, especially for the reversal of vegetative (anergic, hypersonic, or hyperphagic) states in the bipolar patient. A substantially higher rate of antidepressant response was reported in one controlled series for tranylcypromine (Parnate) (81 percent) compared with imipramine (Tofranil) (48 percent) in bipolar disorder patients. Clorgyline, a selective *MAO type A* inhibitor not yet clinically available has been reported to slow cycling frequency. The reversible inhibitor of monoamine exiduse type A (RIMA) moclobemide (Aurorix) (Table 14.8-3) is widely available in Europe and Canada but not in the United States; this drug is not believed to be as effective an antidepressant as the nonselective MAOIs, such as tranylcypromine and phenelzine (Nardil); however, these MAOIs are unique in potentiating all three amine systems (serotonin, noradrenaline, and dopamine). One could attempt such an equivalent effect by using venlafaxine (for its serotonergic and noradrenergic effects) in combination with bupropion (for its dopaminergic effects).

It is possible that the anticholinergic rather than the noradrenergic effects of the tricyclic drugs makes them prone to cause switches or cycle acceleration. A comparison of SSRIs with the noradrenaline selective agents (desipramine, nortriptyline [Aventyl], and maprotiline [Ludiomil]), or to the SNRI venlafaxine would clarify the putative role of norepinephrine reuptake blockade in inducing these phenomena.

Dopamine-Active Compounds and Other Treatments

Bupropion Bupropion in conjunction with a mood stabilizer has shown promise in short-term and prophylactic management of bipolar disorder patients, including rapid cyclers. Although it may be added to lithium or valproate prophylaxis without pharmacokinetic interactions, when used with carbamazepine its blood concentrations are markedly decreased and those of an active metabolite increased (Fig. 14.8-25).

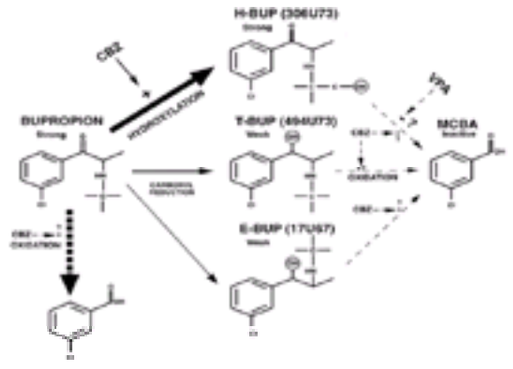

FIGURE 14.8-25 Bupropion metabolism. CBZ, carbamazepine; VPA, valproate; MCBA, metachlorobenzoic acid.

Psychostimulants The role of psychostimulants as short-term augmentation has not been systematically explored, although it is apparently widely used by some experts in the field. However, one investigator has indicated that this is not a useful long-term strategy, since many patients appear to develop tolerance to this

modality. This strategy should perhaps be reserved for temporary augmentation while awaiting more-effective antidepressant response to other modalities.

The same investigator also observed that tolerance does not appear to develop when the psychomotor stimulants are combined with MAOIs. This strategy should be reserved for only the most refractory patients, since the *Physician's Desk Reference* (PDR) lists an absolute contraindication to combining stimulants and MAOIs. Nonetheless, this appears to be effective and tolerated by most patients in many small case series.

Dopamine Agonists Small clinical series have also suggested some antidepressant efficacy of the direct dopamine agonist bromocriptine, which is used to treat parkinsonian patients. One double-blind study indicated that it was as effective as imipramine. A related dopamine agonist, piribedil (Trivastal), has been effective for the occasional refractory depressive patient. Pergolide (Permax) was reported to be an effective augmenting agent in one series on refractory depression but not in another.

Pramipexole, a potent D_3 as well as D_2 agonist recently approved for use in parkinsonism, is reported (at 1 mg a day or higher) to have antidepressant effects equivalent to those of fluoxetine (Prozac). Treatment should be started at low dosages and titrated toward 1 mg a day very slowly to avoid adverse effects such as nausea and orthostatic hypotension.

Dopamine-active drugs has been reported to be more effective in patients with low concentrations of the dopamine metabolite homovanillic acid in their cerebrospinal fluid (CSF). A similar relation to low concentrations of the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) and a better response to the serotonin active compounds clomipramine (Anafranil) and sertraline (Zoloft) have been reported. The results are inconclusive as to whether urinary concentrations of the noradrenergic metabolite 3-methoxy-4-hydroxyphenylglycol (MHPG) can predict the response to noradrenergically active antidepressants. Consistent biochemical markers of antidepressant response have not yet been identified.

Light in Morning and Melatonin at Night Systematic trials of augmentation with bright light (more than 7500 lux) may also be worth considering in patients with marked disruption of circadian rhythmicity and the typical bipolar disorder hypersomnia. In these instances, high-intensity light might be more useful in the morning, although this issue needs to be reexamined with more-systematic prospective randomized studies.

An additional approach to altering sleep activity cycles (which are common in bipolar disorder patients) might be to use melatonin adjunctively at night, although this, too, requires caution and prospective studies. In addition, isolated reports exist of exacerbation of sleep or mood in some patients when using melatonin supplementation.

Sleep Deprivation as a Short-Term Antidepressant Paradoxically, sleep deprivation may be an adjunctive procedure to hasten antidepressant response (Fig. 14.8-26). A rapid, transient, antidepressant response to 1 night of sleep deprivation has been reported consistently in studies from many different laboratories. Preliminary evidence suggests that sleep deprivation in the last half of the night (from 3 to 7 AM) may be just as effective as total sleep deprivation and may thus be more convenient for clinical use and outpatient treatment.

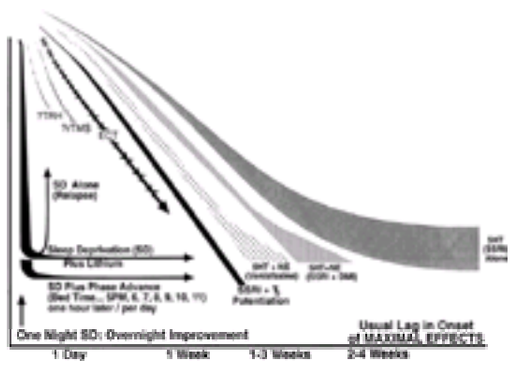

FIGURE 14.8-26 Nine potential clinical approaches to rapid-onset antidepressant effects. rTMS, repeated transcranial magnetic stimulation; NE, noradrenergic; DMI, desipramine.

Although most responsive patients relapse after 1 night's recovery sleep, some modalities (especially lithium) may help sustain the sleep deprivation response. One recent report also indicates that progressive changes in the hours of sleep (from 5 PM on the sleep deprivation day to 6 PM the next, and so forth toward an 11 PM bedtime) also help hold a sleep deprivation response.

The rapid onset (overnight) effects achieved differs from the slower but sustained effects following selective deprivation of rapid eye movement (REM) sleep, that is, a modality that is not readily amenable to clinical use. Response to sleep deprivation may be related to phase or duration of a bipolar disorder depressive episode, with less responsivity early in the episode and a greater responsivity late in the episode. Several, but not all, studies indicate that the degree of antidepressant response to sleep deprivation is correlated with the degree of increase in morning plasma TSH concentration, presumably driven by endogenous increases in TRH. Parenteral TRH administration (500 mg intravenously) has also been reported to have rapid-onset effects, and two case reports suggest more-sustained effects with low dosage (50 μg a day at bedtime).

Inositol Inositol (12 to 16 grams a day) has recently been reported to have antidepressant, antianxiety, and antiobsessive-compulsive effects. This remains to be more systematically explored in bipolar disorder patients (in light of no reports of patients switching in one series reporting a 50 percent response rate in patients who were concomitantly treated with lithium, carbamazepine, or valproate. Theoretically, inositol should not only relieve some lithium-induced adverse effects, but could potentially reverse its therapeutic efficacy to the extent that inositol depletion from reduced phosphoinositide (PI) turnover is related to lithium's mechanism of action. This has not been reported, however. Myoinositol measured by magnetic resonance spectroscopy (MRS) has been reported to be low in brains of bipolar disorder patients (in proportion to the severity of their depression); and lithium lowers it further. One would then predict that inositol augmentation might make carbamazepine even more effective, because carbamazepine has effects opposite to that of lithium, and increases the inositol-1 phosphatase enzyme, which should increase inositol. Lithium, carbamazepine, and valproate are all reported to downregulate the transporter for inositol that has recently been isolated and cloned.

Choline One open study reported that potentiation with choline (3 to 8 grams a day) may be helpful in stabilizing mood in refractory cyclers, and this approach, too, requires further systematic study.

Folate and Ascorbate In two single, randomized, placebocontrolled studies, the vitamins folate (300 to 400 mg a day) and ascorbate (3 grams a day) have each been reported to have some beneficial effects on amelioration of mood in long-term prophylaxis of bipolar disorder patients and, in light of their benign side-effect profiles, might be worthy of consideration in the treatment regimen of the refractory bipolar disorder patient.

Omega-3 Fatty Acids One randomized double-blind study comparing the addition of omega-3 fatty acids (9 grams a day) or an olive oil placebo in bipolar disorder patients poorly controlled on mood stabilizers was terminated early because of the marked superiority of the omega-3 fatty acid to the control. Virtually all of the breakthrough depressive episodes occurred in the placebo control group.

APPROACHES TO SUICIDALITY

Regular psychiatric visits during the prophylactic well phase are recommended on an interval ranging from weekly to biweekly in unstable patients to 1 to 4 months in better stabilized patients, depending on a variety of ancillary circumstances including completeness of response, lack of psychosocial crises, history of compliance, insight into the illness and its treatment, absence of adverse effects, financial constraints, and the wishes of the patient. In addition to periodic assessment of all of these issues, regular treatment visits are recommended to assess the potential risks of suicide independently of the occurrence of discrete episodes. This is particularly important when there is a positive family history of suicide or other risk factors, including male sex, older age, comorbid alcohol abuse, high levels of

anxiety, and prior suicide attempts (particularly if they have been severe).

Suicidal impulses and acts may not always vary directly with either severity of depression or reemergence of a full-blown episode requiring hospitalization and should be part of the careful ongoing clinical assessment of patients in all phases of their illness and treatment. Severe overwhelming psychic anxiety and agitation are predictors of completed suicide, and with the high comorbidity of panic disorder with either phase of bipolar disorder, one should be particularly alert to this and other high-risk factors. Specific contracting for communication with the clinician upon remergence or escalation of suicidal thoughts should be considered in high risk patients (Table 14.8-12).

Dual treatment: Focus acute short-term and prophylaxis
Mania: Treat first, do chemistries later
Load valproate and lithium; slowly start lamotrigine treatment
Use second mood stabilizers over antipsychotics
Benzodiazepines instead of antipsychotics
Combination treatment decreases adverse effects
Chart illness
Augment rather than substitute
Simplify (for adverse effects)
Taper off lithium slowly, if at all
Educate the patient's family
Assess compliance and suicidality
Develop an early warning system
Develop specific contracts
Regular visits; monitor course and adverse effects
Phone contact (PRN) when needed
Develop a "fire drill"
Prevent comorbid alcohol and other substance abuse
Psychotherapy and medicalization of illness
Give statistics: 50% relapse in first 5 months off lithium treatment
Patient as a co-principal investigator
Conservative treatment, if successful
Radical treatment, if inadequate response

Table 14.8-12 Principles in the Treatment of Bipolar Disorders

Electroconvulsive Therapy ECT may benefit bipolar depressed patients who do not respond to lithium or other mood stabilizers and their adjuncts. This is particularly true when intense suicidality presents as a medical emergency. Whether ECT would continue to help abbreviate each bout of recurrent depressive episodes in rapid-cycling patients or whether it would be useful in long-term prophylaxis must be further investigated. The author has observed several instances in which tolerance appeared to develop to the therapeutic effects of repeated series of ECT. Moreover, concern about cognitive adverse effects remains, and the author has recently seen a number of otherwise healthy individuals with rather profound and sustained retrograde memory loss.

TREATMENT OF MANIC BREAKTHROUGHS

A wide range of drugs is available for breakthrough manic episodes occurring during lithium or other prophylactic treatment, including the entire spectrum of drugs indicated for the treatment of acute mania (Table 14.8-5 and Table 14.8-6; Fig. 14.8-24). Ranking high in these treatments are carbamazepine and valproic acid, because of their longer-term prophylactic efficacy. Lamotrigine, nimodipine, and topiramate all require further study. Clonazepam or lorazepam may also be useful acute alternatives to antipsychotic supplementation, even though the benzodiazepines (and antipsychotic agents) appear to have a less primary role in the long-term management of bipolar disorders than the mood stabilizers carbamazepine or valproic acid.

The use of clozapine for bipolar disorder and schizoaffective disorder patients refractory to lithium, carbamazepine, and valproate is now well documented in many case series, especially for those with rapid cycling and dysphoric mania. Its lack of ability to induce tardive dyskinesia makes it particularly attractive, and one looks forward to a possible similar role for other atypical antipsychotics (Table 14.8-8 and Table 14.8-10) without clozapine's liability for agranulocytosis and the attendant need for weekly white blood count monitoring. Given the high liability of tardive dyskinesia even with intermittent use of typical antipsychotics, these drugs should be relatively avoided in favor of the atypical agents and other mood stabilizers whenever possible.

COMPLEX COMBINATION THERAPY

Data from the NIMH also support the notion that many depressed patients with refractory bipolar illness can be treated with a variety of approaches not typically involving the traditional unimodal antidepressant or typical antipsychotic modalities. Analysis of successive 5-year epochs in the tertiary-referral 3-West Clinical Research Unit of the Biological Psychiatry Branch showed that approximately the same high percentage (75 to 80 percent) of patients achieved marked or moderate improvement on the CGI at discharge in the past 25 years. However, patients in the years 1970 to 1974 required only monotherapy on discharge more than 75 percent of the time; this decreased to less than 25 percent in the most recent 5-year period, and the average number of medications on discharge increased from one to three per patient over the same time period (Fig. 14.8-27). Yet, unimodal antidepressants or antipsychotic drugs were used in less than 15 percent of the patients. Although these data based on sequential double-blind trials and augmentation strategies in this discharge phase of the hospitalization, did not involve a systematic randomized approach to therapeutics they nonetheless reveal that the vast majority of patients with refractory depressive and cycling presentations can be managed largely in the absence of the unimodal antidepressants or neuroleptic drugs. Multiple mood stabilizers in combination, often with thyroid augmentation, were used most of the time.

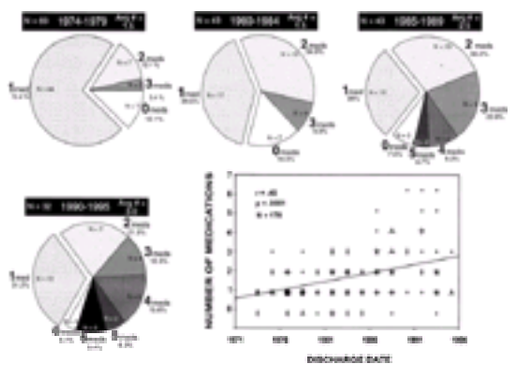

FIGURE 14.8-27 Increasing number of medications at discharge.

As in the late phases of other medical syndromes, complex combination treatment is often required for the treatment-refractory bipolar disorder patient. Although it may at first seem inappropriate to consider a regimen with four or five drugs for the treatment of refractory bipolar illness, this strategy is standard practice in many other areas of medicine such as the treatment of malignancies, tuberculosis, AIDS, or congestive heart failure. In these instances, multiple therapeutic modalities with different symptom targets and different mechanisms of action are often combined for optimal therapeutics.

With the availability of a variety of agents for bipolar disorders, it now befits the field to engage in more systematic clinical trial approaches to delineate the optimal strategies for achieving the most rapid response rates in the highest numbers of patients, so that even the most refractory bipolar disorder patients have an excellent chance at achieving and maintaining clinical remission.

Attempting to supplement the clinical effects of lithium and the mood-stabilizing anticonvulsants such as carbamazepine and valproic acid is often more effective than using lithium or the anticonvulsant alone. By augmenting rather than substituting a mood stabilizer, withdrawal-induced exacerbations will not confound the evaluation of the next agent, and time may be saved in the assessment of the combination in one clinical trial rather than two sequential trials (the anticonvulsant alone and then the combination). For patients who are unable to tolerate lithium carbonate, evidence does suggest that carbamazepine or valproate may be useful long-term maintenance treatments in preventing both manic and depressive episodes. A rather substantial literature on double-blind randomized studies provide evidence of carbamazepine's prophylactic efficacy. Most of the prophylactic data on valproate are based on clinical case series, however, with the exception of one randomized open trial showing efficacy equal to that of lithium and one blind trial showing that valproate has greater efficacy than placebo or lithium for recurrent depression. The

choice of carbamazepine or valproate may depend on the future development of clinical predictors or on the current assessment of their relative side-effects profiles (Table 14.8-13). The data are even more preliminary for the L-type calcium channel inhibitor and the new putative mood-stabilizing agents such as lamotrigine and possibly topiramate and gabapentin.

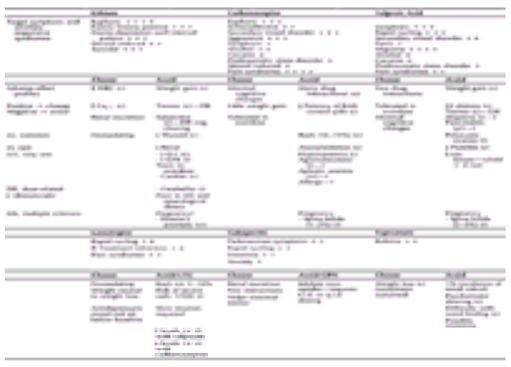

Table 14.8-13 Positive and Negative Selection Factors for Choice of Mood Stabilizer

All of these agents have differential presumptive biochemical mechanisms of action. One can begin to use augmenting strategies (Table 14.8-6), not only empirically (Fig. 14.8-5), but also based on combining agents with different actions (Table 14.8-2, Fig. 14.8-6 and Fig. 14.8-9), symptom targets (Table 14.8-4), side-effect profiles (Table 14.8-7), or benign pharmacokinetic and pharmacodynamic interactions. It is unclear whether using drugs with slightly different actions targeted to a single transmitter system such as GABA (i.e., enhancing GABA by reuptake blockade [tiagabine], transaminase inhibition [g-vinyl GABA], transport effects [gabapentin], or multiple enzymatic actions [valproate]) will be more or less effective than simultaneously targeting two or more entirely different systems (e.g., enhancing GABA and inhibiting glutamate (Fig. 14.8-9).

Using several drugs in combination (Table 14.8-6) may actually help reduce the incidence of adverse effects by keeping each drug below its adverse-effects threshold (Table 14.8-7) rather than pushing one drug to maximum dosages for full therapeutic effect. Preclinical evidence indicates that such a combination strategy may also be less susceptible to the loss of effectiveness via tolerance. Optimally, one would like to use drugs with additive or synergistic therapeutic effects in the relative absence of adverse effects (Table 14.8-13); for this, knowledge of both pharmacokinetic and pharmacodynamic interactions is of considerable importance.

Pharmacokinetic Interactions There do not appear to be major pharmacokinetic interactions among lithium and the other mood stabilizers. There have been occasional reports of neurotoxicity when lithium and carbamazepine are used together. Because both agents can cause these adverse effects at or below clinically accepted dosage ranges, neurotoxicity may occasionally result from the combination treatment as well. In most instances the combination appears to be well tolerated. Many of the adverse effects reported in the literature appear to be caused by starting treatment with relatively large dosages of carbamazepine (rather than using slow increases) in combination with other agents, and assuming that the attendant adverse effects are related to the combination treatment rather than to carbamazepine alone. Carbamazepine enhances its own metabolism and that of other agents metabolized by the hepatic microsomal P450 system (CYP) isoenzyme CYP, 3A4 such as haloperidol or estrogen, and concentrations of these substances (as well as birth control pills) are markedly reduced by carbamazepine (Fig. 14.8-28). Despite this reduction in haloperidol blood concentrations, most studies report improvement with carbamazepine supplementation, suggesting that carbamazepine might potentiate antipsychotic effects because of actions other than dopamine receptor blockade.

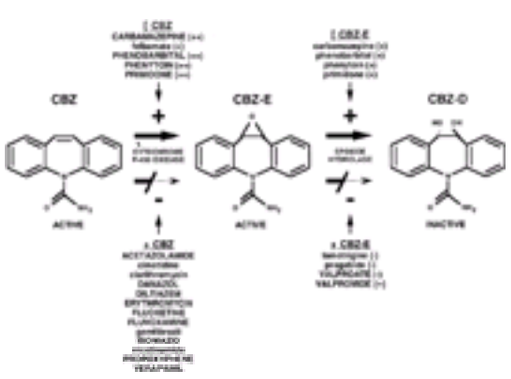

FIGURE 14.8-28 Carbamazepine (CBZ) metabolism.

Agents commonly used in medical practice can markedly increase carbamazepine concentrations and thus produce attendant toxicity (Table 14.8-14, Fig. 14.8-28). The most frequent dose-related toxic manifestations are dizziness, drowsiness, ataxia, diplopia, and confusion. These may occur in someone otherwise tolerating the drug well until other drugs are added. Erythromycin, triacetyloleandomycin (TAO), isoniazid (Nidrazid) (but apparently not other MAOIs), fluoxetine and fluvoxamine (Luvox), and the calcium channel inhibitors verapamil and diltiazem (Cardizem) (but not nifedipine, nimodipine, amlodipine [Norvasc], or isradipine) will increase carbamazepine concentrations. Less marked increases occur during cotreatment with propoxyphene (Darvon) and, transiently, with cimetidine (Tagamet). Carbamazepine will lower the blood concentrations of various agents (especially birth control pills) and interfere with some tests that depend on protein binding, including some pregnancy tests.

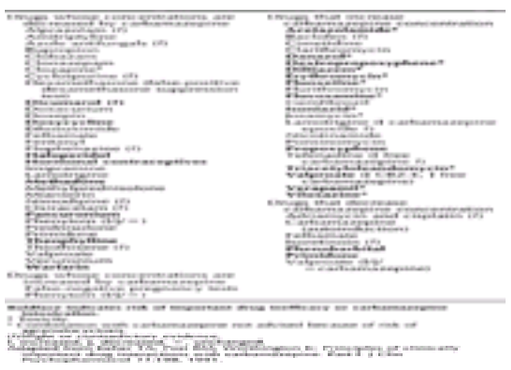

Table 14.8-14 Carbamazepine-Drug Interactions

In contrast to the multiple pharmacokinetic interaction of carbamazepine with other drugs, based largely on its properties as an inducer of hepatic P450 enzymes, valproate has few problematic effects in this area. However, if carbamazepine and valproate are used together, one should consider reducing the carbamazepine dosage (because valproate increases concentrations of the 10,11-epoxide metabolite) as well as increasing the free fraction of carbamazepine (Fig. 14.8-28). Lithium and valproate are generally well tolerated in combination, but effects on tremor, weight gain, and gastrointestinal distress may be additive.

Carbamazepine markedly reduces the concentration of bupropion but increases that of its active hydroxy metabolite (Fig. 14.8-25), an action not shared by valproate.

Valproate approximately doubles blood concentrations of lamotrigine and thus increases the likelihood of a severe lamotrigine rash; starting dosages of lamotrigine should be halved accordingly. If no rash occurs, lamotrigine and valproate have excellent tolerability and efficacy in epilepsy (and perhaps in affective illness) when used in combination. In contrast, carbamazepine decreases lamotrigine concentrations by about one-half, and these two drugs may be less useful in combination because of their similar adverse effects and pharmacodynamics.

Fluoxetine and paroxetine (Paxil) are inhibitors of CYP 2D6, and may increase concentrations of many agents such as desipramine and the secondary tricyclic antidepressants and phenothiazines (Table 14.8-15). Fluvoxamine is a potent inhibitor of CYP 1A2 (potentially producing theophylline toxicity) and CYP 2C19 (increasing warfarin [Coumadin] levels) as well as CYP 3A4. Nefazodone (Serzone) is also potent at CYP 3A4, producing cardiac arrhythmias with astemizole (Hismanal), cisapride (Propulsid), and terfenadine (Seldane), and likely increasing carbamazepine concentrations.

Table 14.8-15 Substrates, Inhibitors, and Inducers of Some Important Cytochrome P450 Isoforms

SENSITIZATION EFFECTS ON THE MOOD DISORDERS AND IMPLICATIONS FOR PROPHYLAXIS

Early clinical observations and more-recent systematic controlled studies suggest that recurrent bipolar affective disorders may undergo a transition from initial episodes that are typically precipitated by psychosocial stressors to later episodes that tend to occur more spontaneously. This transition often occurs in the context of an overall pattern of cycle acceleration with a trend toward shorter well interval between successive episodes (Fig. 14.8-29). Both the effects of psychosocial stressors and recurrent mood episodes themselves may not only cause acute biological perturbations, but may also leave behind residual biological vulnerabilities, or memory traces, based on their ability to alter gene expression (Fig. 14.8-30). Preliminary data from the Stanley Foundation Bipolar Treatment Outcome Network suggest that experiences of early verbal, physical, or sexual abuse are associated with a greater incidence of early-onset bipolar disorder and ultra-ultra-rapid (ultradian) cycling; physical abuse in childhood was associated with increased mania and sexual abuse with increased suicidality.

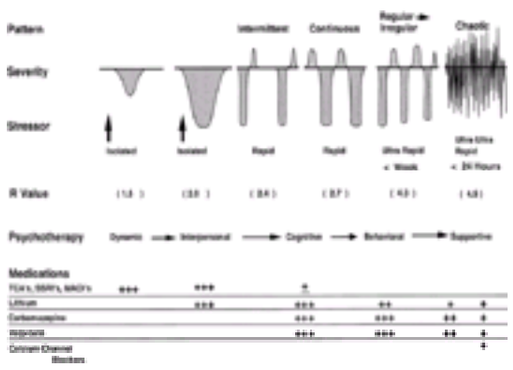

FIGURE 14.8-29 Phases in evolution of mood cycling: potential relation to treatment response.

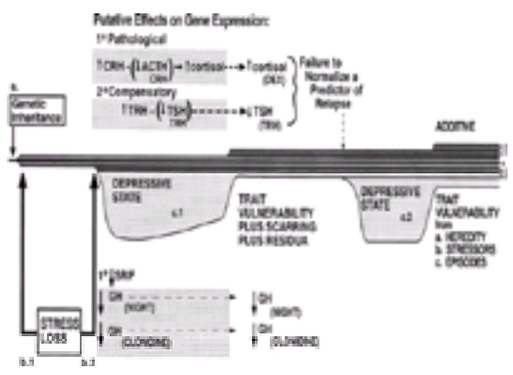

FIGURE 14.8-30 Accumulating experiential genetic vulnerability in recurrent mood disorders. CRH, corticotropin-releasing hormone; ACTH, adrenocorticotropic hormone; DEX, dexamethasone; SRIF, somatostatin release-inhibiting factor.

Following stress and episode-induced changes in neurotransmission, a cascade of neurobiological effects is thought to take place that includes not only short-term adaptations but also longer-lasting alterations initiated by a variety of transcription factors, including the immediate early genes, such as the transcription factors c-*fos* and c-*jun* as well as a variety of neurotrophic factors. These transcription factors can then induce changes in the long-term regulation of late effector genes (i.e., transmitters, receptors, and neuropeptides). This type of episode-related upregulation in transcript could account for the increase in corticotropine releasing hormone (CRH) in brain and CSF of depressed patients and its associated hypercortisolemia as well as the microstructural and synaptic organization of the brain revealed in many models of maternal deprivation and learning and memory.

If this conceptualization proves correct, it suggests the potential dual importance of preventing episodes of affective illness. Not only would episode-associated morbidity and potential mortality be prevented, but the longer-lasting neurobiological vulnerabilities associated with the experience of repeated affective episodes themselves (sensitization) might be attenuated as well. Although the mechanisms and direct causality have not been clarified, greater numbers of prior mood episodes are associated with greater degrees of cognitive dysfunction on a variety of neuropsychological tests in euthymic bipolar disorder outpatients.

Thus, given the increasing evidence that greater numbers of affective episodes are a poor prognostic sign and may be associated with resistance to effective treatment with lithium, both the clinical and theoretical data speak to the importance of early institution and long-term maintenance of prophylaxis, particularly in patients already identified as being at high risk for recurrence.

Treatment efficacy may thus also vary as a function of the stage of illness evolution (Fig. 14.8-29). For example, pharmacotherapies such as lithium and unimodal antidepressants may be more effective in initial and midphases of the illness, but with the emergence of rapid and ultra-rapid cycling, adjunctive treatments with the anticonvulsants may be required, with the antidepressants used more sparingly. In the latest stages of illness, sometimes associated with ultradian cycling,

dihydropyridine *L*-type calcium channel inhibitors augmented by mood-stabilizing anticonvulsants may be required.

Similar transitions may occur in psychotherapeutic approaches wherein psychotherapy may be effective in the early, milder forms of stress-related depressive illness, but with major recurrent episodes (and particularly, melancholic and psychotic syndromes), aggressive acute and maintenance pharmacotherapy may be mandatory. Adjunctive interpersonal, cognitive, and behavioral techniques may become increasingly important in (1) the later, more automatic shifts in mood, (2) helping to maintain active treatment compliance with pharmacotherapies, (3) implementing an early intervention system based on the development of a structured early warning system; and (4) maintaining morale in the face of therapeutic adversity and incomplete response, all of which, in turn, may prevent suicide.

The past several decades have seen important advances in the understanding of the neurobiology of the depressive and bipolar disorders. Clearly these illnesses involve multiple areas of brain dysfunction and affect a variety of organ systems, altering not only mood, but also motor, cognitive, sleep, appetite, hedonic reward, and other somatic systems. Neurobiological alterations are evident at the level of endocrine dysfunction, reflected not only in altered regulation of glucocorticoids and CRH, TRH, and somatostatin release-inhibiting factor (SRIF) but even the size of the pituitary and the adrenals.

Some of these changes may involve episodic and cyclic alterations in gene transcription related to the primary pathology of the illness (such as increases in CRF), but others may be secondary and adaptive (e.g., increases in TRH) (Fig. 14.8-30). The author has postulated that the ratio of a host of pathological factors ("the bad guys") to the compensatory adaptations ("the good guys") determines the proportions of periods of illness versus well intervals (Fig. 14.8-31). To the extent that exogenous medications can change this ratio by either inhibiting the bad guys or enhancing the good guys, sustained remissions can be achieved, if adequate prophylactic treatment is maintained. This conceptual model based on preclinical data also predicts that clinical loss of prophylactic efficacy via development of tolerance would be delayed or prevented by (1) earlier rather than later treatment; (2) sustained full dosages rather than marginally effective ones; (3) use of the most effective agents with a wide therapeutic margin; and (4) combinations of several marginally effective agents (Table 14.8-16, Fig. 14.8-32). These propositions remain to be directly tested, however.

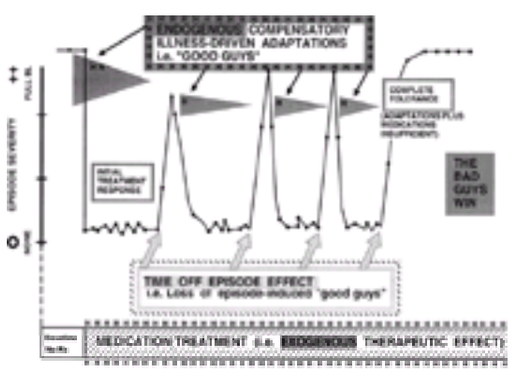

FIGURE 14.8-31 Ratio of "good guys" and "bad guys" drives episode cycling.

Treatment resistance showed by
Higher dosages
Not escalating dosages
More efficacious drugs: valproate carbamazepine
Treatment initiated early in illness
Combination treatment: carbamazepine plus valproate

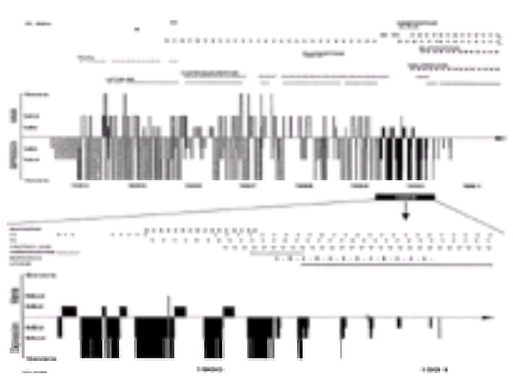

FIGURE 14.8-32 Response to combination therapy in a patient with refractory bipolar I disorder. TCAs, tricyclic antidepressants.

Functional brain imaging has revealed alterations in blood flow and glucose utilization, often reflecting hypofrontality in depression, at times in direct proportion to the severity of the depressive syndrome. Evidence of hyperactivity in the ventral anterior cingulate gyrus and the medial temporal lobes is also present in some patients, and these differential patterns may be linked to differences in therapeutic outcome. Both patient and clinician should be aware that a wealth of clinically relevant neurobiological evidence indicates that the mood disorders are potentially life-threatening medical illnesses not different from those that afflict the other major organ systems of the body and, as such, should be treated with equal care and vigor.

FUTURE DIRECTIONS

During this most exciting era for the development of psychobiological theories and therapies for the mood disorders, one hopes for clearer definitions of the different psychotherapies and pharmacotherapies critical for adequate therapeutic intervention in individual patients whose severities, types, patterns, and stages of illness differ. Since the last half of the century, successive generations of pharmacotherapies have led to critical neurobiological hypotheses of the mechanisms underlying the mood disorders, and one hopes that a continued mutually interactive process of more specific treatments, theories, and therapies will be derived from synergistic clinical and basic research in this area.

Not only is there a wealth of information to be learned through controlled research, but each patient has much to teach the practitioner and the theoretician. Precise life charting of the course of recurrent mood disorders and its response to treatment may be invaluable to the patient and clinician in arriving at optimal therapeutics, particularly when evidence from controlled studies currently provides so little direction for most crucial decisions. Although a host of well-tested, promising treatment alternatives are now available and one can anticipate many novel interventions in the near future, a much wider systematic clinical research base is urgently needed to guide the physician to the best therapeutic regimen for each individual bipolar patient. The author hopes that some of the preliminary data, guidelines, and principles outlined in this chapter will assist in this process and that more rapid progress occurs in the study and treatment of this relatively neglected major

psychiatric illness.

SUGGESTED CROSS-REFERENCES

Biological therapies are discussed in Chapter 31. Section 14.7 provides a thorough discussion of the treatment of depressive (unipolar) disorders. Obsessive-compulsive disorder is covered in Chapter 15. The rest of Chapter 14 can be consulted for other aspects of mood disorders.

14.9 MOOD DISORDERS: PSYCHOTHERAPY

ROBERT M. A. HIRSCHFELD, M.D., AND M. TRACIE SHEA, PH.D.

The interpersonal nature of depression was noted and emphasized in the earliest psychoanalytic writings on depression, as was the centrality of the regulation of self-esteem. In *Mourning and Melancholia*, Sigmund Freud stated that a vulnerability to depression caused by an interpersonal disappointment early in life led to future love and relationships marked by ambivalence. Actual or threatened interpersonal losses in adult life trigger a self-destructive struggle in the ego that is manifested as depression. That theory was significantly refined by later psychoanalysts who described the depression-prone personality as needing constant reassurance, love, and admiration and being dependent on others for narcissistic gratification and maintenance of self-esteem. Frustration of these dependency needs leads to decreased self-esteem and subsequent depression. This notion was later expanded to include any person with a fragile self-esteem system. Another dynamic approach focuses on the cognitive aspects of depression, highlighting the recognition of the disparity between one's actual and idealized situation. That realization leads to a sense of helplessness and powerlessness and ultimately to depression.

Little empirical research has been conducted and published on psychoanalytic and psychodynamic approaches to depression. Psychotherapies have been subjected to clinical trials similar in design to those used to test new antidepressant medications. In addition, modern treatment trends have favored more-focused, short-term therapies at the expense of longer-term therapies, such as most of the psychodynamic therapies.

Although psychoanalytic approaches were the predominant mode of treatment for depression in the early to middle part of this century, now many types of psychotherapy based on a variety of concepts are in use. Psychotherapeutic approaches have been developed specifically for depression that aim to correct specific manifestations including cognition, behavior, and affect. In general, those treatments are short term and seek to alleviate the depressive condition, not to change the character of the patient.

INTERPERSONAL THERAPY (ITP)

Theoretical Concepts Interpersonal therapy was developed by Gerald Klerman and Myrna Weissman as part of their extensive research on the nature and treatment of depression over the past two decades. The theoretical basis of interpersonal therapy includes the work of Adolf Meyer and Harry Stack Sullivan. In contrast with the predominantly intrapsychic orientation of classic psychoanalysis and Emil Kraepelin's biomedical model, Meyer's psychobiological approach emphasizes the interaction between the individual and the psychosocial environment over the patient's entire life course. The patient's current interpersonal experiences and attempts to adapt to environmental change and stress are seen as critical factors in psychiatric illness. Sullivan's interpersonal theory, which views interactions between people as the focus for study and treatment in psychiatry, draws heavily from the social sciences, including anthropology and sociology. A second major influence comes from John Bowlby's studies of attachment. These studies demonstrate the importance of attachment and social bonding to human functioning and the connection between disruption of these bonds and vulnerability to depression.

Interpersonal therapy conceptualizes depression from a medical model: depression is something that happens to the person that requires treatment. The depressed person is allowed to assume the sick role and is not blamed for the affliction any more than someone would be blamed for having cancer, heart disease, or pneumonia. The issue of attribution of blame is important. Many other approaches view depression as something patients have brought on and must end by their own efforts.

The interpersonal therapy approach to depression involves three interacting components: symptom formation, social and interpersonal experiences, and enduring personality patterns. Medication may be recommended or symptom reduction; psychotherapy focuses on improving the patient's interpersonal functioning. Although the causes of depression may vary with regard to a person's biological vulnerability, personality predispositions, or psychosocial precipitants, depression always occurs in a psychosocial and interpersonal context. Depression can predispose a patient to interpersonal problems, or interpersonal problems can precipitate depression. An interpersonal focus in the treatment process is thus presumed essential for recovery.

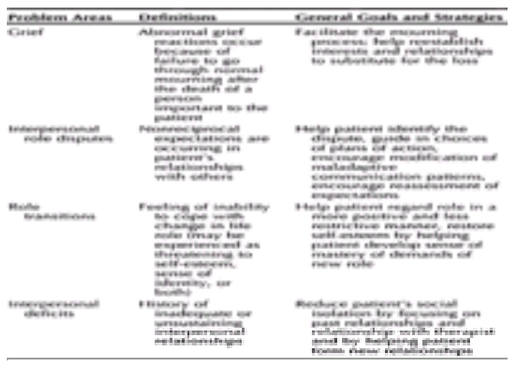
Goals Interpersonal therapy sets two therapeutic goals: (1) to reduce the patient's depressive symptoms and improve self-esteem and (2) to help the patient develop more-effective strategies for dealing with current social and interpersonal relations. As a short-term psychotherapy, interpersonal therapy does not attempt to restructure the patient's personality. It does, however, recognize the importance of early developmental experiences and assumes the importance of early developmental experiences and that historical conflicts are manifested in current relationships.

General Considerations Interpersonal therapy, a short-term psychotherapy normally consisting of 12 to 16 weekly sessions, was developed specifically to treat nonbipolar, nonpsychotic, ambulatory patients suffering depressive disorders. It is characterized by an active approach on the part of the therapist and by an emphasis on current issues and social functioning in the life of the patient. Intrapsychic phenomena such as defiance mechanisms of internal conflicts are not addressed. Discrete behaviors such as lack of assertiveness, social skills, or distorted thinking may be addressed, but only in the context of their meaning or effect on interpersonal relationships.

Strategies and Techniques

General Strategies For goal 1, reduction of symptoms, an educational approach is used. The patient is told about the clinical syndrome of depression, including its components and course. The therapist reviews the symptoms with the patient, gives a sense of optimism and hope, and emphasizes that depression is a common disorder with a good prognosis. Pharmacotherapy may be considered for symptom reduction if appropriate.

For goal 2, interpersonal therapy defines four major problem areas commonly presented by depressed patients: grief, interpersonal role disputes, role transitions, and interpersonal deficits (Table 14.9-1). Associated therapeutic goals and recommended treatment strategies are outlined for each. The choice of specific strategies and techniques depends on the problem area considered most salient for the patient. The four areas are not mutually exclusive, and patients may have multiple problems in more than one area; however, the focus is on only one or two current interpersonal problems, to allow realistic goals and productive treatment strategies. Abnormal grief may involve delayed or distorted mourning or both. The following example is cited in the interpersonal therapy manual.



Problem Areas	Definitions	General Goals and Strategies
Grief	Abnormal grief reactions occur because of failure to go through normal mourning after the death of a person important to the patient	Facilitate the mourning process; help reestablish interests and relationships to substitute for the loss
Interpersonal role dispute	Nonreciprocal expectations are occurring in patient's relationships with others	Help patient identify the dispute, guide in choices of plans of action, encourage modification of maladaptive communication patterns, encourage reassessment of expectations
Role transitions	Feeling of inability to cope with change in life role (may be experienced as threatening to self-esteem, sense of identity, or both)	Help patient regard role in a more positive and less restrictive manner, restore self-esteem by helping patient develop sense of mastery of demands of new role
Interpersonal deficits	History of inadequate or unsustaining interpersonal relationships	Reduce patient's social isolation by focusing on past relationships and relationships with therapist and by helping patient form new relationships

Table 14.9-1 Focal Problem Areas of Interpersonal Therapy

A 68-year-old woman became depressed following the death of her husband, who had suffered a long course of physical and mental deterioration that resulted in considerable constraints and isolation on the part of the patient. Her symptoms included pervasive sadness and preoccupation with feelings of guilt and hopelessness. The first aim of treatment was to help the patient successfully mourn the loss, as the mourning process had been blocked by anger. The second aim was to help her to reestablish interests and relationships to substitute for what she had lost.

Interpersonal issues in a troublesome, conflicted marriage may include role disputes or role transitions. The choice between the two problem areas depends on whether the patient believes that the marriage is salvageable and whether the patient wants to stay in the marriage. If the patient decides to leave the marriage and the problem area is defined as role transition, the therapist attempts to help the patient make the transition. That goal may include identifying new sources of emotional support, overcoming irrational fears and regarding the new role more positively, and helping the patient master the demands of the new role. Alternatively, if the problem area is defined as role dispute, the treatment strategies include identifying the dispute and working toward its resolution, improving communication patterns, examining appropriateness of expectations, outlining various options, and deciding on a plan of action.

The interpersonal deficit problem area is appropriate for patients who are socially isolated or who have a sufficient number of relationships but feel unable to enjoy them. Interpersonal deficits may exist in patients who are chronically depressed and experience chronically impaired interpersonal functioning. Problems with social isolation may be longstanding or temporary; for each, treatment strategies aim to reduce social isolation. In the absence of current relationships, discussion of positive and negative features of past relationships may be used as a model for the development of new relationships. Treatment may also focus on the relationship between therapist and patient. The following example of an interpersonal deficit is cited by the interpersonal therapy manual.

A 22-year-old unmarried man became severely depressed 1 month after the breakup of a 3-year relationship with his girlfriend. The patient, a part-time student employed as a cook, lived with his mother, who had stopped working after being hospitalized for physical problems; subsequently, he had become depressed. Discussion of the patient's current relationship revealed that he felt close to no one but his mother.

The patient's history revealed inadequate social relationships and lack of interpersonal skills. Treatment focused on past significant relationships and conflicts over his relationship with his mother. The patient-therapist relationship provided a direct source of information about the patient's style of relating to others, which was used to modify maladaptive interpersonal patterns and improve his ability to form relationships with others.

Specific Techniques The specific techniques used in interpersonal therapy may be applied to any of the four interpersonal problem areas. In the general order of their use in the course of treatment, they are (1) exploratory techniques, (2) encouragement of affect, (3) clarification, (4) communication analysis, (5) use of therapeutic relationship, and (6) behavior change techniques (Table 14.9-2).

Techniques	Definition
Exploratory techniques	Collect (by directive or nondirective methods) information about the patient's symptoms and problems
Encouragement of affect	Help patient recognize and accept painful affects, help patient use and manage affects positively in interpersonal relationships, encourage expression of suppressed affect
Clarification	Restructure and feed back patient's communications
Communication analysis	Identify maladaptive communication patterns, help patient communicate more effectively
Use of therapeutic relationship	Examine patient's feelings and behaviors in therapeutic relationship as model of patient's interactions in other relationships
Behavior change	Use to help patient solve simple life problems, teach patient to consider range of options for solving problems, use role playing to explore and understand patient's relationship with others, and train patient in new ways of interacting with others

Table 14.9-2 Interpersonal Therapy Techniques

Efficacy In depression interpersonal therapy has been tested in two large controlled studies. The first involved four groups (approximately 25 outpatients) treated by interpersonal therapy alone, interpersonal therapy plus amitriptyline (Elavil), amitriptyline alone, and a nonscheduled treatment comparison group. All active treatments, including interpersonal therapy alone, were significantly more effective in reducing depressive symptoms than nonscheduled treatment; the combination of interpersonal therapy and amitriptyline was most effective. In addition, the interpersonal therapy groups had much lower dropout rates than those without interpersonal therapy.

In the second study, the National Institute of Mental Health (NIMH) Treatment of Depression Collaborative Research Program, 250 outpatients with major depressive disorder were randomly assigned to one of four 16-week treatment conditions: interpersonal therapy, cognitive-behavioral therapy, imipramine (Tofranil) with clinical management, and placebo with clinical management. In this study all four treatment conditions significantly reduced depressive symptoms. For severely depressed patients interpersonal therapy was significantly more effective than placebo with clinical management in achieving remission of symptoms at 16 weeks. Imipramine with clinical management tended to have the best outcome, particularly for patients with impaired functioning. Imipramine yielded more-rapid effects, with significantly better outcome than all other conditions at 12 weeks. A reanalysis of the NIMH Treatment of Depression Collaborative Research Program supported the superiority of antidepressant medication for depressions that are more severe on the basis of symptoms or psychosocial status.

Among psychotherapies, depressive severity did not appear to predict outcome to treatment. Interpersonal therapy was compared with supportive therapy in depressed human immunodeficiency virus (HIV)-positive patients. Although both treatments reduced depressive symptoms, interpersonal therapy was superior, and gains were sustained.

Interpersonal therapy has been adapted and tested in several different patient types. Interpersonal therapy late-life maintenance, developed for geriatric patients, incorporates approaches to special problems of elderly adults and allows shortened sessions for those who cannot sustain 50-minute sessions. Interpersonal therapy has been modified for use in adolescents, incorporating developmental and interpersonal issues frequently occurring in this age group.

Interpersonal therapy has also been adapted for use in chronic depression, specifically dysthymia. Pilot results from a 16-week open trial of patients with dysthymia were extremely positive in this group of difficult-to-treat patients. A version for patients with bipolar disorder includes material aimed at normalizing sleep-wake cycles, whose alterations often trigger a manic episode. Interpersonal therapy has been adapted specially for depressed patients with marital disputes. A study comparing patients randomly assigned to regular interpersonal therapy or the adapted therapy found similar reductions in depressive symptoms, but better marital outcomes (e.g., greater marital affection) in those receiving the adapted version. In addition to these modifications for different populations with depression, interpersonal therapy has been modified for use in other psychiatric disorders; among these are interpersonal counseling for distress, for hospitalized elderly patients, for substance abuse, and for bulimia nervosa.

COGNITIVE-BEHAVIORAL THERAPY

Theoretical Concepts Cognitive-behavioral therapy stems from four major previous theories: psychoanalytic theory, phenomenological philosophy, cognitive psychology, and behavioral psychology. Salient common features include recognition of the importance of the subjectiveness of conscious experience (one's perceptual experience of reality rather than the objective reality) and recognition of the emotional consequences of irrational beliefs and thoughts.

Aaron Beck, the originator of cognitive-behavioral therapy, developed a comprehensive, structured theory of depression. According to this theory, depression is associated with negative thought patterns, specific distorted schemas, and cognitive errors or faulty information processing (Table 14.9-3). Such cognitive

dysfunctions form the core of depression, while affective and physical changes and other associated features of depression are its consequences.

Element	Definition
Cognitive triad	Beliefs about oneself, the world, the future
Schemas	Ways of organizing and interpreting experiences
Cognitive distortions	
Arbitrary inference	Drawing a specific conclusion without sufficient evidence
Specific abstraction	Focus on a single detail while ignoring other more important aspects of an experience
Overgeneralization	Forming conclusions based on too little and too narrow experience
Magnification and minimization	Over- or undervaluing the significance of a particular event
Personalization	Tendency to self-reference external events without basis
Absolutist, dichotomous thinking	Tendency to place experience into all-or-none categories

Table 14.9-3 Elements of Cognitive Theory

Cognitive theory conceptualized depression as involving negative cognitions regarding the cognitive triad (ideas of oneself, the world, and one's future). The self is perceived as defective, inadequate, deprived, worthless, and undesirable. The world appears as a negative, demanding, and defeating place, and one expects failure and punishment, continued hardship, deprivation, and failure in the future. Underlying the negative conditions are stable cognitive structures, called schemas, that include core beliefs or assumptions through which one interprets experience. Schemas associated with depression are analogous to viewing the world through dark glasses (e.g., the core belief that one is unlovable). Cognitive errors, or systematic errors in thinking, allow the persistence of negative schemas despite contradictory evidence. A cognitive error frequently associated with depression is dichotomous thinking, the tendency to view one's experiences as black or white without shades of gray or to believe that people are either all bad or all good. Symptoms of depression follow from the cognitive error. For example, apathy and low energy result from the individual's expectation of failure in all areas. Similarly, a paralysis of will stems from the individual's pessimism and feeling of hopelessness.

Goals The goal of cognitive-behavioral therapy is to change the way a person thinks and, subsequently, to alleviate the depressive syndrome and prevent its recurrence. This is accomplished by helping the patient (1) identify the test negative conditions; (2) develop alternative, more flexible schemas, and (3) rehearse both new cognitive and new behavioral responses.

General Considerations Cognitive-behavioral therapy is a short-term, structured therapy that involves active collaboration between the patient and therapist in achieving set goals. It is oriented toward current problems and their resolution. Therapy is usually conducted on an individual basis, although group techniques have been developed and tested. Cognitive-behavioral therapy may be used in conjunction with pharmacotherapy.

Strategies and Techniques As with other psychotherapies, the attributes of the therapist are fundamental to successful cognitive-behavioral therapy. Therapists must be empathetic, able to understand the life experience of each patient, and capable of being genuine and honest with themselves and their patients. Therapists also must be able to relate skillfully to patients in their own experiential world in an interactive way. As a highly structured therapeutic approach, cognitive-behavioral therapy involves setting the agenda at the beginning of each session, assigning homework to be performed between sessions and teaching specific new skills. The active collaboration between the therapist and the patient provides a genuine sense of teamwork.

Cognitive-behavioral therapy has three basic components: didactic aspects, cognitive techniques, and behavioral techniques (Table 14.9-4).

Didactic issues
Learning rationale and strategy of the therapy
Cognitive techniques
Eliciting automatic thoughts
Testing automatic thoughts
Identifying maladaptive underlying assumptions
Analyzing validity of maladaptive assumptions
Behavioral techniques
Scheduling activities
Mastering activities
Graded task assignment
Cognitive rehearsal
Self-reliance training
Role playing
Diversion techniques

Table 14.9-4 Components of Cognitive-Behavioral Therapy

Didactic Aspects The didactic aspects include explaining the cognitive triad, schemas, and faulty logic to the patient. The therapist tells the patient that they will formulate hypotheses together and test them over the course of treatment. The therapist presents a full explanation of the relation between depression and thinking, affect, and behavior as well as the rationale for all aspects of the treatment. This contrasts with the more psychoanalytically oriented therapies, which involve little explanation.

Cognitive Techniques The cognitive approach has four strategies: eliciting automatic thoughts, testing automatic thoughts, identifying maladaptive underlying assumptions, and testing the validity of maladaptive assumptions.

ELICITING AUTOMATIC THOUGHTS Automatic thoughts are cognitions that intervene between external events and the individual's emotional reaction to the event. For example, a man invited to go bowling may think, negatively, “everyone is going to laugh at me when they see how badly I bowl,” before he actually bowls with this group of people. Another example is when a woman thinks “that person doesn't like me” if someone passes her in the hall without saying hello.

TESTING AUTOMATIC THOUGHTS The therapist, acting as teacher, helps the patient test the validity of the automatic thought. The goal is to encourage the patient to formulate alternative possible interpretations and reject inaccurate or exaggerated automatic thoughts, after carefully examining them. For example, patients often set unrealistic expectations for themselves, then blame themselves when they cannot live up to these expectations.

A 32-year-old depressed computer programmer had self-denigrating thoughts about his ability to complete homework assignments.

Patient: I don't know what's been wrong with me this week. I just don't seem to be as interested in doing my homework assignments. I don't know if I'm ever going to get better.

Therapist: Can you think of a specific time this week that you had problems doing homework because of disinterest?

Patient: Yes, on Thursday I tried to do my relaxation exercises, but I eventually gave up.

Therapist: Can you tell me what you were thinking at the time?

Patient: Well, I started doing my breathing, but I couldn't calm my thoughts and stop thinking about other things, like the instructions in the manual said. Then I started thinking about how long I've been working on this and how I should know how to do it by now.

Therapist: And how long have you been working on the breathing technique?

Patient: Uh, one week.

Therapist: Let's review the evidence that supports your statement that you should be performing this exercise with no problem at this time.

In this example, when the patient and therapist carefully reviewed the situation, it became apparent that the patient's expectation that he should be able to perform this exercise perfectly after 1 week of practice was unreasonable. After considering that the ability to breathe and maintain calm thoughts is a skill that normally takes many weeks to perfect, the patient realized that his belief about his inability to learn was distorted and incorrect.

Generating alternative explanations is another technique used to undermine inaccurate and distorted automatic thoughts.

A 29-year-old secretary with a 2-year history of depression reported that she frequently felt sad and hurt at work because of the curt and gruff way her boss interacted with her. She reported an automatic thought following an interaction in which her boss stated “I wish things around here ran smoother.” “He doesn't like me. He doesn't think I'm doing a good job.” The therapist helped her generate a list of other interpretations of her employer's statement and behavior including the possibility that he interacted with all people this way, that he was a generally unhappy person, that he did not like his job and was allowing this unhappiness to influence how he interacted with the patient, and that he was preoccupied with personal problems that made him unhappy at work and inattentive to the way he interacted with his employees.

IDENTIFYING MALADAPTIVE ASSUMPTIONS As the patient and therapist continue to identify automatic thoughts, patterns usually become apparent that represent underlying rules or maladaptive general assumptions that guide the patient's life. Examples of such rules include, “To be happy, I must be perfect” or “If everyone doesn't like me, I'm not lovable.” Such rules inevitably lead to disappointment, failure, and subsequent depression.

ANALYZING MALADAPTIVE ASSUMPTIONS Testing the accuracy of maladaptive assumptions is similar to testing the validity of automatic thoughts. In one particularly effective technique the therapist asks the patient to defend the validity of an assumption.

Patient: I guess I believe that I should always work up to my potential.

Therapist: Why is that?

Patient: Otherwise I would be wasting time.

Therapist: What is the long-range goal in working up to your potential?

Patient: I've never really thought about that. I've just assumed that I should.

Therapist: Are there any positive things you give up by always having to work up to your potential?

Patient: I suppose it makes it hard to relax or take a vacation.

Therapist: What about living up to your potential to enjoy yourself and relax? Is that important at all?

Patient: I've never really thought of it that way.

Therapist: Maybe we can work on giving yourself permission not to work up to your potential at all times.

In this example, the therapist is helping the patient recognize how maladaptive it is to strive to work up to one's potential at all times.

Behavioral Techniques Behavioral techniques are used conjointly with cognitive techniques to test and change maladaptive or inaccurate cognitions, to help patients understand the inaccuracy of their cognitive assumptions and learn new strategies and ways of dealing with issues. A repertoire of behavioral techniques is used in cognitive-behavioral therapy.

1. Among the first things done is scheduling activities on an hourly basis. The patient keeps a record of these activities and reviews it with the therapist.
2. Patients are asked to rate their mastery of these activities and the pleasure derived from them. They are often surprised how much more mastery and pleasure they gain than they had believed.
3. To simplify the situation and allow miniaccomplishments, tasks are often subdivided into subtasks, as in graded task assignments, to show patients they can succeed.
4. In cognitive rehearsal the patient first imagines the various steps involved in meeting and mastering a challenge and then rehearses various aspects of them.
5. Self-reliance training involves encouraging patients to become more self reliant by doing such simple things as making their own beds, doing their own shopping, or preparing their own meals, rather than relying on other people.
6. Role playing, a particularly powerful and useful technique, is used to elicit automatic thoughts and learn new behaviors.
7. Diversion techniques help patients get through particularly difficult times by means of physical activity, social contact, work, play, or visual imagery.

The techniques used are highly structured and goal oriented and require active collaboration between the therapist and patient. Emphasis is on identifying maladaptive, inaccurate cognitions in various forms, seeking alternative explanations, and learning new behaviors to reverse the affective and drive disturbances and other associated features of depression and (it is hoped) help prevent their recurrence.

Efficacy Cognitive therapy has been studied extensively in the treatment of outpatients with major depressive disorder. Of 34 such reports, 9 included a pill placebo, waiting list, or nonspecific treatment as a control. In most studies, cognitive-behavioral therapy was superior to the control condition in reducing depressive symptoms. The one notable exception is the NIMH Treatment of Depression Collaborative Research Program, in which cognitive-behavioral therapy did not differ significantly from the placebo clinical management condition. Cognitive-behavioral therapy was found to be superior to pharmacotherapy alone in two studies conducted in the 1970s. In three more-recent studies, including the Treatment of Depression Collaborative Research Program, there were no differences in efficacy between antidepressant medication and cognitive behavioral therapy. However, in the NIMH study, imipramine (Tofranil) was significantly more effective than cognitive-behavioral therapy for more severely depressed and impaired patients. In six studies that compared cognitive-behavior therapy alone with that therapy plus

pharmacotherapy, five found no differences between the two outcomes and one found the combined treatment superior to cognitive-behavioral therapy alone.

BEHAVIORAL APPROACHES

Theoretical Concepts Although a number of behavioral approaches to depression exist, each with somewhat different theoretical assumptions and specific treatment methods, they have a common source in the work of B. F. Skinner, who incorporated the principles of classical and operant conditioning in an empirical analysis of behavior. Skinner's research provides the basic framework, methodology, and assumptions for current behavioral theories and their clinical applications. Application of that model to complex human behavior led some theorists to expand the framework. For example, social learning theory includes cognitive phenomena, such as emphasizing the role of subjective expectations and value in reinforcement. Although interested in the role of cognition, behavioral theorists assume that cognitions follow the same laws of learning followed by more-observable behavioral events and, while related, do not determine behavior in a causal sense. This assumption distinguishes behavioral approaches from the cognitive-behavioral approach described below. Despite some differences in focus, behavioral therapies are commonly characterized by an emphasis on (1) the links between an observable or operationally definable behavior and the conditions that control or determine it and (2) the role of rewards or reinforcement in determining behavioral change.

The behavioral approach was first applied to depression in 1965 by Charles B. Ferster, who proposed that depression is caused by a person's loss of positive reinforcement (e.g., through separation, death, or sudden environmental change), which results in reduction of the entire behavioral repertoire, depressed behavior, and dysphoric feelings. That concept of depression is central to all behavioral approaches. A change in the rate of reinforcement is believed to be a key factor in generating and maintaining depression (through lack of available reinforcers or when the available reinforcers are not contingent on the person's behavior) and also reversing it. Ferster also proposed that a social skills deficit—characterized by difficulty in obtaining social reinforcement—might increase a person's difficulty in coping with the loss of the usual supply of reinforcement.

Goals The goals of the behavior therapies are to increase the frequency of the patient's positively reinforcing interactions with the environment and decrease the number of negative interactions. Some behavioral treatments aim also at improving social skills. Alteration of personal behavior is believed to be the most effective way to change the associated depressed thoughts and feelings.

At this time behavioral approaches have been incorporated into cognitive approaches to the treatment of depression. An exception to this is the Coping with Depression Course developed by Peter Lewinsohn and colleagues at the University of Oregon, which encourages increasing the number of pleasurable events and improving social skills in a group format.

SELECTION OF TREATMENT APPROACH

The availability of several effective treatment approaches for the treatment of patients with depression means that the clinician must choose a treatment strategy for an individual patient with depression, which raises several questions. When is it appropriate to use these short-term psychotherapies as a sole treatment? Are there patients for whom the use of antidepressants, a less expensive treatment strategy, is equally or more beneficial? When is it warranted or advisable to use a combined-treatment approach including the use of psychotherapy and antidepressants simultaneously or sequentially? In addition, there is the question of whether the different types of psychotherapy might be more or less effective for different kinds of patients

A wealth of studies have examined the association between patient characteristics (including features characterizing the depression) and outcome within and across different psychotherapeutic and antidepressant treatments. Findings have often been inconsistent, but some themes have arisen that have important implications for treatment choice.

Who Should Receive Psychotherapy and Who Should Get Antidepressants? The psychotherapeutic treatment approaches described above were developed for use with outpatients with nonbipolar, nonpsychotic depressions. They were neither developed for nor intended for sole use of severely depressed inpatients or for patients with bipolar disorder depression, although evaluation of their use in combination with pharmacotherapy for such patients has begun.

Nonetheless, within the population of nonbipolar, nonpsychotic outpatients with major depressive disorder, the question of whether or not the use of psychotherapy alone can provide an outcome equal to that with antidepressants and if so, for which outpatients is a controversial subject. There is a long-standing clinical belief that antidepressants should be used for more severely depressed patients or for endogenous depressions. Findings regarding endogenous depression have been mixed, but most show that outpatients with endogenous depression (as defined by the Research Diagnostic Criteria) do not respond better to pharmacotherapy than to psychotherapy. Antidepressants are preferred for patients with melancholia marked by vegetative symptoms and psychomotor disturbances. Outpatients with major depressive disorder are characterized by a range of symptom severity and a range of impaired functioning associated with the depression. The NIMH Treatment of Depression Collaborative Research Program examined the efficacy of cognitive-behavioral therapy, interpersonal therapy, pharmacotherapy (imipramine plus clinical management), and pill placebo plus clinical management for more- and less-severely depressed outpatients with major depressive disorder. Severity was defined in two ways: one based on symptom severity and one based on symptoms and impaired functioning. For the patients with more-severe symptoms, interpersonal therapy was comparable to imipramine treatment, suggesting that interpersonal therapy may be an effective alternative treatment for patients who cannot or do not want to use medications. Imipramine treatment was superior to both psychotherapies for patients with more severely impaired functioning. Patients with less severe depression by both definitions showed no differences in response to the treatments, including placebo plus clinical management. Other studies examining the comparative efficacy of cognitive-behavioral therapy and antidepressants with more severely depressed patients (defined by symptom severity) have not found an advantage for pharmacotherapy. Such studies have not examined whether treatment differences exist for patients with more severely impaired functioning.

Choice of Psychotherapy Providing efficacious psychotherapy the treatment of depression requires trained clinicians in the various modalities. Whether different patients respond preferentially to specific forms of psychotherapy is important for several reasons, including the ability to provide more-efficient, targeted treatments as well as increasing the understanding of the mechanisms by which these treatments effect change. To date, studies examining predictors of treatment response to psychotherapy have been disappointingly inconsistent and inconclusive. Few studies have included more than one form of psychotherapy to allow examination of predictors of differential treatment response within the same study.

The NIMH study found significant interactions between treatment and pretreatment levels of social functioning and dysfunctional attitudes. Patients with relatively less impairment in social functioning responded better to interpersonal therapy than those with more impairment. Patients with lower levels of dysfunctional attitudes did better in cognitive-behavioral therapy than those with higher levels. Other studies have also shown that high scores on measures of dysfunctional attitudes predict a poorer outcome in cognitive-behavioral therapy although one study reported no association. Together these findings suggest that patients may require a minimal level of proficiency in the area of functioning that the treatment targets to benefit from the treatment, at least in the short term.

In general, the more severe the dysfunctional attitudes, the poorer the response to cognitive-behavioral therapy. Since this therapy theoretically and practically focuses on identification and reversal of negative cognitions about oneself, the world, and the future, one would expect that patients with dysfunctional attitudes would profit most from this specific therapy. Most of the studies support just the opposite conclusion. One study did find that a negative life event (e.g., divorce, or death of a loved one) mitigated this association and rendered severity of dysfunctional beliefs nonpredictive.

The beliefs and expectations of the patient regarding depression and treatment should also be considered. Some patients who consider depression to be a psychological disorder that should be amenable to psychotherapeutic approaches are resistant to using medication. Others consider their depression to be a biochemical disturbance that will require medication to be corrected, not psychotherapy. A good therapist may be able to modify such expectations when necessary, but a positive attitude toward treatment on the part of the patient may be significantly important to a successful outcome.

In general, the therapist should be cautious in making attributions about premorbid personality problems during the depressed phase. Many interpersonal and cognitive styles may appear different to the patient and the therapist after the acute phase of the disorder has been alleviated. Nonetheless, several studies have found that the presence of a personality disorder is associated with a slower or generally worse response to treatment. For depression, such patients are likely to need longer periods of treatment.

Role of Biological Measures Evidence is mounting that depressions associated with biological abnormalities respond less well to psychotherapy. In a study of patients with recurrent major depression, 50 patients had normal sleep profiles and 41 had abnormal profiles (in terms of sleep efficiency, rapid eye movement [REM] latency, and REM density). All patients received short-term interpersonal therapy. Those with abnormal sleep profiles responded significantly more poorly than those with normal sleep profiles, and most nonresponders responded to subsequent pharmacotherapy. In a study of unmedicated inpatients with major depressive disorder,

those with abnormally high hypothalamic-pituitary-adrenocortical activity were less responsive to cognitive-behavioral therapy than those with normal hypothalamic-pituitary-adrenocortical activity. Other investigations focused on sleep abnormalities. Reduced REM sleep latency was associated with a poor response to placebo and a favorable response to antidepressants; studies examining reduced REM latency and psychotherapy response have not shown it to predict a poorer response. Michael Thase and colleagues studied a composite measure of sleep abnormality, including REM latency, REM density, and sleep efficiency, and its association with response to cognitive-behavioral therapy or interpersonal therapy. Patients with an abnormal sleep profile have a poorer response to both forms of psychotherapy. These patients were also more likely to have recurrent episodes of depression. The abnormal sleep profiles were not simply markers of depression severity.

Some other patient characteristics have been found to predict response across treatments in general. Longer duration of the current episode and the diagnosis of dysthymic disorder prior to the onset of the major depressive disorder (double depression) predict a poorer response; higher expectations of improvement are associated with better outcomes with different forms of treatment.

Combined Pharmacotherapy and Psychotherapy When should patients be treated with a combination of psychotherapy and pharmacotherapy? Clinical practice commonly provides both forms of treatment; the rationale is that the antidepressant medication is most effective for such vegetative symptoms as sleep disturbance, appetite disturbance, and anhedonia, while psychotherapy improves marital and family relationships, social functioning, and occupational performance. The empirical evidence supporting this belief is minimal.

Nonetheless, is combined treatment more efficacious than either treatment modality alone? Is there a subgroup of patients for whom combined treatment may be more efficacious? Is combined therapy of more benefit when a broader range of outcome measures (e.g., different aspects of functioning, time to remission, prophylactic effects) is considered? Numerous studies have compared combined treatment with single-modality treatment; sometimes pharmacotherapy alone, sometimes psychotherapy alone, and sometimes both single modalities in the same study. The results of such studies have been inconsistent but, more often than not, have shown no clear advantage to the use of combined treatment over a single modality. Results from a meta-analysis showed a modest advantage of combined treatment. More recently, data from several treatment studies of nonbipolar, nonpsychotic, major depressive disorder, using similar assessment and standardized treatment protocols, were combined in a meta-analysis of original data from the same institution, which yielded a much larger sample than previously studied. The single-modality psychotherapy protocols included either cognitive-behavioral therapy or interpersonal therapy; the combined modality was interpersonal therapy plus antidepressant pharmacotherapy. Combined treatment was not significantly more effective in the milder (less severe symptoms) depressions; however, among patients with more-severe and recurrent depressions, combined treatment was of highly significant advantage.

Thus, while no clear, definitive answers exist, evidence is accumulating that patients with milder depressions may be offered psychotherapy first. Patients with more-severe symptoms and more seriously impaired functioning should receive treatment that includes an antidepressant. Biological measures, including indicators of hypothalamic-pituitary-adrenocortical axis abnormality and sleep abnormalities, hold promise as indicators of differential treatment assignment but unfortunately are not feasible for use in most clinical settings currently. The research on combined treatment to date has focused primarily on acute-phase treatment and on simultaneous administration of both forms of treatment. The strategy of combining psychotherapy and pharmacotherapy in sequenced treatments remains to be examined. For more severe depression characterized by impaired ability to think and concentrate, for example, it may make sense to begin treatment with antidepressant treatment, adding psychotherapy when cognitive functioning and energy levels improve.

PHASE OF ILLNESS

Nearly all studies of psychosocial treatments for depression have focused on the acute phase of treatment; that is, they have tested the performance of a specific psychotherapeutic approach in resolving depressive symptoms within 12 to 16 weeks. These studies have generated considerable evidence of the efficacy of interpersonal therapy, cognitive-behavioral therapy, and behavioral therapy in certain groups of patients during this period. However, an episode of depression does not necessarily end when the acute symptoms have abated. In fact, symptoms may relapse if treatment is discontinued too soon after their initial control; presumably because the short-term treatment (especially pharmacotherapy) has not cured the illness but ameliorated or reduced the symptoms temporarily. This situation is analogous to the effect of insulin on diabetes mellitus. Depression is now recognized as recurrent and often chronic; therefore, withdrawal of the treatment may result in return of the illness.

An important consequence of our recognition of the long-term nature of the illness is the need for treatment beyond the acute phase, into the continuation and maintenance phases. Continuation treatment is the ongoing treatment from the point of clinical remission to the point at which spontaneous remission is expected in untreated patients (i.e., to the putative true end of an untreated episode). For depression, the continuation phase in pharmacological treatments generally lasts approximately 6 to 9 months following acute treatment. Maintenance treatment is longer term and is intended to prevent future depressive episodes or decrease their intensity. The model for psychotherapeutic treatments, in contrast, is that the strategies and techniques change maladaptive patterns that are linked to depression and thus should reduce the risk for future episodes or symptoms of depression. Do short-term psychotherapies confer a prophylactic effect in the future? Following a positive response, is it helpful to continue the treatments into the continuation and maintenance phases?

Prophylactic Effect of Short-Term Therapies Follow-up studies of patients responding positively to short-term treatment for depression have attempted to determine whether treatment offers long-term prophylactic effects.

For interpersonal therapy, one study reported no difference in relapse or recurrence at 1-year follow-up among patients in a 16-week clinical trial who were treated with interpersonal therapy, amitriptyline, amitriptyline plus interpersonal therapy, or nonscheduled treatment. However, patients treated with interpersonal therapy had better social functioning at a 1-year reevaluation point. Most follow-up studies have examined relapse rates in patients successfully treated with cognitive therapy or antidepressant medication. These studies have shown a clear pattern of lower relapse rates for patients treated with cognitive-behavioral therapy than for those treated with short-term pharmacotherapy. However, the naturalistic designs of these studies precludes conclusions regarding the reasons for the difference (i.e., did the results represent enduring effects of the cognitive therapy or differences in risk for relapse between patients who respond to drugs and those who respond to psychotherapy). The question of what aspects of cognitive-behavioral therapy (specifically, behavioral activation, automatic thought modification and change of core beliefs) might be responsible for the lower relapse rates that have been observed was examined in a study providing one, two, or all three components and assessing outcome over 2 years.

Despite finding that cognitive behavioral therapy decreases symptoms and possibly lowers relapse rates, the perceived success of both psychotherapy and pharmacological treatments depends on how outcome is defined. When outcome is defined as complete remission of symptoms and maintenance of symptom-free remission for an extended period following treatment, 12 to 16 weeks of treatment (with psychotherapy or pharmacotherapy) is insufficient for most patients with major depression. The NIMH Treatment of Depression Collaborative Research Program reported the proportion of all patients starting treatment who achieved complete remission (at least 8 weeks without symptoms) at the end of treatment and maintained remission for 18 months: 30 percent of patients receiving cognitive-behavioral therapy, 26 percent of those receiving interpersonal therapy and 19 percent of those receiving placebo with clinical management. Another study of cognitive-behavioral therapy with a 2-year follow-up similarly reported that 25 percent of patients recovered and remained in remission. Considering optimal outcome highlights the need for longer treatment for full recovery as well as the need for continuation and maintenance treatments.

Treatment During the Continuation Phase Does continued treatment after successive resolution of symptoms help prevent relapses and recurrences? This clinically important question has received some attention in recent years for cognitive-behavioral therapy. In one study 42 subjects who received short-term therapy were followed for 1 year. At 3 months into the follow-up study, half of those who responded to treatment were given additional treatment (booster sessions) until completion of the study while the other half of the responder group received no additional treatment. The authors found no difference in relapse rates or depressive symptoms between the two groups at 1 year, suggesting that continued treatment with cognitive therapy after successful resolution of symptoms does not improve outcome. However, this is a single study, and further research is needed. There are no studies on the use of interpersonal or behavior therapy in the continuation phase. Another effectiveness study examined whether providing cognitive-behavioral therapy following successful antidepressant treatment of recurrent major depressive disorder reduced relapse rates. Cognitive-behavioral therapy reduced residual symptoms following drug discontinuation and reduced relapse rates over 2 years compared with clinical management.

Treatment During the Maintenance Phase Does therapy continued a year or more after successive treatment help prevent the occurrence of new episodes? In a landmark study by Ellen Frank and colleagues, 128 patients with recurrent major depressive disorder who had responded to a combined short-term and continuation treatment of imipramine and interpersonal therapy were randomly assigned to different maintenance treatment groups. The results strongly support long-term, continued treatment (especially pharmacotherapy) in patients with a history of recurrent episodes of depression. Some evidence indicates that long-term treatment is useful in delaying or preventing recurrences in patients with recurrent depression. However, the value of continuation and maintenance treatment with psychotherapy

awaits further research.

DYSTHYMIC DISORDER AND CHRONICITY

Most of our knowledge on the treatment of depression comes from the study of patients with acute major depression, and far less is known about the treatment of chronic depression. This is unfortunate, given the prevalence of dysthymic disorder. Over 3 percent of adults in the United States suffer from dysthymic disorder during any 6-month period, according to the Epidemiologic Catchment Area (ECA). In addition, approximately one-third of psychiatric outpatients suffer from dysthymic disorder. Nearly one in five patients with a major depressive episode fails to recover and becomes chronically depressed.

The importance and potential usefulness of psychosocial treatments for such patients is demonstrated by (1) the notable morbidity and impaired quality of life associated with dysthymic disorder, which exceeds that associated with most medical illnesses; (2) the fact that a substantial proportion of patients with dysthymic disorder either fail to respond to medication or cannot tolerate the adverse effects; and (3) with or without medication, the long-standing patterns of social withdrawal, lack of assertiveness, impaired family, marital, and occupational functioning, and chronic pessimism and hopelessness associated with dysthymic disorder need to be addressed. When depression is severe, pharmacological treatments are encouraged to alleviate suffering and increase the patient's ability to engage in the therapy. There are no controlled studies of the effectiveness of this treatment approach; however, two naturalistic follow-up studies have suggested that long-term analytic therapy can have long-term benefits.

More-recent developments in the treatment of dysthymic disorder include modification of psychotherapeutic approaches specifically for the treatment of dysthymic disorder as well as preliminary open-trial studies investigating their effectiveness. The chronic interpersonal and social deficits associated with dysthymic disorder provide a strong rationale for the use of interpersonal therapy with dysthymic patients, and a manual was recently developed. Aspects of dysthymic disorder that distinguish it from acute depression and require modification of interpersonal therapy include the lack of an acute precipitant, the characterological features often associated with the presence of a chronic mood disorder (e.g., paucity of interpersonal relationships, lack of self-assertion, poor social skills), and the lack of euthymic memories. Given the typical absence of an acute precipitant in dysthymic disorder, choosing a focus of treatment becomes more difficult. While all four interpersonal therapy problem areas occur in dysthymic patients, their frequency as a primary focus differs from that in acute depression. Grief is rarely the primary focus, interpersonal deficits more frequently are. The frequent absence of interpersonal relationships in the patient's life requires increased focus on the therapeutic relationship, which is used as a model for other interpersonal interactions.

Participation in activities is used to examine social behaviors, expectations, and desires. Relationships that do exist are often unsatisfactory because of the difficulty these individuals have in asserting themselves, expressing anger, or setting limits. Interpersonal therapy for these patients emphasizes exploring what the patient desires from the relationships and what options are available to alter the relationships. The patient is helped to begin to identify personal needs, assert them, and set limits. The expression of anger is encouraged and supported. Preliminary support for the use of interpersonal therapy for dysthymic disorder was provided by a nonrandomized pilot study of 19 patients treated with interpersonal therapy, desipramine (Norpramin), or both.

Cognitive-behavioral therapy was adapted for patients with dysthymic disorder by James McCullough. This modification was piloted in an open study of 10 patients, 9 of whom improved substantially and sustained their remissions for 2 years. The goal of the therapy is to teach the patient to accept total responsibility for the depression and to achieve and maintain mood control by enacting adaptive daily-living strategies. The approach, cognitive-behavior therapy for the chronic depression is being tested in a multicenter random-assignment study of it and nefazodone (Serzone) alone or in combination in a sample of patients with chronic and double depression.

PSYCHOSOCIAL TREATMENT OF BIPOLAR DISORDER

The clinical and research literature on major depressive disorder is replete with both psychotherapeutic and psychopharmacological approaches. In sharp contrast, the literature on treatment of bipolar disorders focuses almost exclusively on psychopharmacology, specifically on the use of lithium (Eskalith) as the treatment of choice. The introduction of lithium has influenced the diagnostic system, clinical practice, and the therapeutic outcome of patients with bipolar disorders for 20 years. It is as close to a wonder drug as has been experienced in psychiatry.

However, lithium is far from a cure for bipolar disorders; about one-third of patients either do not respond or respond only partially. Even for those who respond fully, many serious social, occupational, familial, and marital problems often remain.

Psychological and behavioral problems are frequently associated with bipolar disorders, and alcohol and substance abuse, violence, and suicide can result from inadequate treatment. Psychotherapeutic interventions may be particularly relevant for these problems.

Another major rationale for adjunctive psychotherapy is to improve medication compliance. An estimated 20 to 50 percent of patients with bipolar disorders who are on a prescribed medication regimen either do not comply fully with their doctor's instructions or discontinue treatment altogether. Physical adverse effects and the psychological unwillingness to take pills add to the noncompliance problem. Lithium noncompliance or discontinuation increases relapse. Psychotherapy combined with lithium may increase medication compliance and yield a better clinical outcome.

Adjunctive psychotherapy can also provide important educational benefits. It can help the patient and family members learn to identify early warnings of impending mania so that more-rapid interventions can occur and to identify problems that exacerbate or precipitate episodes.

Little has been written about psychotherapeutic approaches to bipolar disorders since the report of 12 cases by Mabel Blake Cohen in 1954. In recent years, however, several approaches have been developed for psychosocial and psychotherapeutic treatment of bipolar disorders. Unfortunately no empirical research has been published on the efficacy of these approaches, but they are sufficiently important that a description of each is included here. These short-term, outpatient interventions, were inspired by the well-documented success of similar programs used with schizophrenia patients.

Miklowitz and Goldstein The treatment package developed by David J. Miklowitz and Michael J. Goldstein is based on behavioral family-management techniques. Based on the premise that the family attributes considered important in predicting the course of schizophrenia are also associated with the course of bipolar disorders, the program focuses on educating the family about bipolar disorders and aiding in the development of communication and problem-solving skills. This approach (like all psychosocial approaches for bipolar disorders) is not intended to substitute for a traditional medication regimen but to be adjunctive therapy. The program for patients recently discharged after an episode of hypermania includes 21 1-hour sessions conducted in the patient's home over a 9-month period. They include seven sessions dealing with family education, seven on communication-skills training, and seven on problem-solving skills training. In a pilot trial with nine patients, only one patient relapsed over the 9 months during which treatment was implemented. In comparison, a 61 percent relapse rate was reported from a naturalistic outcome study using traditional medication regimens without family management.

Basco and Rush The treatment package developed by Monica R. Basco and A. John Rush is designed around four goals: (1) educating the patient about bipolar disorder; (2) teaching cognitive-behavioral skills for coping with the psychosocial stressors and cognitive and behavioral problems associated with manic and depressive symptoms; (3) facilitating compliance with a prescribed medication regimen; and (4) monitoring the occurrence, severity, and course of manic and depressive symptoms. The protocol is divided into three phases. The first phase, consisting of 1-hour sessions, once a week for 5 weeks, teaches the patient about the causes, systems, and treatment of bipolar disorder. The second phase, which teaches cognitive-behavioral skills, consists of weekly sessions lasting approximately 75 to 90 minutes. The third phase, maintenance, provides an opportunity to monitor the patient's symptoms, reinforce skills, and facilitate medication compliance. This final phase is held in 1-hour sessions no less than once a month and no more than four times a month.

The treatment protocol is highly structured. Each session covers one component of the treatment package and includes (1) a summary of the intention and direction of the session, (2) background information about the intervention technique, (3) goals of the session, (4) a step-by-step description of the intervention procedures, and (5) a homework assignment to reinforce what was learned in the session or prepare for the next session.

Investigators have developed and are currently studying the effectiveness of an adaptation of interpersonal therapy disorder for bipolar patients, called social rhythm interpersonal psychotherapy. Interpersonal interventions are integrated with a structured focus on stabilizing daily activities, including sleep, eating, work, and interpersonal interactions. This treatment is being examined in the acute and maintenance treatment of bipolar disorder patients.

SUGGESTED CROSS-REFERENCES

Information regarding related aspects of mood disorders are discussed further in the other sections of Chapter 14, Chapter 30 on psychotherapies also outlines behavioral and cognitive therapies and other psychosocial treatments. Psychiatric treatments of adolescents are reviewed in Chapter 48, and treatments in the elderly population are included in Section 51.4. Application of psychosocial treatment to schizophrenia may be found in Section 12.9.

CHAPTER 15. ANXIETY DISORDERS

15.1 ANXIETY DISORDERS: INTRODUCTION AND OVERVIEW

JACK M. GORMAN, M.D.

Anxiety disorders are among the most prevalent psychiatric condition in the United States and in most other populations studied. Further, studies have persistently shown that they produce inordinate morbidity, utilization of health care services, and functional impairment. Recent studies also suggest that chronic anxiety disorder may increase the rate of cardiovascular-related mortality. Hence, clinicians in psychiatry and other specialities must make the proper anxiety disorder diagnosis rapidly and initiate treatment.

From a neurobiological perspective, study of anxiety disorders is now seen as compelling. Although validation of animal models of many psychiatric disorders, including depressive disorders, eating disorders, bipolar disorders, and schizophrenia is difficult, constructing animal models of fear and anxiety that appear relevant to human psychopathological states is relatively straightforward. This tool for understanding the neuroanatomy and molecular biology of anxiety promises new insights into etiology and more specific (and thus more effective) treatments in the next decade.

At the same time, the treatments currently available for anxiety disorders are among the most effective in clinical medicine. Pharmacological, cognitive-behavioral, and psychodynamic approaches have all proved useful in combating anxiety disorder. For many conditions (e.g., panic disorder), most patients should expect substantial relief from their symptoms in a relatively brief period.

Another fascinating aspect of anxiety disorders is the exquisite interplay of genetic and experiential factors. While there is little doubt that abnormal genes predispose to pathological anxiety states, evidence clearly indicates that traumatic life events and stress are also etiologically important. Study of the anxiety disorders thus presents a unique opportunity to understand the relation between nature and nurture. This arena should show little regard for purely biological versus psychological explanations about pathogenesis or therapeutics. Rather, anxiety disorder research aims at presenting a view of human function under pathological conditions that integrates multiple sources of theory and information.

The sections that follow review progress in our understanding of panic disorder with and without agoraphobia, social phobia, generalized anxiety disorder, specific phobia, and posttraumatic stress disorder. Each section is intended to provide an up-to-date assessment of the field at the time of its writing.

EPIDEMIOLOGY

Ewald Horwath and Myrna Weissman review epidemiological data and studies on the anxiety disorders. Few published studies have appeared that specifically use the fourth edition of *Diagnostic and Statistical Manual of Mental Disorder* (DSM-IV) criteria; hence, most studies of interest involve the older third edition of DSM. Third edition of DSM (DSM-III) and revised third edition (DSM-III-R) criteria sets. This is not expected to make a substantial difference because most changes from DSM-III to DSM-IV have been relatively minor. The data presented demonstrate that anxiety disorders are highly prevalent and that rates of illness are fairly uniform across cultures. In most cases, women are more likely to have anxiety disorder than men, a phenomenon that still begs for adequate explanation. Of particular interest is the finding that social phobia is more common in women than men. Early textbooks gave the opposite view, but that turned out to be a mistake based on overgeneralization of populations seeking treatment rather than community-based studies. While women are about twice as likely to have social phobia as men, men appear more likely to seek treatment. One might speculate that as more women enter the workforce and assume performance roles, they will increasingly find that social phobia symptoms interfere with career success and seek treatment at higher rates.

Horwath and Weissman argue that the data do not substantiate that agoraphobia without panic attacks is nearly as common as an initial glance at available epidemiological studies might suggest. Rather, follow-up studies indicate that panic attacks were missed in such patients or that they actually suffer from other phobic disorders. This remains controversial, and the primacy of the panic attack in leading to agoraphobia remains a subject of investigation (using DSM-IV criteria in the future, one hopes).

CLINICAL FEATURES

The phenomenology of anxiety disorders is reviewed extensively by Daniel Pine. Here, the DSM-IV criteria are used. Some of the differences between DSM-IV and earlier versions are interesting. For example, no longer is a specific number of panic attacks necessary in a specific period of time to meet criteria for panic disorder. Rather, the attacks must be recurrent and at least one attack must be followed by at least 1 month of anticipatory anxiety or phobic avoidance. This recognizes for the first time that although the panic attack is obviously the seminal event for diagnosing panic disorder, the syndrome involves a number of disturbances that go beyond the attack itself. Furthermore, isolated panic attacks without functional disturbance are not uncommon, occurring in approximately 15 percent of the population.

Social phobia has received increasing research and clinical attention in recent years. It is now clear that this condition is not uncommon and that it significantly impairs work and social function. Social phobia is also associated with high rates of substance abuse and, like all anxiety disorders, with depression. One challenge is deciding where to draw the line between social phobia and performance anxiety. Rates of speech phobia may exceed 50 percent in the population, but it is unclear whether such fear and avoidance of public speaking warrants a psychiatric diagnosis and what the appropriate clinical approach should be. On the other hand, generalized social phobia is clearly a serious condition that warrants clinical attention.

Pine notes significant alteration in criteria for posttraumatic stress disorder between DSM-III-R and DSM-IV. The criteria for the earlier version suggest that anyone exposed to particular traumatic events would be expected to develop posttraumatic stress disorder. Furthermore, the qualifying traumas were considered “outside of the range of ordinary human experience.” Two things changed this view. First, clearly fairly ordinary traumatic events can produce posttraumatic stress disorder and there is no adequate definition of “outside the range of ordinary human experience.” Second, only a subset of people exposed to the same traumatic event actually develop posttraumatic stress disorder. The number of previous traumatic events, the severity of the events, and certain precipitating factors such as previous psychiatric illness all seem to increase the likelihood that an individual exposed to severe traumatic stress will actually develop posttraumatic stress disorder. Hence, the DSM-IV criteria make no statement about the commonality of the required traumatic events but stipulate that they must involve a threat of death or physical injury.

What has emerged is a clear picture of separate anxiety syndromes under the rubric of anxiety disorder. These can be reliably diagnosed, but clearly substantial comorbidity exists among them, and each is frequently complicated by depression and substance abuse. Increasingly, investigators are attempting to define common denominators among the mood and anxiety disorders and to discern whether certain childhood conditions specifically predispose to any adult disorders.

GENETICS

Many studies have shown that anxiety disorders tend to run in families. For most medical conditions, this would suffice to conclude that abnormal genes must be etiologically relevant. However, it is not difficult to conceive that growing up with anxious parents or siblings might influence the development of anxiety in any individual. Therefore, family studies are only leads that prompt genetic investigators to attempt to determine whether any anxiety disorders are indeed inherited.

Abby Fyer accomplishes two things in her chapter on genetic aspects of anxiety disorders. First, she instructs the reader about the current techniques used to attempt to disentangle genetic and environmental influences for anxiety disorders. Then she reviews several types of studies that have already been published. What

emerges is a clear picture that genetics has something to do with anxiety disorders but that no anxiety disorder is likely to be the result of a simple Mendelian abnormality. That is, there probably is no specific “gene” for panic disorder or social phobia or generalized anxiety disorder. Fyer's review indicates that what is inheritable is a susceptibility to develop anxiety disorder. It is not even entirely clear at this point whether this susceptibility predisposes to the development of a specific anxiety disorder e.g., panic) or to any one of the anxiety disorders. Further, it is not entirely clear to what extent these genetic influences overlap between susceptibility to anxiety disorder and to depression.

One compelling hypothesis is that individuals inherit a temperament like shyness, hyperactive autonomic nervous system responses, or behavioral inhibition. Then, depending on a variety of life circumstances, these genotypes are expressed as specific phenotypes—one or more of the anxiety disorders themselves. It may also be that more powerful “anxiety genes” require less environmental stress to be expressed.

Modern understanding of molecular genetics makes the above notion entirely plausible. Although the actual genes an individual receives cannot be altered by experience, most genes are only variably expressed. Every cell in the human body contains all of the approximately 100,000 genes in the human genome. A liver cell, for example, has all the same genes as a neuron in the brain's frontal cortex, but the liver cell does not sprout axons and dendrites or generate neural impulses. The genes for these functions are not expressed in the liver cell. Clearly a variety of environmental influences activate latent genes through complex biochemical process, and these operate in the central nervous system. Hence, it is likely that genetic susceptibility to an anxiety disorder becomes an actual anxiety disorder when some set of environmental influences causes anxiety proneness genes to become active.

NEUROBIOLOGY

Attempts are now being made to link the extensive data on the biology of the fear response in animals to observations in humans with anxiety disorder. Two interesting leads are provided from the preclinical literature. First, conditioned fear in animals depends absolutely on normal function of the central nucleus of the amygdala (CNA). This work, pioneered by neurobiologists such as Joseph LeDoux, Trevor Robbins, and Michael Davis, has elegantly shown that afferent projections from the CNA during fear reactions in animals activate autonomic nervous system centers of the brain that reproduce most of the behavioral and physiological manifestations of the acute anxiety response. Second, studies in rodents and nonhuman primates indicate that early separation distress changes function of the hypothalamic-pituitary-adrenal axis that endures throughout the life span of the affected animal.

Gregory Sullivan and Jeremy Coplan review what is now known about the neurobiology of human anxiety. Studies in panic and posttraumatic stress disorders are now extensive. Since the original finding that sodium lactate infusion can induce panic attacks in patients with panic disorder, many substances have shown similar panicogenic properties including the noradrenergic stimulant yohimbine (Yocon), carbon dioxide, the respiratory stimulant doxapram (Dopram), and cholecystokinin. Disordered serotonergic, noradrenergic, and respiratory systems are clearly implicated in panic disorder, and the condition appears to be caused both by a genetic predisposition and traumatic separation distress. More recently, neuroimaging studies revealed that patients with panic disorder have abnormally brisk cerebral vascular responses to stress, showing greater vasoconstriction during hypocapnic respiration than normal controls.

Studies of patients with posttraumatic stress disorder have revealed a downregulated hypothalamic-pituitary-adrenal axis with reduced secretion of cortisol, presumably a result of chronically increased production of corticotropin releasing factor. Studies also suggest that the hippocampus may show neuronal degeneration in patients with posttraumatic stress disorder, probably as a result of increased central glucocorticoid effects. Because the hippocampus is critical for memory function, this could explain any loss of memory for the original traumatic event in these patients.

To date, there is no coherent biology for social phobia. Generalized anxiety disorder has also been inadequately studied, with most interest focused to date on possible abnormalities in the central benzodiazepine receptor and its associated site for binding of the inhibitory neurotransmitter g-aminobutyric acid (GABA). Further research is needed into the biology of these two very common illnesses.

Overall, neurobiological studies, particularly with respect to panic disorder and posttraumatic stress disorder have elucidated a specific set of neurotransmitter and central nervous system abnormalities that can now be addressed with more-specific treatment approaches. For the first time, treatment research can finally be guided to some degree by an understanding of basic pathological mechanisms within the brain.

PSYCHODYNAMIC ASPECTS

Glen Gabbard provides a modern understanding of the psychodynamic aspects of anxiety disorder. One can only admire the insights he derives from Freud's seminal work on the subject, *Inhibitions, Symptoms, and Anxiety*. It is fascinating to recognize that some findings of current neurobiologists substantiate many of Freud's original ideas. For example, the existence of an unconscious memory system for anxiety responses is well substantiated by work demonstrating that the amygdala subserves the fear response without any reference to conscious memory. Gabbard shows the development of Freud's theories through subsequent psychodynamic writers, including Melanie Klein and Heinz Kohut, and demonstrates how psychodynamic concepts of anxiety disorder are indeed fully consonant with observations from neuroscience. For example, he points out that panic attacks may not be entirely “out of the blue” phenomena but are likely to be related to “meaningful stressors” in the patient's life. This view accords with modern ideas about fear conditioning. He also discusses childhood precusors to panic disorder, again finding much in common with preclinical scientists who show that early separation distress in infant animals produces an “anxiety prone” adult animal.

Similarly, in his discussion of phobias, Gabbard draws on the exciting work of Jerome Kagan and colleagues at Harvard University who have identified a state in young children called “behavioral inhibition to the unfamiliar.” This temperamental disposition can apparently be altered by a variety of powerful life experiences. This gives credence to the idea that psychodynamic treatments may be able to alter genetically mediated personality traits.

Although no controlled trials of psychodynamic therapy for anxiety disorders exist, only the rare psychiatrist does not use these techniques even when prescribing medication or using cognitive-behavioral therapy to treat anxiety disorder. When large scale studies are mounted to test the efficacy of psychodynamic treatments for anxiety disorders they are expected to reveal an effective treatment approach.

SOMATIC TREATMENT

Medication to treat anxiety is centuries old if one includes alcohol. As Laszlo Papp details, somatic treatments have gone through many incarnations. Until recently, most antianxiety medications were developed empirically rather than on the basis of known organic pathology. Benzodiazepines remain one of the most often prescribed class of drugs for anxiety, but whether they address any actual brain abnormality or work nonspecifically is not known.

One of the great challenges in prescribing medication to patients with anxiety disorder is their known sensitivity to even relatively minor adverse effects. Because anxious patients generally maintain fear of physical sensations, medication adverse effects are sometimes viewed catastrophically. Hence, as Papp discusses, most treatment should be started at relatively low doses of the selected medication, with slow titration to a fully therapeutic dose. On the other hand, evidence clearly shows that anxiety disorders are, in general, chronic illnesses that often require long-term therapy. Thus the medication selected must be well tolerated and safe even if the patient must continue to take it for a prolonged period to prevent relapse.

Antidepressant medication is increasingly seen as the medication treatment of choice for the anxiety disorders. More specifically, drugs with primary effects on the serotonin neurotransmission system have become first-line recommendations for panic disorder, social phobia, obsessive-compulsive disorder, and posttraumatic stress disorder. Evidence also now exists that such medications are also effective for generalized anxiety disorder. Although they generally take longer to work than benzodiazepines, the selective serotonin reuptake inhibitors such as fluoxetine (Prozac), sertraline (Zoloft), paroxetine (Paxil), fluvoxamine (Luvox), and citalopram (Celexa), as well as venlafaxine (Effexor) and nefazodone (Serzone) are probably more effective than benzodiazepines and easier to discontinue. Increasingly, benzodiazepines are used only for the temporary relief of extreme anxiety as clinician and patient wait for the effects of antidepressants to take hold. Longer-term administration of benzodiazepines is reserved for patients who do not respond to, or cannot tolerate, antidepressants. Monoamine oxidase inhibitors are given only to anxiety disorder patients who do not respond to trials with several medications.

Placebo-controlled trials leave little doubt, as Papp notes, that newer antidepressants are effective for anxiety disorders. Because they work fairly quickly and have fewer adverse effects than tricyclic drugs and monoamine oxidase inhibitors, a low threshold for prescribing them to anxious patients should be maintained. However, most clinicians believe that the best result for anxiety disorder patients comes with combination of medication with one or more types of psychotherapy.

COGNITIVE-BEHAVIORAL APPROACHES

One remarkable recent advance in therapeutics for anxiety disorders is the rigorous testing of cognitive and behavioral psychotherapies. Although many claim that it is difficult to submit psychosocial treatments to experimental investigation, scientists have developed the capacity to apply excellent research designs including randomization and blinded assessment to cognitive behavioral therapy. As Lawrence Welkowitz describes, the result has been documentation that cognitive-behavioral therapy is effective for most anxiety disorders.

A large number of studies have now shown that cognitive-behavioral therapy of various types is effective for panic disorder. The response rate after acute treatment is comparable to that achieved with tricyclic drugs or benzodiazepines. Furthermore, some, but not all, studies indicate that once a patient with panic disorder has completed this therapy, the response may be long-lived. Many different techniques are incorporated into standard cognitive-behavioral packages for panic disorder, including breathing retraining, deconditioning, cognitive restructuring, relaxation, exposure, and psychoeducation. It is not clear which among these is critical for favorable outcome. Studies are also needed to determine if some kind of maintenance, or booster, therapy would help prevent symptomatic relapse.

At least one group has shown that cognitive-behavioral therapy is effective for social phobia, and many studies have documented its benefits for obsessive-compulsive disorder. Studies also report favorable outcome with patients suffering from generalized anxiety disorder or posttraumatic stress disorder. These treatments may be given as first-line approaches to patients who refuse or cannot tolerate medication or in combination with medication. The latter approach may be particularly effective, but empirical justification for it is lacking.

Not only has cognitive-behavioral research provided another effective way to treat anxiety disorders, it has also heartened psychotherapists in general because it proves that one can demonstrate scientifically that psychotherapy works. This should be considered just as exciting a development as anything generated by the neuroscience community. One intriguing challenge for research will be understanding how the psychosocial treatments affect central nervous system processes. Indeed, some imaging studies already suggest that psychotherapy may alter abnormal patterns of brain activation, but much more work is required in this area.

SUGGESTED CROSS-REFERENCES

Chapter 1 covers the neural sciences, and Chapter 2 covers neuropsychiatry and behavioral neurology. The sections provided in this chapter should serve as a guide to research and treatment developments in the anxiety disorder field: Epidemiology of anxiety disorders is discussed in Section 15.2, biochemical aspects of anxiety disorders in Section 15.3, genetics of anxiety disorders in Section 15.4, psychodynamic aspects of anxiety disorders in Section 15.5, diagnosis and clinical features of anxiety disorders in Section 15.6, biological therapies for anxiety disorders in Section 15.7, and psychological therapies for anxiety disorders in Section 15.6. Chapter 46 covers anxiety disorders in children, and Section 51.3c discusses anxiety disorders in the elderly.

15.2 ANXIETY DISORDERS: EPIDEMIOLOGY

EWALD HORWATH, M.D., M.SC., AND MYRNA M. WEISSMAN, PH.D.

Anxiety has been recognized as a symptom for centuries. However, only recently, with the incorporation into the third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) and the revised third edition of DSM (DSM-III-R) of Donald Klein's conceptualization of panic disorder as a separate entity, have anxiety states begun to be subdivided into distinct entities such as panic disorder with and without agoraphobia, social phobia, posttraumatic stress disorder, obsessive-compulsive disorder, and generalized anxiety disorder.

In a review of five population studies conducted in the United States, the United Kingdom, and Sweden prior to the development of specified diagnostic criteria, other workers found that anxiety states were fairly common (about 2.0 to 4.7 per 100, point prevalence) and more prevalent in women than men, particularly women between 16 and 40 years of age. In a separate epidemiological review, the second author identified nine additional community studies of anxiety states that showed rates in the range reported above and also showed that rates were higher in women than in men. This chapter focuses on more recent epidemiological studies in which specific anxiety disorders were diagnosed on the basis of DSM-III or DSM-III-R criteria. Although the criteria for anxiety disorders were modified somewhat in the fourth edition of DSM (DSM-IV), no community studies using DSM-IV criteria are currently available.

The epidemiological approach to the study of anxiety disorders has certain strengths and weaknesses. Epidemiological studies are very informative because they gather data from large numbers of subjects, use powerful statistical techniques, and survey community samples of people who are not in treatment. The study of large numbers of subjects allows comparisons across relevant groups on the basis of differences in sex, race, education, occupation, ethnicity, and other factors. Large numbers also provide the statistical power to use sophisticated analytical strategies such as multivariate regression analysis, which can dissect the effects of complex sociodemographic variables. Community surveys can sample nonclinical populations, which allows investigation of many variables without the confounding factor of treatment seeking, which is strongly influenced by gender, education, and other socioeconomic and cultural factors.

Epidemiological studies also are limited in their capacity to answer certain questions about anxiety disorders. Complex sociodemographic variables such as gender, race, education, ethnicity, language, and religion are measured in epidemiological surveys in an attempt to identify factors that may influence psychiatric symptom formation. But the ability to capture these concepts successfully in fairly simple variables across large community surveys is far from perfect. Further, the diagnostic constructs used in epidemiological surveys may be well established in industrially developed, Western societies, but their reliability and validity may not be tested adequately across other cultures. This review attempts to minimize the problems of diagnosis across different cultures by relying, when possible, on data gathered and analyzed by uniform cross-national procedures.

PANIC DISORDER

Definition The key feature of panic disorder in DSM-III is the occurrence of three or more panic attacks within a 3-week period. These attacks cannot be precipitated only by exposure to a feared situation, cannot be due to a physical disorder, and must be accompanied by at least four of the following symptoms: dyspnea, palpitations, chest pain, smothering or choking, dizziness, feelings of unreality, paresthesias, hot and cold flashes, sweating, faintness, trembling or shaking. In DSM-III-R, the definition was revised to require four attacks in 4 weeks or one or more attacks followed by a persistent fear of having another attack, and the list of potential symptoms was revised to include nausea or abdominal distress and to exclude depersonalization or derealization.

More importantly, DSM-III-R changed the diagnostic hierarchy so that panic disorder could be diagnosed as a primary disorder with or without agoraphobia and dropped the category of agoraphobia with panic attacks. This change placed the emphasis on identifying panic disorder as a discrete entity and reflected the clinical experience that panic attacks tended to occur before development of agoraphobia, which was increasingly viewed as a phobic avoidance response to the frightening experience of spontaneous panic attacks, near-panic experiences, or limited symptom attacks.

DSM-IV criteria require recurrent unexpected panic attacks and persistent concern about having further attacks, worry about the implications of the attacks, or a significant change in behavior because of the attacks. No epidemiological data using these criteria is available.

Prevalence Rates Table 15.2-1 shows prevalence rates for panic disorder from a cross-national collaborative study of 10 countries, using the Diagnostic Interview Schedule (DIS) and DSM-III criteria. These 10 community studies included over 40,000 subjects and were analyzed with appropriate standardization for age and sex differences among subjects from different countries. For comparison purposes, Table 15.2-1 also includes data from the National Comorbidity Study (NCS) of a representative sample of 8098 persons living in the 48 contiguous United States conducted in 1990 to 1992 using the University of Michigan version of the Composite International Diagnostic Interview (UM-CIDI) and DSM-III-R criteria. The annual rate of DSM-III panic disorder ranged from 0.2 per 100 in Taiwan to 2.1 per 100 in Beirut, Lebanon. The NCS reported an annual prevalence of 2.2 per 100 for DSM-III-R panic disorder.

Site	Annual	Lifetime			
		Total	Female	Male	F/M Ratio
United States (ECA)[a]	1.0	1.7	2.3	1.0	2.3
Edmonton	0.9	1.4	1.9	0.9	2.1
Puerto Rico	1.1	1.7	1.8	1.4	1.3
Savigny, France	0.9	2.2	3.0	1.3	2.3
West Germany	1.7	2.6	3.8	1.4	2.7
Florence, Italy	1.3	2.9	3.9	1.2	3.2
Beirut, Lebanon	2.1	2.1	3.1	1.1	2.8
Taiwan	0.2	0.4	0.6	0.2	3.0
Korea	1.5	1.7	2.9	0.5	5.8

The cross-national epidemiology of panic disorder. Arch Gen Psychiatry 54:305, 1997.

Table 15.2-1 Prevalence Rates for Panic Disorder per 100 Subjects: Age 18–64 Years

Lifetime rates of DSM-III panic disorder showed excellent agreement, with the prevalence varying from 1.4 per 100 in Edmonton, Canada, to 2.9 per 100 in Florence, Italy. The exception to this narrow range was Taiwan, where DSM-III panic disorder had a lifetime prevalence of 0.4 per 100. The lower rates of panic disorder in Taiwan are consistent with lower Taiwanese rates for most other disorders studied. The reason for these lower rates is not clear. The only study that reported on lifetime DSM-III-R panic disorder was the NCS, which found a rate of 3.5 per 100, somewhat higher than the lifetime rates based upon DSM-III. The higher annual and lifetime rates reported in the NCS may reflect a period effect, with rates increasing between the ECA of the early 1980s and the NCS of the early 1990s. The higher rate in the NCS may also reflect the broader concept of panic disorder in DSM-III-R than in DSM-III or the differences in memory probes used in the NCS interview

(the UM-CIDI) and the DIS used in the cross-national collaboration.

Age at Onset The age at onset of panic disorder is usually in the early to middle 20s, with a later onset in West Germany and Korea (35.5 and 32.1, respectively). The NCS data showed a bimodal distribution of age of onset, with an early mode for panic disorder in the 15- to 24-year age range for both men and women and a later mode in the 45- to 54-year range.

Sex Differences Comparing lifetime prevalence rates, all studies reporting on panic disorder showed higher rates for women than for men. An analysis of the NCS data found uniformly higher rates of panic attacks and panic disorder for women than in men within every age group. Another study analyzed incidence rates from the Epidemiologic Catchment Area (ECA) study and found a twofold higher risk of incident panic disorder in women than in men. This finding is analogous to the higher incidence and prevalence rates for major depression in women than in men and suggests that for both panic disorder and major depression, the higher rates in women reflect a true increase in the risk for new-onset panic disorder and major depression rather than a greater tendency to seek treatment or have longer episodes of illness.

Race and Ethnicity The ECA study found no significant differences in prevalence rates between African-American, Hispanic, and white groups. Similarly, the NCS found no main effects of race or ethnicity but did report an interaction effect of age and race or ethnicity. For young adults in the NCS, differences between racial or ethnic groups were minor, but in the 45 to 54 age range, blacks and Hispanics had substantially lower rates than whites. The cross-national comparisons are more remarkable for the cross-cultural similarities in rates of panic disorder, with the exception of the Taiwan study, which found substantially lower rates of panic. As with major depression, Korean prevalence rates of panic disorder were comparable to those in the West, while Taiwan's were much lower.

Comorbidity At every cross-national site and in the NCS, panic disorder was associated strongly with an increased risk for major depression and agoraphobia. The odds ratios for comorbidity of lifetime panic disorder with agoraphobia ranged from 7.5 in the ECA to 21.4 in Puerto Rico, with the NCS reporting a odds ratio of 10.6 (Table 15.2-2). Based on lifetime rates, the odds ratos for comorbidity of panic disorder with major depression ranged from 3.8 in Savigny, France, to 20.1 in Edmonton, Canada, with an odds ratio of 5.7 reported in the NCS.

	Agoraphobia			Major Depression		
Site	In Persons With Panic (%)	In Persons Without Panic (%)	Odds Ratio (95% CI)	In Persons With Panic (%)	In Persons Without Panic (%)	Odds Ratio (95% CI)
United States (ECA)	33.8	5.5	7.5 (5.3–10.0)	32.8	4.7	8.7 (6.4–11.7)
Edmonton, Alberta	31.8	2.7	15.1 (7.6–29.9)	68.2	9.2	20.1 (10.4–38.8)
Puerto Rico	58.2	6.0	21.4 (9.2–50.2)	38.2	3.7	15.3 (6.4–36.6)
Savigny, France	48.9	6.5	12.7 (6.6–24.8)	48.9	17.3	3.8 (2.1–7.1)

Table 15.2-2 Comorbidity of Panic Disorder With Lifetime Agoraphobia and Major Depression

AGORAPHOBIA

Definition DSM-III agoraphobia is defined as a fear and avoidance of being in places or situations from which escape might be difficult or in which help might not be available in the event of sudden incapacitation. As a result of such fears, the agoraphobic person avoids travel outside the home or requires accompaniment when away from home. Moderate cases may cause some constriction in lifestyle, while severe cases of agoraphobia may result in the person being completely housebound or unable to leave home unaccompanied.

DSM-III-R revised the diagnosis of agoraphobia to a condition accompanying panic disorder (panic disorder with agoraphobia) or paniclike symptoms. Although the diagnosis of agoraphobia without history of panic disorder was retained, this category emphasized the avoidance behavior as a response to the sudden development of anxiety or somatic symptoms. DSM-IV further emphasizes that the agoraphobic avoidance behavior occurs specifically in response to the fear of developing paniclike symptoms.

Prevalence Rates Lifetime prevalence rates of agoraphobia have been reported from a number of studies. If one considers only the studies carried out in primarily English-speaking countries, the lifetime prevalence rates vary over a narrow range, from 2.9 per 100 in Edmonton, Canada, to 6.7 per 100 in the NCS. In spite of the changes in the diagnostic definition between DSM-III and DSM-III-R, the lifetime rates from the ECA and NCS studies showed remarkable consistency (5.6 and 6.7 per 100, respectively). As with other disorders, Taiwan reported a lower rate of agoraphobia.

Risk Factors Lifetime rates of agoraphobia were significantly higher for women than for men in each of the community studies. This is consistent with the sex differences found for panic disorder.

In the ECA study, lifetime prevalence of agoraphobia was higher among African-Americans than among whites or Hispanics. The effects of race or ethnicity and sex or gender combined to produce a considerable range in lifetime prevalence, from 2.9 per 100 white males to 12 per 100 African-American women. In the NCS, current agoraphobia (past month) was associated with higher risk in African-Americans than in whites. Current agoraphobia was inversely related to income and education in a bivariate analysis of the NCS data.

RELATION BETWEEN AGORAPHOBIA AND PANIC ATTACKS

As Table 15.2-2 shows, the Cross-National Collaborative Study and the NCS identified panic disorder as a uniformly powerful risk factor for agoraphobia across a wide array of study sites. Nonetheless, in DSM-III, agoraphobia was considered a separate phobic disorder that might or might not be accompanied by panic attacks. Largely because of the influence of Klein's hypothesis that agoraphobia is a conditioned avoidance response to the aversive stimulus of spontaneous panic attacks, the diagnostic view of agoraphobia changed considerably in DSM-III-R, in which panic disorder is viewed as primary, with or without secondary development of agoraphobia. An important factor in this change was the observation by Klein and others that in clinical settings, agoraphobia rarely occurs without preceding spontaneous panic attacks or limited symptom attacks. However, other investigators have questioned the temporal precedence and causal role of panic attacks in the development of agoraphobia.

Contributing to the controversy are the large differences between clinic and community studies in their estimates of the relative prevalence of agoraphobia with and without panic attacks. Population-based surveys have identified a substantial number of subjects with agoraphobia and no history of panic attacks. For the most part, subjects in these surveys were interviewed by lay persons using the DIS. In contrast, clinic-based studies using less structured interviews administered by clinicians almost invariably found much lower rates of agoraphobia without panic.

Several explanations for this discrepancy have been suggested. One is that samples of treated persons with any illness have higher rates of comorbidity than samples of untreated persons. An alternative explanation is that population studies may have overestimated the rate of agoraphobia without panic disorder.

In a reanalysis of the ECA data on agoraphobia without panic attacks, 22 community cases of agoraphobia without panic attacks were clinically reappraised, and only a single case of probable agoraphobia without panic attacks was found. The diagnostic reappraisal found that 19 (87 percent) of the sample had simple or social phobias rather than agoraphobia or had no DSM-III phobia at all. The reappraisal also identified six cases of panic disorder, panic attacks, or limited symptom attacks that had been missed by the DIS. The authors concluded that community studies using the DIS may have overestimated the prevalence of agoraphobia without panic attacks in the community.

An initial analysis of the NCS data found that only about one third of NCS subjects with agoraphobia reported a history of a panic attack. More-detailed analyses of

the NCS data are under way to determine whether agoraphobia without panic is in fact as common as the initial analyses suggest.

SOCIAL PHOBIA

Definition The central feature of DSM-III social phobia is a persistent, irrational fear accompanied by a compelling desire to avoid situations in which a person might act in a humiliating or embarrassing way while under the scrutiny of others. DSM-III-R allowed the phobic situations to be avoided or endured with intense anxiety and required that the avoidant behavior interfered with occupational or social functioning or that there was marked distress about having the fear. DSM-IV adds that the person recognizes the fear as excessive or unreasonable. Common social phobias involve fears of speaking or eating in public, urinating in public lavatories, writing in front of others, or saying foolish things in social situations.

Prevalence Rates Table 15.2-3 shows the lifetime prevalence of DSM-III social phobia from a cross-national study reporting on the United States, Canada, Puerto Rico, and Korea. For comparison, the lifetime prevalence of DSM-III-R social phobia is also included at the bottom of the table. Lifetime rates of DSM-III social phobia varied somewhat, with a low of 0.5 per 100 in Korea and a high of 2.6 per 100 in the United States. It is not clear whether these contrasting rates reflect true cross-cultural differences or are due to differences in methodology or translation of the DIS.

Site	Males	Females	Total
United States (ECA)	2.1	3.1	2.6

United States (NCS)	11.1	15.5	13.3

Adapted from Weissman MM, Bland RC, Canino GJ, Greenwald S, Lee C-K, Newman SC, Rubio-Stipec M, Wickramaratne PJ: The cross-national epidemiology of social phobia: A preliminary report. Int Clin Psychopharmacol 11(Suppl):9, 1996.

Table 15.2-3 Lifetime Prevalence Rates of Social Phobia per 100 Subjects

The rate of lifetime DSM-III-R social phobia from the NCS was considerably higher (13.3 per 100) than that in any of the DIS and DSM-III studies. These differences were attributed by some workers to the higher prevalence to differences between the DIS and UM-CIDI. The UM-CIDI uses a stem question based on the broader DSM-III-R criteria allowing either avoidance of a feared situation or endurance with intense anxiety, and it also asks about six specific social phobic fears (versus three in the DIS), including the high-prevalence fears of using a public toilet, writing in front of others, or talking to people and sounding foolish or having nothing to say.

Age at Onset and Comorbidity In the cross-national collaborative data reported in Table 15.2-3, the mean age at onset of first phobia ranged from the midteens to early 20s. The NCS reported a median age at onset for social phobia of 16 years. The vast majority of social phobias occurred in persons who reported at least one other psychiatric disorder. Both the NCS and the cross-national studies reported that persons with social phobia usually suffered a first onset of phobia prior to the onset of other psychiatric disorders.

Risk Factors An analysis of the ECA data from four sites (the New Haven site used a version of the DIS that did not include social phobia items) found that lifetime prevalence rates of social phobia were highest among women and persons who were younger (age 18 to 29 years), less educated, single, and of lower socioeconomic class. In the NCS, higher rates were found in women, those with less education or income, those who never married, students, and those living with their parents. A higher prevalence of lifetime social phobia was also found among women in Korea, Edmonton, and Puerto Rico. The higher rates among women are in contrast to results of several clinical studies, which reported somewhat higher rates of men seeking treatment for social phobia. Men may be more interested in treatment because of impaired work performance. Further study of the gender distribution is required to determine whether the different rates for men and women reflect true differences in prevalence or differences in treatment-seeking patterns.

OBSESSIVE-COMPULSIVE DISORDER

Definition DSM-III obsessive-compulsive disorder required the presence of obsessions or compulsions that are sources of significant distress or impairment and are not due to another mental disorder. DSM-III-R required that the obsessions or compulsions cause marked distress, consume more than 1 hour a day, or significantly interfere with the person's normal routine or occupational or social functioning. DSM-IV added the requirement that the person recognizes that the obsessions or compulsions are excessive or unreasonable. *Obsessions* are defined as recurrent, persistent thoughts, images, or impulses that are experienced as intrusive and inappropriate. *Compulsions* are repetitive behaviors (e.g., checking locked doors or gas jets, handwashing) or mental acts (e.g., counting, repeating words) that the person feels driven to perform in response to an obsession or according to rigid rules.

Prevalence Rates Table 15.2-4 shows lifetime prevalence rates of DSM-III obsessive-compulsive disorder from the Cross National Collaborative Group. Lifetime prevalence of OCD varied from 0.7 per 100 in Taiwan to 2.5 per 100 in Puerto Rico. The studies in English-language sites showed excellent agreement, with lifetime prevalence of 2.2 to 2.3 per 100 in the United States, Canada, and New Zealand. Most remarkably, these rates contradict the previous traditional view of obsessive-compulsive disorder as a rare disorder on the basis of published clinical reports.

Site	Total	Females	Males	F/M Ratio
United States	2.3	2.8	1.7	1.6
Edmonton, Canada	2.3	2.7	2.0	1.3
Puerto Rico	2.5	2.7	2.3	1.2
Munich, Germany	2.1	1.9	2.5	0.8
Taiwan	0.7	0.9	0.5	1.8
Korea	1.9	2.0	1.7	1.2
New Zealand	2.2	3.4	0.9	3.8

Adapted from Weissman MM, Bland RC, Canino GJ, Greenwald S, Hwu H-G, Lee C-K, Newman SC, Oakley-Browne MA, Rubio-Stipec M, Wells JE, Wickramaratne PJ, Wittchen H-U, Yeh E-K: The cross-national epidemiology of obsessive compulsive disorder. The Cross National Collaborative Group. J Clin Psychiatry 55(Suppl):5, 1994.

Table 15.2-4 Lifetime Prevalence Rates of Obsessive-Compulsive Disorder per 100 Subjects

Age at Onset, Risk Factors, and Comorbidity The mean age at onset of obsessive-compulsive disorder is in the mid-20s to early 30s. The youngest mean age at onset was reported in Edmonton (21.9 years) and the oldest in Puerto Rico (35.5 years).

In the ECA study, prevalence rates of obsessive-compulsive disorder were higher among women than among men. However, when gender comparisons were controlled for marital status, employment status, job status, ethnicity, and age, no differences in prevalence rates for women and men remained. In the Cross National Collaborative Study, rates were generally higher in women than in men, except in Munich, where the rates were higher among men. Persons with obsessive-compulsive disorder had a substantially greater risk of having comorbid major depression or another anxiety disorder than persons without

obsessive-compulsive disorder.

POSTTRAUMATIC STRESS DISORDER

Definition Posttraumatic stress disorder is defined in DSM-III as a constellation of symptoms in response to a stressor, including reexperiencing a traumatic event, numbed responsiveness, and symptoms of an increased level of arousal. In DSM-III-R, the symptoms must persist for at least 1 month, and the criteria are broadened by adding (1) intense psychological distress in response to events that symbolize or resemble an aspect of the trauma and (2) avoidance of stimuli associated with the event. DSM-IV adds the requirement for functional impairment or clinically significant distress.

Prevalence Rates Until recently, no accurate information on the prevalence of posttraumatic stress disorder was available. Earlier studies on the effects of traumatic experiences tended to focus on groups exposed to a common trauma, such as Vietnam war veterans or survivors of natural disasters. In the last decade several surveys have gathered general population data, which have enhanced knowledge of the extent and seriousness of the impact of posttraumatic stress disorder on the community.

Table 15.2-5 shows lifetime prevalence rates of posttraumatic stress disorder from five surveys conducted in the United States using DSM-III or DSM-III-R diagnostic criteria. The DSM-III studies, which were both part of the ECA and used the DIS as the diagnostic instrument, found a low lifetime prevalence rate of 1.0 to 1.3 per 100 subjects. More importantly, these and other studies using DSM-III generated reliable, systematic data on the nature of the response to various traumas, including criminal victimization, sexual assault, exposure to natural disaster, and combat exposure. This empirical information contributed to the revisions of the diagnostic criteria in DSM-III-R. The early studies also led to better understanding of the effects of trauma, and improvements in the assessment of populations for the presence of traumatic life events and the symptoms of posttraumatic stress disorder.

Resnick (1993)	12.3		
Breslau (1991)	11.3	6.0	9.2

Table 15.2-5 Lifetime Prevalence Rates of Posttraumatic Stress Disorder per 100 Subjects

Later studies using DSM-III-R criteria found a lifetime prevalence of posttraumatic stress disorder ranging from 10.4 to 12.3 per 100 women and 5.0 to 6.0 per 100 men. These later studies seem to confirm that posttraumatic stress disorder is highly prevalent and also provide evidence that the traumatic events that cause it are quite commonly experienced in the community. In the NCS, 61 percent of men and 51 percent of women reported at least one traumatic event. Men were more likely than women to experience physical attacks, combat experience, and being threatened with a weapon, held captive, or kidnapped. Women, on the other hand, were more likely to experience rape, sexual molestation, childhood parental neglect, and childhood physical abuse.

Risk Factors and Comorbidity The epidemiological data suggest that the relation between trauma exposure and development of posttraumatic stress disorder is complex. Men and women differ in the types of traumas to which they are likely to be exposed and in their liability to develop posttraumatic stress disorder once exposed. The lifetime prevalence of posttraumatic stress disorder is significantly higher in women than in men. Women are more likely than men to be exposed to high-impact traumas, or traumas that are associated with a high probability of developing posttraumatic stress disorder. Furthermore, once exposed to traumatic events, a higher proportion of women than men go on to develop the disorder. The vast majority of men and women who met criteria for DSM-III-R posttraumatic stress disorder had a lifetime history of at least one other psychiatric disorder.

GENERALIZED ANXIETY DISORDER

Definition The DSM-III criteria for generalized anxiety disorder require the presence of unrealistic or excessive anxiety and worry, accompanied by symptoms from three of four categories: (1) motor tension, (2) autonomic hyperactivity, (3) vigilance and scanning, and (4) apprehensive expectation. The anxious mood must continue for at least a month, and the diagnosis is not made if phobias, panic disorder, or obsessive-compulsive disorder are present or if the disturbance is due to another physical or mental disorder such as hyperthyroidism, major depression, or schizophrenia. By this definition, generalized anxiety disorder was treated primarily as a residual category after the other major anxiety disorders were excluded. DSM-III-R narrowed the definition further by requiring a minimum of six symptoms and a duration of 6 months. DSM-IV requires only three symptoms from a list of six but adds the requirement that the anxiety causes clinically significant distress or functional impairment.

Prevalence Rates Table 15.2-6 shows the lifetime prevalence rates of generalized anxiety disorder from community studies using DSM-III or DSM-III-R criteria. Lifetime prevalence of generalized anxiety disorder in the ECA study was quite consistent across three study sites, varying from 4.1 per 100 in Los Angeles to 6.6 per 100 in Durham and St. Louis. In spite of differences in diagnostic criteria, the ECA and NCS rates were quite similar. Lifetime prevalence varied considerably more in the Taiwan study, from 3.7 per 100 in Taipei to 10.5 per 100 in small-town areas of Taiwan.

Site	Females	Males	Total

Small towns			10.5
Rural			7.8
Korea			3.6
DSM-III-R studies			
United States (NCS)	6.6	3.6	5.1
Florence, Italy			3.9

Table 15.2-6 Lifetime Prevalence Rates of Generalized Anxiety Disorder per 100 Subjects

The Florence study provides an interesting example of the effects of requiring the longer 6-month duration of DSM-III-R. For DSM-III, the lifetime rate was 5.4 per 100, while the narrower DSM-III-R definition resulted in the lower rate of 3.9 per 100.

Risk Factors, Comorbidity, and Impairment The ECA and NCS studies found significantly higher rates of generalized anxiety disorder in women than in men. The NCS also found that being 25 years or older, being previously married, being unemployed, being a homemaker, and living in the Northeast significantly increased the risk of generalized anxiety disorder. The NCS found that 90 percent of subjects with lifetime generalized anxiety disorder had at least one other psychiatric disorder, with affective disorders, panic disorder, and agoraphobia being the most common. The NCS also found substantial evidence for impairment due to generalized anxiety disorders, with 82 percent of those with lifetime generalized anxiety disorders reporting that they sought professional help or took medicine for it or that the

disorder interfered with their life.

ANXIETY DISORDERS AND DISABILITY

Epidemiological studies have shown a strong association between anxiety disorders and functional disability. Recently, the World Health Organization (WHO) Collaborative Study on Psychological Problems in General Health Care examined the relationship between common mental disorders and disability across cultures. This WHO study collected data on psychiatric status and levels of occupational and physical impairment in primary care settings in 15 different sites around the world. Study sites included Ankara, Turkey; Athens, Greece; Bangalore, India; Berlin, Germany9 Groningen, the Netherlands; Ibadan, Nigeria; Mainz, Germany; Manchester, England; Nagasaki, Japan; Paris, France; Rio de Janeiro, Brazil; Santiago, Chile; Seattle, Washington; Shanghai, China; and Verona, Italy. The investigators found panic disorder and generalized anxiety to be strongly associated with functional disability consistently across major cultures around the world. This consistency across cultures is of particular interest given the substantial differences in cultural and socioeconomic environments across included in this study.

FUTURE DIRECTIONS

In spite of methodological limitations, lifetime prevalence rates of panic disorder are remarkably consistent across the community studies and across cultural, racial, and ethnic boundaries, with the exception of the higher rates in the NCS, which may relate to differences in interview method, and much lower rates in Taiwan, where lower rates were reported for several disorders. Cross-nationally, panic disorder is consistently associated with substantial levels of occupational impairment and is more common among women than men. Panic disorder is highly comorbid with agoraphobia and major depression.

In contrast to panic disorder, the epidemiological data on agoraphobia show considerable variation in rates across studies and cross-culturally. A recent clinical reappraisal of the ECA data on agoraphobia without panic suggests that community studies relying upon the DIS and DSM-III may have overestimated the prevalence of agoraphobia without panic. Thus prevalence estimates from such studies should be regarded with caution until their accuracy can be more thoroughly tested.

Analyses of relative risks showed higher rates of agoraphobia for women than for men, just as with panic disorder. Unlike panic disorder, however, agoraphobia was associated with higher rates for African-Americans than whites and higher rates among those with less education or income. The differential effects of race and socioeconomic factors on panic disorder and agoraphobia suggest that the factors that cause panic disorder may differ from those that lead to the subsequent development of agoraphobia.

The ECA and NCS studies found prevalence rates of social phobia to be highest among women, those with less education or income, and those who never married. Posttraumatic stress disorder and generalized anxiety disorder are more prevalent among women than men. Based on community data, obsessive-compulsive disorder turned out to be much more prevalent than previous clinical studies suggested.

In conclusion, community studies have shown anxiety disorders to be highly prevalent and important causes of functional impairment. The data on anxiety disorders are interesting both for their consistency across quite different settings and for some of the questions they raise. Further study is needed to clarify the comorbidity between anxiety disorders, the consistently higher rates of anxiety disorders in women than in men, and the differential effects of socioeconomic and cultural factors on panic disorder and phobias. Further investigation of the complex relation between exposure to traumatic events and the development of posttraumatic stress disorder is needed. Epidemiological data are needed to answer basic questions regarding the etiology and prevention of all anxiety disorders, as well as clinical studies to improve their treatment and prevent the disability they cause.

SUGGESTED CROSS-REFERENCES

Epidemiology is covered in Section 5.1; statistics and experimental design is covered in Section 5.2. Classification of mental disorders is discussed in Chapter 9. Section 15.6 describes the clinical features of anxiety disorders.

15.3 ANXIETY DISORDERS: BIOCHEMICAL ASPECTS

GREGORY M. SULLIVAN, M.D. AND JEREMY DAVID COPLAN, M.D.

Anxiety disorders research is undergoing a revolutionary paradigmatic transformation as disparate areas of psychiatric nosology, pharmacologic dissection, and cognitive neuroscience converge toward an integrated neurobiological understanding of the pathologies. The study of fear conditioning in rodents has identified neuroanatomical pathways that (assuming a phylogenetic conservation of function) are putative anatomical substrates for aspects of human fear and anxiety. The limited access to pathophysiological changes in the human brain in anxiety disorders that has historically plagued psychiatry is being removed by the guidance of such preclinical findings combined with the new window offered by rapidly advancing neuroimaging technologies. Highly complex functional neuroanatomical pathways are being proposed for specific aspects of anxiety disorders, and a research boom is aimed at elucidating the true correlates. In keeping with this paradigm shift, the biochemical aspects of anxiety disorders are reviewed in the light of these hypothetical pathways. The anxiety disorders are separated as per the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) although it is assumed that many aspects of the functional-neuroanatomical pathways cross diagnostic boundaries.

AMYGDALA, CORTICOTROPIN-RELEASING FACTOR, AND MONOAMINES

An abundance of preclinical evidence now points to the amygdala as the major mediator of the stress response, fear, and possibly also anxiety. The amygdala receives excitatory glutamatergic thalamic and cortical sensory input that it appears to process in series and in parallel through an organized array of intraamygdaloid circuitries nuclei. Such a pathway allows a stimulus representation to be modulated by different functional systems such as those mediating memories from past experience and information about the hormonal and homeostatic milieu of the organism. The amygdala also has caudal projections to monoaminergic loci such as noradrenergic neurons of the locus ceruleus, dopaminergic neurons of the ventral tegmental area, and serotonergic neurons of the raphe nuclei. The amygdaloid nuclei appear to have the appropriate connections to orchestrate the simultaneous elaboration of individual anxiety disorder correlates such as cognitive misappraisal and fear (cortical areas), escape and freezing behavior (periaqueductal gray), hyperventilation (parabrachial nucleus), sympathetic activation (lateral hypothalamus), endocrine activation (paraventricular nucleus of the hypothalamus), gastrointestinal distress (dorsal motor nucleus of the vagus), increased startle (nucleus caudalis pontis), and motor activation (striatum).

Lesions of the amygdala in animal models lead to attenuated fear and emotional responsiveness as well as blockade of autonomic and neuroendocrine responses to learned stress. Direct electrical stimulation of the amygdala in animal models elicits both fear-like behavior and autonomic arousal. Stereotaxic electrical stimulation of the amygdala in conscious humans has been reported to elicit symptoms of anxiety including fear, anxiety, depersonalization, visceral sensations in the chest and epigastric region, and changes in autonomic function.

Also emerging is the recognition of a wide extrahypothalamic network of corticotropin-releasing factor (CRF)-secreting neurons originating in the central amygdaloid nuclei. These neurons project to regions of neuroendocrine and autonomic function, to monoaminergic nuclei that project back to the forebrain, and to regions that modify or initiate specific components of the response to threat such as the periaqueductal gray. Intracerebroventricular injection of CRF in animals produces physiological changes similar to those produced by stimulation of the amygdala and a range of behaviors analogous to components of human anxiety and affective disorders; these include anorexia, insomnia, decreased libido, hyperactivity, reduced exploratory activity, and increased startle response. Transgenic mice with enhanced CRF expression are described as expressing a constitutive, persistent phenotype of emotionality including prominent anxiety-like behavior. Indeed, CRF is now hypothesized to facilitate both the cognitive and physical symptoms of anxiety and panic by enhancing bidirectional communication through an activated central nucleus of the amygdala. These are just a few examples of the immense amount of preclinical data implicating a fear system coordinated through the amygdaloid nuclei and using CRF as an effector neuropeptide.

One model relevant to anxiety and panic puts forth that the serotonin pathway originating in the dorsal raphe nucleus and running along the medial forebrain bundle innervates the amygdala and frontal cortex, thus facilitating active escape or avoidance behaviors in response to distal threat. This pathway likely involves postsynaptic serotonin (5-hydroxytryptamine [5-HT]) type 2A/2C (5-$HT_{2A/2C}$) and 5-HT_3 receptor activation. It is assumed that such resultant behavior relies on learning and relates to conditioned or anticipatory anxiety. Such a pathway therefore may be relevant to generalized anxiety disorder. A separate pathway originating in the dorsal raphe nucleus involves innervation of the periventricular and periaqueductal gray region such that serotonin neurons inhibit inborn fight or flight reactions in response to proximal danger, acute pain, or asphyxia. This pathway may be relevant to panic attacks and is likely to be mediated by 5-$HT_{2A/2C}$ and 5-HT_{1A} postsynaptic receptors. A further suggestion is that with chronic stress, the serotonin pathway connecting the median raphe nucleus to the hippocampus, likely mediated by postsynaptic 5-HT_{1A} receptors, promotes resistance to such stress by disconnecting the aversive events from processes underlying appetitive and social behaviors. It has been suggested that this pathway may be relevant to avoidance and numbing found in posttraumatic stress disorder.

The locus ceruleus noradrenergic and dopaminergic systems are believed to increase autonomic arousal and vigilance in response to threat. Prefrontal dopamine release is associated with immediate aversive encounter. The bed nucleus of the stria terminalis, known to have dense noradrenergic innervation, has been implicated in conditioned fear to contextual cues and inhibitory avoidance. Noradrenergic neurons of the locus ceruleus appear to be excitatory to serotonin neurons of the dorsal raphe nucleus, while 5-HT neurons of the dorsal raphe nucleus inhibit locus ceruleus firing. The locus ceruleus may also stimulate the periaqueductal gray via an indirect pathway through the amygdala. So again, the amygdala may mediate in a complex orchestration of coping behaviors and adaptive responses to future stressors. Overstimulation of such adaptive mechanisms by repeated or chronic stressors as well as deficits in function of components of these systems could theoretically lead to the pathological responses observed in anxiety disorders.

PANIC DISORDER

Panic attacks, the hallmark of panic disorder, are unexpected and rapidly progressing bursts of anxiety accompanied by an array of cognitive and autonomic symptoms such as immense fear, palpitations, hyperventilation, lightheadedness, and sweating. By definition, the intensity of symptoms should reach a peak within 10 minutes, and most attacks have a relatively short time course of about 5 to 30 minutes. According to DSM-IV, the sequelae of such attacks are necessary for a diagnosis of panic disorder. These can include anticipatory anxiety (“persistent concern about having additional attacks”), worry about the mental and physical implications of the attacks, and phobic avoidance of situations associated with the attacks (or “a significant change in behavior related to the attacks”). To date, no consistent biological differences have been detected between panic disorder patients with and without agoraphobia, therefore these diagnostic categories are discussed together.

Panicogenic and Anxiogenic Challenge Studies Sodium lactate has been used as a panicogenic agent in biological anxiety research since 1967, when it was first infused in patients with “anxiety neurosis.” Sodium lactate provokes acute panic attacks in about two thirds of panic disorder patients and not in healthy controls. Various hypothetical mechanisms of sodium lactate panic induction have been proposed. After the discovery of similar panic induction by inhalation of 5 percent carbon dioxide (CO_2), it was hypothesized that both lactate infusion, via peripheral catabolism to CO_2, and CO_2 inhalation precipitate panic attacks by increasing the partial pressure of CO_2 (pCO_2) in the central nervous system, activating the medullary chemoreceptors. Yet intravenous lactate in nonhuman primates did not change the pCO_2 of the cisternal fluid during or after lactate infusion. Further, the putatively metabolically inactive enantiomer of L-lactate, D-lactate, also is panicogenic at similar rates in panic disorder patients. This raises the question of a recognition site for unmetabolized lactate that is not specific to the metabolically active isomer. A simpler explanation is they both cause an alkalosis which activates the panic pathway. More recently, proton magnetic resonance spectroscopy of humans has shown increased uptake of lactate in the temporoparietal region during intravenous infusion of lactate in normal controls; although signal due to increased lactate in cerebral

blood potentially confounds determination of blood-brain barrier penetration. A recent preclinical study identified the organum vasculosum lamina terminalis, which is not protected by the blood-brain barrier, as a lactate-sensitive site that leads to anxiety-like autonomic activation when g-aminobutyrate (GABA) neurotransmission is inhibited in the dorsomedial hypothalamus. The investigators propose a mechanism for the panicogenesis of lactate that involves direct stimulation of this circumventricular organ by lactate, resulting in activation of a compromised panic-generating site such as the dorsomedial hypothalamus or amygdala.

The body's normal homeostatic response to a metabolic alkalosis is hypoventilation, as a compensatory measure, resulting in lower blood pH. Yet panic disorder patients who panic during lactate infusion paradoxically hyperventilate, suggesting respiratory stimulation that cannot be overridden by the metabolic alkalosis. It has been hypothesized that panic disorder patients have a hypersensitive suffocation alarm system whereby increasing pCO_2 and brain lactate concentrations prematurely activates a physiological asphyxia monitor. The question has also been raised whether hyperventilation leads to local relative vasoconstriction in the brains of panic disorder patients.

A variety of agents have been successfully used to induce paniclike reactions in efforts to elucidate the underlying pathophysiology. A distinction has been proposed between pharmacological challenge agents that induce significant respiratory symptoms and those that have few, if any, respiratory symptoms but significantly activate the hypothalamic-pituitary-adrenal (HPA) axis and result in significant anxiety. The former group of “respiratory panicogens” includes sodium lactate, CO_2, sodium bicarbonate, isoproterenol (Isuprel), and doxapram (Dopram); these agents induce a state more closely resembling spontaneous panic attacks. The latter group of “hypothalamic-pituitary-adrenal”–activating anxiogens” includes yohimbine (Yocon), *m*-chlorophenylpiperazine (mCPP), fenfluramine, and b-carboline. These agents are more notable for inducing a more generalized or anticipatory anxiety. Cholecystokinin (CCK) agonists appear to induce both a prominent respiratory component and robust hypothalamic-pituitary-adrenal activation and thus have qualities of both classes of agents. It has been suggested that over the course of panic disorder, the pathophysiology evolves from one associated with spontaneous panic attacks to one associated with anticipatory anxiety, paralleling the different responses seen with respiratory panicogens versus the hypothalamic-pituitary adrenal–activating anxiogens.

Noradrenergic System A large body of evidence has accumulated implicating noradrenergic system dysregulation in panic disorder. Apparent abnormalities of presynaptic a_2-adrenergic receptors have been identified by pharmacological challenges with the a_2-receptor agonist clonidine (Catapres) and the a_2-receptor antagonist yohimbine. Possibly the most replicable finding from clonidine challenge studies in panic disorder patients is a blunted growth hormone (GH) response compared with controls. It has also been reported, though less consistently, that clonidine administration in panic patients results in less sedation, a greater hypotensive response, and a disproportionate reduction in the principal noradrenergic metabolite, 3-methoxy-4-hydroxyphenylglycol (MHPG). Some have interpreted the blunted GH response to indicate postsynaptic a_2-receptor subsensitivity in panic disorder.

Yohimbine, which stimulates firing of the locus ceruleus, elicits high rates of paniclike anxiety in panic disorder patients accompanied by increased serum MHPG concentration. It has also been proposed that panic disorder patients have increased sensitivity to challenge with isoproterenol because of increased peripheral b-receptor sensitivity. Particular adrenergic agonists and the carotid chemoreceptor stimulator doxapram may in part act via peripheral receptors that relay information via vagal and glossopharyngeal afferents to the nucleus tractus solitarius. The nucleus traclus solitarius is known to have connections with the amygdala, hypothalamus, parabrachial nucleus, and indirect connections with the locus ceruleus. Interestingly, atrial natriuretic factor (ANF) enhances norepinephrine uptake in the circumventricular organs, locus ceruleus, and nucleus tractus solitarius of the rat. Panic disorder patients who have panic attacks in response to lactate infusion have more-pronounced surges in ANF than nonpanicking controls. Aside from the known antagonism of ANF on CRF-stimulated secretion of ACTH, this peptide might possibly attenuate overactivation of panicogenic loci by increasing presynaptic uptake of norepinephrine. Finally, the successful treatment of panic disorder with imipramine (Tofranil) is attributed to noradrenergic modulation.

Serotonergic System An important role for serotonergic dysregulation is also evident in panic disorder, particularly when considering the clinical efficacy of the selective serotonin reuptake inhibitors (SSRIs) and clomipramine (Anafranil), a tricyclic drug with a potent serotonin reuptake component. Challenge studies with the mixed serotonin agonist-antagonist mCPP and the indirect serotonin agonist fenfluramine have demonstrated increased rates of anxiety, though not necessarily overt panic attacks, to these agents, particularly in panic disorder patients. Such exaggerated responses to serotonergic challenges have been hypothesized to be due to postsynaptic serotonin hypersensitivity in panic disorder. Preclinical studies implicate serotonergic neurons originating in the raphe nuclei in modulation of an evolved complex response to threat. Such serotonin pathways appear activating to more evolutionarily sophisticated neuroanatomical centers involved in processing information relevant to threat. They appear restraining to more primitive brainstem centers involved in escape behavior.

GABAergic System High-potency benzodiazepines such as alprazolam (Xanax) and clonazepam (Klonopin) are clearly efficacious in blocking panic attacks. Reduced sensitivity of saccadic eye movements in panic disorder, whose velocity is partially mediated by GABA-sensitive neurons in the midbrain/pons, has been suggested to indicate GABA dysfunction. Preclinical studies indicate that CO_2 alters the tone of GABA receptors, though immediate relevance to panic disorder is lacking. There is also preclinical evidence that attenuation of local inhibitory GABAergic transmission in the basolateral amygdala, midbrain central gray, or dorsomedial hypothalamus can elicit anxiety-like physiological and behavioral responses.

CRF and the Hypothalamic-Pituitary-Adrenal Axis Clonidine induces a greater decrease in cortisol in panic disorder patients than in controls. In a healthy state a close functional relation obtains between the locus ceruleus noradrenergic system and the hypothalamic-pituitary adrenal axis. These two systems are apparently uncoupled in panic disorder, as correlations observed in controls between MHPG and cortisol, at baseline or maximal change to clonidine, are significantly reduced in panic disorder. Analysis of a decade of sodium lactate studies at one institution indicated the strongest predictors of panic during the baseline period before lactate infusion were fear, high cortisol concentration, and low pCO_2. Such predictors are consistent with a hypothetical CRF-mediated amygdaloid system effecting changes in cortical areas (cognitive misappraisal), the paraventricular nucleus of the hypothalamus (hypothalamic-pituitary adrenal axis), and the parabrachial nucleus (hyperventilation), respectively. The development of panic attacks in pharmacological challenge paradigms then may involve an abrupt switch from an anxiogenic pathway to a panicogenic pathway, differing in activation of specific neuroanatomical loci such as the paraventricular nucleus and periaqueductal gray.

GENERALIZED ANXIETY DISORDER

According to DSM-IV, generalized anxiety disorder is characterized by excessive and uncontrollable anxiety or worry persisting for at least 6 months, combined with three of six additional symptoms (“restlessness or feeling keyed up or on edge,” “being easily fatigued,” “difficulty concentrating or mind going blank,” “irritability,” “muscle tension,” and “sleep disturbance”). Recent epidemiological studies indicate that generalized anxiety disorder is one of the most common anxiety disorders; despite such prevalence, a paucity of research on its neurobiology exists.

Panicogenic and Anxiogenic Challenge Studies Both sodium lactate infusion and CO_2 inhalation have been investigated in generalized anxiety disorder. Those studies generally demonstrated that generalized anxiety disorder patients panic at a much lower rate in response to challenge than panic disorder patients but often have higher rates of panic, subjective anxiety, or somatic symptoms than normal controls. On the other hand one small study using the CCK analogue pentagastrin demonstrated panic attacks at a higher rate (5 of 7) in generalized anxiety disorder patients than in controls (1/7). The implications of this are unclear, as CCK agonists have diverse properties such as increasing firing of adrenergic neurons in the locus ceruleus, activation of the hypothalamic-pituitary adrenal axis and cross-regulation with the GABA system, and their anxiogenic-like effects in rodents are blocked by the 5-HT_3 antagonist ondansetron (Zofran).

Autonomic, Noradrenergic, and Neuroendocrine Systems Normal stress reactions are typically accompanied by increased autonomic activity and stress-related hormone production. These include increased heart rate, blood pressure, minute ventilation, muscle tension, skin conductance, and plasma concentrations of epinephrine, norepinephrine, cortisol, GH, and prolactin. Oddly, generalized anxiety disorder patients appear not to differ from controls with any consistency in baseline blood pressure, heart rate, respiration, or skin conductance. More remarkably, particular studies show evidence of hyporeactivity to stress challenge. Women with generalized anxiety disorder have attenuated skin conductance response to stress and slower recovery to baseline, leading some investigators to suggest decreased “autonomic flexibility” in generalized anxiety disorder. Further, after early positive results, it now appears that baseline plasma catecholamine concentrations in patients with generalized anxiety disorder do not differ from those in normals. Challenge with the a_2-adrenergic agonist clonidine did demonstrate a blunted GH response in generalized anxiety disorder (suggesting possible a_2-adrenoceptor subsensitivity) but indicated no difference in blood pressure, heart rate or MHPG concentrations in generalized anxiety disorder patients and controls after clonidine. The a_2-receptor antagonist yohimbine failed to demonstrate differences from controls in subjective anxiety level, blood pressure, heart rate, plasma MHPG, or cortisol. Fewer a_2-adrenergic binding sites exist on platelets of generalized anxiety disorder patients, raising the possibility of a prior hypercatecholaminergic state downregulating postsynaptic a_2-adrenoceptors. Though baseline cortisol levels appear normal in generalized anxiety disorder, challenge with dexamethasone (Decadron), which normally suppresses the hypothalamic-pituitary adrenal axis, results in nonsuppression in up to a third of patients with generalized anxiety disorder. Thus patients with generalized anxiety disorder appear to have autonomic hyporesponsiveness, subtle changes in adrenergic receptor sensitivity, abnormal regulation of GH secretion, and altered glucocorticoid feedback inhibition.

Serotonergic System The anxiolytic effects of 5-HT_{1A} partial agonists (buspirone [BuSpar] and ipsapirone) and 5-HT_{2} antagonists (ritanserin and serazepine) in generalized anxiety disorder patients has suggested serotonin involvement. A challenge study with the mixed serotonin agonist-antagonist mCPP, which has greatest agonist activity for 5-HT_{2C} and 5-HT_{3} receptors and less for 5-$HT_{1A/1D}$, demonstrated greater rates of anxiety and anger in generalized anxiety disorder patients than in controls. These pharmacological dissection results in generalized anxiety disorder patients are consistent with the model of excessive limbic forebrain 5-HT_{2} and 5-HT_{3} activity leading to anxiety by overstimulation and hippocampal 5-HT_{1A} stimulation leading to anxiolysis by adaptation. A contrasting hypothesis suggests that 5-HT_{1A} agonists are efficacious due to stimulation of presynaptic 5-HT_{1A} autoreceptors, thus reducing the elevated serotonin activity responsible for activating the hypothalamus, basal ganglia, and limbic system.

GABAergic System Certainly benzodiazepines have been a mainstay of treatment for generalized anxiety disorder. Further, platelet and lymphocyte benzodiazepine receptors have decreased binding in generalized anxiety disorder patients and increased binding after treatment with benzodiazepines. Scant clinical evidence is available for central GABA receptor complex abnormality, although saccadic eye movement velocity (thought to be partially mediated by GABA-responsive neurons of the midbrain and pons) may be reduced in generalized activity disorder as it is in panic disorder.

SOCIAL PHOBIA

According to DSM-IV, social phobia is characterized by fear of social or performance situations involving exposure “to unfamiliar people or possible scrutiny by others,” combined with fear of acting in a way that “will be humiliating or embarrassing.” The exposure also almost invariably provokes an anxiety reaction, which may have prominent cognitive and autonomic components similar to a situationally bound or predisposed panic attack. The situations are “avoided or else are endured with intense anxiety or distress,” and the fears are recognized as “excessive or unreasonable.”

Challenge Studies Public speaking has been used in a naturalistic challenge model of social phobia. Although no differences in blood pressure, heart rate, or catecholamines between social phobia patients and controls have been found, greater increase in heart rate was observed in patients with public speaking phobia than in those with generalized social phobia. Norepinephrine concentrations increase in normal subjects during the first several minutes of public speaking and decline to levels not significantly different from baseline by 15 minutes. Indirect evidence for abnormal plasma norepinephrine level regulation in social phobia is suggested by orthostatic studies in which higher supine and standing norepinephrine levels were demonstrated than those in panic disorder patients and controls. Increased blood pressure response to Valsalva's maneuver and exaggerated vagal withdrawal in response to isometric exercise has also been found in social phobia. A greater pressor effect of thyrotropin-releasing hormone (TRH [Thyrel TRH]) also differentiated social phobia patients from panic disorder patients and controls. Limited data suggest that yohimbine increases social anxiety in social phobia and is associated with elevated plasma MHPG concentrations. Clonidine challenge has elicited both blunted and normal GH response, depending on route of administration. Investigation of lymphocyte b-receptors showed no difference between social phobia patients and normal controls. Taken together, these preliminary results vaguely suggest abnormality in the noradrenergic system, though more in-depth investigation is necessary.

Results from lactate infusion and CO_2 inhalation studies are limited by small numbers of subjects but indicate low rates of panic compared with patients with panic disorder. Caffeine challenge did differentiate patients with social phobia and panic disorder from normals, but the symptoms reported by subjects with social phobia differed from their naturally occurring symptoms, thus calling into question the specificity of such challenge in social phobia. Pentagastrin, a selective cholecystokinin-B receptor agonist, is another agent that induces panic attacks in social phobia at a high rate, more similar to what is found in panic disorder than in normal controls. Thus, limited data from panicogen studies in social phobia suggest a possible shared neurobiology with panic disorder only with respect to hypothalamic-pituitary adrenal-activating anxiogens not with the pure “respiratory panicogens.”

Investigation of the hypothalamic-pituitary adrenal axis in social phobia by measurement of urinary free cortisol and the dexamethasone suppression test has not revealed differences from controls. The TRH stimulation test also failed to reveal a difference in the change in thyroid-stimulating hormone (TSH) from controls.

Dopaminergic System The favorable clinical effect of the monoamine oxidase inhibitors in the treatment of social phobia and their superiority to tricyclic drugs has led some to suggest a role for dopamine in social phobia. One study of panic disorder patients with social phobia reported significantly lower homovanillic acid concentration than in normal controls, although diagnostic specificity is certainly a question in this group with comorbid disorders. Prolactin and eyeblink response to levodopa (Larodopa) in social phobia patients did not differ from those of controls in one study. Single photon emission computed tomography (SPECT) study with [$_{123}$I]b-CIT, a labeled cocaine analogue, demonstrated decreased striatal dopamine reuptake site density in social phobia patients. Magnetic resonance spectroscopy studies of social phobia patients have suggested decreased cellular energy activity and neuronal activity and abnormal membrane function in regions that include the basal ganglia. Also, magnetic resonance imaging demonstrated greater reduction in the size of the putamen with aging in social phobia. Thus some evidence (albeit limited and indirect) suggests dopaminergic dysfunction in social phobia.

Serotonergic System Fenfluramine challenge in social phobia patients indicated that the prolactin response is not different from that of controls, but social phobia patients did show a significantly greater rise in cortisol concentration. Platelet tritiated paroxetine (Paxil) binding appears the same in social phobia patients and controls. Serotonergic therapies have shown therapeutic success in studies with social phobia patients, but further study of the serotonergic system is needed before any definitive conclusions can be made.

SPECIFIC PHOBIA

According to DSM-IV, specific phobia is characterized by a “marked and persistent fear that is excessive or unreasonable” and is brought on “by the presence or anticipation of a specific object or situation (e.g., flying, heights, animals, receiving an injection, seeing blood).” The response may take the form of a situationally bound or predisposed panic attack, and the phobia causes marked distress or interferes with role functioning. Little biological research has been done on specific phobia, and studies that have been carried out have not found striking differences from controls. A prominent vasovagal response was observed in a subgroup of patients with specific phobia.

POSTTRAUMATIC STRESS DISORDER

DSM-IV defines posttraumatic stress disorder (PTSD) as a disorder in which a person has been exposed to a traumatic event or events that included “actual or threatened death or serious injury, or threat to the physical integrity of self or others,” and “the person's response involved intense fear, helplessness or horror.” The symptomatic sequelae of the event or events include more than 1 month of persistent reexperiencing in thoughts, images, and dreams; behaving or feeling the event is recurring; and intense psychological or physiological reactivity to cues that are reminders of the event. There is also avoidance of stimuli associated with the trauma and numbing of general responsivity. Symptoms of increased arousal are also present and can include sleep disturbance, irritability, poor concentration, and exaggerated startle reflex.

Panicogenic Challenge Though panicogenic challenge studies using “respiratory panicogens” are very limited, one study found sodium lactate–induced flashbacks accompanied by panic attacks in combat veterans with comorbid panic disorder and PTSD. A more recent study indicated that lactate induces flashbacks in patients without comorbid panic disorder. This study also demonstrated lower cortisol and higher epinephrine concentrations at end of infusion than those in panic disorder patients and controls.

Noradrenergic System PTSD has a long and rich history. Soldiers with PTSD-like syndromes were formerly diagnosed with “shell-shock” or “irritable heart.” Pharmacological challenge with epinephrine was carried out in 1919 on traumatized soldiers with “irritable heart.” Unlike soldiers without this condition, these soldiers manifested nervousness with signs of autonomic arousal such as increased blood pressure and heart rate, palpitations, sweating, flushing, and tremors. More recently, stressful trauma-related sound and visual stimuli were used to challenge patients with PTSD. Plasma epinephrine and norepinephrine concentrations rose with temporal relation to subjective psychophysiological arousal elicited by this material. Studies of baseline heart rate and blood pressure indicated elevations in combat veterans, though results were inconsistent. Studies have found increased 24-hour urine epinephrine concentrations in veterans with PTSD, and increased urine catecholamine concentrations in sexually abused girls. Further, platelet a $_{2}$- and lymphocyte b$_{2}$-adrenoceptors are downregulated in PTSD, possibly in response to chronically elevated catecholamine concentrations.

Challenge with agonist yohimbine has elicited panic attacks at rates of 42 to 70 percent, similar to rates observed in panic disorder. These induced panic attacks were

accompanied by increased heart rate, blood pressure, and plasma MHPG. More remarkably, about 30 to 40 percent of PTSD patients report flashbacks after yohimbine administration, and yohimbine can elicit increases in intrusive traumatic thoughts, hypervigalence, startle amplitude, and emotional numbing. Positron emission tomography (fluorodeoxyglucose) measurement of brain metabolism following yohimbine administration demonstrated decreased activity in prefrontal, orbitofrontal, temporal, and parietal regions in PTSD patients who experienced increased anxiety, and increased activity in controls who were without anxiogenic response. Such findings are strong evidence for altered function in the noradrenergic system in PTSD and may indicate neurobiological overlap between PTSD and panic disorder.

Serotonergic System The SSRIs have shown partial efficacy in treating an array of symptoms in at least a subgroup of PTSD patients. As well, platelet paroxetine binding is reduced in PTSD. More recently, challenge with mCPP, in a comparison study with yohimbine administration, demonstrated a panic rate of 31 percent compared with 42 percent with yohimbine. Twenty-seven percent of the patients also had flashbacks with mCPP. An intriguing observation in this study was that 81 percent of the PTSD patients had a panic attack to yohimbine or mCPP but not both, raising the possibility of subtypes of PTSD with either selective-serotonergic or selective-noradrenergic dysfunction.

Opioid System Abnormality in the opioid system is suggested by reduced plasma beta-endorphin concentrations in PTSD. Because hypothalamic b-endorphin is at least partially mediated by CRF, these reduced concentrations may occur via a mechanism similar to that of lowered adrenocorticotropin (ACTH) release in response to CRF challenge. Though plasma concentrations of metenkephalin were similar to those of controls, the in vitro degradation half-life was reduced, suggesting decreased secretion. Although patients with chronic PTSD have a reduced pain threshold, combat veterans with PTSD also demonstrate a naloxone-reversible analgesic response to combat-related stimuli, raising the possibility of opioid system hyperregulation similar to that postulated in the hypothalamic-pituitary adrenal axis. Currently no studies of PTSD are investigating a-melanocyte-stimulating hormone, a hypothalamic peptide known preclinically to cause hyperalgesia and increased arousal and which appears to antagonize many neuroendocrine effects of beta-endorphin.

Dopaminergic System Increased concentrations of dopamine plasma and urine have been reported in PTSD. One study of subjects in addiction treatment who had been exposed to severe combat conditions demonstrated a significantly higher rate of the D2A1 receptor allele in the subjects who met criteria for PTSD. Otherwise, data on the dopamine system in PTSD are scant.

CRF and the Hypothalamic-Pituitary-Adrenal Axis Several lines of evidence point to dysfunction of the hypothalamic-pituitary adrenal axis and possibly extrahypothalamic CRF in PTSD. Studies have demonstrated low plasma and urinary free cortisol concentrations in PTSD. Consistent with low circulating cortisol, PTSD patients have more glucocorticoid receptors on lymphocytes. Challenge with exogenous CRF in PTSD has shown a blunted ACTH response but a normal cortisol response compared with those of controls. Further, suppression of cortisol by challenge with low-dose dexamethasone (Decadron) is enhanced in PTSD. These latter two challenge paradigms indicate hyperregulation of the hypothalamic-pituitary adrenal axis in PTSD. Dexamethasone suppression is also evident in PTSD patients with comorbid depression, which suggests that such hyperregulation overrides the expected nonsuppression usually associated with depression. A negative correlation between urinary cortisol concentration and novelty seeking was found in combat veterans.

Abundant preclinical evidence implicates hippocampal glucocorticoid receptors as a site for negative-feedback regulation of CRF and arginine vasopressin (AVP) synthesis. Also, prolonged high concentrations of glucocorticoids secreted by the adrenals during stress can have neurotoxic effects on hippocampal neurons. Magnetic resonance imaging study of combat veterans with PTSD demonstrated smaller right hippocampal volume than in matched controls.

Cerebrospinal fluid (CSF) concentrations of CRF are higher in PTSD patients than in controls, consistent with a hypothesis of hypersecretion of neuronal CRF in PTSD. Such elevated CSF CRF has also been identified in depression, but in depression cortisol concentrations are high.

Hypothalamic-Pituitary-Thyroid Axis Although little research has investigated the hypothalamic-pituitary-thyroid axis in PTSD, there have been positive findings. Mean total triiodothyronine (T_3) levels are significantly higher in veterans with PTSD than in normal controls. A high rate of blunted TSH response to TRH stimulation was reported in PTSD, and this abnormality did not appear to respond to 4 weeks of desipramine (Norpramin) treatment. Positive correlations have been found between novelty seeking and serum T_3, free T_3, and the T_3 to free thyroxine (FT_4) ratio in Vietnam veterans with PTSD. Positive correlations between free T_3, total T_3, total T_4, and hyperarousal symptoms, measured by the Clinician-Administered PTSD Scale, have also been reported.

OBSESSIVE-COMPULSIVE DISORDER

According to DSM-IV, obsessive-compulsive disorder (OCD) is characterized by repetitive thoughts, impulses, or images that are intrusive and inappropriate and cause anxiety or distress, or repetitive behaviors that the person feels driven to perform in response to an obsession or rigid rules that must be applied. These persons also recognize that the obsessions are a product of their own mind. The obsessions or compulsions are time consuming or interfere with role functioning.

OCD is unique among the anxiety disorders by appearing to be much more dominated by cognitive and related complex behavioral symptomatology, with autonomic dysregulation playing little role. This view is strengthened when considering rare panic and uncommon increased anxiety in OCD patients challenged with typical panicogenic and anxiogenic agents such as lactate, CO_2, yohimbine, and caffeine. Several investigators have questioned the grouping of OCD with the other anxiety disorders; in many ways it has more in common with obsessive-compulsive spectrum disorders such as Tourette's disorder. This spectrum of pathology appears more associated with corticostriatal pathways than with the amygdalofugal pathways that are the current focus of much anxiety disorder research. Neuroimaging in OCD has produced converging data implicating altered function in the neurocircuitry between the orbitofrontal cortex, caudate, and thalamus.

Serotonergic System The neurobiology of OCD is remarkable for consistently robust findings of abnormalities in the serotonergic system. Part of the focus on the serotonergic system is due to the exclusive response of OCD symptoms to agents with predominant serotonin reuptake blockade such as the SSRIs and clomipramine. Also, the high pretreatment CSF concentration of the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) and correlation of 5-HIAA decrease with clinical improvement during clomipramine treatment focused attention on the serotonergic system. Other studies investigating CSF 5-HIAA concentrations in OCD have produced inconsistent results. Platelets of OCD patients have reduced tritiated-imipramine binding-site density, indicating abnormality in the serotonin transporter, though these findings have not been consistently replicated.

Depletion of the serotonin precursor tryptophan in OCD patients who had responded to SSRIs or clomipramine did not increase obsessions or compulsions, but mean depression ratings significantly increased. Challenge with the serotonin precursor L-tryptophan demonstrated a small yet significant increase in prolactin in OCD patients, compared with controls. Prolactin response to fenfluramine (a nonspecific serotonin agonist) was inconsistent. Challenge with the partial serotonin agonist mCPP, with complex activity involving several serotonin receptor subtypes, was first observed not only to increase anxiety and depression but also to exacerbate acutely OCD symptomatology in about half of patients. Blunted responses of prolactin, cortisol, and ACTH have been found inconsistently during mCPP challenge. Despite inconsistent results in both behavioral and neuroendocrine response to mCPP challenge, the transient exacerbation of OCD symptoms appropriately drew attention to particular aspects of the serotonin system. Prechallenge blockade of 5-HT_{1A}, 5-HT_{1D}, and 5-HT_{2C} receptors with the nonselective serotonin receptor antagonist metergoline appears to attenuate the behavioral and neuroendocrine response to mCPP. Separate challenge study with MK-212, an agonist with 5-HT_{1A} and 5-HT_{2C} affinity, did not alter behavior but did produce a blunted cortisol response. Also, treatment with clomipramine reduced the behavioral response to mCPP, though abnormalities in prolactin and cortisol responses were not significantly different from those of untreated OCD patients. Both blunted prolactin rise to mCPP and blunted cortisol response to fenfluramine were specifically identified in the female subjects of two studies, suggesting a sexual dimorphism in the neuroendocrine component of OCD.

Noradrenergic System Currently less evidence exists for dysfunction in the noradrenergic system in OCD. Still, there are reports of improvement in OCD symptoms with oral clonidine. One small study of intravenous clonidine also demonstrated a dramatic decrease in the severity of symptoms; however, clonidine may have nonspecific sedating effects. Clonidine also may not be a specific probe of the noradrenergic system, as it binds to rodent imidazole receptors and FONT face=symbol>a_2-heteroreceptors located on serotonergic neurons. GH response to clonidine challenge is blunted while remaining intact with GH-releasing hormone challenge, suggesting possible subsensitivity of a_2-adrenergic receptors.

Neuroendocrine Systems Several abnormalities in baseline and challenge response have been found with hypothalamic-pituitary hormones. Increased CSF oxytocin concentrations were found in a subgroup of OCD patients without a personal or family history of tic disorder, and the oxytocin concentration correlated with the current severity of OCD. Concentration of the GH negative-regulator, somatostatin, is higher in the CSF of OCD patients, which may explain the blunted GH response to clonidine. Recently CSF CRF concentrations have come under investigation. Though mostly negative, one study did find that male OCD patients have higher CSF CRF concentrations than panic disorder or generalized anxiety disorder patients and normal controls. Also, cytokine interleukin-6 (IL-6) concentration, known to

increase in the peripheral blood in response to CRF stimulation, correlates with the severity of compulsive (but not obsessive) symptoms in OCD. Baseline elevations in plasma cortisol have also been found in OCD patients as a group, and one small study showed increased circadian secretion of cortisol that was not altered after 8 weeks of symptom-remitting fluoxetine (Prozac) therapy.

Neuroimmunology Interest has developed in a possible link between streptococcal infection and OCD. Group A b-hemolytic streptococcal infection can lead to rheumatic fever about 2 to 3 percent of the time, and approximately 10 to 30 percent of patients with rheumatic fever develop Sydenham's chorea. It has been reported that over 70 percent of patients with Sydenham's chorea manifest obsessive-compulsive symptoms. A monoclonal antibody to B lymphocytes, D8/17, developed using mice immunized with B lymphocytes from a patient with rheumatic carditis, has been used to measure B-cell D8/17 antigen in a small sample of patients with childhood onset of OCD or Tourette's syndrome. All 31 patients, 29 percent of whom had pure OCD, showed an elevated percentage of D8/17 antigen, contrasted with only 1 of 21 controls. Thus this antigen may serve as a marker for vulnerability to some forms of childhood OCD. Further, infectious or immune-mediated factors may play a role in at least a subgroup of OCD patients.

SUGGESTED CROSS-REFERENCES

Neurotransmitters are discussed in Section 1.4 and Section 1.5, and the contributions of the neural sciences in general are the focus of the other sections of Chapter 1. The biological therapies are discussed in Chapter 31.

15.4 ANXIETY DISORDERS: GENETICS

ABBY J. FYER, M.D.

What is currently known about the contribution of genetic factors to the development of anxiety disorders is based on data of six types of studies. Twin, adoption, and deoxyribonucleic acid (DNA) marker (linkage or association) studies can provide definite evidence of a genetic contribution. In the case of twin studies genetic influence is demonstrated if monozygotic (MZ) twins (who share 100 percent of their genetic material) are more often alike (concordant) with respect to a trait than are dizygotic (DZ) twins (who, like sibs, share only 50 percent of their DNA). Adoption studies indicate a genetic contribution if adopted offspring are more similar to their biological parents than to the adoptive parents who are raising them. DNA marker studies, not yet successful in psychiatry, offer the possibility of using molecular genetic methods to identify chromosomal loci or actual genes associated with clinical syndromes.

Important corroborative evidence of genetic influence is provided by family and segregation analytic studies as well as animal models. Family studies can indicate intergenerational transmission and are helpful identification of heritable phenotypes; however, they do not distinguish between genetic and environmental influences. Segregation analysis can demonstrate that familial prevalence patterns are consistent with a particular mode of genetic transmission (e.g., major dominant locus, polygenic). Although this does not prove that genes are responsible, identifying the correct genetic model may be critical to the success of linkage studies. Animal models of fear and anxiety may provide more neurophysiologically specific hypotheses concerning the origin of pathology. Many functional gene families are conserved across species, and this in turn may provide clues about genetic mechanisms.

The classification of anxiety disorders has become increasingly specific since the late 1970s. In 1968 the second edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-II) included three anxiety disorders (anxiety, phobic and obsessional neuroses) while the current fourth edition of DSM (DSM-IV) includes six: panic disorder with or without agoraphobia, generalized anxiety disorder, simple and social phobias, obsessive-compulsive disorder, and posttraumatic stress disorder.

Heritability refers to the proportion of the liability for a disorder that is estimated to be due to genetic factors. Disorders (or traits) in which genetic influences dominate (e.g., Huntington's disease, cystic fibrosis) have high heritabilities >.6). Moderate heritability (.3 to .5) suggests that the studied phenotype (1) results from a more even interaction between genetic and nongenetic influences; or (2) contains several genetically different syndromes, some with high and others with low or no heritability. Examples of this latter situation are common in other areas of medicine in which actual genetic mechanisms have been identified (e.g., diabetes, breast cancer, Alzheimer's disease).

PANIC DISORDER AND AGORAPHOBIA

Panic disorder is the best studied anxiety disorder with respect to intergenerational transmission. Accumulated data strongly suggest a genetic contribution to its etiology. However, heritability estimates are variable (from .3 to .6 percent) and the mode of transmission is unknown. Although several DNA marker studies are now under way, no positive results have been reported.

Twin Studies Four twin studies of panic disorder have been reported. Three indicate greater concordance for the diagnosis for MZ twin pairs than for DZ twin pairs, supporting a genetic contribution to the disorder. The fourth study indicates a genetic role in the predisposition to anxiety symptoms but not to any of the specific revised third edition of DSM (DSM-III-R) anxiety disorders.

When 1033 twin pairs from the Virginia Twin Registry were studied, diagnosis of panic disorder was made in 5.8 percent of the 2163 interviewed twins. Assessments were done using a semi-structured clinician-administered interview. Probandwise concordance for DSM-III-R panic disorder was 24 percent in MZ twin pairs and 11 percent in DZ twin pairs. The highest heritability (46 percent) was found using a narrow (strict adherence to the DSM-III-R criteria) definition of panic disorder. The heritability (and by extention the estimate of strength of genetic contribution) was lower when the criteria were broadened to include cases that did not meet full criteria (e.g., recurrent panic attacks with only three rather than four associated symptoms).

Contrasting results were reported in a smaller sample of twins drawn from the Norwegian Twin registry (32 MZ and 53 DZ). Concordance for strict third edition of DSM (DSM-III) panic disorder was 1 of 5 in MZ and 0 of 6 in DZ pairs. However, if the phenotype was broadened to include an anxiety disorder that included recurrent unexpected panic the concordance pattern (4 of 13 versus 0 of 16;31 percent vs 0 percent $P < 0.05$) indicated a strong genetic contribution. A study using a larger but overlapping sample reported similar results; concordance for panic disorder in MZ versus DZ pairs was 42 percent versus 17 percent.

A subset of Australian twin registry was studied using clinical interviews. In 34 twin pairs at least one twin had panic disorder. No difference in concordance for panic disorder was found in MZ versus DZ pairs.

Family Studies Six direct-interview family studies of panic disorder have been reported—all indicate that panic disorder is highly familial. Rates of panic disorder in the relatives of panic disorder patients are 4 to 10 times as high as those in the relatives of never–mentally-ill or community controls. With the exceptions of social phobia and alcohol abuse, excess risk for disorders other than panic was not seen.

Several studies have also used the family study method to investigate possible heterogeneity within the DSM-IV category. This approach is based on the principle that if two syndromes are associated with different patterns of familial aggregation, they may differ with respect to some aspect of their etiology. For example, one investigation divided panic disorder patients into those with early- (at or before 20 years old) versus; later- (after age 20) onset panic disorder. Significantly higher rates of panic disorder were found in relatives of the early-onset patients as compared to the relatives of later-onset patients or controls. A second study using the family history method found that panic disorder patients who reported at least one relative affected with panic disorder also had an earlier onset of panic disorder than did patients who had no affected relatives. These data are of interest in that they suggest that early-onset panic disorder may be a more severe or etiologically different form of the illness; however, further investigations are needed.

Another interesting area of current research concerns response to carbon dioxide. A number of studies indicate that individuals with panic disorder are significantly more likely than well individuals to become anxious or panic during exposure to carbon dioxide (5 to 35 percent). Two recent studies have extended this work by studying never–mentally-ill relatives of panic disorder patients, patients with depression, and never–mentally-ill controls. Mentally healthy relatives of panic patients have significantly higher rates of panic during carbon dioxide exposure than either of the other groups. This finding suggests that carbon dioxide sensitivity may be a familially transmitted marker of an inherited susceptibility to panic disorder. Family and follow-up studies to clarify these findings are now under way.

Some individuals with panic disorder also develop agoraphobia while some do not and the reasons for this variation are not known. It is possible that panic disorder with agoraphobia is a more severe form of panic disorder. Alternatively, the development of agoraphobia may be related to separate inherited or environmental factors; or some mixture of these. Two studies have addressed these questions. Rates of panic disorder with and without agoraphobia in relatives of three groups of individuals patients with panic disorder and no agoraphobia, patients with panic disorder and agoraphobia, and nonanxious controls were compared; results indicated that relatives of the agoraphobia patients had higher rates of both panic disorder (7.0 versus 3.5) and agoraphobia (14.9 versus 3.5) than the relatives of the controls, although the difference reached the .05 level of significance only in the latter group. In contrast, the relatives of the panic disorder patients had significantly higher rates of panic disorder (14.9 versus 3.5, $P < .005$) but not agoraphobia (1.7 versus 3.5, not significant) as compared to relatives of controls. These data may be interpreted as indicating that with respect to intergenerational transmission agoraphobia (with panic attacks) is either a more severe form of panic disorder or possibly

a different but partially overlapping illness. A twin study tested the fit of their data with several genetic models in which panic disorder with avoidance was hypothesized to be a more genetically severe form of panic disorder without avoidance and good fit was found in three out of four cases; heritability estimates ranged from .34 to .40.

Segregation Analyses Several segregation analytic studies of panic disorder have been reported. Results are consistent with genetic transmission but inconclusive as to the genetic model. Support was found for a single major locus dominant model. Another study found equal support for the single major dominant or recessive models in two independent samples; however, in none of these cases could polygenic transmission be excluded.

DNA Marker Linkage and Association Studies of Panic Disorder Although there is significant evidence for a genetic contribution to panic disorder, at this point there is no data indicating association between a specific chromosomal location or mode of transmission and this disorder. Two large genomic screening studies are in progress and both have reported only negative findings. One study has reported exclusion of linkage between the DSM-III-R panic disorder phenotype for over 95 percent and 60 percent of sites in the human genome under the dominant and recessive models of transmission respectively. Other researcher have excluded linkage between panic disorder and several candidate genes including: five adrenergic receptors, a-haptoglobin, and several components of the g-aminobutyric acid (GABA) receptor system.

Accumulated twin and family study data indicate that panic disorder does not follow a Mendelian mode of transmission and is therefore considered a complex disorder in terms of genetic studies. Experience with complex disorders in other areas of medicine indicates that multiple genes may be involved in determination of a single aspect of clinical pathology. Moreover, both pleiotropy (different clinical syndromes associated with the same genetic underpinnings) and genetic heterogeneity (different genes can lead to the same clinical phenotype) are ubiquitous. In this setting it is not surprising that the current effort to identify a gene for panic disorder has not yet been successful. Genetic heterogeneity can greatly impair the power of linkage analyses by introducing inadvertent false positives. Similarly, pleiotropy can lead to inadvertent exclusion of genetically affected individuals and consequent reduction in power to identify linkage. Current efforts to resolve these difficulties are directed at: (1) using epidemiological biological, and family study data to identify phenotypes that may be closer to the gene; (2) enlarging samples to provide sufficient power to identify smaller gene effects; and (3) improvement of molecular genetic technologies.

GENERALIZED ANXIETY DISORDER

In 1980 DSM-III subdivided anxiety neurosis into panic disorder and generalized anxiety disorder depending on the presence or absence of recurrent spontaneous panic attacks. Although several earlier studies suggested a genetic contribution to anxiety neurosis, their relevance to the residual category of generalized anxiety disorder is unclear. This section focuses on work using the DSM-III and subsequent criteria for generalized anxiety disorder. Several twin and family studies indicate a genetic role in the etiology of this syndrome. However, the extent of the relationship between the disorder and depression as well as the symptom and duration boundaries of generalized anxiety disorder itself require further study. Adoption and DNA marker studies of this disorder have not been reported.

Twin Studies Six twin studies have examined heritability of DSM-III or DSM-III-R generalized anxiety disorder. Although results are mixed, taken as a whole these data suggest a moderate genetic contribution to this disorder. Three of the six studies used epidemiological twin samples and bivariate genetic modeling to investigate both the genetic contribution to generalized anxiety disorder and its relation to major depressive disorder. One study evaluated subjects by direct semistructured interview, the other two by questionnaire. Similar results were found across the three samples. Generalized anxiety disorder was found to be moderately heritable (heritability ~.4 to .5). However, according to this model the genetic factors that make an individual vulnerable to this disorder completely overlap with those that predispose an individual to major depressive disorder. Whether an individual with this genetic loading develops generalized anxiety disorder, major depressive disorder, or both depends on individual-specific environmental factors. No significant effect was found for common family environment.

The remaining three twin studies of generalized anxiety disorder used direct interview procedures in smaller samples derived from a combination of population and hospital registries. Genetic contribution was examined by contrasting probandwise concordance for generalized anxiety disorder in MZ versus DZ twin pairs. One study found no difference in rates of concordance for the disorder in monozygotic and dizygotic pairs (0/12 versus 1/20). Major depressive disorder did not aggregate in the cotwins of generalized anxiety disorder probands. The two remaining studies found somewhat higher concordance rates in the MZ pairs. However, these differences did not reach the .05 level of significance. The relationship between generalized anxiety, disorder and major depressive disorder was not systematically examined. One hundred and forty-four twin pairs from a geographical subsample of the Australian Twin Registry in which the index twin met DSM-III criteria for generalized anxiety disorder were interviewed. Concordance for the disorder was 21.5 percent (13/63) in the MZ versus 13 percent (11/81) in the DZ pairs (NS). A sample of 49 twin pairs, which included 12 index twins with generalized anxiety disorder, were found to have MZ versus DZ concordance rates of 3/5 versus 1/7 (NS).

Family Studies Two family studies of generalized anxiety disorder have been reported. In both, psychiatric disorder in relatives of probands with the disorder is compared to that in the relatives of not-ill controls as well as patients with panic disorder or major depressive disorder or both. One hundred and twenty-three relatives of 20 both generalized anxiety disorder probands with similarly evaluated relatives of 20 control, 40 panic disorder, and 40 agoraphobic probands (N = 113, 241, and 236 respectively) were compared. Significantly higher rates of generalized anxiety disorder were found in the relatives of the probands compared to those of the other groups (19.5 percent versus 3.5 percent versus 5.4 percent versus 3.9 percent; $P < .001$) The two-way contrast between the relatives of the subjects with generalized anxiety disorder versus control patients was significant at $P < .001$ (chi squared = 14.37). There were no significant differences between rates of other anxiety and mood disorders (7.3 percent versus 7.1 percent) in the relatives of the anxiety disorder patients versus relatives of controls. The latter argues against the overlap in heritability of generalized anxiety disorder and major depressive disorder reported by the twin studies cited previously. Panic disorder was significantly elevated in relatives of panic patients versus controls. The absence of an excess of panic disorder in the relatives of the generalized anxiety disorder patients versus controls (4.5 versus 3.5 percent) supports the DSM-III separation of these two syndromes.

The second family study compared relatives of four proband groups: generalized anxiety disorder, major depressive disorder, panic disorder, and controls. Rates of the anxiety disorder were higher in relatives of the probands but did not differ significantly across groups (8.9 versus 4.9 versus 4 versus 1.9 percent). There was no evidence of a shared familial diathesis between generalized anxiety disorder and either panic disorder or major depressive disorder.

SOCIAL PHOBIA

Data on genetic contributions to social anxiety are drawn from three sources: (1) twin and family studies of DSM-III-R social phobia; (2) twin studies of irrational social fears in adults; and (3) studies of childhood temperament.

Twin and Family Studies of Social Phobia Of 2163 twins (1033 pairs) drawn from the Virginia Twin Registry, 11.5 percent met criteria for social phobia. Probandwise concordance for social phobia was 24 percent in monozygotic versus 15 percent in dizygotic pairs. The best-fitting model suggested that genetic and environmental factors contribute respectively 30 and 70 percent of the liability for social phobia. Two thirds of the genetic liability is made up of factors specific to social phobia and the remaining one third comes from genetic liability that contributes to all phobias (e.g., phobia proneness).

One direct-interview family study and one family history study of social phobia have been reported. Each found moderate, specific familial aggregation of this disorder. One study compared rates of psychiatric disorders in the directly interviewed relatives of social phobia (N = 105), specific phobia (N = 49), agoraphobia with panic (N = 164), and never-ill controls (N = 231). Rates of social phobia but not of other anxiety disorders were significantly elevated in the relatives of the social phobia probands as compared to the relatives of the other groups. Relatives of social phobia probands had an almost threefold increased risk for social phobia as compared to relatives of controls (16 versus 6 percent, $P < .05$). Similar results were found using the family history method (in this method the data on relatives came from interviewing patients about their relatives). Relatives of social phobia patients were reported to have a higher risk for social phobia (6.6 percent) as compared to both the relatives of panic disorder patients (.4 percent, $P < .001$) and not ill controls (2.2 $P < .1$).

The DSM-III-R and DSM-IV have divided social phobia into two subtypes: generalized (most social situations) and nongeneralized. If these represent two causally different syndromes they would be expected to be associated with different patterns of intergenerational transmission. For example, relatives of patients with generalized social phobia would be expected to have an elevated rate of generalized but not nongeneralized social phobia and vice versa. A 1998 direct interview family study addressed one aspect of this question. Rates of generalized and performance social phobia were compared in relatives (N = 111) of generalized social phobia patients and controls (N = 74). Significantly higher rates of generalized (24 versus 4 percent, odds ratio = 7.6) but not performance (15 versus 14 percent, NS) social phobia were found in the relatives of the generalized social phobia patients. This finding suggests a possible causal distinction between the two subtypes. However, since the study did not include a proband group of performance social phobia patients, it was not possible to determine whether this group would transmit an increased risk for generalized social phobia to their relatives. If so, this would suggest a partial overlap between the subtypes. Further studies in samples that

include larger numbers of nongeneralized social phobia probands are needed to clarify the relationship of these subtypes with respect to heritability.

Twin Studies of Irrational Social Fears A series of twin studies indicate a moderate genetic contribution to irrational social fears and shyness. It is not possible to determine the exact proportion of individuals in these studies who would meet criteria for DSM-IV social phobia. However, the consistency of these data makes a strong argument that genetic factors play an important if partial role in this area of human behavior.

Two reports have been published on a large twin-family study of individuals recruited through university registries in Indiana and the Indiana University Twin panel. A survey questionnaire was used to assess existence and severity of 51 commonly seen irrational fears, several related to social anxiety, in this population. Seven factors accounted for 45 percent of the variance in fear survey responses. Two of these (Negative Social Interactions/Social Criticism and Social Responsibility) are made up of fears that are considered to be part of social phobia. Negative social interactions included fears of making mistakes, looking foolish, or being criticized. Items loading on the social responsibility factor included public speaking, being a leader, and meeting new people.

The 1983 report by these investigators included 222 MZ and 132 DZ twin pairs. The heritability of the Negative Social Interactions and Social Responsibility factors in this sample was .44 and .60, respectively. This is interpreted as indicating that 44 percent of the liability to have irrational fears of negative social interaction and 60 percent of the liability to fears of social responsibility items is determined by genetic factors. The second report included 341 families (250 twin families and 91 sib families); the overlap between this and the 1983 sample is unclear. A multivariate path analysis was used to examine the relative fit of various genetic models. The best fitting model indicated: (1) moderate heritability of the two social fear factors; (2) a single genetic factor that accounted for most of the genetic liability for all 51 fears; (3) smaller genetic contributions that were specific to each of the fear factors; and (4) a moderate contribution from the common twin environment.

A similar study was conducted in 99 same-sex twin pairs (50 MZ and 49 DZ) from the Norwegian National Twin Register. However, in this case fear survey answers were elicited during a face-to-face clinical interview. Five factors accounted for over 50 percent of the variance in fear responses. Heritability of the social fears factor was .50 (fears of eating with strangers; being watched writing, working, or trembling). Using a slightly different approach a study was conducted of 99 MZ and DZ twin pairs using the California Personality Inventory (CPI). Forty-one of the 82 items in the inventory showed differences between MZ and DZ pairs, indicating genetic influence. A factor analysis of the 41 items revealed two factors related to social behavior (conversational poise and social ease). Items in these factors included: fear of finding anything to talk about with people, difficulty talking to or meeting new people, and fear of public speaking.

Childhood Temperaments Related to Social Behavior Two well-studied childhood temperaments (behavioral inhibition and shyness) may also contribute to the understanding of the development of social phobia. Each shares some clinical features with social anxiety and has been shown to have a genetic contribution to its etiology. However, there are also clear differences between each of these syndromes and social phobia. Moreover, as longitudinal studies have not been carried out, there is as yet no prospective evidence that either of these childhood syndromes increases the risk for adult social phobia.

Extensive studies have been conducted on the childhood temperament *behavioral inhibition*, which is found to occur in approximately 10 to 15 percent of white children and is characterized by timid, fearful, and withdrawn behavior on encountering unfamiliar people or situations. Another 10 to 15 percent of children show an opposite temperament (behaviorally uninhibited), which is characterized by outgoing, active, and exploratory behavior in new situations. More recent work indicates that these temperaments are distinguishable at as early as 4 months of age and are stable in 50 to 75 percent of individuals over the first 7 years of life. The suggestion that behavioral inhibition is linked to social phobia comes from both the observation of overlap in certain clinical symptoms and a family study that indicated higher rates of social phobia were found in the parents of behaviorally inhibited versus behaviorally uninhibited children versus controls (18 versus 0 versus 3 percent, $P < .05$).

A recent twin study of behavioral inhibition carried out in connection with a larger study of childhood temperaments reported the heritability at .49 (i.e., about 50 percent of the liability to develop behavioral inhibition comes from genetic factors). This moderate genetic contribution is consistent with those found in other studies of social anxiety. A second piece of evidence on genetic contribution to behavioral inhibition comes from breeding and cross-fostering (i.e., adoption) studies using animal models. There are several animal models of variation in reactivity to the unfamiliar; in each of these cases the more reactive strain shows the timid behavior and increased arousal that characterize Kagan's behaviorally inhibited children. That these behaviors can be bred in strains even if offspring are raised by unaffected individuals suggests a genetic contribution. For example, in a breeding study of rhesus monkeys it was found that the similarity with regard to extent of high reactive (i.e., behaviorally inhibited) behavior was proportional to degree of biological relatedness. High reactivity also persisted in monkeys who were cross-fostered (i.e., adopted) by low reactive mothers, suggesting that pedigree rather than mothering style is the predominant determinant of this trait.

A second set of developmental studies have focused on shyness. In this context shyness is defined as timid, avoidant, and passive behavior when confronted with an unfamiliar person. The Institute for Behavioral Genetics in Colorado has carried out several twin and adoption studies of this temperament in children. The results of the twin studies indicate significantly greater correlation of shyness scale scores between MZ versus DZ twins, supporting a genetic contribution to variation in this behavior. For example, 21 MZ and 25 DZ twin pairs aged 22 months were studied by observing their social response to structured situations involving their mothers and the research rater in their own homes. The types of social situations included: how long it takes the child to engage and interact with the researcher and how the child reacts to playing alone with the researcher or being separated from the mother. Correlation of scores between members of MZ pairs were in the range of .40 to .67 and were higher than those between members of DZ (–.05 to .34) pairs for all but one situation (time to smiling MZ .08 versus DZ .25). Similar results were found for children ranging from 4 to 10 years using both parental rating and direct observation.

In contrast to the twin data, the Colorado Adoption Project data were equivocal with respect to the possibility of a genetic contribution to shyness. This project included 182 adoptive and 164 nonadoptive families. Parents rated infant shyness at 12 and 24 months using a specially developed social ability-and-shyness scale. Typical items included: “child tends to be shy,” child takes a long time to warm up to strangers.” Parental shyness was measured using three self-report adult temperament scales. There were small but significant correlations between infant shyness and parental self-ratings on all three scales in the nonadoptive families (i.e., families in which biological parents raised their biological children) suggesting some degree of familial transmission of these behaviors. A genetic contribution would be indicated by high correlations between biological mothers and their adopted-away children and low correlations between adoptive parents and their adopted children. In actuality, in this sample there were very few strong correlations among any of these groups. Social ease in biological mothers was negatively correlated with shyness in their adopted-away 24-month-old infants (–15, $P < .05$). Correlations of similar strength were seen between this measure in adoptive mothers and fathers and shyness in their adopted (i.e., nonbiological) children.

Twin and family studies of social phobia and social fears indicate a moderate genetic contribution to these behaviors. Two childhood temperaments (shyness and behavioral inhibition), which also have a moderate genetic basis, show symptomatic overlap with social phobia. However, further studies of the adult outcome of these temperaments are needed to clarify their relationship to social phobia. Systematic DNA marker studies have not been reported.

SPECIFIC PHOBIAS

Although specific irrational fears and phobias had often been thought to originate completely through learned conditioning, there is significant evidence that genetic factors also play a definite (though partial) role in their development. However, neither adoption, DNA marker, nor segregation analytic studies have been reported. In addition to the obvious unanswered questions concerning mode and mechanism of transmission, two issues have been the subject of discussion in this field. These are: (1) the extent to which one inherits a susceptibility to a particular phobia versus a general phobia proneness; and (2) whether the genetic factors that influence irrational fears and phobias are the same. Irrational fears are distinguished from phobias by the fact that they do not involve either impairment or distress about the fear and therefore do not meet the DSM-III-R criteria for phobic disorder.

Twin Studies of Specific Fears and Phobias The Virginia Twin Registry study assessed heritability of two specific phobia subtypes: animal and situational (e.g., fears of tunnels, closed places, bridges, airplanes, high places). Each was found to have moderate heritability, although the genetic modeling analyses indicated different mechanisms of transmission. Animal phobias occurred in 11 percent of the sample. Probandwise concordance was 26 percent for MZ and 12 percent for DZ pairs. The best-fitting genetic model suggested that the major contributions to heritability of animal phobias were genetic factors common to all phobias (35 percent) and specific environmental events (59 percent; e.g., getting stuck in a tunnel). A completely different pattern was seen for situational phobias. Here probandwise concordance was similar in MZ versus DZ twin pairs (22 versus 24 percent). The best-fitting model indicated that 53 percent of the liability to these phobias comes from specific environmental events, 20 percent from specific, and 9 percent from common genetic factors.

Several additional twin studies have used the fear survey method to assess specific irrational fears. Subjects were asked to rate the severity of their fear of a variety of different situations on an ordinal scale (e.g., 0 = no fear, 5 = extremely anxious) As fear-related impairment and distress were not assessed, this methodology identified a mixed group some of whom will and some of whom will not meet the DSM-III-R or DSM-IV criteria for specific phobic disorder. These data must be

interpreted in light of this limitation.

Irrational fears were studied in a large twin sample recruited from university students and their families throughout Indiana. The first investigation included 222 MZ and 132 DZ same-sex twin pairs who were assessed for severity of fear of 51 commonly feared situations. Seven factors were found to account for 45 percent of the variance in fear response; two were related to social anxiety. The remaining five factors include irrational fears that are commonly the subject of specific phobic disorders. Each of these five fear factors was found to be influenced by genetic factors; however, the magnitude of heritability varied considerably. Relatively high heritabilities (indicating a large genetic contribution) were found for irrational fears of dangerous places (.58) for example, closed places, crowded places, heights; small organisms (.66) for example, snakes, mice, spiders; and personal death (.72), for example, death, untimely or early. Moderate heritabilities were found for the factors including fears of deep water (.32), including boating, swimming, deep water, and loved one's misfortunes (.28), for example, death, illness or injury of a loved one).

In a second study path analytic methods were applied to genetic analysis of 341 families (250 twin pairs, 91 sib pairs, and their parents). Assessment and data reduction methodology were similar to that used in the previous work. Seven factors accounted for over 50 percent of response variance. Two factors were comprised of social and four of specific irrational fears. The specific fear factors were similar to those identified in the earlier investigation. A seventh factor that is not clearly related to a particular DSM-IV phobia diagnosis included fears of death and illness of loved ones. A single genetic factor accounted for 80 percent of the variance in all fear responses in this sample and contributed to the development of each of the types of fears. In addition, specific genetic factors of varying strength were found for each fear type. Overall heritability was moderate. Heritabilities of each of the irrational fear types were: heights (.22), water (.20), dangerous places and organisms (.39), morbid settings (e.g., cemeteries, dead bodies, needles; .34).

Ninety-nine twin pairs from the Norwegian Twin Registry were studied using a fear survey administered during a clinical interview. Five factors, three of which are relevant to specific phobia, were found to account for over 50 percent of the variation in fear responses. For each of the three specific phobia factors the correlation of fear scale scores was significantly greater between MZ as compared to DZ twins, supporting a genetic contribution. Although the factors largely overlap with those identified in earlier research, the heritabilities were slightly higher. The three factors and their heritabilities were as follows: fears of animals (rats, mice, insects) .47; mutilation (blood, injury, medical procedures) .48; and nature (e.g., bridges, high places, closed places, tunnels, sharp objects, the ocean, fire).

These data indicate a genetic contribution to both irrational fears and phobias but do not address the question of their interrelationship with respect to intergenerational transmission. Two smaller studies provide some preliminary information on this issue. Both suggest that the transmitted component may be a susceptibility to a particular irrational fear whereas the possible consequence of avoidance or impairment is determined by other factors. However, further studies in larger and more well-defined samples are needed to further explore this question.

Forty-nine twin pairs from the Maudesly Twin Registry were studied. Twenty-one index twins had a phobia diagnosis. There was little difference between MZ versus DZ pairs in concordance for treatment of a phobia (13 percent in MZ versus 8 percent in DZ). However, when the diagnostic criteria were broadened to include phobic symptoms with or without treatment, concordance rates for MZ twins were substantially higher although not significantly different from those for DZ twins (88 versus 33 percent).

A subset of the Virginia Twin Registry study participants (541 MZ and 388 DZ twin pairs) were called back a year later to assess presence of phobias and irrational fears of blood, needles, hospitals, and illness. The best-fitting model indicated a genetic contribution to irrational fears of the first three items. However, occurrence of the DSM-IV disorder blood injury phobia (i.e., irrational fear of any of these situations, which interfered with the subject's life) was best explained by environmental factors.

Family Studies Several family and family history studies indicate a greater risk for phobic disorders among the relatives of phobia patients as compared to the relatives of controls. However, these data are somewhat difficult to interpret because most have used mixed proband groups that include patients with both social phobia and agoraphobia. The one direct interview family study of DSM-III-R simple phobia found a threefold increased rate of simple phobia among relatives ($N = 49$) of simple phobia probands as compared to relatives (119) of never–mentally-ill controls (31 versus 11 percent, $P < .005$, relative risk = 3.3). There was no evidence of familial aggregation of subdisorder irrational fears. Although this study is consistent with the twin data it requires replication in a larger sample.

Animal Models One striking feature of phobias is that they are irrational. That is, individuals with phobias are fearful of objects or situations that are not, from most people's point of view, realistically dangerous. This observation has led to the hypothesis that at least some phobias are acquired through conditioning. Conditioning is a process by which the animal acquires fear of a previously neutral stimulus through its repeated association with a noxious stimulus (e.g., shock). In a typical experiment a rat would be trained to fear a soft tone (conditioned stimulus) by repeated exposure to the tone followed by an electric shock (unconditioned stimulus). When conditioning takes place the rat will react to the tone as though it were the shock (i.e., with fear), even if the shock is no longer given. Animal models of conditioned fear are used to study the neurobiology of fear as well as of learning and memory. Experiments with fear conditioning have indicated that: (1) it is possible to breed strains of animals who are more or less fearful of specific stimuli and (2) there is genetic variability between strains in the strength and persistence of conditioned fear. Although this work is not directly applicable to the case of specific phobias in humans, it may provide starting points for development and testing of molecular genetic models.

These data indicate that genes contribute to the development of specific irrational fears and phobias. However, their role is moderate, leaving substantial influence to environmental factors (e.g., interpersonal, chance events). Most studies also indicate complexity in the structure of the genetic contribution. That is, there may be two types of genetic factors involved: those which influence an individual's likelihood to develop any phobia and those that are specific to fears or phobias of a particular situation. This suggestion of genetic heterogeneity within and across the DSM-IV categories is consistent with the diversity seen in studies of onset and course of specific phobias. Recent findings in animal models offer the possibility of dissecting phenotypes that may be more amenable to successful application of molecular genetic techniques.

OBSESSIVE-COMPULSIVE DISORDER

Data on the heritability of obsessive-compulsive disorder are inconclusive. Most but not all modern family studies have been positive, suggesting that there is intergenerational transmission of susceptibility to at least some subset of these cases. However, a genetic contribution to this disorder has not been well documented and there are no large systematic twin studies of this disorder. Recent findings in neuroimaging and treatment studies indicate that some cases of obsessive-compulsive disorder may be associated with specific autoimmune, receptor, or neuroanatomical abnormalities. These data suggest etiologic heterogeneity within the DSM-IV category; they have also increased interest in and provided some clues for understanding the possible genetic underpinnings of obsessive-compulsive disorder.

Twin and Family Studies Only one systematic twin study has assessed obsessive-compulsive symptoms and its results are suggestive but inconclusive concerning a genetic contribution to the disorder. Thirty (15 MZ and 15 DZ) of 49 twin pairs admitted to the Maudesly Twin Register had an index twin with obsessional symptoms. Probandwise concordance for treated obsessional symptoms that met DSM-III criteria was higher but not significantly different in MZ versus DZ twin pairs (33 versus 7 percent) When the diagnostic criteria were broadened to include either obsessive-compulsive disorder or untreated subclinical obsessional features, concordance rates were higher but still not significantly different (MZ versus DZ: 87 versus 47 percent). Diagnostic evaluations were not blind to diagnosis of cotwin.

Thirteen family studies of obsessive-compulsive disorder have been reported; however, only three employed state-of-the-art research methods (i.e., controls, blind assessment of relatives, and operational diagnostic criteria). Of these three studies two indicate familial aggregation in relatives of patients with obsessive-compulsive disorder versus relatives of normal controls, the third did not. One study found the disorder in 10.3 percent of the first-degree relatives of patients with obsessive-compulsive disorder as compared to only 1.9 percent of the relatives of psychiatrically well controls ($P < .005$). In one study the disorder was diagnosed in 7 percent of relatives of patients with the disorder as compared to 2 percent of relatives of controls ($P < .050$). In contrast, the third study found an increased rate of generalized anxiety disorder and any anxiety disorder among the relatives of patients with obsessive-compulsive disorder as compared to relatives of nonpsychiatrically ill controls. However, rates of the disorder did not differ between groups (2.5 percent versus 2.3 percent).

Interestingly, this mixed pattern of results is similar to that seen in earlier, less methodologically rigorous work. For example, of two earlier controlled (but not blind) studies, one reported a significantly higher rate of obsessive-compulsive disorder in relatives of probands with the disorder as compared to relatives of controls while the other study did not. A third study reported on families of early-onset obsessive-compulsive disorder (mean onset 10 years ± 3) using blind diagnostic ratings and DSM-III criteria, but no control group. Considerably higher rates of the disorder (13 percent) and subdisorder of the disorder symptoms (17 percent) among relatives

of childhood-onset probands with obsessive-compulsive disorder than are expected in the general population.

It has been suggested that these mixed findings on familial aggregation of the disorder reflect differences in methodology as well as etiologic heterogeneity within the diagnostic category. That is, some cases of obsessive-compulsive disorder have a heritable contribution whereas others do not. If so, then whether a study shows familial aggregation or not depends on the proportion of familial cases that are included in its sample. To investigate this hypothesis several recent studies have began to subtype patients by such variables as age at onset, presence of neurological symptoms, and symptom patterns of the disorder.

Relation Between Obsessive-Compulsive Disorder and Tourette's Disorder One interesting set of findings concerns the possible relationship between a subset of these cases and certain types of motor tic syndromes (i.e., Tourette's disorder and chronic motor tics). Increased rates of obsessive-compulsive disorder, Tourette's disorder, and chronic motor tics were found in the relatives of Tourette's disorder patients as compared to relatives of controls whether or not the patient had obsessive-compulsive disorder. However, most family studies of probands with obsessive-compulsive disorder have found elevated rates of Tourette's disorder and chronic motor tics only among the relatives of probands with obsessive-compulsive disorder who also have some form of tic disorder. Taken together these data suggest that there is a familial and perhaps genetic relationship between Tourette's disorder and chronic motor tics and some cases of obsessive-compulsive disorder. Cases of the latter in which the individual also manifests tics are the most likely to be related to Tourette's disorder and chronic motor tics. As there is considerable evidence of a genetic contribution to Tourette's disorder this finding also supports a genetic role in a subset of cases of obsessive-compulsive disorders.

POSTTRAUMATIC STRESS DISORDER

Posttraumatic stress disorder (PTSD) is the least studied anxiety disorder with respect to heritable or genetic contributions to etiology; only one twin and a few family studies have been reported. However, the data are intriguing and suggest further investigation in this area will both help clarify the causes of PTSD, and also improve the overall understanding of the multiple ways in which genes and environment can interact in the development of pathology.

The major indication of a genetic contribution to PTSD comes from a large twin study whose subjects were drawn from the Vietnam era veterans registry. Approximately two thirds of the registry twins (N = 4042 male twin pairs) responded to a mailed questionnaire. Independent genetic effects were found to influence both exposure to combat and development of PTSD symptoms. Within-pair correlation for most of the DSM-III-R PTSD symptoms was twice as high for MZ as compared to DZ twins. Although the prevalence of PTSD symptoms increased in proportion to extent of combat exposure, the MZ versus DZ twin pair difference held true even among veterans who did not serve in combat zones. Using a quantitative genetic model, genetic factors were estimated to account for approximately one third of the variance in liability to develop each of the DSM-III-R PTSD clusters in the overall sample (arousal cluster 28 to 32 percent, reexperiencing cluster 30 to 34 percent, and avoidance cluster 13 to 30 percent).

These findings must be considered with caution because the diagnoses are based completely on self-report rather than clinical evaluation and only two thirds of the sample responded. However, the suggestion of genetic influence on both (1) variation in response to stress; and (2) likelihood to expose oneself to situations leading to greater probability of trauma is consistent with several previous findings in epidemiological, personality, and animal model research.

In contrast to these twin study findings, several reported family history studies have not found increased rates of PTSD relatives of PTSD probands as compared to relatives of normal and psychiatrically ill controls. However, the significance of these results is difficult to interpret because the family information or sample sizes were insufficient to examine PTSD rates in relatives who were exposed versus not exposed to trauma. One study yielded family history data indicating an increased rate of anxiety disorders among relatives of PTSD probands compared to relatives of combat-exposed non-PTSD probands. This finding would suggest a heritable relationship between PTSD and other anxiety disorders. However, it was not confirmed in a subsequent direct interview family study and no adoption studies on PTSD have been reported.

Another interesting approach to this problem is reported by researchers who studied the occurrence of PTSD in adolescent Cambodian refugees and their parents. Although subjects were currently living in the United States, all had had significant exposure to war trauma before immigration. Within each family the trauma exposure of the parent and adolescent was similar. Assessments were by direct interview. Significantly higher rates of DSM-III-R PTSD were found among adolescents whose parents had versus those who did not have PTSD (16/60 versus 4/58, 27 versus 7 percent, $P < .05$). This effect was independent of socioeconomic status, amount of reported war trauma, living arrangements, or treatment.

The data summarized above indicate that genetic factors play an important role in the development of anxiety disorders. However, as the heritability of these syndromes is only moderate, nongenetic factors are equally crucial. In addition, as the patterns of intergenerational transmission do not follow Mendelian rules, anxiety disorders fall into the ever-enlarging category of genetically complex disorders. Future research will have to take into account the high probability that there is widespread pleiotropy (i.e., different clinical syndromes associated with the same genetic underpinnings) and genetic heterogeneity (i.e., different genes can lead to the same clinical phenotype). It will also need to focus not only on genetic mechanisms that underlie susceptibility to pathological anxiety states, but also on nongenetic contributions and how (and if) there is interaction between several different genes as well as between genetic and nongenetic causes.

The classification of anxiety disorders has become increasingly specific. Overall the family study and genetic data are supportive of these new distinctions. For several anxiety disorders there is evidence of specific genetic contributions that increase susceptibility to that illness but not to the other anxiety syndromes. However, there are also data that indicate the existence of genetic factors that increase an individual's likelihood for any anxiety disorder; at least one investigation finds that both types of genetic effects (general and disorder specific) are important. These data are completely consistent with the current knowledge of the etiological heterogeneity seen in genetically complex disorders. However, taken together they suggest that the actual genetics of anxiety disorders may be much more complicated than suggested by previous etiological theories.

SUGGESTED CROSS-REFERENCES

Population genetics in psychiatry is discussed in Section 1.17 and genetic linkage analysis of psychiatric disorders is in Section 1.18. Epidemiology is covered in Section 5.1.

15.5 ANXIETY DISORDERS: PSYCHODYNAMIC ASPECTS

GLEN O. GABBARD, M.D

FREUD'S THEORY OF ANXIETY

Sigmund Freud placed anxiety at the core of neurosis; hence the history of the development of psychoanalytic theory can be linked to the evolution of Freud's understanding of anxiety. In 1895 he put forth his original theory of anxiety, which postulated a biologically based cause. Specifically Freud believed that the accumulation of undischarged libido was transformed into anxiety. In his view the "dammed-up" libido could either result from external obstacles to its appropriate discharge or from internal inhibitions related to unconscious conflicts about sexual gratification. Freud did not fully explain how the transformation of accumulated libido into symptomatic anxiety occurred—he merely suggested that such a transformation must occur.

Freud referred to this form of anxiety as *actual neurosis*, and this designation clearly referred to a pathological type of overwhelming fear. It was directly linked to drive energy and associated with a number of physiological symptoms, including manifestations of autonomic discharge, such as profuse sweating, diarrhea, and increased respiratory and heart rates. He also connected it with an overwhelming sense of panic and terror.

This rather nonpsychological formulation of anxiety was retained until 1926, when Freud wrote his classic monograph *Inhibitions, Symptoms, and Anxiety*. This publication appeared 3 years after *The Ego and the Id*, which suggested that the tripartite structural model of *id, ego, and superego*, was the key to understanding mental phenomena. His 1926 monograph was essentially a new theory of anxiety based on his understanding of interagency conflict in the structural model. Although he had now abandoned the original idea that undischarged libido is transformed into anxiety, he nevertheless continued to regard anxiety as having a biological or genetic basis. He recognized that there was clearly a Darwinian survival value in reacting to external threats with anxiety; hence he believed that every human organism must be congenitally endowed with this capacity to respond to danger situations both physiologically and psychologically. However, Freud's theory of anxiety was not designed to identify the origin of anxiety as a human phenomenon; instead, its emphasis was on how to understand the role of anxiety in the individual's mental life.

Traumatic situations were regarded as central to the development of anxiety according to Freud's new theory. The prototype of the traumatic situation was the experience of birth, when the infant is overwhelmed by a flood of stimuli arising from external sources as well as from internal sensations. Freud believed that this prototypical model could be used to understand anxiety in other situations in the course of development where individuals are overwhelmed by an influx of stimuli that they are incapable of mastering. The emphasis in his theory was primarily on stimuli arising from the id, specifically aggressive and sexual wishes that had been repressed and are striving to make their presence known.

A second aspect of Freud's new theory on anxiety involved "danger" situations. Freud suggested that as children develop they learn to anticipate a traumatic situation before it happens and to react to it with anxiety. Freud termed this reaction *signal anxiety* because it was produced by a situation in which the individual anticipated danger. In response to this signal of danger, the ego mobilized defense mechanisms to prevent unacceptable thoughts and feelings from emerging into conscious awareness.

Freud used the situation of an infant being left alone by its mother as a way of illustrating a typical danger situation. Infants learn that a relationship exists between the absence of the mother and the experiencing of unpleasurable states of internal turmoil. Based on this experience, the ego learns that separation from the mother is a danger situation and responds accordingly with signal anxiety. If the signal anxiety fails to activate the ego's defensive resources adequately, more persistent or even neurotic symptoms will result. In this regard, Freud conceptualized anxiety as both a symptomatic manifestation of neurotic conflict and an adaptive signal to avoid awareness of neurotic conflict.

In this second aspect of Freud's new theory of anxiety, the pleasure principle was intimately related to the function of the anxiety. The signal anxiety that the ego learns to produce in response to the anticipation of danger was viewed as relatively less unpleasurable than the anxiety that would develop if there were no signal and the traumatic situation of abandonment developed fully. Signal anxiety is a way of attenuating a more profound and terrifying anxiety.

In this model the phenomenon of anxiety is an ego affect. The signal of danger produced by the ego offers opposition to the emergence of repressed id impulses into conscious awareness. The ego's defense mechanisms are marshaled in response to the signal anxiety. One such defense mechanism is *repression*, which keeps undesirable id impulses, whether desires, wish-fulfilling fantasies, memories, or affects, from entering the consciousness. The ego serves to censor both the impulse itself and the corresponding intrapsychic representation of that impulse. Nevertheless, the impulse or drive-related wish that has been repressed may still find a way to express itself in the form of a symptom. By the time it manifests itself as a symptom, however, it is likely to be disguised and displaced. For example, the symptom of hysterical paralysis might reflect an underlying wish to strike a parent with murderous intent.

The underlying wish related to drive pressures may also be defended against through *reaction formation*. This defense mechanism involves an overemphasis on one side of an ambivalent attitude. If love and hate are both directed towards a parent, the defense of reaction formation maintains the hate as an unconscious part of the affective state while emphasizing love. The manifestation of this reaction formation might be excessive devotion to the parent and professions of love without any conscious awareness of negative feelings. Hence an exaggeration of a feeling or attitude led Freud to wonder about the other side of the equation buried in the unconscious. This awareness of reaction formation had been observed by writers years before Freud's formulation of anxiety. Ralph Waldo Emerson, for example, once noted, "The louder he spoke of his honor, the faster we counted our spoons."

KLEIN'S VIEWS OF ANXIETY

Melanie Klein expanded on Freud's view by developing a theory of internal object relations linked to drives. She regarded fear of annihilation as the most fundamental anxiety and related it to Freud's death instinct. In her view, the ego engaged in a splitting process to deal with that fear of annihilation. All the derivatives of the death instinct, such as sadism, hatred, aggression, and any form of "badness," were evacuated from the infant and projected into the mother. The infant then began to suffer *persecutory anxiety* from the death instinct derivatives projected into the mother. This form of anxiety, which Klein linked to the paranoid-schizoid position, involved a fear that the "bad" mother created by the infant's projections would invade the infant and destroy all the "good" aspects of the infant.

As the infant moved from the paranoid-schizoid position to the *depressive position*, splitting of the ego was overcome by an integrative effort that was designed to link good and bad aspects of the self and of objects. Instead of viewing the mother as "all bad," the child is now able to see that mother has both good and bad qualities. Similarly, infants also become aware of the presence of good and bad within themselves. When the child becomes aware that the loving and nurturing mother is basically the same person as the hateful, rejecting mother, an important developmental moment has been achieved. Now the infant becomes concerned that it may have harmed or destroyed its mother through its hostile and sadistic fantasies directed toward her. This developmental achievement leads to *depressive anxiety*. While the infant was mainly concerned about being attacked by the persecutory object during the paranoid-schizoid position, in the depressive position the infant's primary anxiety is that it may hurt love objects, particularly the mother. The child then worries that the good object may be lost through the child's own aggression and sadism. Hence depressive anxiety can be summarized as a concern about the loss of the love object through one's own destructiveness. The child learns to deal with

these guilt feelings through a process of *reparation*, in which the child attempts to repair the perceived damage through loving behavior toward the ambivalently regarded object.

SELF PSYCHOLOGICAL VIEWS OF ANXIETY

Heinz Kohut developed self psychology in the late 1960s and continued his work until his death in 1981. He deemphasized drives and conflicts and emphasized a deficit model in which the self was regarded as immature and lacking in maternal supplies. The emphasis in self psychology is on infantile needs rather than repressed wishes or drives. Kohut felt that the need to maintain self-esteem and well-being was just as powerful as sexuality and aggression in molding the human organism. In his view the child has powerful needs to idealize a parent; to receive affirmation, validation, and empathy from that parent; and to maintain a sense of wholeness of the self.

Within this model, *disintegration anxiety* is the most fundamental concern of the individual. This anxiety is generated by the child's concern that the failure of adequate selfobject responses from persons in the environment will lead to fragmentation of the self. If empathy, affirmation, and validation are not forthcoming from significant individuals, such as parents, the child may then resort to pathological behavior to restore harmony to the self. In adult life these behaviors may include such things as gambling, perverse sexual behavior, disordered eating behaviors, substance abuse, and a myriad of other so-called “acting-out” behaviors. Kohut believed that the anxieties based on the internal drive pressures, such as sexuality and aggression, were breakdown products of preOedipal failures in the provision of selfobject needs.

HIERARCHY OF ANXIETY

It is possible to construct a developmental hierarchy of anxiety based on Freud's contributions to the subsequent elaborations by Klein and Kohut (Table 15.5-1).

- Superego anxiety
- Castration anxiety
- Fear of loss of love
- Separation anxiety (fear of the loss of the object—Kleinian depressive anxiety)
- Persecutory anxiety (Klein)
- Disintegration anxiety (Kohut)

Adapted from Gabbard GO: *Psychodynamic Psychiatry in Clinical Practice: The DSM-IV Edition*. American Psychiatric Press, Washington, DC, 1994.

Table 15.5-1 A Developmental Hierarchy of Anxiety

The psychodynamic clinician can use this hierarchy to guide the understanding of the unconscious origins of anxiety in a specific patient. These may be regarded as “danger situations” in terms of Freud's 1926 model. The highest level of developmental danger is that of guilt. The presence of superego anxiety reflects that moral standards of conduct have been internalized in the form of parental introjects. The superego provides love and approval or punishment and disapproval based on how closely the individual's behavior (or fantasy life) adheres to these standards of conduct.

Moving down the developmental hierarchy, the next typical danger situation is associated with the oedipal phase of development and focuses on the potential damage to or loss of the genitals at the hands of a retaliatory parental figure. This fear is often expressed metaphorically as a loss of a different body part or any other form of physical injury. The next type of anxiety involves the loss of parental love. In this situation, even though the parent (or parent substitute) is present physically, the child may still fear the loss of that object's love. In the adult patient this anxiety may manifest itself as a preoccupation with behaving in a manner that ensures a significant object's ongoing love and attention to fend off the anxiety that the object may become disappointed with the patient.

Although the foregoing forms of anxiety are typical of neurotically organized patients, the last three points in the hierarchy are often found as the predominant anxiety in more severely disturbed patients. For example, separation anxiety or the fear of abandonment by the love object is typical of patients with borderline personality disorder. Many of these patients lack object constancy, so they cannot internalize a soothing internal presence in the absence of the parental object. They often develop intense anxiety that a significant other, such as a therapist, a parent, a spouse, or a close friend, will suddenly disappear and no longer be there as a source of support. Margaret Mahler linked this to the rapprochement subphase of separation-individuation.

The most primitive forms of anxiety are often found in patients with borderline personality disorder or narcissistic personality disorder and those with psychotic disorders. Those with persecutory anxiety often use projection as a defense and have a paranoid mode of organizing experience, believing that there are outside malevolent forces that will invade and destroy them from within unless vigilance is maintained. Disintegration anxiety can manifest itself either through the fear of fragmentation (the loss of one's sense of a cohesive self) or through merger or fusion with an object. This form of anxiety is particularly prominent in patients who have poorly developed ego boundaries.

The hierarchical nature of these developmental anxieties may lead the clinician to assume that the more primitive levels of anxiety are “outgrown” as the child develops. Clinical wisdom, however, has taught us that to some degree the most primitive levels of anxiety persist in everyone. In a well-integrated and high-functioning individual superego anxiety may be the most prominent or leading anxiety, the more fundamental forms of anxiety may be activated in situations of great stress or trauma. Similarly, large group situations are often highly conducive to triggering persecutory anxiety, in which “outsiders” or those with different political views are seen as monstrous attackers. The history of Western civilization is characterized by the development of warring factions based on relatively minor differences in culture, religion, or politics.

A corollary of this view that all levels of anxiety persist to some extent in every individual is that symptoms may be multiply determined by anxiety stemming from different developmental levels. Consider the following example:

A 26-year-old man came to psychoanalytic treatment because of anxieties triggered by sexual intercourse with his fiancée. Although he professed to love this woman and considered their relationship to be mutually satisfying, he found himself much less interested in sexual intercourse than she was. During the act of intercourse he found himself wishing his fiancée would reach orgasm more quickly so he could retract his penis from her vagina. At the same time he felt reluctant to ejaculate in her, and he often stopped intercourse before reaching orgasm.

When his analyst asked him about his fear of ejaculating during intercourse, he said that he wanted to avoid an out-of-wedlock pregnancy. The analyst noted that the patient had previously conveyed that his fiancée was taking oral contraceptives. The patient confirmed that indeed she was, but he recognized that there was still a slight risk of pregnancy associated with birth control pills. The analyst asked the patient if he had any other fears associated with ejaculation.

The patient initially said that he did not, but he then associated to a dream in which he was having intercourse with a former high school girlfriend, and after the sexual act was consummated, he noticed that his voice had gone up two octaves and he “talked like a girl.” He looked in the mirror and he had become a woman who looked exactly like his fiancée. As the analyst and the patient worked together to analyze the dream through understanding the patient's associations, it became clear that two separate but related anxieties were operating together to produce the symptom. At one level the patient was worried about losing his penis in his fiancée's vagina. This form of castration anxiety was acting in concert with a more primitive concern—that at the moment of orgasm he would fuse and become one with his fiancée and lose his own identity. The patient stressed that orgasm seemed to be the one moment when he tended to lose a sense of his own boundaries and felt like he was merging with the other person.

This clinical vignette illustrates that a patient often is not aware of the source of anxiety because it is unconscious. Although in this case a vivid dream and its accompanying associations made the meaning of the anxiety much clearer, in many other cases much more psychotherapeutic or psychoanalytic exploration is necessary before the unconscious sources are accessible. The developmental hierarchy provides a set of guidelines for clinicians to think about when they are trying to understand a patient's anxiety. However, there are infinite individual variations on these different themes of loss of the object, persecutory anxiety, loss of the object's love, and so forth. The psychodynamic approach to anxiety is one that acknowledges the uniqueness of each individual's intrapsychic world. In each case the clinician must allow for the possibility that the origins of anxiety may not fit these guidelines precisely and may involve a blend of other concerns that may expand psychodynamic theory.

CONTEMPORARY VIEWS OF ANXIETY

The publication of the third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) marked the beginning of an effort to make the official nomenclature of the American Psychiatric Association atheoretical. An unfortunate consequence of this shift has been the decline of interest in the classical neurotic entities along with the psychodynamic model of symptom formation inherent in them. Three separate categories have replaced the neuroses: dissociative disorders, somatoform disorders, and anxiety disorders. The category of anxiety disorders has been further subdivided in the fourth edition of DSM (DSM-IV) into the following entities: panic disorder, phobias, obsessive-compulsive disorder, posttraumatic stress disorder, acute stress disorder, and generalized anxiety disorder.

This classification reflects growing empirical evidence linking biological mechanisms to the generation of anxiety. Panic attacks, for example, can be experimentally induced by lactate infusion. Moreover, genetic studies suggest a higher concordance rate for certain anxiety disorders in monozygotic twins than in dizygotic twins. Acute panic attacks appear to arise in the brainstem and represent spontaneous hyperactivity of noradrenergic nuclei in conjunction with lowered firing thresholds in medullary respiratory chemoreceptors. By contrast, anticipatory anxiety seems to represent the effect of a kindling in the limbic lobe. Phobic avoidance appears to be cortical in origin.

Although these advances in the field of neuroscience are impressive and of considerable heuristic value in understanding anxiety, they by no means preclude a psychodynamic understanding or the use of psychotherapeutic techniques. Of greater concern is that the rise of the atheoretical categorizations in the official nomenclature and the associated research on the biological underpinnings of anxiety may encourage clinicians to think about anxiety as only an illness rather than an overdetermined symptom of unconscious conflict. This view of anxiety may be linked to a specific form of treatment designed to eradicate or at least to reduce the anxiety. This perspective fails to recognize the value of anxiety as a signal of internal distress and conflict that may require some reflection and introspection. In the Menninger Foundation's Psychotherapy Research Project, 18 of 35 patients showed increased anxiety at the termination of psychoanalysis or psychotherapy even though 13 of these 18 cases were judged by independent raters to have undergone substantial improvement. These results were regarded by the investigators as a sign that primary anxiety, which is disorganizing to the patient, must be differentiated from anxiety used as a signal. They stressed that an increase in *anxiety tolerance*, defined as the capacity to experience anxiety without having to discharge it, may be one positive outcome of dynamic psychotherapy or psychoanalysis and may reflect an expansion of the ego's capacity to deal with anxiety. The presence or absence of anxiety after treatment was insufficient to understand or evaluate the change, because many of the patients with good outcomes showed dramatic improvement in their capacity to use ideational activity more efficiently in the service of understanding the anxiety.

Anxiety is likely to surface at various developmental crises throughout one's life. It is a regular accompaniment of existential uncertainty inherent in life. The expansion of ego mastery over anxiety as a result of psychoanalytic therapy appears to facilitate the patient's capacity to use and understand anxiety in a variety of circumstances in which it arises. The anxiety can be normal, adaptive, or maladaptive, and the assumption that all anxiety should be eradicated is certainly unwarranted.

Any neurophysiological mechanism involved in the generation of anxiety may produce an adaptive form of signal anxiety as well as the more pathological forms of chronic symptomatic anxiety. It would be erroneous to assume that the biological mechanisms are only associated with highly pathological or symptomatic anxieties, or that psychotherapeutic treatments should deal only with signal aspects of anxiety. Psychoanalytic therapy obviously must work by altering brain functioning.

Recent genetic studies have demonstrated that individuals with a somewhat shorter gene involved in serotonin transport may have greater anxiety than those with the longer version. Although the investigators have speculated that many other genes as well as numerous environmental factors may be involved in the generation of anxiety, the findings are encouraging because the shorter gene also is functionally different from the longer gene. It is relatively weaker in terms of its capacity to transport serotonin compared to the longer gene. Of particular interest to this discussion is that nearly 70 percent of people have the shorter and less vigorous version of the gene, which results in greater anxiety. This skewed distribution may well reflect natural selection in that individuals with greater anxiety might be better equipped to survive the dangers in the environment than those who experience less worry or concern.

Other problems also have resulted from the differentiation of Axis I anxiety disorders in DSM-IV according to specific symptom profiles and temporal criteria. Many researchers as well as a good many more clinicians have argued that the anxiety syndromes have reified distinctions that are more illusory than real. In actual clinical practice there is a growing recognition of comorbidity among anxiety disorders, largely because many of the disorders are not as separate from one another as the criteria imply. Nevertheless, in this chapter the psychodynamic considerations of each of the major anxiety disorders will retain the DSM-IV classification to promote uniformity across the chapters and to illustrate that a psychodynamic perspective can be applied separately or be integrated with the descriptive and biological approaches to these entities.

PANIC DISORDER

Patients with panic disorder generally experience a good deal of distress during the few minutes that the typical panic attack lasts. They may find themselves gasping for breath, shaking uncontrollably, feeling lightheaded, sweating profusely, and feeling certain that death is imminent. The majority of such patients also struggle with agoraphobia, in that they are intensely afraid of being stuck in a situation from which they cannot escape. Many patients with panic disorder develop anticipatory anxiety secondarily because they are worried most of the time about when and where the next panic attack will strike them. In some cases patients with panic disorder accompanied by agoraphobia severely restrict their travel so they will not have to encounter a situation in which a panic attack occurs in a place from which they cannot make a ready escape.

Many patients suffering from panic disorder experience the attacks as if they “came out of the blue.” They cannot necessarily identify a precipitating factor linked to the onset. Such patients, and often clinicians as well, may thus regard panic attacks as psychologically “contentless.” Yet careful psychodynamic interviewing of such patients often reveals overlooked factors that may be involved in triggering the onset of panic.

Experienced psychoanalysts interviewed nine consecutive patients with panic disorder on videotape. A research psychiatrist with psychoanalytic training then reviewed the videotapes and was able to identify psychologically meaningful stressors preceding the onset of panic in each patient evaluated in this manner. These stressors were connected with an alteration of or decrease in the level of expectations placed on the patient. The expectation changes were often related to job situations in which patients had to take on increased responsibilities. Loss events generally involved emotional or physical separations from key figures in the patients' lives. These events were typically associated with childhood experiences where an attachment to an important person in the patients' lives was threatened. Sexual conflicts did not appear to be prominent in triggering the onset of panic, but seven of the nine patients had considerable difficulty dealing with anger. Another common denominator was the perception of parents as frightening, controlling, demanding, temperamental, and critical.

Further analysis of the interviews suggested a pattern of childhood difficulties. Anxiety about socializing with others, parental relationships that were perceived as unsupportive, a sense of frustration or resentment, and a feeling of being trapped were experienced by the patients. Aggression was difficult to handle, and most of the patients described feelings of self-reproach and inadequacy.

Some of these observations have been borne out by empirical studies. Compared to normal control subjects, patients with panic disorder report higher rates of dysfunctional parenting and more intense separation anxiety in childhood. In a large study of 1018 female twin pairs, the relationship between parental loss prior to the age of 17 and adult psychopathology was investigated. Panic disorder was strongly and significantly associated with both parental separation and death. Early maternal separation in particular was linked to panic disorder. Other studies have suggested higher rates of stressful life events, especially loss, when compared with controls in the months preceding the onset of panic disorder. There is also preliminary evidence of attachment disturbance in adulthood as well as a pattern of insecurity and dependency in relationships.

There may be a predisposing neurophysiological vulnerability that may interact with certain kinds of environmental stressors to produce the end result of a panic attack. Researchers have identified an inborn temperamental characteristic in a number of children that has been termed behavioral inhibition to the unfamiliar. These children have a tendency to be easily frightened by anything unfamiliar in the environment. To deal with their fear, they tend to rely on their parents to protect them. As they grow they often are afraid that their parents will not be there to protect and comfort them. They may externalize their own inadequacies on their parents, whom they regard as unpredictable and unreliable. These children then become angry at their parents' inconsistent availability, but the anger creates new problems in that they worry that their angry fantasies will be destructive and drive their parents away, leaving them with the loss of a parent who they depend on to provide safety. A vicious cycle results where the child's anger threatens the connection with the parent and thus increases the child's hostile and fearful dependence.

The alternative scenario is that an individual without the inborn temperamental predisposition to fear the unfamiliar is sufficiently traumatized by a series of stressors in development such that the same type of cycle results. These individuals may experience rejection or extremely controlling behavior by parents or parental substitutes that contribute to the same pattern of fearful dependence.

Some form of attachment difficulty appears to be involved in the pathogenesis of panic disorder. A small preliminary study of attachment style in 18 women suffering from anxiety disorders suggested that all had problematic attachment styles. Fourteen of the 18 were diagnosed with panic disorder. These patients had higher rates of preoccupied attachment. Other studies have shown patients with panic disorder to have greater separation anxiety. Fearful individuals tend to view separation and attachment as mutually exclusive. They have difficulty developing the normal oscillation between separation and attachment because they have a heightened sensitivity to both loss of safety or protection and loss of freedom. Hence they end up operating in an extremely narrow range of behavior that attempts to avoid attachment that is too intense or separation that is too frightening. The end result is an overcontrolling style of interaction.

To use Freud's terminology, the signal anxiety function is insufficient to deal with anxiety, leading to an overwhelming and uncontrollable level of panic. Threats to attachment in particular appear to trigger this kind of overwhelming panic. Patients who develop panic disorder are prone to feelings of self-fragmentation and may need a companion (or therapist) to help them feel that they have a firm sense of identity. Some investigators have suggested that the presence of ego defects involving self-other confusion may be related to difficulties in using anxiety as a signal. The intensity of panic attacks may appear to be so biologically driven that medication appears to be the only viable treatment approach. However, when the underlying fear of separation and abandonment is seen to be connected with the panic, psychotherapeutic interventions may be equally effective.

A patient with borderline personality disorder and poorly established object constancy could not deal with her psychotherapist's absence over extended weekends. While sitting in her apartment she would be unable to visualize her therapist's face or imagine his voice as a way of soothing herself. She began to hyperventilate, experience tachycardia, feel that her death was imminent, and would become terrified that her therapist would not be there for her next session. When the panic became overwhelming, she would call her therapist on the weekend. The call would generally last less than 30 seconds. The patient would report that she was afraid something terrible had happened to her therapist and that she would never see him again. The therapist would reassuringly state that everything was fine and he would see her at their Tuesday appointment. The patient's panic symptoms including tachycardia and hyperventilation, immediately dissipated on hearing the therapist's voice, and she was able to get off the telephone and return to her weekend activities. In the psychotherapy sessions the patient corroborated that hearing her therapist's voice restored a sense of attachment to him. Such situations confirm the fact that the physiological symptoms such as tachycardia and hyperventilation may be reduced just as dramatically with psychotherapeutic as with pharmacotherapeutic interventions.

Another etiological factor in women patients appears to be childhood physical and sexual abuse. Both forms of abuse have been found to be significantly higher in persons with anxiety disorder when compared to a control group. Childhood sexual abuse in particular has been found to occur at a rate of 45.1 percent in women with anxiety disorders compared to a rate of 15.4 percent in a comparison group. The link with panic disorder is even more striking—60 percent of women with panic disorder have a history of childhood sexual abuse compared to 31 percent of women with other anxiety disorders. Since childhood trauma interferes with the child's attachment to the parents, childhood sexual abuse could account for some of the difficulties that panic disorder patients have in feeling safe and secure with significant objects in their lives. These patients may have internal representations of abusive relationships that interfere with the development of trust.

The psychodynamics of panic disorder are summarized in Table 15.5-2.

1. Difficulty tolerating anger.
2. Physical or emotional separations from significant person both in childhood and in adult life.
3. May be triggered by situations of increased work responsibilities.
4. Perception of parents as controlling, frightening, critical, and demanding.
5. Internal representations of relationships involving sexual or physical abuse.
6. A chronic sense of feeling trapped.
7. Vicious cycle of anger at parental-rejecting behavior followed by anxiety that the fantasy will destroy the tie to parents.
8. Failure of signal anxiety function in ego related to self fragmentation and self-other boundary confusion.
9. Typical defense mechanisms: reaction formation, undoing, somatization, and externalization.

Table 15.5-2 Psychodynamic Themes in Panic Disorder

Psychotherapeutic Techniques In the course of psychodynamic therapy the patient's difficulties in relationships often become centered in the transference to the therapist. Conflicts around separation, independence, and anger are particularly prominent. Active exploration of the patient's fears of becoming overly dependent on the therapist are a crucial part of the psychotherapeutic work. Conversely, anxieties over the loss of the therapist may be equally meaningful to the patient.

The patient's difficulty with anger may take the form of avoidance. Patients who feel particularly threatened by anger towards the therapist may simply forget the session or find an excuse not to appear. The fears of anger can often be clarified by an examination of childhood situations in which anger was expressed in the family. Anger may be regarded as uncontrollable because of the patient's experiences with parental anger. When the patient became angry with the parent as a child, the parent may have emotionally abandoned the child. Because patients with panic disorder often avoid expressing anger, the therapist's initial task may be to actively explore the resistances to acknowledging anger.

As the transference fantasies about the therapist develop, there is generally a great deal of useful information contained in these fantasies. For example, patients may be convinced that they must operate within a narrow range of behavior or risk losing the therapist's interest or investment. These fantasies can often be traced back to childhood fears of being alone or independent.

An integral part of the psychodynamic approach to psychotherapy is the examination of characteristic defense mechanisms. Patients with panic disorder typically use any combination of the following defenses: reaction formation, undoing, somatization, and externalization. Both reaction formation and undoing serve to reassure the patient that negative affects are either absent or completely controllable. The psychotherapist's strategy with such defenses is to make the patient aware of his or her anxiety about the expression of anger and the associated need to disavow it. Hence a patient who repeatedly assures the therapist that he loves his father and that his father can do no wrong may be actively disavowing his anger. The therapist might intervene by noting the defense, as in the following observation: “I often feel that you're very invested in letting me know how much you love your father. It makes me wonder what other feelings you have about him.”

The defenses of somatization and externalization are both designed to avoid reflection and introspection. Somatization places the patient's focus on what is happening physiologically. It is an attempt to make the panic attack a phenomenon that is devoid of psychological causes or meaning. Externalization places the origin of the problem in external persons who are viewed as mistreating the patient in some way. In some cases the focus on somatization may unconsciously create a specific form of object relationship in which the patient enlists others as healers who are supposed to fix something in the body. This object relationship may be activated in the transference, and the therapist may clarify how the preoccupation with bodily symptoms establishes a dependent relationship with the therapist. Anger at the therapist may then be explored by examining the patient's disappointment that the therapist is unable to “fix” the patient's problems. A long-range

psychotherapeutic strategy is to help the patient view the panic as an internally generated phenomenon rather than to blame others for it.

There is a good deal of outcome data suggesting that cognitive therapy and pharmacotherapy are effective in treating panic disorder. Psychodynamic therapy has not been studied as extensively as the other two modalities, but there are numerous case reports in the literature suggesting that dynamic therapy is useful. Moreover, at least one study used a randomized, controlled design that demonstrates the effectiveness of dynamic therapy at reducing relapse in patients with panic disorder. In this study patients were randomized to treatment with either clomipramine (Anafranil) for 9 months or clomipramine for 9 months combined with 15 weekly sessions of brief dynamic therapy. Whereas all patients in both groups were free of panic attacks within 26 weeks of the start of treatment, the relapse rate was significantly higher in the group that received only clomipramine when the pharmacotherapy was terminated. The investigators concluded that brief dynamic therapy may reduce the psychosocial vulnerability that is associated with panic disorder.

Integrations of cognitive techniques with dynamic psychotherapy are also useful. In virtually every case of panic disorder, distortions of thinking need to be addressed as part of the psychotherapeutic strategy.

Although both cognitive therapy and pharmacotherapy are effective in the short run, long-term follow-up studies suggest that some patients continue to experience symptoms when the medication is withdrawn or when the brief cognitive therapy has terminated; most patients will require additional treatment. Studies are needed to demonstrate which patients may be particularly suited to extended psychoanalytic therapy either alone or in combination with medication and other techniques.

PHOBIAS

Phobias are the most common of all anxiety disorders. In DSM-IV they are subdivided into three categories: (1) agoraphobia without history of panic disorder, (2) specific phobia, and (3) social phobia. Social phobia, which is the most common of all phobias, is further subdivided into two subtypes. The *nongeneralized type* is characterized by a fear of public situations such as public speaking or performing on stage. As many as 20 percent of the populations surveyed have acknowledged this fear. The second variety is a *generalized type* in which almost all social interactions are feared. This variant may be difficult to differentiate from avoidant personality disorder.

Freud regarded the phobias as neurotic entities and therefore understood the mechanism of symptom formation to be consistent with his 1926 theory of anxiety. When unacceptable aggressive or sexual thoughts that could lead to a fantasy of punishment begin to emerge from the unconscious, signal anxiety is produced, which then leads to the deployment of specific ego defense mechanisms. The first of these is *displacement*, which involves the redirection of anxiety associated with an unconscious source to a conscious substitute that is often intrinsically harmless. *Projection* is the second specific defense mechanism used by phobics to get the source outside of themselves and into the external world. The third defense is *avoidance*, which is simply a systematic process of not coming into contact with the displaced and projected item that the anxiety is associated with. If that item is elevators, the individual always takes the stairs. If the item is dogs, the individual avoids dogs. The end result is that the three combined defenses may eliminate the anxiety because the unacceptable or forbidden thought is re-repressed. However, the anxiety generated by the thought is controlled at the cost of creating a phobic neurosis with all its associated inconvenience.

Behavioral therapies using relaxation and in vivo exposure procedures have been highly effective in treating phobias. Cognitive therapies, which usually include an exposure element, have also been effective. There are few controlled studies of psychotherapies other than those of the cognitive or behavioral orientation. Nonetheless, psychodynamic understanding may enhance a broad-based overall treatment plan.

Phobias are best understood as reflecting a genetic-constitutional diathesis that is acted upon by environmental stressors. A study of 2163 female twins concluded that the best model for the disorder is the inheritance of a vulnerability to phobias that require environmental factors specific to the individual to produce a diagnosable phobic syndrome. In this study population, parental death before the age of 17 was clearly associated with an increased risk for phobia.

Work on the temperamental construct of behavior inhibition to the unfamiliar appears to be applicable to social phobia in much the same way it is relative to panic disorder. The expectation that one will be embarrassed and humiliated by the critical scrutiny of others appears to have some origin in temperamental disposition. Children who are behaviorally inhibited appear to be born with a much lower threshold for limbic-hypothalamic arousal in response to unexpected or novel events in the environment that are difficult to assimilate. To result in shy, withdrawn, and timid behavior at 2 years of age, however, chronic environmental stressors must act on the basic temperamental disposition that was present at birth. It has been suggested that some of these stressors might include criticism and humiliation from an older sibling, parental fighting, and separation from a parent through death or divorce. It was also possible to differentiate children who develop shyness purely in response to environmental factors alone without the underlying temperament.

A clinical cohort study examined the families of these children and found that the parents were at greater risk for most anxiety disorders, and particularly social phobia. Compared with parents in control groups, they had higher rates of two or more anxiety disorders. The investigators speculate that such children with behavioral inhibition may go on to develop anxiety disorders in part because of genetic factors and in part because their parents may have greater anxiety and thus convey messages to their children that the world is unsafe.

Social phobia is an example of an anxiety disorder that may have been artificially distinguished from other related disorders. The lifetime comorbidity approaches 70 percent with persons with social phobia. This entity is rarely treated by mental health professionals unless it is accompanied by other disorders that bring the person to attention. An underlying genetic constitutional diathesis may actually predispose an individual to several anxiety disorders.

Psychotherapeutic Techniques Dynamic psychotherapy with individuals who have social phobia attempts to get to the heart of the patient's fears. Embarrassment and shame are central affects, and the patient's affect states are a good starting point. As the patient begins to feel embarrassed, the therapist encourages exploration of the patient's fantasies of how others will react to him or her. Within these perceptions or fears of other people's reactions, the therapist will find a characteristic pattern of internal object relationships within the patient that is then externalized in any social situation. Patients with social phobia often have internalized representations of others, usually parents, siblings, or caretakers, that involve shaming, ridiculing, humiliating, criticizing, and abandoning the patient. In some cases these representations will be distortions of the way childhood interactions actually occurred; in others they will be closely related to the actual behavior by family members. In either case the therapist's task is to help the patient see that the fantasies of how others react are largely based on adverse childhood experiences rather than on the reality of the interactions in the patient's current environment. Often therapeutic work within the transference is extremely helpful in this regard, as in the following example:

A 27-year-old woman who could not finish her PhD in history came to psychotherapy because a selective serotonin reuptake inhibitor had not significantly helped her with her social phobia. She was too anxious to meet with her dissertation committee so her academic progress had been seriously delayed. After missing one session of her therapy, she came to the next session and apologized for her absence. The therapist asked, “What made you stay away last time?”

The patient responded, “I was afraid you were going to criticize me for not going to my meeting with my dissertation committee.”

The therapist asked, “Have you experienced me as critical of you in the time we've worked together?

The patient replied, “No, not really. You're actually the opposite of critical. You're patient with me, supportive, and always trying to help in any way you can.”

The therapist then said, “It may be then that the perception of me being critical arises from within yourself rather than being based on my actual behavior with you.”

The patient reflected for a moment and said, “There must be something to that. I'm always imagining that others are going to criticize or embarrass me, even when I don't have any hard evidence that such a response is likely.”

The therapist made the following observation, “Your dissertation committee has not actually been critical of you, so it may be that the same concerns you have here with me are applicable with your committee. In other words, your fear of negative responses from them may largely be an internal one rather than a reality-based fear.”

Discussion In this case, the therapist is drawing a link between the anxiety in the transference and the anxiety in a present-day situation outside of the therapy. As the therapy progressed, he also made a linkage to the patient's childhood when the patient felt repeatedly humiliated and criticized by her parents.

The interpersonal dimensions of phobias are often crucially important in the treatment of phobias. In the case of individuals for example, one often finds that the spouse of such a patient may be instrumental in maintaining the symptomatic behavior. For example, the husband of a woman with agoraphobia may feel much more secure with his wife in the house because he fears that she will find another man if she leaves the home. The husband's jealousy is controlled by keeping his wife indoors. Any treatment effort that tries to change the nature of this system may be doomed because the husband will not cooperate with the treatment plan. The patient herself may also resist the treatment because she fears her husband's jealous rage. Hence in many cases of resistance to behavioral or cognitive-behavioral interventions, a psychodynamic approach may be needed either in a marital or an individual context.

An overview of psychodynamic aspects of phobias is summarized in Table 15.5-3.

- Principle defense mechanisms include: displacement, projection, and avoidance.
- Environmental stressors, including humiliation and criticism from an older sibling, parental fights, or loss and separation from parents, interact with a genetic-constitutional diathesis.
- A characteristic pattern of internal object relations is externalized in social situations in the case of social phobia.
- Anticipation of humiliation, criticism, and ridicule is projected onto individuals in the environment.
- Shame and embarrassment are the principal affect states.
- Family members may encourage phobic behavior and serve as obstacles to any treatment plan.
- Self-exposure to the feared situation is a basic principle of all treatment

Table 15.5-3 Psychodynamic Themes in Phobias

OBSESSIVE-COMPULSIVE DISORDER

Within the psychoanalytic literature there has been a frequent confusion between obsessive-compulsive personality disorder and obsessive-compulsive disorder. While they were previously thought to reside on the same continuum of symptomatology, the evidence is mounting that the two are somewhat distinct entities. Patients with obsessive-compulsive disorder view their symptoms ego-dystonically, that is, they experience distress connected with their symptoms. By contrast, the traits of patients with obsessive-compulsive personality disorder are often ego-syntonic and may disturb others more than the patient. Moreover, the vast majority of patients with obsessive-compulsive disorder do not have symptoms of the other condition. Finally, although obsessive-compulsive personality disorder generally responds very well to psychoanalytic therapy, obsessive-compulsive disorder is notoriously refractory to psychodynamic treatment.

Much of the confusion began with Freud's classic 1909 paper describing his psychoanalysis of the “Rat Man.” He referred to this condition as obsessive-compulsive neurosis and developed a compelling psychodynamic formulation of the symptoms. According to this formulation the anxiety produced by the fear of retaliation associated with the oedipal situation leads the individual with obsessive-compulsive neurosis to regress to a more primitive psychosexual developmental stage, specifically to the anal phase. Freud suggested that certain characteristic defense mechanisms were associated with the anal phase, including reaction formation, doing and undoing, and isolation of affect. He believed that the regression was more likely because of the long standing presence of anal fixations related to disturbances during toilet training.

Freud's sophisticated psychodynamic formulation has not been able to eradicate the rituals and obsessional thoughts of most patients with obsessive-compulsive disorder. The resistance of these symptoms to interpretation may relate to the biological underpinnings of the disorder. In comparison to normal controls, patients with obsessive-compulsive disorder manifest increased metabolism in the orbitofrontal cortex, the anterior cingulate cortex, and the caudate nuclei. Some studies using magnetic resonance imaging (MRI) have found significantly less total white matter associated with significantly greater total cortex and opercular volumes in these patients as compared to normal controls. There are also higher rates of concordance for obsessive-compulsive disorder in monozygotic than in dizygotic twins. Studies of computed tomography have found a smaller caudate nucleus volume in these patients as well. Animal models have suggested serotonergic abnormalities in obsessive-compulsive disorder and the fact that symptomatic improvement occurs with serotonin reuptake inhibitors suggests that this hypothesis has some merit.

Behavior therapy has been shown in numerous studies to be successful in reducing the symptoms of obsessive-compulsive disorder. Many clinicians now regard the combination of a selective serotonin reuptake inhibitor (SSRI) and behavior therapy as the treatment of choice. Despite the lack of data that psychoanalytic or psychodynamic therapy reduces the symptoms of obsessive-compulsive disorder, a psychodynamic approach may still be of considerable value. Psychodynamic clinicians are always thinking in terms of resistance, transference, countertransference, and unconscious meanings, even if they are not involved in the provision of formal psychoanalytic psychotherapy. Hence when treating patients who have obsessive-compulsive disorder, even if the treatment involves prescribing an SSRI, a clinician nevertheless may think about the patient's situation and the overall treatment within a psychodynamic framework. Part of this framework is the notion that symptoms, no matter how biologically based, nevertheless have meanings to the patient. Psychodynamic conflicts frequently attach themselves to neurophysiologically driven symptoms and use them as a vehicle for their expression. Moreover, the symptoms often result in secondary gains that serve as powerful resistances to treatment. Often a psychodynamic understanding of the resistance may lead a patient who is reluctant to seek help to consider behavior therapy and an SSRI.

Another area in which psychodynamic theory has relevance to obsessive-compulsive disorder is in understanding the impact of stressors on the condition. Research suggests that while genetic processes are clearly involved in the development of the disorder, environmental stressors also are important. Issues involving child care and pregnancy appear to be particularly influential. In one study 69 percent of patients with obsessive-compulsive disorder could link exacerbation or onset of their symptoms to childbirth, pregnancy, or child care issues. Another study found that pregnancy was associated with the onset of symptoms of obsessive-compulsive

disorder far more than any other life event. In clinical work with young mothers or young women who are pregnant, unconscious or nearly conscious feelings of hostility toward the child often increase anxiety, which in turn increases a reliance on the rituals of obsessive-compulsive disorder to bind the anxiety.

A 24-year-old woman who was learning to take care of her 2-month-old infant was deeply distressed by thoughts that she might accidentally kill the baby by dropping her. She found herself constantly checking the floor to see if there was a soft area in case the baby fell. She also found herself washing her hands up to 60 times a day because of her concern that she might transmit an infection of some sort to the baby, who would then die from the transmitted agent. When she was evaluated for treatment, she adamantly denied any hostile thoughts toward the child. However, when the clinician explained to her that wishes to harm the child and hostile feelings toward the child are part of the normal mothering experience, the patient's defensiveness decreased and she was able to acknowledge that she harbored such thoughts. She immediately condemned herself for having them and was deeply worried that the interviewer would be just as harsh on her as she was on herself.

Psychodynamically Informed Treatment Psychodynamic therapy is not usually indicated as the exclusive treatment for obsessive-compulsive disorder, but in patients who tenaciously hang on to their symptoms because of their special meanings or because of the interpersonal control they exercise over others a psychodynamic approach may be extremely useful. Similarly, problems of compliance with medication and difficulties in interpersonal relationships may all be productively addressed through psychodynamically informed strategies. The mean reduction of symptoms of obsessive-compulsive disorder when treated with pharmacotherapy is in the range of 38 to 40 percent, so a variety of problems persist despite the partial efficacy of medications. Many of these difficulties lie in the area of personal relationships. A high risk of separation or divorce has been linked to obsessive-compulsive disorder. The illness itself is extraordinarily stressful to those in close relationships with the patient, and psychodynamic understanding may be useful in this regard.

A study of 34 parents or spouses of obsessive-compulsive disorder patients examined the extent to which these relatives would accommodate the patient through active participation in rituals or significant modifications of their daily routines. Of those relatives, 88.2 percent reported accommodating the patient in some way. This form of family accommodation was clearly correlated with stress in the family, rejecting attitudes toward the patient, and poor family functioning. These accommodations often involve an effort to reduce the patient's anxiety or to control expressions of anger by the patient. Many relatives describe feeling bullied by the patient into doing things to accommodate the patient's obsessions or compulsions.

A 26-year-old single man was admitted to a psychiatric hospital with obsessive-compulsive disorder because he had refused to cooperate with pharmacotherapy and behavior therapy approaches. He was obsessed with the concern that his father and mother might bring the “AIDS virus” into the home, so he asked that everything be sprayed with disinfectants. He also insisted that his parents wear gloves around the house and specifically when handling his personal items or touching the doorknob of his room. His parents had reluctantly complied with these instructions because they feared his wrath when they did not go along with him.

When he arrived in the hospital, the young man became concerned that the previous occupant of his room might have masturbated and left semen stains in his room that could transmit HIV infection to him. Even though the hospital staff tried to engage him in discussions of other issues, he repeatedly wanted to get everyone to discuss the possibility of human immunodeficiency virus (HIV) contamination in the room. One nurse who was assigned to him was told each day not to touch anything in his room unless he was wearing gloves. Eventually, the nurse capitulated and began wearing gloves when entering the patient's room. The nurse felt embarrassed about this capitulation and tried to keep it secret from the other hospital staff, but he was eventually discovered wearing gloves when he emerged from the patient's room. The behavior led to a useful discussion of countertransference in treating such patients. It also led to a productive exploration of the patient's entitlement. He was indignant when people did not comply with his expectations. In this regard his hospital psychiatrist confronted him with the observation that he tended to deny the autonomy and subjectivity of anyone else in his life. All family members and all treaters were supposed to respond primarily to his needs rather than their own needs. These confrontations eventually helped the patient to recognize his omnipotent control of others, and he began to withdraw his demandingness.

Discussion This case example reflects how patterns of relationships become internalized because of the specific needs of the patient with obsessive-compulsive disorder. His needs to avoid contamination became paramount over every other concern in his environment. This pattern of omnipotent control was internalized as his characteristic mode of object relatedness. His admission into the hospital and the recapitulation of that pattern of relatedness is an example of the time-honored principle of psychodynamic hospital treatment—namely, that the patient attempts to re-create his family situation in the milieu of the hospital with various staff members.

This case also illustrates the extent to which significant characterological issues may operate in concert with the symptoms of obsessive-compulsive disorder. To some degree the patient had everyone in his family waiting on him hand and foot and doing exactly what he wanted them to do. He was thus reluctant to enter into any treatment program that might change his behaviors and loosen the hold he had on his family. Studies have suggested that patients with comorbid personality disorders in association with obsessive-compulsive disorder are much more likely to terminate behavior therapy and be classified as treatment resistant.

Psychodynamically informed treatment has a continued role to play with patients who have obsessive-compulsive disorder. These symptoms, however biologically driven, are nevertheless rich in unconscious meaning. Psychodynamic understanding of those meanings may reveal the key to addressing poor patient compliance with pharmacotherapy or other forms of resistance. A psychodynamic approach is also helpful in understanding the meaning of psychosocial triggers that exacerbate these symptoms, which almost always have interpersonal meanings that must be addressed. Psychodynamic conflicts often use biologically determined symptoms to serve as a vehicle for their expression. Family members and others in significant relationships with the patient often accommodate to the patient's demands as a way of placating the patient. This characteristic pattern of relating to others may also surface in the transference-countertransference dimensions of the treatment. Characterological features are often significant in obsessive-compulsive disorder patients and may influence the response to treatment rather dramatically. Addressing these characterological features must be an overall part of the treatment plan in such cases. The psychodynamic themes of the disorder are summarized in Table 15.5-4.

- Classical psychoanalytic formulation was linked to an anal-phase regression with a specific constellation of defenses: reaction formation, doing and undoing, and isolation of affect.
- The psychodynamic meaning of psychosocial stressors, such as pregnancy or childbirth, may help to explain the onset or exacerbation of symptoms of obsessive-compulsive disorder.
- Psychodynamic conflicts frequently appropriate biologically driven symptoms and use them as a vehicle for the expression of those conflicts.
- Treatment resistance, such as poor compliance with medication, often involves the tendency to hang on to the symptoms because of special meanings to the patient or because of characterological resistances to receiving help.
- Symptoms of obsessive-compulsive disorder almost always have interpersonal meanings, including omnipotent control of family members and others in significant interpersonal relationships.

Table 15.5-4 Psychodynamic Themes in Obsessive-Compulsive Disorder

POSTTRAUMATIC STRESS DISORDER

Posttraumatic stress disorder first entered the official diagnostic nomenclature of the American Psychiatric Association in 1980 when DSM-III was published. The identification of trauma-related psychopathology in returning Vietnam War veterans appeared to have a major influence on the acceptance of the diagnosis in American psychiatry. Nevertheless, there has been a long tradition of psychoanalytic exploration of trauma, beginning with Freud's observations that a splitting of consciousness appeared to occur in hysterical patients who reported a history of childhood sexual trauma. Although his emphasis shifted to infantile sexuality and fantasy in the pathogenesis of neurosis, he never abandoned his belief that childhood sexual abuse was at the core of some neuroses. Freud also noted the existence of traumatic war neuroses and suggested that the external trauma reawakened infantile trauma in these conditions. He postulated that the phenomenon of the repetition compulsion in the form of repeating the traumatic event was a response to overwhelming assault on the individual's stimulus barrier, which activated a

regression.

The seminal work of Abraham Kardiner and Herbert Spiegel with traumatized soldiers in World War II suggested that the external factors related to the trauma were most decisive but that in some instances a preexisting conflict might be symbolically reawakened by the traumatic event. However, their view was that the conflict did not cause the event to be traumatic. In more contemporary studies of the impact of trauma, both the traumatic event itself and its meaning to the individual based on that individual's earlier life experiences are regarded as important in determining whether an event becomes traumatic. Empirical studies support this view in that as the intensity of a violent event increases, so does the number of individuals traumatized by that event. Also, certain types of events appear to be more likely to create traumatic reactions in victims than others. In one study of burn patients, for example, the severity of the posttraumatic symptoms was not necessarily proportional to the severity of the burn. Posttraumatic stress disorder was predicted by smaller burns, by greater emotional distress, and by the perception of inadequate emotional support. Approximately one fourth of people witnessing a violent event may develop posttraumatic stress disorder. Those who are more likely to develop the disorder have a history of early separation from parents; a family history of anxiety and neuroticism; and preexisting depression or anxiety. Hence most researchers today believe that a personal predisposition is necessary to develop posttraumatic stress disorder in the face of trauma.

As the DSM-IV symptoms of this disorder suggest, the basic processes that result from psychic trauma revolve around three different symptoms clusters: (1) intrusive and repetitive reexperiencing of the trauma; (2) avoidance of this reexperiencing; (3) overactivation of the autonomic nervous system that is, sleep difficulties, hypervigilance, startle reactions, and difficulty concentrating. Many other patients adapt to psychic trauma in childhood by shutting down any affective development. As a result, they cannot use affects as signals. Powerful feelings are viewed as a threat that the original traumatic situation will recur, so these patients often use somatization as a defense but do so at a cost. They cannot soothe themselves or relax and are often deficient in self-care. These patients may be incapable of speaking the language of emotions and hence have been referred to as having alexithymia.

Dissociation is another response to trauma. One of the best predictors of the ultimate development of posttraumatic stress disorder is dissociation at the moment of the trauma. Through dissociation trauma victims symbolically remove themselves from the trauma by depersonalizing or perceiving the incident as though it is happening to someone else rather than to them. Dissociation is also connected with affect dysregulation, and this difficulty modulating various affects states, including anxiety, has led the disorder to be grouped among the anxiety disorders.

This multifaceted response to trauma explains why the occurrence of posttraumatic disorder in pure form is unusual. Most people with its symptoms have other diagnoses as well, such as dissociative or somatization disorders. Many borderline personality disorder patients also have significant histories of trauma.

Trauma shatters the individual's view of the world as a place that is safe, predictable, and controllable and forces a confrontation with one's own vulnerability. Consequently, a variety of defense mechanisms are activated to deal with it. Many of these defenses marshaled by the ego in the face of trauma are those commonly thought to be primitive or immature. Hence there is frequently a regression to developmentally earlier modes of dealing with helplessness, vulnerability, fear, and anger.

Many patients use rather extraordinary degrees of denial to avoid facing the severity of the trauma or the extent of distress they feel as a result of it. A related defense is that of minimization, often seen in the wake of trauma when victimized individuals repeatedly tell friends and family that the trauma was really not that bad and that they are doing fine.

The sense of rage at being victimized may be disavowed and projected into others who they view as aggressive and angry. They may become hypervigilant in an effort to protect themselves from the aggression they perceive in others. This defensive projective disavowal may be accompanied by splitting, in which they view themselves as completely free of angry or aggressive impulses. In other patients anger itself may be used as a defense against more disturbing feelings of vulnerability. Some patients pursue litigation in an angry manner that suggests a powerful revenge motive and that also reflects a wish to master the feelings of helplessness by gaining some form of compensation for their suffering.

Another common defense in the wake of trauma is guilt. Many rape victims, for example, feel responsible for what happened to them. Often beneath this feeling of guilt and responsibility is a more disturbing feeling that they are completely helpless in a malevolent universe where violence is random. In more chronic cases of posttraumatic stress disorder a particular relational mode is also observable in the clinical setting as it manifests itself in the transference and countertransference aspects of the therapy. This way of relating to others reflects a constellation of internal self and object representations that are best described as characters in a psychological drama. They include a victim, an omnipotent rescuer, and an abuser. These roles are projected onto the therapist, reintrojected into the patient, and reprojected, creating an oscillating pattern in which at times the therapist is viewed as an abuser and at other times the patient may regard the therapist as an idealized and omnipotent rescuer. Sometimes therapists find themselves feeling victimized by such patients because the patients are demanding and feel entitled to be compensated for their injuries. A common countertransference pattern is to try to avoid the role of the abuser by resorting to a *disidentification with the aggressor* in which the therapist strives to be the most compassionate and loving parent imaginable to make up for the damage that the patient feels was caused in childhood by parental abuse. Psychodynamic themes in posttraumatic stress disorder are summarized in Table 15.5-5.

- The subjective meaning of a stressor may determine its traumatogenicity.
- Traumatic events may resonate with childhood traumas.
- Inability to regulate affect may result from trauma.
- Somatization and alexythymia may be among the aftereffects of trauma.
- Common defenses used include denial, minimization, splitting, projective disavowal, dissociation, and guilt (as a defense against underlying helplessness).
- Mode of object relatedness involves projection and introjection of the following roles: omnipotent rescuer, abuser, and victim.

Table 15.5-5 Psychodynamic Themes in Posttraumatic Stress Disorder

Psychotherapeutic Approaches The psychotherapist must always keep in mind that these roles or “characters” are not unidimensional but involve complexities that vary with the uniqueness of each individual patient and that involve specific meanings and affects that complicate the perception of who is doing what to whom at any given moment.

The research on psychotherapy with posttraumatic stress disorder patients is limited in its ability to answer what kind of treatment works best with which patients. One well-controlled study of brief psychodynamic psychotherapy with victims of fire demonstrated significant improvement in the patients who participated. Nineteen of the 30 patients met DSM-III criteria for posttraumatic stress disorder alone or with comorbid depression. The therapy consisted of 6 to 12 sessions following a manualized protocol that encouraged exposure to feared situations. Another study compared psychodynamic therapy with systemic desensitization, hypnotherapy, and a waiting list control. All three of the treatments resulted in improvements; dynamic therapy seemed to be most helpful in reducing avoidant symptoms and systemic desensitization and hypnotherapy seemed to have a greater impact on intrusive thoughts. However, only 23 of the 112 patients in this sample had actually experienced trauma; the remaining patients had suffered bereavement.

The treatment goals of dynamic psychotherapy with patients who have posttraumatic stress disorder include reducing anxiety, integrating and accepting the trauma as part of the self, regaining a sense of mastery, re-establishing a sense of personal integrity, and moving away from a sense of being haunted by the past toward feeling fully engaged in the present. The earlier that a clinician intervenes in the course of the posttraumatic reaction, the more successful the intervention is likely to be.

Much of the art of the therapy involves striking a balance between forcing the patient to reconstruct a complete picture of the trauma and assuming an observing, detached posture that allows much information to be left out. The therapist must tactfully strive to integrate the memory of the trauma with the patient's continuous sense of self while also being aware that the patients need to proceed at their own pace because the traumatic memories can be overwhelming. Building a therapeutic alliance of safety and security is essential. Without a solid alliance, the patient may not trust the therapist sufficiently to be able to discuss the trauma. The therapeutic

alliance may be particularly problematic because many traumatized patients profoundly distrust everyone, including the therapist.

Educating the patient about the common reactions to trauma may be useful in facilitating an alliance. Similarly, empathically validating patients' rights to feel the way that they do may also create the conditions necessary to explore the trauma. In the case of childhood trauma, such as sexual or physical abuse, the therapist must help the patient see the difference between having no responsibility in childhood for what a parent did and taking full responsibility as an adult for choosing abusive partners that repeat the trauma from childhood.

Differentiating reality from fantasy is a basic technique used to facilitate the integration of the traumatic information. Much of this differentiation involves transference work to help the patient see the distinction between the reality of the therapist's attitude and the representation of the therapist in the patient's mind. Four types of transference have been identified: (1) the transfer of specific disavowed memories of the traumatic event into the treatment situation, (2) the transfer of figures involved in the traumatic event onto the therapist, (3) the transfer onto the therapist of intrapsychic functions in the patient that have been distorted as a result of the trauma (with the hope that healthier function will be restored), and (4) the transfer onto the therapist of an omnipotent and wise role in which the therapist can help the patient make sense out of what happened and restore a sense of personal meaning.

The psychotherapist in turn may feel helpless, overwhelmed, angry for the patient's tenacious hanging on the trauma, omnipotent in fantasies of saving or rescuing the patient from the trauma, indifferent, and hopeless. Some of these transference and countertransference paradigms are reflected in the following case example:

> A 35-year-old woman who had witnessed her son's death in an auto accident felt she could never get over what happened. Much of her psychotherapy focused on her repeated reexperiencing of the event, including vivid nightmares that caused her to wake up crying. The therapist repeatedly tried to get the patient to mourn the loss of her child, but the patient steadfastly refused, saying she did not know how to grieve and she did not think she could ever get over it. The therapist interpreted her wish to hang on the images of the son as a way of avoiding the mourning. The interpretations fell on deaf ears, and the patient continued to talk about the accident and her feelings of guilt in connection with it. After months of this repetitive interaction in the therapy, the therapist began to feel angry and irritated at the patient for thwarting all his attempts. He became more and more forceful in his efforts to provide her with insight about how she was holding on to the past. Finally, the patient experienced him as intrusive and unsympathetic, and she shouted at him: “Would you stop trying to make me do what you want me to do and just leave me alone?!” As the therapist reflected on this outburst, he recognized that he had felt so helpless and inadequate that he had had re-created an abusive situation in the therapeutic relationship. The patient was again feeling victimized, not only by the cruel hand of fate in the death of her son and by the drunken driver who killed him but also by the therapist himself. As this fragment of a psychotherapy process reveals, many patients with posttraumatic stress disorder present formidable challenges to the psychotherapist:

Some cases appear to respond much better than others. Although precise data are not available, a certain percentage of patients do not respond to psychotherapeutic efforts and their symptoms may become chronic. Many of these patients feel that time has frozen for them at the moment of the trauma, and they are unable to move forward in their lives. In the national comorbidity survey, survival analysis showed that more than one third of people with an index episode of posttraumatic stress disorder failed to recover even after many years.

ACUTE STRESS DISORDER

Acute stress disorder is a relatively new diagnostic entity. Although it shares many of the symptoms of posttraumatic stress disorder, this disorder occurs within 4 weeks of the traumatic event; in contrast, posttraumatic stress disorder has its onset at least 1 month after the trauma. Many of the same principles involved in the psychodynamic treatment of the latter disorder apply to acute stress disorder as well. Therapy should begin as soon as possible after the trauma has occurred because better outcomes have been associated with more immediate crisis intervention. The individual who has experienced the trauma must be helped to integrate and process it so that some mastery is gained over the experience. Containment of intense feelings in a safe environment, support, and active listening are all important therapeutic interventions. Normalizing the experience through education and understanding is also helpful. Specific work on grief and loss may be extremely beneficial to patients who have experienced an overwhelming trauma.

GENERALIZED ANXIETY DISORDER

Generalized anxiety disorder was recognized as a disorder in 1987 with the publication of the revised third edition of DSM (DSM-III-R); however, it continues to be a controversial diagnostic category. When classified as the principal diagnosis in a patient, it is associated with the highest rate of comorbidity of any of the other anxiety disorders. Some critics prefer to conceptualize this disorder as a vulnerability located on Axis II. Nevertheless, with the addition of specific somatic symptoms, this disorder has a fairly high degree of construct validity. Moreover, psychodynamic clinicians commonly encounter patients who are chronic worriers. The lifetime prevalence of generalized anxiety disorder is thought to range from 4.1 to 6.6 percent. The condition is also one that tends to be chronic and to lead to a significant amount of disability and impairment in the quality of life. In one survey 27 percent of respondents were receiving disability payments, and only about 50 percent were able to work full time.

Most of the systematic studies on generalized anxiety disorder have involved behavioral or cognitive treatments, which have been shown to be helpful, or pharmacotherapy, which also is efficacious in reducing anxiety. However, there are a variety of limitations inherent in using benzodiazepines, including the fact that as many as 30 percent of patients do not respond to them. Other problems include the fact that benzodiazepines often do not affect the core symptom of worry; cause a variety of adverse effects; have a potential for abuse, physical dependence, and withdrawal; and have fairly high relapse rates when the medication is withdrawn.

Psychotherapeutic Techniques Whereas generalized anxiety disorder was formerly thought to be something of a “wastebasket” category into which all other forms of anxiety were placed, more recent research has begun to identify specific interpersonal issues and traumatic events connected with the diagnosis. In a survey study of over 1000 subjects, the individuals meeting criteria for generalized anxiety disorder had more frequent traumatic events in their history than those who did not meet the criteria. Subjects with this disorder reported trauma involving injury, illness, or death at a rate that was one and a half times greater than the reports from normal controls. Also, traumas related to assault, emotional events, and miscellaneous other traumas were four to six times more prevalent in subjects with generalized anxiety disorder than in those without this condition. Affected patients also tend to avoid thinking about the past events they consider traumatic; worrying appears to distract these patients with superficial matters that prevent them from worrying about more disturbing underlying concerns. In addition to this characteristic defensive pattern of avoidance, generalized anxiety disorder has also been linked to an insecure on conflicted attachment in childhood.

Because the object of the worry is often misleading, the psychodynamic clinician must embark on a collaborative search with the patient to discover the underlying conflicts and the true source of anxiety. As noted previously, the developmental hierarchy may help guide such a search, but the clinician must remain open to surprises rather than forcing the data to fit within a favorite theoretical formulation. Often the underlying conflicts surface in maladaptive and repetitive relationship patterns that are ultimately self-defeating. Table 15.5-6 illustrates the common psychodynamic themes in generalized anxiety disorder.

- Worrying serves a defensive function to avoid thinking about more disturbing issues.
- Increased prevalence of past trauma is highly characteristic.
- Link with an insecure/conflicted attachment in childhood.
- The underlying conflict that creates the anxiety can be related to any number of developmental themes.
- The unconscious conflict continues to be “alive” in self-defeating patterns in relationships.
- Resistance is common in moving below the level of symptoms to underlying sources of conflict.

Table 15.5-6 Psychodynamic Themes in Generalized Anxiety Disorder

When patients with generalized anxiety disorder begin psychotherapy they are likely to focus a great deal on symptoms, especially those related to the body. After listening to this catalog of symptoms, the therapist needs to move the patient further and inquire about work situation, family relationships, and any interpersonal difficulties encountered. Although the patient's goals may be geared to relief of somatic symptoms and anxiety, the therapist should encourage the patient to think in broader terms and to include broader patterns of adaptation to work and to love relationships. The therapist then tries to formulate the major conflicts that arise in interpersonal relationships, looking for this pattern as it recurs in the transference, in discussions of past relationships, and in reports of current relationships. As far as possible the therapist helps the patient to see how patterns of pathological relatedness invariably evoke more anxiety and worry.

Often these patterns can be linked to early traumas and difficulties attaching to others. The therapist demonstrates how anxiety is generated from these recurrent conflicts as well as how they can be mastered through the understanding of the patient's expectations of failure and the experience of trying new ways of relating to others. When attention is drawn away from the somatic focus of worrying, patients often feel that they have renewed energy to devote to the true underlying conflicts.

15.6 ANXIETY DISORDERS: CLINICAL FEATURES

DANIEL S. PINE, M.D.

The last 30 years have seen a dramatic increase in clinical research on a group of mental conditions labeled “anxiety disorders” in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) nomenclature. While the term “anxiety” has been applied to diverse phenomena in the psychoanalytic, learning-based, and neurobiological literature, the term “anxiety” in the clinical psychopathological literature refers to the presence of fear or apprehension that is out of proportion to the context of the life situation. Hence, extreme fear or apprehension can be considered “clinical anxiety” if it is developmentally inappropriate (e.g., fear of separation in a 10-year-old child) or if it is inappropriate to an individual's life circumstances (e.g., worries about unemployment in a successful business executive). The last 30 years of clinical research has led to progressive refinement of the nosology for clinical anxiety disorders. While these disorders were broadly conceptualized in the early twentieth century, narrower definitions have arisen, partially stimulated by Donald Klein's observations on pharmacological distinctions between panic and nonpanic anxiety.

Consensus has emerged on the view of anxiety disorders as a family of related but distinct mental disorders. This consensus is reflected in the relatively minor changes to the broad categorization of anxiety disorders over the last 15 years, between the third edition of DSM (DSM-III) and the fourth edition (DSM-IV). Both DSM-IV and the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) recognize similar groups of syndromes as discrete diagnostic entities. There is some disagreement, however, on whether all of these syndromes are most properly considered anxiety disorders. While DSM-IV considers a group of nine disorders to be the primary anxiety disorders, ICD-10 adopts a broader category of neurotic, stress-related, and somatoform disorders that includes each of the conditions in DSM-IV, as well as a number of disorders not considered anxiety disorders in DSM-IV. Prior to DSM-III, which brought a relatively major revision to the nosology of mental disorders in the United States, anxiety disorders were classified in a group of conditions that included many of the disorders currently listed in DSM-IV along with a set of disorders that have been reclassified. These reclassified disorders included affective disorders (formerly classified as “depressive neurosis”), somatoform and dissociative disorders (formerly classified as “hysterical neurosis”), and neurasthenia, a disorder that was eliminated with the writing of DSM-III.

DSM-III, with its emphasis on empiricism and the validity of nosological categories, reclassified anxiety disorders into categories that were quite similar to the disorders included in the current anxiety section of DSM-IV, which include panic disorder with and without agoraphobia, agoraphobia with and without panic disorder, specific phobia, social phobia, obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), acute stress disorder, and generalized anxiety disorder. This chapter reviews the clinical features of these nine conditions, as conceptualized in DSM-IV. This includes the primary symptomatology, history, epidemiology, differential diagnosis, and course of each disorder, along with a clinical vignette designed to capture the essential features of each disorder as it typically presents in the clinic.

PANIC DISORDER AND AGORAPHOBIA

The panic attack is the key feature of panic disorder, which is characterized by a pattern of recurrent panic attacks. The *panic attack* is defined as an episode of abrupt intense fear that is accompanied by at least four autonomic or cognitive symptoms listed in Table 15.6-1. Such episodes of abrupt fear occur in many situations. For example, a healthy person might experience a panic attack when confronted with sudden extreme danger, and an individual with a phobia of heights might experience a panic attack when confronted with the feared situation.

Note: A panic attack is not a codable disorder. Code the specific diagnosis in which the panic attack occurs (e.g., panic disorder with agoraphobia).

A discrete period of intense fear or discomfort, in which four (or more) of the following symptoms developed abruptly and reached a peak within 10 minutes:

(1) palpitations, pounding heart, or accelerated heart rate
(2) sweating
(3) trembling or shaking
(4) sensations of shortness of breath or smothering
(5) feeling of choking
(6) chest pain or discomfort
(7) nausea or abdominal distress
(8) feeling dizzy, unsteady, lightheaded, or faint
(9) derealization (feelings of unreality) or depersonalization (being detached from oneself)
(10) fear of losing control or going crazy
(11) fear of dying
(12) paresthesias (numbness or tingling sensations)
(13) chills or hot flushes

Table 15.6-1 DSM-IV Criteria for Panic Attack

DSM-IV recognizes three types of panic attacks. The unexpected or spontaneous panic attack occurs without cue or warning; the situationally bound panic attack occurs upon exposure to, or in anticipation of, exposure to a feared stimulus; and the situationally predisposed panic attack is more likely to occur, but does not necessarily have to occur, on exposure to a situational trigger. In panic disorder, panic attacks occur spontaneously, arising without any trigger or environmental cue. As shown in Table 15.6-2, panic disorder requires at least two spontaneous panic attacks, at least one of which is associated with either concern with additional attacks, worry about attacks, or changes in behavior.

Note: Agoraphobia is not a codable disorder. Code the specific disorder in which the agoraphobia occurs (e.g., panic disorder with agoraphobia or agoraphobia without history of panic disorder).

A. Anxiety about being in places or situations from which escape might be difficult (or embarrassing) or in which help may not be available in the event of having an unexpected or situationally predisposed panic attack or panic-like symptoms. Agoraphobic fears typically involve characteristic clusters of situations that include being outside the home alone; being in a crowd or standing in a line; being on a bridge; and traveling in a bus, train, or automobile.

Note: Consider the diagnosis of specific phobia if the avoidance is limited to one or only a few specific situations, or social phobia if the avoidance is limited to social situations.

B. The situations are avoided (e.g., travel is restricted) or else are endured with marked distress or with anxiety about having a panic attack or panic-like symptoms, or require the presence of a companion.

C. The anxiety or phobic avoidance is not better accounted for by another mental disorder, such as social phobia (e.g., avoidance limited to social situations because of fear of embarrassment), specific phobia (e.g., avoidance limited to a single situation like elevators), obsessive-compulsive disorder (e.g., avoidance of dirt in someone with an obsession about contamination), posttraumatic stress disorder (e.g., avoidance of stimuli associated with a severe stressor), or separation anxiety disorder (e.g., avoidance of leaving home or relatives).

Table 15.6-2 DSM-IV Criteria for Agoraphobia

Patients with panic disorder present with a number of comorbid conditions, but there has been considerable interest in the relationship between panic disorder and agoraphobia, which refers to fear or anxiety of places from where escape might be difficult (Table 15.6-2). There has in fact been some debate about whether agoraphobia is best conceptualized as a complication of panic disorder or as a separate condition. This controversy centers on the frequency with which patients develop agoraphobia in the absence of panic disorder or panic attacks (Table 15.6-3) DSM-IV suggests that such patients do exist, noting the existence of panic disorder with agoraphobia (Table 15.6-4) and without agoraphobia (Table 15.6-5). However, even in agoraphobia without history of panic disorder, agoraphobia is considered related to the fear of developing paniclike symptoms.

A. The presence of agoraphobia related to fear of developing panic-like symptoms (e.g., dizziness or diarrhea).
B. Criteria have never been met for panic disorder.
C. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.
D. If an associated general medical condition is present, the fear described in criterion A is clearly in excess of that usually associated with the condition.

Reprinted with permission from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, ed 4. © American Psychiatric Association, Washington, DC, 1994.

Table 15.6-3 DSM-IV Diagnostic Criteria for Agoraphobia Without History of Panic Disorder

A. Both (1) and (2):
   (1) recurrent unexpected panic attacks
   (2) at least one of the attacks has been followed by 1 month (or more) of the following:
      (a) persistent concern about having additional attacks
      (b) worry about the implications of the attack or its consequences (e.g., losing control, having a heart attack, "going crazy")
      (c) a significant change in behavior related to the attacks
B. The presence of agoraphobia.
C. The panic attacks are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hyperthyroidism).
D. The panic attacks are not better accounted for by another mental disorder, such as social phobia (e.g., occurring on exposure to feared social situations), specific phobia (e.g., on exposure to a specific phobic situation), obsessive-compulsive disorder (e.g., on exposure to dirt in someone with an obsession about contamination), posttraumatic stress disorder (e.g., in response to stimuli associated with a severe stressor), or separation anxiety disorder (e.g., in response to being away from home or close relatives).

Table 15.6-4 DSM-IV Diagnostic Criteria for Panic Disorder With Agoraphobia

A. Both (1) and (2):
   (1) recurrent unexpected panic attacks
   (2) at least one of the attacks has been followed by at least 1 month (or more) of the following:
      (a) persistent concern about having additional attacks
      (b) worry about the implications of the attack or its consequences (e.g., losing control, having a heart attack, "going crazy")
      (c) a significant change in behavior related to the attacks
B. Absence of agoraphobia.
C. The panic attacks are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hyperthyroidism).
D. The panic attacks are not better accounted for by another mental disorder, such as social phobia (e.g., occurring on exposure to feared social situations), specific phobia (e.g., on exposure to a specific phobic situation), obsessive-compulsive disorder (e.g., on exposure to dirt in someone with an obsession about contamination), posttraumatic stress disorder (e.g., in response to stimuli associated with a severe stressor), or separation anxiety disorder (e.g., in response to being away from home or close relatives).

Table 15.6-5 DSM-IV Diagnostic Criteria for Panic Disorder Without Agoraphobia

As with most anxiety disorders, panic disorder often co-occurs with a number of mental conditions beyond agoraphobia, particularly anxiety and depressive disorders. These include specific and social phobia, generalized anxiety disorder, and major depressive disorder. Some data also suggest associations with substance use disorders, bipolar disorder, and suicidal behavior. While the high comorbidity seen in the clinic partially reflects referral bias, considerable comorbidity with these anxiety and depressive disorders is also found in epidemiological studies, which suggests that panic disorder in the community is frequently compounded by comorbid mental conditions.

History and Comparative Nosology While the term “panic disorder” was first coined in DSM-III, a syndrome characterized by recurrent episodes of spontaneous fear has been recognized for more than 100 years. This syndrome has been given various labels throughout history, including DaCosta's syndrome in the late nineteenth century, and effort syndrome or neurocirculatory asthenia in the earlier part of the twentieth century. Even Freud's descriptions of “anxiety neurosis” invoked many of the key features of panic disorder.

A major change to the DSM conceptualization of anxiety occurred in 1980, with SM-III, where panic disorder was first recognized as a distinct entity. Between 1980 and 1994 one significant change to the conceptualization of the disorder involved refining the view of panic disorder and agoraphobia as tightly linked constructs. As conceptualized in DSM-IV, agoraphobia invariably involves at least some form of spontaneous crescendo anxiety, even if such episodes do not meet formal criteria for panic attacks (Table 15.6-3 and Table 15.6-4). In the earlier versions of the DSM and in ICD-10, agoraphobia is considered less closely linked to panic disorder. Indeed, ICD-10 classifies agoraphobia as one of many phobic disorders and does not emphasize the relationship with panic disorder to the same degree as DSM-IV. Table 15.6-6 presents the ICD-10 diagnostic criteria for phobic anxiety disorders, including agoraphobia. Table 15.6-7 presents the ICD-10 criteria for other anxiety disorders, including panic disorder.

Table 15.6-6 ICD-10 Diagnostic Criteria for Phobic Anxiety Disorders

Table 15.6-7 ICD-10 Diagnostic Criteria for Other Anxiety Disorders

Differential Diagnosis Panic disorder with or without agoraphobia must be differentiated from a number of medical conditions that produce similar symptomatology. Panic attacks are associated with a variety of endocrinological disorders, including both hypo- and hyperthyroid states, hyperparathyroidism, and pheochromocytomas. Episodic hypoglycemia associated with insulinomas can also produce paniclike states, as can primary neuropathological processes. These include seizure disorders, vestibular dysfunction, neoplasms, or the effects of both prescribed and illicit substances on the central nervous system. Finally, disorders of the cardiac and pulmonary systems, including arrhythmias, chronic obstructive pulmonary disease, and asthma, can produce autonomic symptoms and accompanying crescendo anxiety that can be difficult to distinguish from panic disorder. Clues of an underlying medical cause for paniclike symptoms include atypical features during panic attacks, such as ataxia, alterations in consciousness, or bladder dyscontrol; onset of panic disorder relatively late in life; or physical signs or symptoms indicating a medical disorder.

Panic disorder also must be differentiated from a number of psychiatric disorders, particularly other anxiety disorders. Since panic attacks occur in many anxiety disorders, including social and specific phobia, posttraumatic stress disorders, or even obsessive-compulsive disorder, the key to correctly diagnosing panic disorder involves documenting recurrent spontaneous panic attacks at some point in the illness. Differentiation with generalized anxiety disorder can also be difficult. Classically, panic attacks are characterized by their rapid onset, within minutes, and short duration, usually less than 10 to 15 minutes, in contrast to the anxiety associated with generalized anxiety disorder, which emerges and dissipates more slowly. This distinction can be difficult, however, as the anxiety surrounding panic attacks can be more diffuse and dissipate more slowly. Since anxiety is a frequent concomitant of many other psychiatric disorders, including the psychoses and affective disorders, distinctions between panic disorder and a multitude of disorders can also be difficult.

Course Panic disorder typically has its onset in late adolescence or early adulthood, although cases of childhood-onset and late adulthood–onset disorder have been described. Only tentative data exist on the natural course of panic disorder. The best evidence on the course of any disorder, including panic disorder, derives from prospective epidemiological research, since both retrospective and clinically based studies are vulnerable to biases that preclude firm conclusions on course. Unfortunately, few such studies exist. Retrospective or clinical studies suggest that panic disorder tends to exhibit a fluctuating course, with varying levels of persistence over the life span. Approximately one third to one half of patients are psychiatrically healthy at follow-up, with most living relatively normal lives, despite either fluctuating or recurrent symptoms. Typically, patients with chronic disorders exhibit a pattern of exacerbation and remissions rather than chronic disability.

Ms. S. was a 25-year-old student who was referred for a psychiatric evaluation from the medical emergency room at a larger university-based medical center. Ms. S. had been evaluated three times over the preceding 3 weeks in this emergency room. Her first visit was prompted by a paroxysm of extreme dyspnea and terror that occurred while she was working on a term paper. The dyspnea was accompanied by palpitations, choking sensations, sweating, shakiness, and a strong urge to flee. Ms. S. thought that she was having a heart attack, and she immediately went to the emergency room. She received a full medical evaluation, including an electrocardiogram (ECG) and routine blood work, which revealed no sign of cardiovascular, pulmonary, or other illness. Although Ms. S. was given the number of a local psychiatrist, she did not make a follow-up appointment, since she did not think that her episode would recur. She developed two other similar episodes, one while she was on her way to visit a friend and a second that woke her up from sleep. She immediately went to the emergency room after experiencing both paroxysms, receiving full medical workups that showed no sign of illness.

SPECIFIC AND SOCIAL PHOBIAS

The term “phobia” refers to an excessive fear of a specific object, circumstance, or situation. Phobias are classified on the basis of the feared object or situation, and DSM-IV recognizes three distinct classes of phobia: agoraphobia (discussed above as it is considered closely related to panic disorder), specific phobia, and social phobia. Criteria for specific and social phobia are shown in Table 15.6-8 and Table 15.6-9. Both specific and social phobia require the development of intense anxiety, to the point of even situationally bound panic, upon exposure to the feared object or situation. Both conditions also require that fear either interferes with functioning or causes marked distress. Finally, both conditions require that an individual recognizes the fear as excessive or irrational and that the feared object or situation is either avoided or endured with great difficulty.

Table 15.6-8 DSM-IV Diagnostic Criteria for Specific Phobia

Table 15.6-9 DSM-IV Diagnostic Criteria for Social Phobia

Specific phobia is divided into four subtypes (animal type, natural environment type, blood-injection-injury type, situational type, and other type), with a residual category for phobias that do not clearly fall into any of these four categories. The key feature in each type of phobia is that the fear is circumscribed to a specific object, both temporally and with respect to other objects. Hence, an individual with specific phobia becomes immediately frightened when presented with a feared object. This fear may relate to concern about harm from a feared object, concern about embarrassment, or fear of consequences related to exposure to the feared object. For example, individuals with blood-injury phobia may be afraid of fainting on exposure to blood, and individuals with fear of heights may be afraid of becoming dizzy.

Specific phobia often involves fears of more than one object, particularly within a specific subcategory of phobia. For example, it is common for an individual with a phobia of thunderstorms to also have a phobia of water, both phobias being classified as natural environment type phobias. Further, in the clinical setting, specific phobia often occurs with other anxiety or mood disorders. Since it is rare for patients to seek treatment for an isolated phobia, some of the comorbidity seen in the clinic reflects referral bias. Community-based studies also suggest that specific phobia is associated with other anxiety disorders, although at lower rates than seen in the clinic. Quantifying the impairment associated with a specific phobia is sometimes difficult, since the comorbid disorders typically tend to cause more impairment than specific phobia and since individuals with isolated specific phobia are rarely seen in the clinic. Impairment associated with specific phobia typically restricts the social or professional activities of the individual.

Social phobia involves fear of social situations, including situations that involve scrutiny or contact with strangers. Individuals with social phobia typically fear embarrassing themselves in social situations (e.g., social gatherings, oral presentations, or meeting new people). This can involve specific fears about performing certain activities, such as writing, eating, or speaking in front of others. It can also involve a vague, nonspecific fear of embarrassing oneself. DSM-IV provides a specifier for the diagnosis of social phobia. Individuals with social phobia who fear most situations are considered to suffer from generalized social phobia. Such individuals are fearful of initiating conversations in many situations, about dating or participating in most group activities or social gatherings, and about speaking with authority figures.

The clinician should recognize that many patients exhibit at least some social anxiety or self-consciousness. In fact, community studies suggest that roughly a third of all people consider themselves to be far more anxious than other people in social situations. Such anxiety only becomes social phobia when the anxiety either prevents an individual from participating in desired activities or causes marked distress in such activities. Individuals with the more specific form of social phobia possess fear of specific, circumscribed social situations. For example, extreme anxiety about public speaking that interferes with an individual's job performance is a common type of specific social phobia; it would not be considered generalized social phobia unless it was associated with fears related to many other social situations besides public speaking.

As with other anxiety disorders, social phobia frequently co-occurs with other mood and anxiety disorders. The association of social phobia with both panic disorder and major depression has received considerable attention in recent literature. Associations with substance use disorders and childhood conduct problems have also been documented.

History and Comparative Nosology Phobias have been recognized as incapacitating mental disorders for more than 100 years. The prominent place of phobia in the history of modern mental health science is indicated by the major role case histories of phobic patients played in the development of both psychoanalytic and cognitive therapies. The category of phobia has undergone progressive refinement over the past 20 years, as research has focused on each of the specific classes of phobia described above. Much of this refinement crystallized in DSM-III, which was based on emerging evidence that phobias represent a group of related but distinct conditions, rather than one heterogenous disorder. Such evidence included Isaac Mark's work on differentiating social and specific phobias. The refinement in DSM-III categorized agoraphobia as a condition closely related to panic disorder and distinguished social and simple phobia, which was relabeled specific phobia in DSM-IV.

The view of phobias has changed since the writing of DSM-III. While discussion of agoraphobia has emphasized the role of panic since DSM-III, DSM-IV also contains descriptions of paniclike phenomena in both the specific and social phobia sections, as well as in the discussion of agoraphobia. Beyond this change, the most significant other change for specific phobia between DSM-III and DSM-IV involved inclusion of the above subcategories of phobia, based on research noting distinct physiology and demographics of the subtypes. For social phobia, the most significant other change occurred with the revised third edition (DSM-III-R), which distinguished between generalized and more specific forms of social phobia. This change was based on descriptive phenomenology, epidemiology, and pharmacology studies that validated the two variants of the condition.

The approach to categorization of phobias in the ICD system is quite similar to that in DSM-IV. ICD-10 recognizes specific phobia as a distinct category, including the subtypes in DSM-IV. Social phobia is also classified in ICD-10, although without the qualifier in DSM-IV. Perhaps the major difference between DSM-IV and ICD-10 in the consideration of phobia relates to agoraphobia. While DSM-IV emphasizes the relation between panic disorder and agoraphobia, in ICD-10 the term “panic disorder” is restricted to cases without phobia, and the term “agoraphobia” is applied to all cases that meet criteria, regardless of the presence of absence of panic attacks (Table 15.6-6 and Table 15.6-7).

Differential Diagnosis Specific phobia is usually quite easily distinguished from anxiety stemming from primary medical problems by the focused nature of the anxiety, which is not typical of anxiety disorders related to medical problems. The most difficult diagnostic issues involve differentiating specific phobia from other anxiety disorder. As DSM-IV emphasizes the presence of paniclike symptoms with specific phobia, including situationally bound panic attacks, specific phobia must be differentiated from panic disorder, in which panic attacks occur without a cue. Specific phobia can occasionally be confused with PTSD, as both conditions can involve focused fears of specific objects or situations. The two disorders are most easily differentiated by the marked other features of PTSD, such as reexperiencing the trauma, avoidance, and enhanced startle, which are absent in specific phobia. Similarly, specific phobia can occasionally be confused with generalized anxiety disorder, as both conditions may involve worry about exposure to specific situations. The two disorders are differentiated on the basis of the focused nature of the fear, both over time and with respect to objects, in specific phobia.

Like specific phobia, social phobia is rarely confused with anxiety that is the primary result of medical disorders. However, the number of psychiatric disorders that are associated with social withdrawal make it difficult to diagnose social phobia correctly. Perhaps the most difficult distinction involves differentiating social phobia and agoraphobia, since both conditions involve fears of situations where people typically gather. The key distinction between the disorders centers on the nature of the feared object. Patients with social phobia are specifically afraid of encountering people; individuals with agoraphobia are afraid of situations from which escape would be difficult but do not specifically fear people. Hence, an individual with agoraphobia might be reassured in the presence of other people, provided the physical properties of the location are suitable, while an individual with social phobia flees other people. The clinician might also encounter difficulty in distinguishing social phobia from the social isolation that accompanies a number of psychiatric disorders, including major depression and the early stages of psychosis. Two factors are essential in making this distinction. First, the individual with social phobia must experience anxiety or fear in social situations; individuals who are isolated due to depression or indolent psychosis often isolate themselves for other reasons. Second, with social phobia, symptomatology is restricted to the fears of social situations; with other disorders social isolation is accompanied by a broad array of symptoms that are not found in social phobia.

Course Specific phobia exhibits a bimodal age of onset, with a childhood peak for animal phobia, natural environment phobia, and blood-injury phobia and an early adulthood peak for other phobias, such as situational phobia. As with other anxiety disorders, limited prospective epidemiological data exist on the natural course of specific phobia. Because patients with isolated specific phobias rarely present for treatment, research on the course of the disorder in the clinic is limited. The information that is available suggests that most specific phobias that begin in childhood and persist into adulthood continue to persist for many years. The severity of the condition is thought to remain relatively constant, without the waxing and waning course seen with other anxiety disorders.

> Mr. A. was a successful businessman who presented for treatment following a change in his business schedule. While he had formerly worked largely from an office near his home, a promotion led to a schedule of frequent out-of-town meetings, requiring weekly flights. Mr. A. reported being “deathly afraid” of flying. Even the thought of getting on an airplane led to thoughts of impending doom as he envisioned his airplane crashing to the ground. These thoughts were associated with intense fear, palpitations, sweating, clammy feelings, and stomach upset. While the thought of flying was terrifying enough, Mr. A. became nearly incapacitated when he went to the airport. Immediately before boarding, Mr. A. often had to turn back from the plane and run to the bathroom to vomit.

Social phobia tends to have its onset in late childhood or early adolescence. Social phobia tends to be a chronic disorder, although as with the other anxiety disorders, prospective epidemiological data are limited. Both retrospective epidemiological studies and prospective clinical studies suggest that the disorder can profoundly disrupt the life of an individual over many years. This can include disruption in school or academic achievement, interference with job performance, and

social development.

> Ms. M. was a successful secretary working in a law firm. While she reported a long history of feeling uncomfortable in social situations, Ms. M. came for treatment when she began to feel that her uneasiness was interfering with her social life and job performance. Ms. M. reported that she noticed herself feeling increasingly nervous whenever she met a new person. For example, upon meeting a new member of the law firm, she described feeling suddenly tense and sweaty, noticing that her heart was beating very fast. She had the sudden thought that she would say something foolish in these situations or commit a terrible social gaffe that would make people laugh at her. At social gatherings she described similar feelings that led her to either leave the gathering early or decline invitations to attend.

OBSESSIVE-COMPULSIVE DISORDER

Obsessions and compulsions are the essential features of OCD. As shown in Table 15.6-10, an individual must exhibit either obsessions or compulsions to meet DSM-IV criteria. DSM-IV recognizes *obsessions* as "persistent ideas, thoughts, impulses, or images that are experienced as intrusive and inappropriate," causing distress. Obsessions are anxiety provoking, accounting for the categorization of OCD as an anxiety disorder; they must be differentiated from excessive worries about real life problems; and they must be associated with either efforts to ignore or suppress the obsessions. Typical obsessions associated with OCD include thoughts about contamination ("my hands are dirty") or doubts ("I forgot to turn off the stove").

Table 15.6-10 DSM-IV Diagnostic Criteria for Obsessive-Compulsive Disorder

Compulsions are defined as repetitive acts, behaviors, or thoughts that are designed to counteract the anxiety associated with an obsession. A compulsion reduces the anxiety associated with the obsession. While many compulsions are acts associated with specific obsessions, such as hand-washing or checking, other compulsions can be thoughts. For example, patients may have the obsession that they have committed a sin and might relieve the resultant anxiety by repetitively saying a silent prayer to themselves.

Obsessions and compulsions must cause marked distress, consume at least 1 hour a day, or interfere with functioning to be considered above the diagnostic threshold. At least during some point in the illness, symptoms of OCD must be recognized as unreasonable for adults, though this varies greatly both across individuals and in a given individual over time. For example, early in the course of the disorder patients may recognize their hand washing is excessive or irrational but, over a number of years, lose this recognition. DSM-IV recognizes a poor insight subtype of OCD when an individual fails to recognize the irrational or unreasonable nature of the obsessions. This subtype of OCD has been labeled the psychotic subtype in some of the clinical literature, prompting trials of antipsychotic pharmacotherapy. The criterion related to insight does not apply to children, who may either not possess the insight to recognize the unreasonableness of their condition or may be too embarrassed to discuss the condition as unreasonable.

OCD frequently co-occurs with other disorders. The association with major depression is particularly prominent, although comorbidity with panic disorder, phobias, and eating disorders is also not uncommon. Finally, OCD exhibits a particularly interesting association with Tourette's disorder. Approximately half of all patients with Tourette's disorder meet criteria for OCD, although less than 10 percent of patients with OCD meet criteria for Tourette's disorder. There is also evidence of cotransmission of Tourette's disorder, OCD, and chronic motor tics within families.

History and Comparative Nosology Descriptions of patients with a syndrome of recurrent obsessions and compulsions are found in the nineteenth century, when these conditions were viewed as a form of "depressive state." Descriptions of OCD also played a prominent role in Freud's writings, as captured in the case history of the Rat Man, and in early learning-based theories that attempted to apply treatments developed among patients with phobias to patients with OCD. Research on OCD changed with the ECA study in the early 1980s. Prior to this study, OCD was recognized as a discrete but rare entity, stimulating a modest degree of research. The Epidemiologic Catchment Area (ECA) Study noted that OCD had a prevalence in excess of 1 percent in the population and was associated with marked impairment. This stimulated extensive research on all aspects of OCD, including its phenomenology.

The major change in OCD from DSM-III to DSM-IV involved the conceptualization of compulsions. While DSM-III-R viewed compulsions as behaviors, DSM-IV recognized compulsions as either behaviors or mental acts designed to reduce the anxiety-provoking nature of the obsession. The conceptualization of OCD in the ICD and DSM systems is generally similar with a few exceptions in the emphasis on specific features of the condition. For example, ICD-10 emphasizes that a compulsive act must not be pleasurable. ICD-10 also stipulates that obsessions or compulsions must be present most days for 2 weeks, a requirement not included in DSM-IV, and ICD-10 does not stipulate the amount of time a patient must spend on compulsions. Perhaps the major difference between the DSM-IV and ICD-10 view of the disorder relates to the categorization of the disorder with respect to other anxiety disorders. DSM-IV recognizes OCD as one of the nine anxiety disorders discussed in the current chapter. There has been some debate in the United States and Europe about whether OCD is more properly classified in a distinct category. ICD-10 has adopted such a scheme, using OCD to designate a group of syndromes considered distinct from anxiety disorders (Table 15.6-11).

Table 15.6-11 ICD-10 Diagnostic Criteria for Obsessive-Compulsive Disorder

Differential Diagnosis A number of primary medical disorders can produce syndromes bearing a striking resemblance to OCD. In fact, the current conceptualization of OCD as a disorder of the basal ganglia derives from the phenomenological similarity between idiopathic OCD and OCD-like disorders that are associated with basal ganglia diseases, such as Sydenham's chorea and Huntington's disease. Hence, neurological signs of such basal ganglia pathology must be assessed when considering the diagnosis of OCD in a patient presenting for psychiatric treatment. OCD frequently develops before age 30, and new-onset OCD in an older individual should raise questions about potential neurological contributions to the disorder. Finally, some evidence suggests an association between an immune reaction to streptococcal infections and either initial manifestations or dramatic exacerbation of OCD in children. This syndrome appears to emerge relatively acutely, in contrast

to the more indolent onset of other cases of childhood OCD. Hence, in children with such presentations, the role of such an infectious process should be considered.

Obsessive-compulsive behavior is also found in a host of other psychiatric disorders, and the clinician must also rule out these conditions when diagnosing OCD. OCD exhibits a superficial resemblance to obsessive-compulsive personality disorder, which is associated with an obsessive concern for details, perfectionism, and similar personality traits. The conditions are easily distinguished by the fact that only OCD is associated with a true syndrome of obsessions and compulsions, as described above.

Psychotic symptoms often lead to obsessive thoughts and compulsive behavior that can be difficult to distinguish from OCD with poor insight, in which obsessions border on psychosis. The key to distinguishing OCD from psychosis involves the fact that patients with OCD can almost always acknowledge the unreasonable nature of their symptoms and the fact that psychotic illnesses are typically associated with a host of other features that are not characteristic of OCD. Similarly, OCD can be difficult to differentiate from depression since it is often associated with comorbid major depression and since major depression is often associated with obsessive thoughts that can at times border on true obsessions, as conceived in OCD. The two conditions are best differentiated by their course. Obsessive symptoms associated with depression are only found in a depressive episode; true OCD persists despite remission of depression.

Finally, OCD is closely related to Tourette's disorder; the two conditions frequently co-occur, both in an individual over time and within families. In its classic form, Tourette's disorder is associated with a pattern of recurrent vocal and motor tics that bears only a slight resemblance to OCD. However, the premonitory urges that precede tics often bear a striking resemblance to obsessions, and many of the more complicated motor tics can bear a close resemblance to compulsions.

Course OCD typically begins in late adolescence, though onset in childhood is not uncommon. The disorder tends to exhibit a waxing and waning course over the life span, with periods of relative good functioning and limited symptoms punctuated by periods of symptomatic exacerbation. A small minority of subjects exhibit either complete remission of their disorder or a progressive, deteriorating course.

Ms. B. presented for psychiatric admission after being transferred from a medical floor where she had been treated for malnutrition. Ms. B. had been found unconscious in her apartment by a neighbor. When brought to the emergency room by ambulance, she was found to be hypotensive and hypokalemic. At psychiatric admission, Ms. B. described a long history of recurrent obsessions about cleanliness, particularly related to food items. She reported that it was difficult for her to eat any food unless it had been washed by her three to four times, since she often thought that a food item was dirty. She reported that washing her food decreased the anxiety she felt about the dirtiness of food. While Ms. B. reported that she occasionally tried to eat food that she did not wash (e.g., in a restaurant), she became so worried about contracting an illness from eating such food that she could no longer dine in restaurants. Ms. B. reported that her obsessions about the cleanliness of food had become so extreme over the past 3 months that she could eat very few foods, even if she washed them excessively. She recognized the irrational nature of these obsessive concerns, but either could not bring herself to eat or became extremely nervous and nauseous after eating.

POSTTRAUMATIC STRESS AND ACUTE STRESS DISORDERS

Symptomatology Both PTSD and acute stress disorder are characterized by the onset of psychiatric symptoms immediately following exposure to a traumatic event. As noted in Table 15.6-12, DSM-IV specifies that the traumatic event involves either witnessing or experiencing threatened death or injury or witnessing or experiencing threat to physical integrity. Further, the response to the traumatic event must involve intense fear or horror. Such traumatic experiences might include being involved in or witnessing a violent accident or crime, military combat, assault, being kidnapped, being involved in natural disasters, being diagnosed with a life-threatening illness, or experiencing systematic physical or sexual abuse. Both PTSD and acute stress disorder also require characteristic symptoms following such trauma. There is evidence of a relation between the degree of trauma and the likelihood of symptoms. The proximity to, and intensity of, the trauma relate to the probability of developing symptomatology.

Table 15.6-12 DSM-IV Diagnostic Criteria for Posttraumatic Stress Disorder

In PTSD, the individual develops symptoms in three domains: reexperiencing the trauma, avoiding stimuli associated with the trauma, and experiencing symptoms of increased autonomic arousal, such as an enhanced startle. Flashbacks represent the classic form of reexperiencing: the individual may act and feel as if the trauma were recurring. Other forms of reexperiencing include distressing recollections or dreams and either physiological or psychological stress reactions upon exposure to stimuli linked to the trauma. An individual must exhibit at least one symptom of reexperiencing to meet criteria for PTSD. Symptoms of avoidance associated with PTSD include efforts to avoid thoughts or activities related to the trauma, anhedonia, reduced capacity to remember events related to the trauma, blunted affect, feelings of detachment or derealization, and a sense of a foreshortened future. An individual must exhibit at least three such symptoms. Symptoms of increased arousal include insomnia, irritability, hypervigilance, and exaggerated startle. An individual must exhibit at least two such symptoms. Finally, the diagnosis of PTSD is only made when these symptoms persist for at least 1 month; the diagnosis of acute stress disorder is made in the interim. DSM-IV acknowledges three subtypes of PTSD that differentiate syndromes with varying time courses. *Acute PTSD* refers to an episode that lasts less than 3 months. *Chronic PTSD* refers to an episode lasting 3 months or longer. *PTSD with delayed onset* refers to an episode that develops 6 months or more after exposure to the traumatic event

The diagnosis of acute stress disorder is applied to syndromes that resemble PTSD but last less than 1 month after a trauma. Acute stress disorder is characterized by reexperiencing, avoidance, and increased arousal, much like PTSD. Acute stress disorder is also associated with at least three of the dissociative symptoms listed in Table 15.6-13.

Table 15.6-13 DSM-IV Diagnostic Criteria for Acute Stress Disorder

Because individuals often exhibit complex biological and behavioral responses to extreme trauma, the clinician must recognize other medical and psychiatric conditions in the traumatized patient. Particularly after traumatic events that involve physical injury, the clinician must always consider neurological causes of symptoms that develop after trauma. Traumatized patients also can develop mood disorders, including dysthymia and major depression, as well as other anxiety disorders, such as generalized anxiety disorder or panic disorder, and substance use disorders. Finally, recent research suggests that some psychiatric features of posttraumatic syndromes can relate to the state of a patient before the trauma. For example, patients with premorbid anxiety or affective syndromes may be more likely to develop posttraumatic symptoms than individuals who are free of mental illness before the trauma. Thus, the clinician should consider the premorbid mental state of the traumatized patient to enhance understanding of symptoms that develop following a traumatic event.

History and Comparative Nosology Astute clinicians have recognized the juxtaposition of acute mental syndromes to traumatic events for more than 200 years. Observations of trauma-related syndromes were documented following the Civil War, and early psychoanalytic writers, including Freud, noted the relation between neurosis and trauma. Considerable interest in posttraumatic mental disorders was stimulated by observations of “battle fatigue,” “shell shock,” and “soldier's heart” in World War I and World War II. Moreover, increasing documentation of mental reactions to the Holocaust, to a series of natural disasters, and to assault contributed to the growing recognition of a close relationship between trauma and psychopathology.

The syndrome of PTSD was first recognized in the DSM nosology in DSM-III in 1980; acute stress disorder was first recognized in DSM-IV in 1994. The recognition of acute stress disorder followed observations suggesting that many individuals exhibit mental syndromes immediately following trauma; such individuals might face an elevated risk for PTSD. The original DSM-III definition of PTSD required only one symptom of reexperiencing, two symptoms of “psychic numbing,” and one symptom from a list of miscellaneous items, with no duration criteria. DSM-III-R added a number of symptoms to the DSM-III definition and removed the DSM-III symptom of guilt. DSM-III-R also adopted the symptom groupings found in DSM-IV, where symptoms are classified as manifestations of either reexperiencing, avoidance, or hyperarousal. The major change to the definition in DSM-IV involved the definition of trauma. While DSM-III-R emphasized trauma as an event that was “outside of normal experience,” a number of field studies suggested that the typical traumatic precipitants of PTSD were relatively common events. As a result, DSM-IV emphasizes the threat and fear-provoking nature of a trauma, without reference to “normal experience.”

Some variation exists in the definitions of PTSD and acute stress disorder in DSM-IV and ICD-10. While ICD-10 acknowledges the same core group of symptoms as DSM-IV for PTSD, including exposure to a trauma, reexperiencing, avoidance, and increased arousal, ICD-10 provides considerably less detail than DSM-IV for each of the criteria. For example, unlike DSM-IV, ICD-10 provides only brief examples of reexperiencing or avoidance symptoms. The broader view of PTSD and acute stress disorder also differs in the DSM and ICD systems. As with OCD, ICD-10 groups PTSD and acute stress reaction in a distinct category rather than including them with other anxiety disorders (Table 15.6-14).

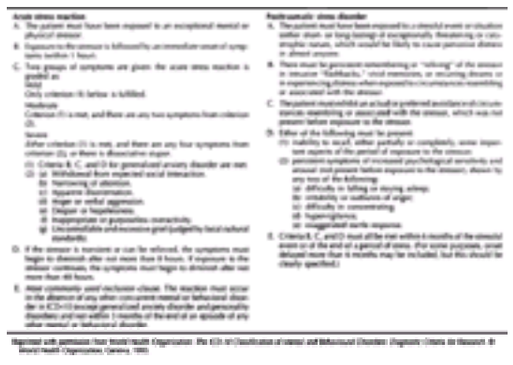

Table 15.6-14 ICD-10 Diagnostic Criteria for Reactions to Severe Stress

Differential Diagnosis Because patients often exhibit complex reactions to trauma, the clinician must be careful to exclude syndromes other than PTSD and acute stress disorder when evaluating patients presenting in the wake of trauma. Recognizing potentially treatable medical contributors to posttraumatic symptomatology is particularly important. For example, neurological injury following head trauma can contribute to the clinical picture, as can psychoactive substance use disorders or withdrawal syndromes, either in the period immediately surrounding the trauma or many weeks after the trauma. Medical contributors can usually be detected through a careful history and physical examination, if the clinician remembers to consider such factors.

Symptoms of PTSD can be difficult to distinguish from those of either panic disorder or generalized anxiety disorder, as all three syndromes are associated with prominent anxiety and autonomic arousal. Keys to correctly diagnosing PTSD involve a careful review of the time course relating the symptoms to a traumatic event. Further, PTSD is associated with reexperiencing and avoidance of a trauma, features typically not present in panic or generalized anxiety disorder. Major depression is a frequent concomitant of PTSD. While the two syndromes are generally readily distinguishable phenomenologically, comorbid depression should be noted because it may affect treatment of PTSD. Finally, PTSD must be differentiated from a series of related disorders that can exhibit phenomenological similarities, including borderline personality disorder, dissociative disorders, and factitious disorders.

Course Much recent research on the course of psychological reactions to trauma focused on the time course of symptoms immediately following a trauma. The likelihood of developing symptoms, the severity of such symptoms, and the duration of the symptoms are each proportional to the proximity, duration, and intensity of the trauma. Many individuals develop acute stress reactions when faced with close, persistent, intense trauma. Moreover, many individuals who develop PTSD exhibit features of the acute stress syndrome prior to developing PTSD, although many individuals with acute stress syndromes do not develop PTSD. Finally, the full syndrome of PTSD also exhibits a variable course, with some evidence that this also relates to the nature of the trauma. A large minority of patients experience complete remissions, while another large group exhibits only mild symptoms. Approximately 10 percent of patients with PTSD exhibit a persistent or chronic course to their disorder.

Mr. F. sought treatment for symptoms that he developed in the wake of an automobile accident that had occurred about 6 weeks prior to his psychiatric evaluation. While driving to work on a mid-January morning, Mr. F. lost control of his car on an icy road. His car swerved out of control into oncoming traffic in another lane, collided with another car, and then hit a nearby pedestrian. Mr. F. was trapped in his car for 3 hours while rescue workers cut the door of his car. Upon referral, Mr. F. reported frequent intrusive thoughts about the accident, including nightmares of the event and recurrent intrusive visions of his car slamming into the pedestrian. He reported that he had altered his driving route to work to avoid the scene of the accident, and he found himself switching the television channel whenever a commercial for snow tires appeared. Mr. F. described frequent difficulty falling asleep, poor concentration, and an increased focus on his environment, particularly when he was driving.

GENERALIZED ANXIETY DISORDER

Generalized anxiety disorder is characterized by a pattern of frequent, persistent worry and anxiety that is out of proportion to the impact of the event or circumstance that is the focus of the worry (Table 15.6-15). For example, while college students often worry about examinations, a student who persistently worries about failure despite consistently outstanding grades displays the pattern of worry typical of generalized anxiety disorder. Patients with generalized anxiety disorder may not acknowledge the excessive nature of their worry, but they must be bothered by their degree of worry. This pattern must occur “more days than not” for at least 6 months. The patients must find it difficult to control this worry and must report at least three of six somatic or cognitive symptoms, including feelings of restlessness, fatigue, muscle tension, or insomnia. Worry is a ubiquitous feature of many anxiety disorders: patients with panic disorder often worry about panic attacks, patients with social phobia worry about social encounters, and patients with OCD worry about their obsessions. The worries in generalized anxiety disorder must be beyond the those that characterize these other anxiety disorders. Children exhibiting characteristic symptoms are also considered to meet criteria for generalized anxiety disorder, but they need only meet one of the six somatic or cognitive symptom criteria rather than three.

A. Excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least 6 months, about a number of events or activities (such as work or school performance).
B. The person finds it difficult to control the worry.
C. The anxiety and worry are associated with three (or more) of the following six symptoms (with at least some symptoms present for more days than not for the past 6 months). **Note:** Only one item is required in children.
(1) restlessness or feeling keyed up or on edge
(2) being easily fatigued
(3) difficulty concentrating or mind going blank
(4) irritability
(5) muscle tension
(6) sleep disturbance (difficulty falling or staying asleep, or restless unsatisfying sleep)
D. The focus of the anxiety and worry is not confined to features of an Axis I disorder, e.g., the anxiety or worry is not about having a panic attack (as in panic disorder), being embarrassed in public (as in social phobia), being contaminated (as in obsessive-compulsive disorder), being away from home or close relatives (as in separation anxiety disorder), gaining weight (as in anorexia nervosa), having multiple physical complaints (as in somatization disorder), or having a serious illness (as in hypochondriasis), and the anxiety and worry do not occur exclusively during post-traumatic stress disorder.
E. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
F. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hyperthyroidism), and does not occur exclusively during a mood disorder, psychotic disorder, or a pervasive developmental disorder.

Table 15.6-15 DSM-IV Diagnostic Criteria for Generalized Anxiety Disorder

History and Comparative Nosology Like those of other anxiety disorders symptoms of generalized anxiety disorder have been noted for more than 100 years. Many syndromes considered to be related to panic disorder (e.g., DaCosta's syndrome or neurocirculatory asthenia) also closely resemble generalized anxiety disorder. In fact, prior to DSM-III, panic disorder and generalized anxiety disorder were both subsumed under the broader category of anxiety neurosis.

The conceptualization of generalized anxiety disorder has changed gradually from DSM-III to DSM-IV. The disorder was originally considered a residual category in DSM-III for anxiety disorders that did not fulfill criteria for another disorder. DSM-III required only 1-month duration of symptoms, and concerns arose about the low reliability of the diagnosis. DSM-III-R increased the duration criterion to 6 months, placed more emphasis on the symptom of worry, and added a list of 18 symptoms, from which patients had to exhibit at least 6. DSM-III-R also removed some of the hierarchical rules that had limited the diagnosis to individuals who were free of specific disorders in DSM-III. Finally, DSM-IV further revised the diagnosis. The list of associated symptoms was narrowed from 18 to 6, from which patients had to exhibit at least 3, and more emphasis was placed on the pervasiveness of the worry. DSM-IV attempted to integrate the approach to worry across development. While DSM-III-R possessed the diagnosis of overanxious disorder for use among children, DSM-IV integrated this DSM-III-R diagnosis into generalized anxiety disorder, with some minor threshold differences in making the diagnosis in children.

ICD-10 includes the diagnosis of generalized anxiety disorder and emphasizes the distinction between generalized anxiety and panic disorders (Table 15.6-7). While ICD-10 places an emphasis on worry that is similar to the emphasis in DSM-IV, ICD-10 adopts an approach to the other symptoms of generalized anxiety disorder that is closer to the approach in DSM-III-R than that in DSM-IV. For example, in ICD-10 the diagnosis requires 4 associated symptoms from a list of 22.

Differential Diagnosis Like other anxiety disorders, particularly panic disorder, generalized anxiety disorder must be differentiated from both medical and psychiatric disorders. Neurological, endocrinological, metabolic, and medication-related disorders similar to those considered in the differential diagnosis of panic disorder must be considered in the differential diagnosis of generalized anxiety disorder. Common co-occurring anxiety disorders must also be considered, including panic disorder, phobias, OCD, and PTSD. A patient must exhibit the full syndrome of generalized anxiety disorder that cannot be explained by the presence of such a comorbid anxiety disorder. Diagnosing generalized anxiety disorder in the presence of such other anxiety disorders requires documenting anxiety or worry related to circumstances or topics that are either unrelated or only minimally related to other disorders. Hence, proper diagnosis involves both definitively establishing the diagnosis and properly diagnosing other anxiety disorders. Patients with generalized anxiety disorder also frequently develop major depressive disorder; thus this condition must also be recognized and distinguished. Again, the key feature to making a correct diagnosis is documenting anxiety or worry that is unrelated to the depressive disorder.

Course The lack of prospective epidemiological studies precludes firm conclusions about the course of generalized anxiety disorder. Prospective research, even among clinical samples, is also insufficient. The most complete data on the course of the disorder derive from retrospective epidemiologically based studies. These studies suggest that generalized anxiety disorder is a chronic disorder, as most patients report symptoms for many years prior to assessment. Given the possible biases in such studies, no definitive statement on the course of the disorder can be made.

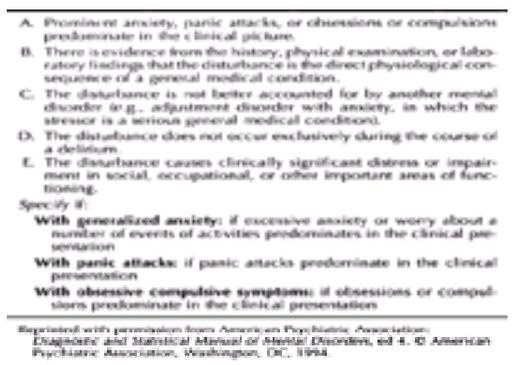
Ms. X. was a successful, married, 30-year-old attorney who presented for a psychiatric evaluation to treat growing symptoms of worry and anxiety. For the preceding 8 months, Ms. X. had noted increased worry about her job performance. For example, while she had always been a superb litigator, she increasingly found herself worrying about her ability to win each new case she was presented. Similarly, while she had always been in outstanding physical condition, she increasingly worried that her health had begun to deteriorate. Ms. X. noted frequent somatic symptoms that accompanied her worries. For example, she often felt restless while she worked and while she commuted to her office, thinking about the upcoming challenges of the day. She reported feeling increasingly fatigued, irritable, and tense. She noted that she had increasing difficulty falling asleep at night as she worried about her job performance and impending trials.

SUBSTANCE-INDUCED ANXIETY AND ANXIETY DUE TO A GENERAL MEDICAL CONDITION

These conditions are characterized by prominent anxiety that arises as the direct result of some underlying physiological perturbation. Hence, for patients with substance-induced anxiety disorder (Table 15.6-16), clinically significant symptoms of panic, worry, phobia, or obsessions emerge in the context of prescribed or illicit substance use. For example, both prescribed and illicit sympathomimetic substances can often produce relatively marked degrees of anxiety. Similarly, for anxiety due to a general medical condition (Table 15.6-17), symptoms develop in the context of an identifiable medical syndrome. For example, panic attacks have been tied to various medical conditions, including endocrinologic, cardiac, and respiratory illnesses.

Specify if:
With generalized anxiety: if excessive anxiety or worry about a number of events or activities predominates in the clinical presentation
With panic attacks: if panic attacks predominate in the clinical presentation
With obsessive-compulsive symptoms: if obsessions or compulsions predominate in the clinical presentation
Specify if:
With onset during intoxication: if the criteria are met for substance intoxication and the symptoms develop during the intoxication
With onset during withdrawal: if criteria are met for withdrawal from a substance and the symptoms develop during or shortly after withdrawal

Table 15.6-16 DSM-IV Diagnostic Criteria for Substance-Induced Anxiety Disorder



A. Prominent anxiety, panic attacks, or obsessions or compulsions predominate in the clinical picture.
B. There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct physiological consequence of a general medical condition.
C. The disturbance is not better accounted for by another mental disorder (e.g., adjustment disorder with anxiety, in which the stressor is a serious general medical condition).
D. The disturbance does not occur exclusively during the course of a delirium.
E. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Specify if:
With generalized anxiety: if excessive anxiety or worry about a number of events or activities predominates in the clinical presentation
With panic attacks: if panic attacks predominate in the clinical presentation
With obsessive compulsive symptoms: if obsessions or compulsions predominate in the clinical presentation

Table 15.6-17 DSM-IV Diagnostic Criteria for Anxiety Disorder Due to a General Medical Condition

The first step in identifying anxiety disorder due to a general medical condition or substance-induced anxiety disorder is to confirm the presence of one or the other complicating factor. Clearly, practitioners should routinely document the medical and substance use status of all patients. However, the clinician should be particularly wary when encountering a patient with an unusual symptomatic presentation. For example, changes in consciousness or neurological function almost never occur in acute anxiety states unless there is also an underlying medical component to the syndrome. In patients where there is a suspicion of such complicating factors, the presence of substance use or medical problems first must be definitively confirmed by obtaining the necessary medical history or evaluative procedures. Next, the clinician must determine that this underlying problem is the cause of the ongoing anxiety symptoms. While there is no definitive test to establish such a causal relationship, several factors can help confirm the diagnosis. These include the timing of the symptoms, the existing literature pertaining to the strength of the association between anxiety and the potential complicating factor, and signs or symptoms (e.g., changes in consciousness) that are atypical for an anxiety disorder. Finally, even more suggestive evidence can be provided if alleviation of the complicating medical factor produces an amelioration of the anxiety symptoms.

ANXIETY DISORDER NOT OTHERWISE SPECIFIED

Anxiety represents one of the most common psychiatric symptoms encountered in various settings, including primary care settings, and it is relatively common to encounter patients who exhibit impairment from anxiety but who do not meet criteria for one of the specific anxiety disorders. These patients are appropriately classified as suffering from anxiety disorder not otherwise specified (Table 15.6-18).

This category includes disorders with prominent anxiety or phobic avoidance that do not meet criteria for any specific anxiety, disorder, adjustment disorder with anxiety, or adjustment disorder with mixed anxiety and depressed mood. Examples include

1. Mixed anxiety-depressive disorder: clinically significant symptoms of anxiety and depression, but the criteria are not met for either a specific mood disorder or a specific anxiety disorder.
2. Clinically significant social phobic symptoms that are related to the social impact of having a general medical condition or mental disorder (e.g., Parkinson's disease, dermatological conditions, stuttering, anorexia nervosa, body dysmorphic disorder).
3. Situations in which the clinician has concluded that an anxiety disorder is present but is unable to determine whether it is primary, due to a general medical condition, or substance induced.

Table 15.6-18 DSM-IV Diagnostic Criteria for Anxiety Disorder Not Otherwise Specified

Two clinical features of this disorder must be recognized to properly identify the condition. First, the anxiety described by the patients must be distressing and interfere with some aspect of functioning. Second, the anxiety must not be attributable to another psychiatric condition. For example, patients with generalized anxiety disorder may not initially report sufficient associated symptoms to meet criteria for this condition. However, on further probing such symptoms may be identified. Particularly in patients with long standing anxiety, it is important to establish that another anxiety disorder does not account for the complaints. Anxiety concerning an embarrassing medical problem or scenario is another frequently encountered form of anxiety disorder not otherwise specified. For example, patients who exhibit excessive concern regarding a dermatological condition might exhibit symptoms of this syndrome.

Perhaps the most consistent research on this condition examines patients with mixed anxiety-depressive disorder, a condition described in an Appendix of DSM-IV (Table 15.6-19). Patients with mixed anxiety-depressive disorder exhibit symptoms both of depression and anxiety that do not meet criteria for another mood or anxiety disorder. Such patients must show signs of consistent low mood for at least a month, accompanied by additional symptoms that include prominent worries. Longitudinal studies find a relatively high risk for later mood or anxiety disorders with this condition, particularly major depressive disorder. Due to the paucity of data on treatment for the condition, clinicians often use approaches that are effective in other mood or anxiety disorders.

A. Persistent or recurrent dysphoric mood lasting at least 1 month.
B. The dysphoric mood is accompanied by at least 1 month of four (or more) of the following symptoms:
   (1) difficulty concentrating or mind going blank
   (2) sleep disturbance (difficulty falling or staying asleep, or restless unsatisfying sleep)
   (3) fatigue or low energy
   (4) irritability
   (5) worry
   (6) being easily moved to tears
   (7) hypervigilance
   (8) anticipating the worst
   (9) hopelessness (pervasive pessimism about the future)
   (10) low self-esteem or feelings of worthlessness
C. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.
E. All of the following:
   (1) criteria have never been met for major depressive disorder, dysthymic disorder, panic disorder or generalized anxiety disorder
   (2) criteria are not currently met for any other anxiety or mood disorder (including an anxiety or mood disorder, in partial remission)
   (3) the symptoms are not better accounted for by any other mental disorder

Table 15.6-19 DSM-IV Research Criteria for Mixed Anxiety-Depressive Disorder

SUGGESTED CROSS-REFERENCES

Other aspects of these disorders are discussed elsewhere, such as theories on etiology (Section 15.3, Section 15.4, and Section 15.5) and treatment (Section 15.7 and Section 15.8). Similarly, substance-induced anxiety disorder and anxiety disorder due to a general medical condition as distinct anxiety disorders are also discussed in Chapter 11 on substance-use disorders and Chapter 10 on the psychiatric complications of medical conditions.

15.7 ANXIETY DISORDERS: SOMATIC TREATMENT

LASZLO A. PAPP, M.D.

After decades of neglect and controversy, anxiety disorders are increasingly recognized as legitimate medical conditions requiring specific treatment. The unproductive debate over the primacy of biological or psychological factors in the pathophysiology of anxiety is gradually being replaced by a pragmatic approach based on research on the relative contributions of both. A parallel, unbiased approach in treatment research began to examine the merits of combined somatic and psychological treatments in anxiety. Recognition of the role of psychological factors in most medical illnesses is breaking down the artificial barrier between psychiatric and medical conditions. While the stigma of psychiatric illness remains a strong deterrent, the availability of effective treatments, frequently a combination of somatic and psychological, is a powerful incentive for patients to come forward.

To date panic disorder remains the best-researched anxiety disorder. Pharmacological treatment trials in panic disorder outnumber those conducted in other anxiety disorders, and most pharmacological challenge studies were first initiated in panic disorder.

HISTORY

The oldest antianxiety drug is alcohol, and it remains the most frequently used and most easily accessible tranquilizer. Modern medical anxiolysis began with the introduction of paraldehyde and bromides around the turn of the century, followed by the first medical use of barbiturates in 1903. While the availability of a number of safer and more effective anxiolytics today makes them mostly obsolete, paraldehyde remains an old-fashioned treatment for alcohol withdrawal, and certain barbiturates retain limited use in anesthesiology and addiction medicine. The development of the so-called nonbarbiturate nonbenzodiazepine hypnotic drugs in the 1930s did not address any of the deficiencies of the barbiturates, and in many cases these drugs proved more problematic. Meprobamate (Equanil, Miltown) and tybamate possess very low therapeutic index, methaqualone and methyprylone (Noludar) are highly addicting and can be fatal in overdose, and glutethimide (Doriden) overdose can result in convulsion and fluctuating coma. The synthesis in 1957 of the first benzodiazepine, chlordiazepoxide (Librium), heralded a new era of safe and effective medical management of anxiety. Because of their safety, efficacy, and high therapeutic index, benzodiazepines have for the most part replaced barbiturates and the nonbarbiturate, nonbenzodiazepine type drugs.

The demonstration in the early 1960s that imipramine (Tofranil) controls panic attacks was the first evidence that antidepressant drugs may alleviate anxiety and that this effect may be independent of their antidepressant property. The historic observation that panic attacks were specifically responsive to antidepressants also marked the beginning of a new diagnostic system that differentiates the subtypes of anxiety neuroses on the basis of medication response. Parallel to the work with imipramine in the United States, British investigators found that another class of antidepressants, the monoamine oxidase inhibitors (MAOIs), specifically benefit hysterical patients with phobic symptoms. Since these patients show many features of panic disorder and agoraphobia, tricyclic and tetracyclic drugs and MAOIs quickly became the first-line treatment choice in panic disorder. The pharmacological dissection of the formally homogeneous anxiety neuroses category into distinct anxiety disorders not only changed diagnostic thinking and the treatment of anxiety but also revolutionized psychopharmacology in general. Symptom-specific rather than diagnosis-specific drug development helped refine and create diagnostic categories for all psychiatric conditions.

Of the many subsequently introduced antidepressants with anxiolytic properties, fluoxetine (Prozac) was the next milestone in the pharmacology of anxiety. This first drug in a series of serotonergic agents became the best-selling antidepressant by 1990. The efficacy of serotonergic drugs in the treatment of panic disorder and obsessive-compulsive disorder significantly advanced the treatment of these anxiety disorders and gave rise to new theories implicating the serotonergic system in the neurobiology of anxiety.

In addition to benzodiazepines and several classes of antidepressants currently available anxiolytic agents include b-adrenergic receptor antagonists and the azapyrone buspirone (BuSpar). New drug development targets neurotransmitter systems identified primarily by pharmacological challenges as pertinent to the neurobiology of anxiety. Candidates include partial benzodiazepine agonists and reverse benzodiazepine antagonists, neurosteroids, neuropeptide agonists and antagonists such as cholecystokinin B (CCK-B) antagonists, corticotropin-releasing factor (CRF) antagonists, neuropeptide Y agonists and serotonergic agents acting on specific serotonin receptor subtypes (e.g., serotonin [5-hydroxytryptamine (5-HT)] subtype 1A [5-HT_{1A}] agonists, and 5-HT_2 and 5-HT_3 antagonists). The accelerated drug development process promises highly effective anxiolytic agents with minimal adverse effects in the near future.

GENERAL PRINCIPLES

The general premise of medication use in anxiety disorders is that an underlying neurochemical imbalance is responsible for the disorder, which can be corrected by administration of drugs affecting specific neurotransmitter systems. Another view of medication use in anxiety disorders posits that anxiety disorders result from underlying cognitive, behavioral, or psychodynamic abnormalities and that the role of medications is to allow the patient to participate in appropriate psychotherapeutic work. The evidence is simply not available at present to adjudicate the primacy of one approach over the other. The knowledge base is rapidly evolving, but it will be many years before definitive statements can be made and causal relationships among neurophysiology, psychopathology, drugs, specific psychotherapeutic interventions, and behavioral outcome can be established. However, medication management of most anxiety disorders with or without psychotherapy is one of the most successful treatments in medicine today. Treatment response rates can reach 80 percent in panic disorder, with steadily improving rates for many other anxiety disorders. Nevertheless, a nonpharmacological treatment will almost always be preferable if comparable efficacy can be established. However benign and tolerable they may be, medication use usually entails some adverse effects. Medications may also be contraindicated because of underlying medical conditions or pregnancy.

EVALUATION

Evaluation of the anxious patient for somatic treatment begins with the psychiatric interview. Particular attention is paid to onset, course, symptomatology and comorbidity. While the anxiety disorders represent distinct diagnostic categories, they also frequently present as comorbid conditions in a given patient. Other comorbid conditions include depression, substance use disorders, and personality disorders. Comorbidity usually complicates the management of anxiety disorders and often predicts poorer outcome. The difficulty in making a differential diagnosis in the presence of comorbid depression and anxiety prompted the suggestion to create a separate diagnostic category, mixed anxiety-depressive disorder. Some believe that this new category will discourage rigorous diagnostic thinking; others consider the issue moot from a pharmacological point of view, since most antianxiety medications have antidepressant properties. In sum, establishing the correct diagnosis remains one of the cornerstones of any therapeutic endeavor.

The initial interview should elicit detailed information about prior treatments. In addition to doses, length of treatment period, response, and adverse effects for each agent, the interviewer should ask about prejudices, attitudes, and reservations about taking medications in general. Family history may help in diagnosis, and treatment history of family members can provide important clues about medication response, which also runs in families.

The initial evaluation should include (when appropriate) a thorough physical examination blood tests for chemistry, hematology, and thyroid function; urinalysis; and an electrocardiogram (ECG). If neurological abnormalities are suspected, a neurological examination may need to be supplemented with appropriate brain imaging

studies. Prominent nocturnal pathology should be investigated in a sleep laboratory.

Choosing the Medication When the decision to use medication is made, the psychiatrist frequently faces a dilemma. Scientifically valid recommendations about anxiety management should be based on rigorous double-blind, placebo-controlled trials. However, even when the data are available, the results of controlled trials do not necessarily reflect clinical reality or guide practice. Patients participating in (usually short-term) treatment trials are preselected to meet entry criteria. Natural comorbidity is limited and severity of symptoms is calibrated to ensure sample homogeneity. Elderly, pediatric, and medically ill patients are specifically excluded from most therapeutic trials. Therefore, the bulk of what psychiatrists do in clinical practice remains empirical, and many recommendations are based on expert clinical consensus.

While the choice of medication for a particular patient involves many considerations, treatment algorithms have recently been developed to guide the practitioner. These algorithms consist of decision trees based on numerous, but necessarily limited factors generally applicable to typical patients. In the absence of conclusive evidence for differential efficacy, the choice is usually determined by adverse-effect profiles. These algorithms frequently include combination treatments. Since most of these recommendations are not supported by systematic data, they should be viewed as preliminary, and periodic revisions are imperative. Whenever available, the most salient features of these algorithms are presented for the specific anxiety disorder.

Duration of Treatment Most information on the pharmacological management of anxiety is limited to short-term treatment trials. Long-term trials and follow-ups are rare; sequential treatment research is practically nonexistent. While some studies suggest that longer maintenance treatments lower relapse rates, the optimal length of medication maintenance treatment is still unknown. Since most anxiety disorders are chronic, frequently life-long conditions, treatment should probably be continued indefinitely but perhaps intermittently. In general, the lowest dosage of medication that controls the patient's symptoms should be prescribed. Slow, gradual taper of medication dosage may be attempted after 1 year in symptom-free patients; recurrence should be retreated promptly. The benefit of freedom from adverse effects should be weighed against developing drug resistance. Retreatment with a previously efficacious agent may not produce the same benefits. Frequently, a former drug responder requires several medication trials before an efficacious drug is again found.

Another, possibly related, problem associated with long-term pharmacotherapy of anxiety is drug burnout. *Burnout* refers to patients who, after a few months of response, develop drug resistance while on medication. In these patients, adjusting the dosage up or down may help, but usually one must augment or replace the original medication. Burnout is unrelated to drug tolerance, which is rare in patients suffering from pure anxiety disorders. Even when treated with benzodiazepines, the drug group claimed to be most addicting, patients with anxiety disorders usually continue to respond to stable or decreasing doses.

Treatment Nonresponse Treatment nonresponse should prompt careful reassessment of the target symptoms, review of adverse effects, discussion of patient expectations, reevaluation of the diagnosis, checking compliance with treatment, identification of comorbid conditions (including personality disorders, substance use, and medical conditions), and potential interactions with concomitant medications (including consideration of pharmacokinetics and pharmacodynamics). The most frequent reason for medication nonresponse remains undermedication (i.e., inadequate dosage or duration). Dosing and length of treatment should be based on valid clinical trials or (in the absence of data) collective clinical experience.

Managing Adverse Effects One of the main reasons for treatment resistance is noncompliance, frequently related to anticipated or actual adverse effects. With the availability of many agents of comparable efficacy, side-effect profiles are increasingly considered in choosing a drug. A less efficacious drug may even be selected because its has a more favorable side-effect profile.

Patients should be well informed about adverse reactions and their management; however, the education and reassurance should match the needs of the patient. An overinclusive presentation may frighten a suggestible patient with anxiety disorder. As an introduction, patients should always be told that most side effects are benign and do not represent clinically significant limitations.

Lower-than-therapeutic starting dosages are generally better tolerated. Even if the initial agitation reaction of panic patients is not expected, a gradual, slow increase gives the anxious patient the best chance to accommodate to adverse reactions. Patients with dry mouth should increase fluid intake, use sugarless gum or candy, and may also try bethanecol (Urecholine). Constipation usually responds to high-bulk diet with plenty of fluid, stool softeners, or milk of magnesia. Avoiding sudden postural changes and using constrictive support hose usually minimizes orthostatic hypotension. If it persists in spite of increased fluid and salt intake, salt tablets, mineralocorticoids, amphetamines, or yohimbine (Yocon) may be tried unless specifically contraindicated. Urinary hesitancy should prompt dosage reduction, and bethanecol may also be tried. In general, anticholinergic side effects are best handled by switching to a less anticholinergic drug. Anticholinergic drugs should not be used in patients with prostatic hypertrophy or narrow-angle glaucoma. Sexual dysfunction is one of the most problematic and resistant adverse effects of drugs with significant serotonergic activity. Dosage reduction is only occasionally helpful. Anorgasmia may respond to bethanecol, cyproheptadine (Periactin), or yohimbine; diminished libido may improve if buspirone (Dulper) or bupropion (Wellbutrin) are added. Sildenfanil (Viagra) is under investigation for use in reversing the adverse sexual effects of SSRIs.

Medication-induced insomnia may improve over time. Switching the dose to the morning should be tried before hypnotic drugs such as a benzodiazepine, zolpidem (Ambien), or trazodone (Desyrel) are added. Sedating drugs should be given at bedtime or in split doses. Patients should be warned that most antidepressants cause photosensitivity. They should also be told that tricyclic and tetracyclic antidepressants may reduce parasympathetic innervation to the heart resulting in decreased beat to beat heart rate variability and potentially increased risks of coronary heart disease and arrhythmia. Antidepressant-induced hypomania may respond to dosage reduction, but if the patient has a history of bipolar disorder, mood stabilizers may be indicated.

Weight gain is one of the most troublesome and limiting adverse effects of antidepressant antianxiety drugs. Tricyclic and tetracyclic drugs with strong anticholinergic profiles and MAOIs are probably the worst offenders, followed by the serotonergic class. Atypical antidepressants such as bupropion, trazodone, and nefazadone (Serzone) are less likely to cause weight gain. If diet and exercise fail, dosage reduction or a switch to a different agent are likely to be more successful.

Antipsychotics As a general rule, antipsychotic medications should not be used for the management of anxiety disorders. However, the new generation of safer, atypical antipsychotics, (i.e., serotonin-dopamine antagonists) appears to have dramatically reduced risks of extrapyramidal side effects and tardive dyskinesia. Antipsychotic drugs may be considered in the treatment of agitation in elderly patients, managing anxiety in patients with organic brain disease, and potentiating antidepressants in patients with refractory obsessive-compulsive disorder with tic disorder or schizotypal personality disorder. Periodic, short-term antipsychotic drug may also be used in patients with histories of multiple substance dependence and those for whom all other alternatives have failed.

Medication Monitoring Duration and frequency of contact between the patient and the medicating doctor vary, depending on many factors (logistics, severity of illness, the patient's response to the medication, and the availability and use of ancillary mental health and medical services), but general guidelines apply. The initial evaluation should last for at least 1 hour. If the patient begins to take medication, a follow-up visit lasting from 20 to 30 minutes should occur within a week or two after the first visit. Another follow-up visit is usually indicated approximately 1 month after the initial evaluation, and if the condition of the patient is stable, monthly visits usually suffice to monitor progress. Face-to-face contact could be less frequent in certain situations, but a visit every 3 months is usually the outside limit. The prescribing physician should always make arrangements for 24-hour coverage and should be available to answer questions on the phone.

PANIC DISORDER WITH OR WITHOUT AGORAPHOBIA

The symptomatic triad of panic disorder consists of panic attacks, usually complicated by anticipatory anxiety and phobic avoidance, or agoraphobia. For a long time the pharmacological approach to panic disorder assumed that blocking panic attacks with medications lead to gradual improvement in both anticipatory anxiety and phobic avoidance. Therefore, panic blockade was the main focus of pharmacotherapy. Response rates to panic blockade alone range from 50 to 80 percent, depending on the definition of response. Since some of these panic-free patients remain avoidant and apprehensive, clinical practice must consider the full spectrum of panic disorder, including anticipatory anxiety, phobia, and comorbid conditions such as mood disorders.

The natural course of panic disorder varies. A significant proportion of these patients have very favorable outcomes, others suffer from long-term disability, and some have an alternating course. To address these problems, the traditional, relatively straightforward, antipanic drug regimens are gradually replaced or modified in clinical practice by complex decision trees, treatment algorithms, drug combinations, and augmentation strategies. The recommendation for refractory cases frequently includes addition of specific psychotherapeutic techniques as well.

At the time of this writing only five drugs have been approved by the Food and Drug Administration (FDA) to treat panic disorder, but the number of efficacious, off-label antipanic agents are in the dozens. They include high- and low-potency benzodiazepines, selective serotonin reuptake inhibitors (SSRIs), tricyclic and

tetracyclic, MAOIs, reversible MAOIs (RIMAs), and novel antidepressants. In explaining the pharmacological options, the clinician should tell the patient about the risks and benefits of these medications. Specifically, the patients should know that most of these medications are equally efficacious and that the choice is usually made on the basis of side effects.

Current consensus is to start treating a patient with uncomplicated panic disorder with low dosages of an SSRI (Table 15.7-1). Even at these low starting dosages many panic patients may experience initial agitation and more-frequent panic attacks. This so-called supersensitivity syndrome is usually limited to the first week or two of treatment. Further dosage reduction, switching to a different compound in the same family, or addition of a high-potency benzodiazepine, such as clonazepam (Klonopin) or alprazolam (Xanax), usually gets the patient through this relatively short period. Dosages can subsequently be increased over several weeks until they reach therapeutic range. For full panic blockade, most patients require dosages equivalent to those used in depression. A therapeutic trial with these agents should last for at least 5 weeks. Panic blockade often leads to improvement in both anticipatory anxiety and phobic avoidance. Preliminary evidence suggests that improvement in phobic avoidance may require higher dosages than panic blockade.

	Starting (mg)	Maintenance (mg)
SSRI		
Paroxetine	5–10	20–60
Fluoxetine	2–5	20–60
Sertraline	12.5–25	50–200
Fluvoxamine	12.5	100–150
Citalopram	10	20–40
Tricyclic antidepressants		
Clomipramine	5–12.5	50–125
Imipramine	10–25	150–300
Desipramine	10–25	150–200
Benzodiazepines		
Alprazolam	0.25–0.5 t.i.d.	0.5–2 t.i.d.
Clonazepam	0.25–0.5 b.i.d.	0.5–2 b.i.d.
Diazepam	2–5 b.i.d.	5–30 b.i.d.
Lorazepam	0.25–0.5 b.i.d.	0.5–2 b.i.d.
MAOIs		
Phenelzine	15 b.i.d.	15–45 b.i.d.
Tranylcypromine	10 b.i.d.	10–30 b.i.d.
RIMAs		
Moclobemide	50	300–600
Brofaromine	50	150–200
Atypical antidepressants		
Venlafaxine	6.25–25	50–150
Nefazodone	50 b.i.d.	100–300 b.i.d.
Other agents		
Valproic acid	125 b.i.d.	500–750 b.i.d.
Inositol	6000 b.i.d.	6000 b.i.d.

Table 15.7-1 Recommended Dosages for Antipanic Drugs (Daily Unless Indicated Otherwise)

Approximately 60 percent of patients respond to this approach. Partial responders can benefit from the addition of a high-potency benzodiazepine or buspirone. Partial responders with tachycardia may try a combination of an SSRI and b-adrenergic receptor antagonists. b-adrenergic receptor antagonists may also alleviate cardiac discomfort associated with mitral valve prolapse. The dosage of b-adrenergic receptor antagonists such as propranolol (Inderal) or atenolol (Tenormin) should be titrated until the heart rate is reduced by 5 to 10 beats per minute. Contraindications to using b-adrenergic receptor antagonists include bradycardia, heart block and asthma. Drug-drug interactions between some SSRIs and some b-adrenergic receptor antagonists should be kept in mind.

Nonresponders should be tapered off the SSRI and offered one of the following options: a second SSRI, venlafaxine (Effexor), a high-potency benzodiazepine, a tricyclic or tetracyclic, or an MAOI. Persistent adverse effects such as weight gain, hypomania, or sexual dysfunction, may also necessitate a switch from an SSRI in otherwise fully responding panic patients, although first an attempt should be made to address these adverse effects.

Originally, one of the most important advantages of SSRI treatment was considered the absence of withdrawal reaction upon discontinuation. However, withdrawal reactions ranging from mild, transient anxiety and insomnia to severe headache, nausea, dizziness, and “electric jolts” lasting for several months have since been reported in up to 86 percent of patients who abruptly discontinue taking SSRIs. Therefore, gradual taper over several weeks is strongly recommended. Anecdotal reports suggest that the addition of benzodiazepines, or trazodone for sleep may alleviate SSRI withdrawal.

MAOIs MAOIs such as phenelzine (Nardil) or tranylcypromine (Parnate) are the most likely to be efficacious in panic disorder, but they present the dilemma of dietary restrictions and the danger of hypertensive reaction, weight gain, orthostatic hypotension, insomnia, and a series of anticholinergic adverse effects. While somewhat less effective, a RIMA, such as moclobemide (Aurorix), is an alternative. After 2 weeks of washout (6 weeks for fluoxetine), the MAOI can be given and the dosage gradually raised to usual antidepressant levels. Comorbid major depressive in disorder in panic disorder patients may respond best to MAOIs. Because of severe withdrawal reactions such as disinhibition, irritability, agitation, insomnia, myoclonic jerks, and occasionally, delirium, thought disorder, cognitive impairment, and mania, gradual taper is strongly recommended before MAOIs are discontinued. The dietary restriction should continue for at least 2 weeks beyond discontinuation.

High-Potency Benzodiazepine High-potency benzodiazepines should be considered if the adverse effects of all other alternatives are unacceptable to the patient, or they may be first-line choices if the patient is unwilling or unable to wait out the 4- to 5-week delay in response associated with most antidepressants. The advantage of switching to a benzodiazepine also includes no wash-out time for the SSRI. In fact, a benzodiazepine can be added to the SSRI during taper. A typical switch would entail adding 0.5 mg of clonazepam twice a day to 40 mg of paroxetine (Paxil). A few days later the paroxetine dose can be lowered to 20 mg, and depending on its sedative effects, clonazepam dosage can be raised to 1 mg twice a day. Every 3 to 4 days the dosage of paroxetine can be halved while clonazepam dosage is adjusted as tolerated.

High-potency benzodiapines and perhaps low-potency benzodiazepines as well are powerful antipanic drugs. Their sedative and habituating potentials are easily managed in most patients and should not significantly diminish their clinical utility. A major advantage of benzodiazepines is their quick onset of action. Most responders benefit within 1 week. Panic patients with prior history of substance use disorder should not be treated with benzodiazepines. Older patients should take significantly lower doses of benzodiazepines because they are more sensitive to sedation and the potential cognitive side effects of benzodiazepines. A history of organic brain disease or significant character pathology may predispose patients to experience disinhibition while taking benzodiazepines.

The serious and clinically limiting problem of withdrawal symptoms from benzodiazepines prompted many studies attempting to alleviate the withdrawal reaction, also referred to as discontinuance syndrome. Studies with clonidine (Catapres), propranolol (Inderal), and carbamazepine (Tegretol) yielded inconsistent results, and substituting other medications such as antidepressants or azapirones that are easier to taper has not been studied sufficiently. Cognitive-behavioral therapy may best counter benzodiazepine withdrawal. The severity of withdrawal is related to the dosage and length of use and to the rate of taper. The rule of lowest efficacious dose for the shortest time needed for improvement should always be observed. Tapering should never exceed a 10 percent dosage reduction every 3 days. Several months of tapering after years of high-dose benzodiazepine use is frequently unavoidable.

Follow-up studies suggest that benzodiazepine-responsive panic patients maintain their gains over several years and do not develop tolerance to the drugs' antianxiety effects. In fact, maintenance dosages of benzodiazepines are frequently lower than dosages during acute treatment. Residual symptoms may require additional treatment. Since use of short-half-life benzodiazepines such as alprazolam may be associated with between-dose rebound anxiety, some clinicians prefer benzodiazepines with longer half-lives, which may also be easier to taper.

Tricyclics and Tetracyclics Switching to a cyclic antidepressant should begin with tapering the SSRI dosage down to the starting dosage. Some clinicians consider it safe to add the tricyclic at low starting dosages while others recommend a drug-free period lasting from 24 hours to 1 week before administering the second drug. The reason for caution is the potential development of the serotonin syndrome, a rare but severe reaction that may occur when two serotonergic drugs are combined. Also, plasma concentrations of tricyclic and tetracyclics may increase due to inhibition of their metabolism by the SSRI.

The first drug ever shown to possess antipanic efficacy is the tricyclic drug imipramine, and many clinicians still consider it the gold standard in panic disorder. Tricyclic and tetracyclic are generally well tolerated. Their clinical utility is clearly limited, however, by anticholinergic and cardiovascular adverse effects and toxicity in overdose. One of the most effective tricyclic drug for panic is clomipramine (Anafranil), which seems to be effective at lower than full antidepressant dosage. A linear relationship may exist between total plasma tricyclic drug concentrations and response rate. In general, agoraphobia may respond to higher dosages than panic attacks alone. Because of the variable nature of the withdrawal reaction upon discontinuation of tricyclic or tetracyclic drugs (somatic distress, sleep disturbance, behavioral activation, cardiac arrhythmias), taper should be tailored to the patient's needs. Halving the original dosage will give an early indication of withdrawal severity.

Secondary Alternatives While controlled data are unavailable, clinicians increasingly turn to venlafaxine (Effexor) as an alternative to SSRIs and tricyclic drugs in the treatment of panic disorder. If such initial adverse effects as nausea and agitation are overcome, venlafaxine is a powerful antipanic agent at a dosage

significantly below its antidepressant dosage. Since the safety of combining venlafaxine and an SSRI has not been systematically assessed, the SSRI should be tapered and discontinued before switching to venlafaxine. A potential limitation of venlafaxine is an unusually severe reaction to taper. Many successfully treated patients complain of nausea, headache, fatigue, dizziness, and gastrointestinal disturbance when trying to reduce the venlafaxine dosage. Anecdotal evidence suggests that the temporary addition of fluoxetine (10 mg a day) may reduce the withdrawal reaction and allow discontinuation of venlafaxine.

Switching to a second SSRI may be justified if the adverse effects of all alternative possibilities are unacceptable to the patient or there is a relative contraindication to using anything but an SSRI. Again, in the absence of controlled data, opinions differ on how to switch between two SSRIs. Since the potential for the serotonin syndrome is even higher than in the case of combining an SSRI and a tricyclic antidepressant, caution is warranted, and most clinicians recommend a drug-free period between two SSRIs.

Buspirone was promoted as a less-sedating alternative to benzodiazepines in the treatment of panic disorder. Buspirone has lower potential for abuse and dependence than benzodiazepines and produces relatively few adverse effects and no withdrawal syndrome. Buspirone does not alter cognitive or psychomotor function, does not interact with alcohol, and is not a muscle relaxant or an anticonvulsant. However, the efficacy of buspirone in panic disorder is disappointing, and with its further handicap of delayed onset of action and the need for multiple dosing, its use is limited to potentiating the efficacy of other antidepressants and countering the adverse sexual effects of SSRIs. Also, buspirone seems even less effective in patients previously exposed to benzodiazepines.

Bupropion, maprotiline (Ludiomil), and trazodone have not been found efficacious for panic disorder in controlled studies, while the anticonvulsants divalproex (Depakote) and gabapentin (Neurontin), the polyol second-messenger precursor inositol, nefazodone, and the calcium channel inhibitor verapamil (Calan, Isoptin) have shown promise as antipanic agents.

While the short-term efficacy of antipanic medications has been established, the question of how long to treat a panic patient who responds to treatment remains open. The results of follow-up studies are mixed. Several reports indicate that most panic patients relapse within 2 months to 2 years after the medication is discontinued. A recent review concludes that following medication discontinuation, only about 30 to 45 percent of the patients remain well, and even remitted patients may display a variety of symptoms. Others find that while occasional panic attacks are quite common, otherwise responding patients rarely revert back to significant phobic avoidance or serious vocational or social disability. Improvement may continue for years following a single course of medication treatment. This favorable outcome may be explained by the heterogeneity of panic disorder, spontaneous learning experience of patients in clinical trials, and concomitant self-monitoring. Given the uncertainty about the optimal duration of treatment, the current recommendation is to continue full-dosage medication for panic-free patients for at least 1 year. Medication taper should be slow, with careful monitoring of symptoms. Distinction should be made among return symptoms, withdrawal, and rebound anxiety.

Since longer duration of illness at baseline predicts poor long-term outcome, all efforts should be made to identify and treat panic patients as early as possible. More-severe phobic avoidance and comorbid depression and social phobia at baseline also predict poor long-term outcome. Higher depression scores coincide with greater severity of avoidance and disability. The poorer overall outcome in panic disorder patients with comorbid recurrent depression is more likely due to the simultaneous presence of the two conditions. Comorbid depression usually improves in parallel with panic symptoms.

Atypical responses to medications have been reported in panic patients whose first panic attacks were precipitated by cocaine use. These patients respond preferentially to benzodiazepines and anticonvulsants, while tricyclic drugs seem to worsen their anxiety symptoms. This pattern of medication response suggests that cocaine-induced panic attacks may be related to a kindling-like phenomenon.

In a small series of patients with comorbid depression and panic disorder electroconvulsive therapy (ECT) seemed highly effective. None of these patients experienced panic attacks after their fourth ECT treatment until discharge.

GENERALIZED ANXIETY DISORDER

Patients with generalized anxiety disorder suffer from excessive and uncontrollable anxiety and worry for at least 6 months and experience a series of somatic symptoms such as restlessness, irritability, insomnia, and muscle tension. The illness is chronic, with periodic exacerbations and relative quiescence. The relative sparsity of biological data and pharmacotherapy research is due to a number of factors. First, because of their multiple somatic complaints, patients with generalized anxiety disorder are usually seen by generalists and medical specialists other than psychiatrists; generalized anxiety disorder is more likely to be diagnosed as a comorbid condition in psychiatric practices. Second, pharmacotherapy is considered less effective in generalized anxiety disorder than in some other anxiety disorders. Third, the diagnostic features are not clear-cut, and comorbid conditions make the diagnosis difficult.

The efficacy of benzodiazepines in the pharmacological treatment of generalized anxiety disorder gave rise to theories implicating the benzodiazepine–g-aminobutyric acid (GABA) receptor system in the pathophysiology of generalized anxiety disorder, but evidence exists for the involvement of the serotonergic and noradrenergic systems as well. Benzodiazepines remain the traditional medication choice for patients with generalized anxiety disorder. Data do not support the advantage of any one benzodiazepine over others, and no correlation has been established between clinical response and dosage or plasma concentration. A daily equivalent of 15 to 25 mg of diazepam usually suffices to relieve most symptoms in up to 70 percent of generalized anxiety disorder patients. Both somatic and psychic anxiety symptoms respond within the first week of treatment. Tolerance to the sedative effects of benzodiazepines develops quickly, but the antianxiety effect of a given dosage is well maintained over time in generalized anxiety disorder. However, the relapse rate upon discontinuation of benzodiazepines is high.

Buspirone, the only currently available azapirone, is a potential alternative to benzodiazepine treatment in generalized anxiety disorder. Response rates between 60 and 80 percent have been reported at dosages ranging from 30 to 60 mg a day in three divided doses. While response rates seem comparable, more patients drop out of buspirone trials than benzodiazepine trials. The relative merits of buspirone and benzodiazepines are further detailed under panic disorder. One notable exception is that generalized anxiety disorder patients exposed to benzodiazepines may still be responsive to buspirone unlike panic patients.

Antidepressants are also effective in generalized anxiety disorder patients. Dosages and response patterns are similar to those observed in panic disorder (Table 15.7-1). Increased initial physiological symptoms and anxiety may be related to adverse effects such as dry mouth, constipation, sedation, and positional hypotension rather than to the hypersensitivity syndrome described in panic disorder.

Isolated (but prominent) symptoms such as palpitation, tremor, and sweating may respond to b-blockers within 1 week of treatment, but the full generalized anxiety disorder picture usually requires the use of benzodiazepines, antidepressants, or buspirone. Controlled studies are unavailable, but clinical experience suggests the benefits of combination treatments for generalized anxiety disorder. For instance, the combination of benzodiazepines or b-adrenergic receptor antagonists with antidepressants could yield a rapid response, and when the antidepressant becomes effective, the benzodiazepine or b-adrenergic receptor antagonists can be tapered off. Several new drugs, currently unavailable in the United States, have also been found promising in recent clinical trials. The only double-blind, placebo-controlled study with the partial benzodiazepine agonist abecarnil showed significant improvement on many measures in patients with generalized anxiety disorder. Tropisetrone, a 5-HT_3 antagonist, has good antianxiety efficacy with few, mild adverse effects, and serazepine, a 5-HT_2 antagonist, also worked well. Gepirone and ipsapirone, two compounds related to buspirone, have demonstrated efficacy comparable to that of buspirone.

Maintenance pharmacotherapy of patients with generalized anxiety disorder should follow the principles given above for long-term treatment of anxiety disorders. Given the fluctuating course of this disorder, periodic discontinuation may be attempted.

OBSESSIVE-COMPULSIVE DISORDER

Patients with OCD suffer from recurrent ruminations, the need for repeated performance of useless stereotyped rituals, or both. The initial assessment of patients with OCD should include a detailed description of type, severity, and onset and identification of target symptoms. Comorbid conditions frequently complicating the treatment of OCD include depression, other anxiety disorders, substance use disorders, schizophrenia, bipolar disorders, and personality disorders. OCD is probably the most difficult anxiety disorder to treat and has the highest rate of nonresponse.

Finding that medications that increase serotonergic transmission in the central nervous system (CNS) are efficacious in OCD revolutionized treatment and suggested that the pathophysiology of OCD is related to changes in serotonin function. Subsequently, a series of these medications such as clomipramine, fluvoxamine (Luvox), fluoxetine, paroxetine, and sertraline (Zoloft) have been shown in double-blind controlled trials to alleviate the symptoms of OCD. These drugs are used at relatively high daily dosages (clomipramine, 250 mg; fluvoxamine, 300 mg; fluoxetine, 80 mg; paroxetine 60 mg; sertraline, 200 mg a day or more), although recently the high-dosage strategy is being challenged. Some investigators believe that longer duration of treatment rather than higher dosage is required for response. Ten weeks

of treatment trial is currently the minimum recommendation, but it is not unusual to have treatment continue for several months before peak efficacy is reached. The average response rate to these agents ranges from 40 to 60 percent, but nonresponders to one drug can respond to another. Therefore, several anti–obsessive-compulsive OCD drugs should be tried sequentially before making conclusions about drug resistance. Recent studies suggest that intravenous pulse loading or gradual infusion of clomipramine may convert oral clomipramine–refractory patients into responders.

Based on meta-analysis of effect sizes in placebo-controlled trials, clomipramine is considered more effective than the SSRIs. However, recent direct comparisons failed to confirm this observation. Also, the potential advantage of clomipramine should be weighed against its more troublesome (primarily anticholinergic) adverse-effect profile.

A significant proportion of OCD patients remain refractory to SSRI monotherapy, which suggests diagnostic heterogeneity and also that the psychophysiology of OCD may involve abnormalities other than serotonin dysregulation. Patients with comorbid chronic tic disorders such as Tourette's disorder may represent a subgroup of OCD and may require the combination of SSRI and an antipsychotic drug such as pimozide (Orap) or haloperidol (Haldol). Addition of a low-dosage antipsychotic to an SSRI may also be justified for comorbid schizotypal personality disorder. In general, however, addition of an antipsychotic should only be considered if all other approaches including trials of several SSRIs and cognitive-behavioral therapy have all failed. Since most of these patients require long-term pharmacotherapy, the potential risk of tardive dyskinesia should be weighed against the benefits. The availability of serotonin-dopamine antagonists, with more-favorable adverse-effect profiles, may change this conservative view.

The presence of neurological abnormalities or abnormal electroencephalogram (EEG) may indicate a need for a trial concomitant use of anticonvulsants such as valproate (Depakene) or carbamazepine, while prominent impulsivity may respond to sympathomimetics (psychostimulants) alone or in combination with other antiobsessional drugs. Earlier case reports of the antiobsessional effects of phenelzine were confirmed in one double-blind trial but not in a subsequent controlled study. The efficacy of phenelzine may be limited to patients with symmetry obsessions. Augmentation strategies to enhance the anti–obsessive-compulsive properties of SSRIs have used lithium (Eskalith), buspirone, pindolol (Visken), fenfluramine, 5-hydroxytryptophan, and L-tryptophan. In the absence of controlled studies confirming their efficacy, the addition of most of these agents cannot be recommended as augmenting strategies with scientific certainty. For example, lithium and buspirone augmentation failed in double-blind controlled trials. Case reports suggest that pindolol (2.5 mg three times a day) may help with comorbid depression but has no additive antiobsessional effect.

Relapse rates are high following medication discontinuation. In one study over 90 percent of the patients relapsed after abrupt discontinuation of clomipramine. Medication maintenance treatment seems to be associated with maintained, and even improved, overall functioning. Dosage titration during maintenance treatment could further improve outcome with few late-emergent adverse events.

The most important predictor of poor outcome in OCD is early onset. The presence of schizotypal, borderline, and avoidant personality disorders, and greater number of personality disorders also predict poorer outcome. Severity and duration of illness, sex, age, and type of symptoms have no predictive value.

Psychosurgery remains the last-resort treatment for intractable OCD. The most frequently performed operation, stereotactic subcaudate tractotomies or capsulotomy, intersects the connections between the frontal lobe and the thalamus and exerts its efficacy on the proposed functional imbalance in OCD between the frontal lobe and other parts of the brain. Stereotactic leukotomy seems to decrease glucose metabolism in the orbital part of the frontal lobe. Cingulotomy resulted in significant improvement in 25 to 30 percent of patients previously unresponsive to medication and behavioral treatments. This rate of improvement seems independent of the changes in anxiety and depression scores. Personality changes following psychosurgery are infrequent, but most patients display lower initiative, drive, and energy levels at follow-up. Capsulotomy can lead to perservative behavioral responses. Striatal lesions may lead to the development of substance use disorders following surgery. Phenytoin (Dilantin) usually controls the symptoms in the few cases when seizure develops following surgery.

The few ECT case studies in intractable OCD show considerable benefits up to a 1-year follow-up and suggest that these benefits are independent of changes in measures of depression. These reports must be viewed with caution until confirmed in controlled trials. Preliminary evidence suggests that plasmapheresis, antibiotics, or both may be indicated in a subgroup of children whose obsessive-compulsive symptoms are associated with a specific autoimmune response in the brain.

SOCIAL PHOBIA

Social phobia is an exaggerated fear of negative evaluations, ranging from specific to generalized types. Some consider avoidant personality disorder to be the most severe form of social phobia. Social phobia is a chronic, disabling condition whose prevalence is being increasingly recognized.

Double-blind, placebo-controlled studies confirmed that the most effective medication for the treatment of generalized social phobia is the MAOI phenelzine. Therapeutic dosages of phenelzine range from 45 to 90 mg a day, with response rates ranging from 50 to 70 percent. Approximately 5 to 6 weeks are needed to assess the efficacy of phenelzine. Responders should continue treatment for at least a year. Dietary restriction and numerous troublesome adverse effects put MAOIs at a significant disadvantage compared with less-efficacious but more acceptable medication choices. For instance, the SSRIs have recently emerged as viable alternatives to phenelzine. Although not subjected to the same rigorous evaluations, the results of controlled trials (fluvoxamine, paroxetine, sertraline), a controlled discontinuation study (paroxetine), and open-label case reports (citalopram [Celexa]) with SSRIs suggest that their ease of administration and tolerability more than make up for their slightly lower efficacy.

Most clinicians consider SSRIs the first-line treatment choice for patients with generalized social phobia. Since patients with social phobia do not exhibit the supersensitivity syndrome described in panic disorder, SSRI administration can be initiated at usual antidepressant starting dosages (e.g., fluoxetine, 20 mg; paroxetine, 20 mg) and titrated on the basis of clinical response. The benzodiazepines alprazolam and clonazepam also seem efficacious in both generalized and specific social phobias. Their favorable adverse-effect profile and quick onset of action are countered by lower response rates and earlier relapse upon discontinuation than with phenelzine. As in panic disorder, tolerance does not develop to the therapeutic effects of benzodiazepines. Starting and therapeutic dosages for benzodiazepines are the same as those for panic disorder (Table 15.7-1).

Specific social phobias such as fear of public speaking respond moderately well to b-adrenergic receptor antagonists, although the data are mostly anecdotal. Propranolol (20 to 60 mg per dose) counters several of the physiological symptoms of excessive autonomic arousal. Propranolol's short half-life makes it necessary to repeat the effective dose every 2 to 4 hours. If propranolol works but the social phobic situations are unpredictable during the day, a b-adrenergic receptor antagonists with a longer half-life can be tried. Atenolol (Tenormin), 50 to 100 mg before sleep, should control the symptoms for 24 hours. The adverse effects of b-blockers may include sedation, fatigue, dry mouth, gastric cramping, and occasionally confusion and memory problems. Long-term use can lead to depression. Because of the adverse effects and unpredictability of response, the patient is strongly encouraged to test these drugs before the actual event or performance. The utility of b-adrenergic receptor antagonists in generalized social phobia is much more limited. Preliminary evidence supports the use of buspirone as well. Modest response has been noted in patients with social phobia at dosage above 45 mg a day.

Hyperhidrosis (excessive sweating) may be controlled by topical application of aluminum chloride in alcohol (Drysol) while a generalized form of the symptom usually responds to clonidine or terazosin (Hytrin). Ondansetron (Zofran) is the preferred medication for patients with social phobia if the most disabling symptom is nausea or the fear of vomiting. Nausea may also respond to cisapride (Propulsid), but caution should be exercised when prescribed concomitantly with drugs that inhibit cytochrome P450 (CYP) A4 (CYP 3A4). Paruresis a frequent symptom of social phobia, manifesting as the inability to void in public restrooms, usually requires in vivo exposure and relaxation training. Pharmacological approaches have been largely disappointing but a trial of furosemide and bethanechol may be warranted during behavioral treatment.

The RIMA brofaromine (150 mg a day) was found efficacious in a controlled trial. The finding that most patients maintained their gains at a 9-month follow-up assessment suggests that brofaromine could play an important role in the management of social phobia if it becomes available in the United States.

SPECIFIC PHOBIAS

Specific phobias are quite common and only require treatment if they interfere significantly with the functioning. Treatment is usually behavioral exposure. Medications are used occasionally to alleviate the anticipatory anxiety associated with beginning exposure treatment. Low-dose benzodiazepines and b-adrenergic receptor antagonists can be used for this purpose on an as-needed basis.

POSTTRAUMATIC STRESS DISORDER

Patients with posttraumatic stress disorder (PTSD) by definition have experienced a life-threatening trauma. These patients continue to relieve the experience and complain of flashbacks and vivid dreams of the original trauma. Blunted emotions coupled with a wide range of anxiety, mood, and sleep disorders are frequent manifestations of PTSD.

Prior to being assigned to a separate diagnostic entity, trauma survivors were treated according to the most prominent symptom clusters (e.g., anxiety or depression). Consequently, antidepressants and benzodiazepines were the mainstay of pharmacotherapy, with occasional use of antipsychotics for flashbacks and behavioral discontrol. Interpretation of medication trials in PTSD populations is complicated by a number of factors. First, most early medication trials were conducted in war veterans with chronic PTSD and a number of comorbid conditions such as substance use and severe personality disorders. They tended to have undergone several unsuccessful treatment trials and were considered refractory to psychiatric interventions. It has been suggested recently that the results of these earlier trials may not be applicable to well-diagnosed, previously untreated civilian populations. Civilian trauma survivors seem more responsive to pharmacotherapy than veterans. Second, some studies excluded PTSD patients with comorbid depression. Since this strategy eliminated over 50 percent of the otherwise eligible patients, the clinical relevance of these studies may be quite limited. Third, there is no consensus on how to rate improvement in PTSD. Some studies focus on intrusive thoughts; others on avoidance and hyperarousal. The field is in the process of teasing out medication-responsive symptom clusters and perhaps identifying subgroups of PTSD patients. As biological abnormalities are increasingly recognized in the pathophysiology of PTSD, recent pharmacological trials have begun to target neurotransmitter systems thought to be relevant in PTSD.

Currently, the medication treatment of PTSD is mostly based on clinical experience, case studies, open trials, and retrospective chart reviews; comparatively few controlled trials exist. Almost all antidepressants and antianxiety medications have been tried. It is rather unusual to have an agent show no therapeutic benefit in PTSD, but no medication has covered the full spectrum of PTSD symptomatology. Substantial heterogeneity with regard to type and severity of trauma, developmental phase of the patient at the time of the trauma, comorbid conditions, and psychiatric history may explain relative treatment resistance.

Intrusive thoughts, insomnia, recurring dreams and memories may respond to phenelzine at antidepressant dosages (45 to 90 mg a day). Brofaromine, while not yet available in the United States, may be a good alternative to the MAOIs in PTSD; over half of PTSD patients responded to brofaromine in a double-blind trial. Tricyclic drugs such as amytriptyline (Elavil) or imipramine may improve depressive and anxiety symptoms but have modest effect on intrusive thought. Global improvement is evident even in the absence of prominent depression, but it may not be observable before 8 weeks of treatment. Benzodiazepines, such as alprazolam, have only modest effect on anxiety, and the risk of dependence and abuse potential contraindicate their use in PTSD patients with substance use disorders. Numbing and hyperarousal in civilians but not in veterans, and impulse control, labile affect, and disturbed interpersonal relationships in both populations may respond to fluoxetine in dosages of 60 mg a day and above. Antipanic, low starting dosages of fluoxetine usually circumvent the initial agitation in patients with prominent anxiety; paroxetine may be less activating than fluoxetine in these patients. Fluvoxamine and sertraline reduce hyperarousal, intrusion, and explosiveness. Since SSRIs may be the only medications targeting the full symptom spectrum of PTSD, they are usually considered the first-line pharmacological treatment.

While not considered first-line approaches, clonidine (Catapres) buspirone, and high-dosage propranolol may be used alone or as adjuncts to an SSRI or a tricyclic drug for hyperarousal, nightmares, and flashbacks. Refractory impulsivity and aggressive outbursts in combat veterans may be treated with lithium, carbamazepine, or valproate, alone or in combination with an SSRI. Mood stabilizers have not been tested in civilian PTSD populations.

In the absence of data about optimal duration of pharmacotherapy and relapse upon discontinuation, the recommendations should follow those given for other chronic anxiety and affective disorders. Medication treatment should continue for at least 1 year. Given the considerable uncertainty surrounding the illness, flexibility in tailoring medication combinations according to individual patients is recommended, and psychotherapy should always be part of the management of PTSD.

SUGGESTED CROSS-REFERENCES

Generic discussion of medications used in anxiety disorders can be found in Chapter 31. Side effects, interactions, pharmacodynamics, and pharmacokinetics are described in Section 31.1. The neurobiology of anxiety disorders and the hypothesized basis of the efficacy of antianxiety medications is given in Section 15.3. The serotonin syndrome, encountered when several serotonergic agents are combined, is described in Section 31.25. Detailed diagnostic description of various anxiety disorders is given in Section 15.6. The epidemiology of anxiety disorders is discussed in Section 15.2.

15.8 ANXIETY DISORDERS: PSYCHOLOGICAL TREATMENTS

LAWRENCE A. WELKOWITZ, PH.D.

Since the late 1980s there has been tremendous progress in the nonpharmacological treatment of anxiety disorders. Cognitive-behavioral therapies, which reflect a recent integration of the cognitive theories and methods associated with Aaron Beck, Albert Ellis, and David Clark, and the behavioral theories and methods of B.F. Skinner and Ivan Pavlov, currently have the greatest degree of empirical validation. Panic disorder, which has been said to be the most disabling of the anxiety disorders in terms of social and occupational functioning is a case in point in that recently developed treatments contain elements based on classical or Pavlovian conditioning, behavioral techniques of exposure, and cognitive restructuring of irrational beliefs and overvalued ideas. Other anxiety disorders for which cognitive-behavioral approaches have been particularly effective include social phobia (both generalized and nongeneralized type), obsessive-compulsive disorder, specific phobia, social phobia, and generalized anxiety disorder. Further validation is needed for two recently developed treatments for posttraumatic stress disorder, one based on exposure methods, and the other based on classical conditioning *(eye movement desensitization* and *reprocessing* [EMD/R]). Psychosocial (e.g., supportive and psychodynamic) therapies have also been used in the treatment of anxiety disorders.

COGNITIVE-BEHAVIORAL THERAPY

Panic Disorder Cognitive-behavioral treatment of panic disorder or *panic control therapy* produces 80 to 90 percent panic-free status, at least within 6 months of treatment. Two-year follow-up indicates that more than 50 percent of those patients who originally responded to panic control therapy have occasional panic attacks, and more than a quarter will seek additional treatment. Nonetheless, these treatment responders do tend to have a significant decline in panic-related symptoms and most maintain many of their treatment gains. A large multi-center study comparing medication and panic control therapy treatment being carried out at the University of Pittsburgh, Yale University, State University of New York at Albany, and Columbia University should help to resolve many questions about long-term gains in panic control therapy and pharmacological treatment.

Panic control therapy is an amalgam of techniques drawn from a variety of cognitive and behavioral methods and based largely on Peter Lang's three-system model of cognitive psychophysiology, which focuses on the interactions of three systems affecting the human experience of panic and anxiety: physiological (e.g., palpitation, sweating, dizziness, nausea), cognitive (fears of losing control or going crazy), and behavioral (avoidance, pacing). Panic control therapy techniques are thus directed towards each of these systems: breathing control techniques are designed to control the physiological effects of hyperventilation and progressive muscle relaxation helps reduce the overall negative effects of muscle tension on anxiety. Cognitive restructuring techniques, which focus on catastrophic thinking errors (e.g., “I will have a heart attack and die”) as well as on misinterpretation of harmless bodily associations, are directed towards problems in the cognitive system. Education about the nature of anxiety and panic, which also counters the myths of panic attacks, (i.e., that they are associated with schizophrenia or heart disease) also serves as a form of stress inoculation in the cognitive domain. Exposure to feared situations and events, such as crowded public areas, helps to reduce avoidance symptoms of the behavioral domain. A novel technique called *interoceptive exposure* involves repeated exposure to the physical sensations associated with panic. This method, which is based on a classical or Pavlovian conditioning model of panic, consists of a series of activities, such as deliberately overbreathing (to produce physical effects of hyperventilation), breathing through a straw while holding one's nose (feelings of breathlessness), spinning in a chair (dizziness), running in place (increased heart rate), staring at one's hand (feelings of unreality), and so on. These activities are rehearsed until an habituation of the anxiety response has been achieved.

In clinical practice the degree to which various techniques are emphasized may depend on particular features of the panic disorder. For example, a patient with a high degree of agoraphobic avoidance may require additional exposure to fearful situations. The house-bound person with agoraphobia may require therapist-assisted in vivo exposure therapy as opposed to less labor intensive and more instruction-oriented exposure therapy for the patient with minimal agoraphobia and panic disorder. These panic control therapy techniques may also be carried out successfully by therapists whose primary mode of treatment is pharmacological. Finally, further research is needed to identify effective components of treatment and to determine whether certain subtypes of patients may require certain components of panic control therapy over others. In clinical practice, for example, it appears that a substantial number of patients with panic disorder respond well to education and breathing control alone whereas others seem to require more extensive treatment.

> José was a 27-year-old laboratory technician who began having full-blown panic attacks 8 months prior to seeking help at our research clinic. While he was unable to identify specific situations that elicited attacks, he was particularly concerned about the possibility of them occurring while he was engaged in laboratory procedures with patients. His attacks typically involved a sudden explosion of autonomic arousal and included palpitations, sweating, dizziness, feelings of unreality, and tingling in his arms and legs. He dreaded the idea that the attacks might reoccur. In the beginning of his cognitive-behavioral program, he found an educational handout that described the myths of panic attacks (e.g., that they will lead to heart attacks, losing control, or going crazy) particularly reassuring. He began practicing diaphragmatic breathing each evening, and after several weeks, became effective in challenging his negative way of thinking about the consequences of panic attacks. In the latter few weeks of his 12-week program, he practiced exposing himself to physical sensations of panic by doing a variety of interoceptive exercises at home, including hyperventilating for 1 or 2 minutes at a time (designed to help José acclimate to the physical sensations associated with overbreathing), and spinning in a chair repeatedly (designed to help acclimate him to symptoms of dizziness and feelings of unreality). At the conclusion of the treatment program José's panic attacks had disappeared, and at 6-month follow-up he had maintained his treatment gains by attending “booster sessions” with his therapist once every 2 months.

In contrast to cognitive-behavioral formulations, it has been reported that patients who develop panic symptoms in their late 20s have histories replete with relationship problems as well as other neurotic symptoms stemming from parent-child disruptions. These patterns, in turn, are said to lead to disturbances in empathy and understanding, which may ultimately elicit panic symptoms. Recently, detailed treatment protocols have been developed that are based on psychodynamic formulations of anxiety, consisting primarily of supportive-expressive psychodynamic psychotherapy. Preliminary outcome research indicates that these psychodynamically oriented protocols are useful in modifying anxiety, depression, and related interpersonal problems. Studies on hypnotherapy and hypnoanalysis, in which early childhood conflicts are identified and ultimately tied to the origins of panic and anxiety, provide some support for a more traditional analytic approach.

The importance of cultural issues in the treatment of anxiety disorders should not be overlooked. African-Americans with panic disorder appear to respond less with panic control therapy compared with whites. This may be related to the high prevalance of untreated hypertension among African-Americans, which may, in turn, exacerbate anxiety symptoms or possibly lead to higher comorbidity of emotional problems. Conversely, it has been observed that Asian Americans and Native-Americans, whose philosophical systems emphasize the control of mind over body and who have also utilized breathing control methods for centuries, are particularly receptive to the breathing and cognitive control aspects of panic control therapy. Interestingly, data from the Epidemiologic Catchment Area (ECA) study did not detect any differences in prevalence of panic disorder between African-American, Hispanic, and white groups.

Social Phobia As with panic disorder, considerable progress in the psychological treatment of social anxiety or social phobia is linked to the application of cognitive-behavioral methods. Unlike more traditional psychotherapies, cognitive-behavioral approaches do not address the origins of social anxiety, but instead focus on the use of coping strategies that can be implemented in current fearful situations. The most thoroughly studied form of cognitive-behavioral therapy for social phobia is a group therapy consisting of several discrete entities including (1) presentation of a three-system (cognitive-behavioral-physiological) model of social anxiety; (2) training in identification and restructuring of irrational beliefs regarding social performance; (3) in-session exposure to feared social situations via group role-playing scenarios; and (4) homework assignments directing patients to utilize cognitive and exposure techniques in vivo). Groups are particularly amenable to the treatment of social phobia in that they provide natural opportunities for patients to practice feared behaviors in a supportive and informative context.

Outcome research is somewhat limited but one study showed that cognitive-behavioral group therapy was nearly twice as effective as standard educational-supportive group psychotherapy. Responders to cognitive-behavioral group therapy were also shown to maintain treatment gains to a considerable extent

at 5-year follow-up. Questions remain as to the effective treatment component in these therapies that blend cognitive and exposure-based methods. For example, it is unclear whether exposure to feared situations alone, without cognitive therapy, would be just as effective as the combined treatment. Also, it is not known whether group therapies other than educational or supportive group therapy, such as interpersonal group therapy, may be effective in treating social phobia.

In terms of the differential effects of cognitive-behavioral group therapy on patients of varying subtypes (generalized versus nongeneralized social phobia), it appears that patients with more discrete or nongeneralized fears, such as of public speaking, respond best to these type of treatments. Pharmacological research has also shown differential effects based on subtype, with beta-blockers being more effective for nongeneralized fears, and antidepressant agents such as the monoamine oxidase inhibitor (MAOI) phenelzine (Nardil), being more effective for generalized social phobia. For generalized as well as more severe forms of social phobia, a combination of psychological and pharmacological therapy may be in order. Alternatively, it may be that longer-term cognitive-behavioral therapy, with or without medication, is warranted.

Despite the lack of empirical validation via controlled studies on large samples, social phobia is commonly treated with other behavioral methods. Systematic desensitization, first described in 1958, is based on a classical conditioning model of fears. It involves a pairing of previously conditioned stimuli (e.g., hierarchical presentation of images of feared social situations) with a relaxed state (promoted by means of progressive muscle relaxation). This new pairing is said to create a new set of associations that lead the patient to no longer fear previously feared stimuli. Regardless of the specific behavioral technique utilized, the key mechanism of effective treatment is related to the development of self-efficacy, or a sense of confidence that a patient experiences when confronting challenging social events or situations.

Jane was a 31-year-old marketing executive at a rapidly expanding technology company. She contacted our research clinic for help with her fear of public speaking, which had become so severe in recent months that she was at risk for losing her job, which required a considerable amount of public presentation and leading training programs. Jane was assigned to a treatment program that entailed a combination of medication (b-adrenergic receptor antagonist the beta-blocker atenolol [Tenormin]) and a 12-week group-based cognitive-behavioral treatment program for nongeneralized social phobias, such as fear of public speaking. Before beginning the group program, Jane met with her behavior therapist who helped her develop a hierarchy of the public-speaking situations she feared. Difficulty levels ranged from speaking up at meetings involving five or fewer colleagues, which caused a low level of anxiety, to leading a training program for 100 or more employees and colleagues at annual corporate gatherings, which caused a very high level of anxiety. In her group treatment, Jane began by identifying and challenging negative thoughts associated with each situation (e.g., “They won't understand what I am saying” became “I have always explained myself clearly in the past”). The other group members then assisted Jane in designing and carrying out role-plays that allowed her to practice employing her new coping responses and helped her to develop new public speaking skills. By the end of treatment, Jane still experienced occasional anxiety when making a public presentation to large numbers people, but she no longer avoided such situations.

Finally, it is important to consider cultural factors when treating social phobia. In Japan, a condition called *Taijin Kyofusho* refers to a type of social anxiety in which the sufferers become preoccupied with the idea that they are causing others to be embarrassed or humiliated. Other *Taijin* fears include fear of emitting a body odor and fear of one's facial expression becoming too stiff. In utilizing cognitive therapy with Japanese and other Asian patients, it is important to consider general cultural characteristics, such as the importance of displaying hierarchical deference (i.e., respect for those in authority) as well as an emphasis on communal versus individual expression. The emphasis on rigid moral codes and religious ritual and custom in Arab culture is said to place individuals at higher risk of social phobia, reflecting an underlying fear of betraying valued ideas and formalities. It has been reported that 13 percent of all outpatient psychiatric visits (excluding for schizophrenia) in Saudi Arabia are for treatment of social phobia.

Posttraumatic Stress Disorder Treatment of posttraumatic stress disorder is based largely on the aversive effects of a traumatic event or series of traumatic events. Specifically, fears related to this disorder are developed via classical or Pavlovian conditioning in which the unconditioned stimulus (e.g., a horrible accident or sexual assault) that automatically produces a fear response or unconditioned response is paired with other stimuli (e.g., the sounds, smells, and sights associated with the traumatic event). These conditioned stimuli then come to elicit a fear response independent of the original unconditioned stimuli. According to O. Hobart Mowrer's two-factor theory these new classically conditioned fears are subsequently maintained via operant conditioning in that escape or avoidance behaviors are reinforced by their anxiety-relieving effects. Through a process of *higher-order conditioning*, increasing numbers and types of stimuli may become elicitors of an anxiety or a posttraumatic stress disorder response. For example, if particular smells present during the original trauma are later present in more innocuous situations, such as when walking down the street or visiting a friend or relative, the patient may eventually evidence a fear response.

It has been argued that Mowrer's two-factor theory only partially explains the cognitive, affective, and physiological response unique to posttraumatic stress disorder. Symptoms such as trauma-related nightmares and psychological numbing are believed to be best understood by cognitive network theories, which posit the development of a “fear network” of memories. These cognitive networks, which include cognitive, behavioral, and physiological information about trauma responses, are formed following a traumatic event and are activated by trauma-related stimuli. According to this model, posttraumatic stress disorder responses can change across time as the *interpretation* of original trauma events produces changes in its meaning. Thus, a delayed response in this disorder can be explained by a subsequent change in the personal meaning of the original trauma, such as when an originally asymptomatic woman who has been sexually assaulted later discovers that her assailant has been released from prison and has been stalking previous victims.

Regardless of the emphasis on cognitive or conditioning processes, empirically validated treatments of posttraumatic stress disorder employ similar components, including (1) cognitive monitoring and restructuring, (2) exposure in imagination to the original traumatic event, and (3) exposure in vivo to trauma-related stimuli. The overall goal is to reduce or eliminate the patient's anxiety reaction to trauma-related cognitive and environmental stimuli. Cognitive restructuring is based on the notion that fear networks or structures can be directly modified by identifying and modifying negative or nonproductive thinking patterns related to concerns about threat or danger. Cognitive therapy may proceed in traditional fashion, based largely on therapist-patient dialogue, or may utilize homework-based written exercises in which the patient records irrational beliefs and composes more adaptive, coping-oriented responses that are based on new interpretation of the meaning of these trauma-related events. At least one study has found this cognitive processing therapy to be more effective than a no-treatment control group in reducing the symptoms of posttraumatic stress disorder.

In vivo and imaginal exposure techniques, which involve graduated exposure either to real life or cognitive trauma-related stimuli, are clearly useful in reducing overall anxiety as well as trauma-related fears. Both imaginal and in vivo techniques may involve return to the original place where the traumatic event occurred, or may be limited to situations that produce anxiety in the present (e.g., approaching certain people or places that evoke trauma-related memories). These methods have been shown to be effective for combat veterans suffering from the disorder and for women who have been sexually assaulted. More recently, a 4-week program has been developed to prevent the symptoms of this disorder for women who have been recently raped or assaulted. This program consists of (1) education about common reactions to trauma, (2) relaxation skills, (3) exposure in imagination to the original trauma, and (4) cognitive restructuring. A preliminary study comparing 10 women participants and 10 nonparticipants showed that 70 percent of the untreated women and only 10 percent of the treated women suffered symptoms of posttraumatic stress disorder at 2 months following the original trauma.

Jennifer was a 21-year-old college student who sought treatment in the anxiety clinic after being raped repeatedly at a fraternity party. She had difficulty immediately remembering details of the rape because she had ingested an unknown recreational drug that had been slipped into the punch bowl at the party. In the days following the rape, she slowly began to remember details of the traumatic event, often in the form of flashbacks and nightmares. She also experienced increased generalized anxiety, feelings of unreality, and an intense fear reaction to stimuli associated with the attacks, such as the sight of college men wearing sweat shirts with fraternity names and logos, as well as certain odors present during the party. Her treatment program was administered one-on-one by a psychologist who specialized in posttraumatic stress disorder. In the first few sessions, Jennifer was educated about the disorder and the nature of anxiety and was provided a rationale for an exposure-based treatment program. Ensuing sessions involved extensive discussion about the details of the traumatic event, as well as in-session exposures in-imagination to the original trauma. Exposure-based homework assignments complemented these in-session activities and were designed to treat Jennifer's new tendency to avoid trauma-related situations, including campus parties and other social gatherings. Slowly, Jennifer experienced decreased reactivity to trauma-related stimuli and began to enter situations she had previously avoided. After approximately twenty-five sessions Jennifer's symptoms were almost gone and she had nearly returned to normal in terms of participating in campus-related social events and parties. Despite her gains, Jennifer remains, in her words, “more careful” about certain high-risk social events (e.g., she will rarely enter a fraternity house), and finds that her trust in men is markedly diminished. A previous supporter of fraternities on campus, Jennifer is now an ardent advocate of removing fraternities from all colleges.

Unfortunately, little has been written about cross-cultural aspects of treatment of posttraumatic stress disorder. This is surprising in light of its particular relevance for minority groups in the United States, such as African-Americans from socially disadvantaged groups who witness a great deal of violence in their communities. For example, anxious black children, compared with their non-anxious peers, were found to experience a significantly greater degree of trauma. Observers of

Caribbean-American immigrants have noted an association between acculturation and symptomatology of posttraumatic stress disorder. These researchers support the use of group supportive treatments of the disorder for this ethnic group, but warn against the practice of mixing patients with those whose disorder is of differing causes (e.g., sexual assault versus acculturation).

Generalized Anxiety Disorder Recent data from the National Anxiety Disorders Screening Day (NADSD) revealed a surprisingly high 1-month prevalence (11.5 percent) of generalized anxiety disorder for those participants in an anxiety screening program who met criteria for one anxiety disorder only as compared with 5.4 percent for panic disorder, 3 percent for posttraumatic stress disorder, 3.4 percent for social phobia, and 0.7 percent for obsessive-compulsive disorder. Generalized anxiety disorder is particularly prevalent among those with multiple anxiety problems; For example, in the NADSD sample 10.2 percent met the criteria for panic disorder and generalized anxiety disorder, and 7.9 percent met criteria for panic, social phobia, and generalized anxiety disorder. The latter may therefore be considered a hidden problem in that other comorbid anxiety problems may supercede it in terms of focus of treatment.

Cognitive-behavioral formulations and treatment programs dominate this area, despite the lack of data on etiology or psychotherapy outcome. Debate continues as to whether generalized anxiety disorder should be considered a discrete anxiety disorder at all, with some arguing that high comorbidity with other anxiety and depressive disorders suggests that it is merely a basic anxiety trait that serves as a platform for the development of other related problems. Citing the inability of the Center for Epidemiologic Studies Depression Scale (CES-D) to distinguish between depression and generalized anxiety disorder, at least in a sample of mothers of handicapped children, symptoms were noted as being, in some circumstances, a natural component of more severe depression. Data from the ECA study revealed that generalized anxiety disorder was more common among people of lower socioeconomic status as well as in African-Americans, thus suggesting a sociocultural factor in etiology.

Psychological theories and treatment programs alike have tended to focus on the issue of chronic and excessive worrying among individuals who have generalized anxiety disorder. Unlike those suffering panic attacks who experience catastrophic-type cognition (e.g., “I'm going to have a heart attack and die”), those with generalized anxiety disorder exhibit less emotionally charged cognitions on an ongoing basis (e.g., “I'll never make it through the day,” or “I'm sure something will go wrong”). Excessive worriers actually experience less physiological arousal (e.g., decreased heart rate) in response to a fearful stimuli as compared with nonworriers, and it has been speculated that generalized anxiety disorder may actually serve as a type of defense against response to more fearful events.

Treatment programs to date contain one or both of the following components: (1) *cognitive restructuring* designed to identify worry-related thoughts and replace them with more positive coping responses and (2) *relaxation training* designed to reduce excessive physiological arousal. While controlled studies have shown that these methods are superior to either nondirective therapies or no-treatment controls, identification of the most effective treatment components remains unclear as does the superiority of these methods to other types of treatments, such as interpersonal-oriented therapies or other more alternative treatments, such as biofeedback or meditation.

A large-scale study comparing cognitive restructuring, relaxation training, a combined cognitive plus relaxation program, and a no-treatment group revealed improvements in all three active treatments relative to the control condition. While responders were remarkably successful in maintaining gains at 2-year follow-up, no differences were found among the three active treatments. Additionally, study dropouts and nonresponders remained symptomatic at follow-up. In similar fashion, a study comparing relaxation training, a combined cognitive therapy with relaxation training, and a nondirective psychotherapy demonstrated the superiority of the cognitive-behavioral programs compared to a treatment consisting of Rogerian-style reflecting about worrisome thoughts. A longer-term follow-up indicated the slight superiority of the combined cognitive-behavioral treatment over the relaxation-alone condition.

Melinda's friends and family refer to her as a “worrywart.” She constantly worries about something, whether it be that the chicken she is cooking may have salmonella, that her children may not be safe while driving to school, or that her family will not have enough money to pay for expenses. As Melinda put it during her initial evaluation, “I never seem to stop worrying.” In addition to her chronic worrying, Melinda experiences ongoing physical discomfort, including headaches, nausea, sweating, and occasional shortness of breath. She does not, however, experience full-blown panic attacks. Her treatment consisted of a combination of relaxation (specifically, progressive muscle relaxation practiced on a twice-daily basis) and cognitive therapy (identifying and challenging worry-related thoughts and replacing them with more productive coping responses). For example, she applied a type of “probability analysis” to her constant fear that her children would be harmed in a car accident and produced a coping response along the lines of “It is unlikely that they will be in an accident” as well as “My son is an excellent driver.” Following completion of treatment, Melinda reported that her family saw a tremendous improvement in terms of her chronic worrying. While worry-type thoughts would still occasionally enter her consciousness, she now felt that she had effective tools for dealing with them.

PSYCHOSOCIAL THERAPY

Supportive and psychodynamic therapies have been widely used in the treatment of generalized anxiety disorder, panic disorder, and posttraumatic stress disorder, although further research is needed to establish their efficacy.

According to the 1998 American Psychiatric Association's Practical Guidelines for the Treatment of Patients with Panic Disorder, psychosocial therapies may be of use. They have some application to the other anxiety disorders discussed in this section. A summary of the relevant areas of the report follows.

Psychodynamic Psychotherapy Psychodynamic psychotherapy is based on the concept that symptoms result from mental processes that may be outside of the patient's conscious awareness and that elucidating these processes can lead to remission of symptoms. Moreover, in order to lessen the patient's vulnerability to panic, the psychodynamic therapist considers it necessary to identify and alter core conflicts. The goals of psychodynamic psychotherapy may be more ambitious and require more time to achieve than those of a more symptom-focused treatment approach. There are some case reports of brief dynamic psychotherapies that took no longer than cognitive-behavioral therapy to achieve reasonable treatment goals for patients with panic disorder.

In psychodynamic psychotherapy, the successful emotional and cognitive understanding of the various elements of psychic conflict (impulses, conscience, internal standards that are often excessively harsh, psychological defense patterns, and realistic concerns) and reintegration of these elements in a more realistic and adaptive way may result in symptom resolution and fewer relapses. To achieve this insight and acceptance, the therapist places the symptoms in the context of the patient's life history and current realities and extensively uses the therapeutic relationship to focus on unconscious symptom determinants.

Combined Treatments Investigators have examined use of the combination of medication and cognitive behavior therapy for patients with panic disorder and agoraphobia. Several short-term treatment studies have shown that the combination of the tricylic medication imipramine (Imipramine) with one component of cognitive behavior therapy, behavioral exposure, may be superior to either treatment alone. Another study showed that selective serotonin reuptake inhibitors, such as paroxetine (Paxil), plus cognitive therapy worked significantly better for patients with panic disorder than cognitive therapy plus placebo. There has been one study of the combination of psychodynamic psychotherapy with medication. This study suggested that psychodynamic psychotherapy may improve the long-term outcome of medication-treated patients.

Group Therapy Reports on group therapy in the treatment of panic disorder have consisted primarily of cognitive behavioral approaches; the improvements with group cognitive behavior therapy were comparable to those in studies of individually administered cognitive behavior therapy and pharmacological treatment.

Patient Support Groups Patient support groups are very helpful for some patients suffering from panic disorder. Patients have the opportunity to learn that they are not unique in experiencing panic attacks and to share ways of coping with the illness. Support groups may also have a positive effect in encouraging patients to confront phobic situations. Finally, family members of patients with panic disorder may benefit from the educational aspects of patient support groups. In deciding to refer a patient to a support group, however, it is imperative that the psychiatrist obtain information about the nature of the group and the credentials of its leader. Support groups are not a substitute for effective treatment but are complementary to it.

FUTURE DIRECTIONS

There has been significant progress in recent years in the psychological treatment of anxiety disorders. Most of this progress can be linked to research on cognitive behavioral therapies, which are symptom-directed and relatively short-term. A common feature of all these treatments is active exposure to distressing stimuli, either in vivo or in imagination. These exposures vary depending on the type of anxiety disorder (e.g., the patient with social phobia is exposed to distressing social stimuli, such as parties or public-speaking events). Psychological treatments also include various forms of cognitive therapy that target irrational ideas emblematic of a particular disorder (e.g., the catastrophic fears of a patient with panic disorder). In all cases the goal is to assist the patient to endure discomfort by regularly practicing

stress-reducing techniques.

SUGGESTED CROSS-REFERENCES

The other sections of Chapter 15 describe the various aspects and areas of study of anxiety disorders. Cognitive therapy is presented in Section 30.6 and behavioral therapy is covered in Section 30.2.

CHAPTER 16. SOMATOFORM DISORDERS

FREDERICK G. GUGGENHEIM, M.D.

Disorders of the mind are often linked to physical symptoms and signs of psychiatric disorders: for example, the trembling, palpitations, and hyperpnea of panic disorder and the constipation, dry mouth, furrowed brow (omega sign), and weight loss of depressive disorders. The connection between somatic symptoms and depression or panic disorder, for example, is almost always readily accepted by patient and primary care physician; the task is to chart a course of action to treat symptoms with medication and psychological intervention. However, the primary care physician often misses the diagnosis of somatoform disorders for weeks to years. When finally informed of the diagnosis by the primary care physician, the patient is typically not prone to accept it. The patient is convinced of the physical origin of the undiagnosed distress and is equally convinced that the psyche plays no part in the disease process. Thus, when a patient has a somatoform disorder, a disconnect is initially established between patient and physician in the diagnostic process.

As the term *somatoform* implies, this heterogeneous group of disorders are at the mind-body interface: bodily symptoms as psychiatric disorder. Somatoform disorders thus exemplify mind-brain interactions: the brain, in ways still not well understood, sends various signals that impinge on the patient's awareness, indicating a serious problem in the body.

From a nosological perspective somatoform disorders were only grouped together for the first time in 1980 in the third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) as those disorders in which bodily sensations or functions, as the patient's predominant focus, are influenced by a disorder of the mind. This clustering was not based on theoretical construct or laboratory findings.

There are now five specific somatoform disorders: (1) somatization disorder, (2) conversion disorder, (3) pain disorder, (4) hypochondriasis, and (5) body dysmorphic disorder. There are also two residual categories that do not meet the fullblown criteria of the other five: (1) undifferentiated somatoform disorder and (2) somatoform disorder not otherwise specified.

In routine medical practice, classic cases of somatoform disorders are less common than less well differentiated syndromes.

Chronic fatigue syndrome is a recently prevalent disease without identified pathogen. The Centers for Disease Control (CDC) has recently set up criteria for this disorder. Several features of this syndrome seem to overlap with some of the somatoform disorders and might be considered in the differential diagnosis of somatization disorder. From a symptom perspective, chronic fatigue syndrome has much in common with certain other ill-defined maladies such as multiple chemical sensitivity syndrome, the syndrome of clinical hypoglycemia, the effort syndrome, and neurasthenia. There is no doubt that those afflicted with these disorders of unknown cause suffer. Those disorders do have some syndromic overlap with clearly defined psychiatric disorders such as the somatoform disorders.

CORE FEATURES

Characteristic of somatoform disorders are three enduring clinical features: (1) somatic complaints that suggest major medical maladies yet have no associated serious, demonstrable, peripheral organ disorder; (2) psychological factors and conflicts that seem important in initiating, exacerbating, and maintaining the disturbance; and (3) symptoms or magnified health concerns that are not under the patient's conscious control.

Because of their intense bodily perceptions, restricted level of physical functioning, and morbid beliefs, these patients have become convinced they harbor serious physical problems. Moreover, their symptoms are not willfully controlled. Whatever their faults and problems, these patients are not malingerers. Yet their physicians' physical and laboratory examinations persistently fail to evince significant substantiating data about physical infirmity other than the patients' vigorous and sincere complaints. Patients with somatoform disorders are convinced that their suffering comes from some type of presumably undetected and untreated bodily derangement.

DIAGNOSTIC ISSUES

When a somatoform disorder occurs without another comorbid psychiatric condition, the primary care physician and the patient usually do not initially consider a psychiatric condition. The patient's morbid preoccupation with bodily concerns, not emotional feelings or disordered interpersonal relationships, is paramount. Often this preoccupation is so severe that it interferes with the patient's capacity for living, loving, or working; it usually has sent the patient on a ceaseless odyssey from physician to physician looking for effective symptomatic relief.

Because of the patient's focus on bodily issues, the psychiatrist's questions (should such a referral ever occur) about stress and family matters might seem off the mark to the patient. However, research literature as well as the clinical experience of seasoned psychiatric consultants has demonstrated the utility of psychiatric input into managing somatoform patients from a psychosocial perspective with attention to physical health status, mental health status, global outcome, and cost.

The 10th edition of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10), which includes most of the somatoform disorders in the fourth edition of DSM (DSM-IV) (except for conversion disorders, which are included with the dissociative disorders), states that “the main feature of [the somatoform] disorders is the repeated presentation of physical symptoms together with persistent requests for medical investigations, in spite of repeated negative findings and reassurances by doctors that the symptoms have no physical basis. If any physical disorders are present, they do not explain the nature and the extent of the symptoms or the distress and preoccupation of the patient.” The ICD-10 criteria for somatoform disorders are presented in Table 16-1.

Table 16-1 ICD-10 Diagnostic Criteria for Somatoform Disorders

Primary Physician's Diagnostic Process Physicians have been trained to record faithfully the patient's medical history, to perform a physical examination, and to make use of laboratory tests. Often during the primary care physician's evaluation of the patient for tiredness, poor appetite, weakness, or tense nerves, an underlying psychiatric condition is spotted by the astute clinician who senses considerable emotional turmoil. The clinician then elicits specific findings on the mental status examination. In the routine practice of medicine, as long as the patient can render a concise chronicle of events and present a straightforward account of bodily perceptions underlying pathophysiological events, the primary care physician has a remarkably good chance of making an appropriate diagnosis and instituting corrective treatment. However, it becomes understandably difficult for the physician to develop an accurate diagnosis when the somatoform patient forgets (represses) or refuses (suppresses) to share with the physician certain medically relevant, critical events or when the somatoform patient continually attributes potentially fatal diseases to benign internal stimuli.

Moreover, when the patient's expectations of a clear-cut diagnosis of physical illness are not substantiated by the results of the physical examination and laboratory findings, the clinician may have questions about the somatoform patient's competency, motivation, or even integrity. Is this account of suffering actually deliberate distortion? Is it simple forgetfulness when the patient fails to tell the physician that there was a similar episode of such symptoms 10 years ago (with benign outcome)? To the probing clinician it might appear at first that somatoform patients are guilty of blatant, intentional manipulation, or at the least of considerable distortion. Most physicians are not primed to consider that the lack of concordance between subjective suffering and objective physical findings can stem from a set of distorted perceptions and attributions or unusual beliefs.

In an emergency room or office practice setting, the application of specific diagnostic criteria for the somatoform disorders can be helpful. Even patients with somatoform disorders do get ill and eventually die of something. In the past physicians have been far too ready to attribute atypical presentations of certain protean medical diseases (e.g., multiple sclerosis, lupus, or myasthenia gravis) to psychiatric causes—coupling such reductionistic thinking with the conclusion that a putative psychiatric disorder does not merit further investigation or even referral.

Since the 1970s clinical research has allowed the inclusion criteria for some of the somatoform disorders to be considerably simplified, which has helped to make some of these diagnoses easier to use. More concise criteria have further supported the maxim that it is inappropriate to make a psychiatric diagnosis just because another medical diagnosis cannot be determined (i.e., the process of psychiatric diagnosis by exclusion). Table 16-2 lists a few of the disorders commonly confused with somatoform disorders, especially early in their course.

Multiple sclerosis	Acute intermittent porphyria
Central nervous system syphilis	Lupus erythematosus
Brain tumor	Hyperthyroidism
Hyperparathyroidism	Myasthenia gravis

Table 16-2 Conditions Commonly Confused With Somatoform Disorder

BIOMEDICAL THEORIES

Of the few research findings on somatoform disorders that are relevant to underlying physiological or structural brain abnormalities, few have been widely disseminated. This makes the internist's task of telling patients that they have a psychiatric disorder even more complicated.

To comprehend the underlying basis of the somatoform disorders, the brain should be viewed both as a transducer of experience and as a practiced, highly trained organizer of perceptions from the *milieu interieur* and the *milieu exterieur.* The brain filters, amplifies, or dampens afferent and efferent stimuli from all parts of the body and from the brain itself. It then produces messages that explain the matrix of the patient's experiential world; that is, the brain edits and interprets its material (signals) and then sends out “sound bites” and an executive summary about bodily function in light of past incidents (including material seen on television or in the press). Somatoform disorders may involve a considerable variety of neuronal pathways—from brain-brain signals to pain pathways and perceptual pathways, in addition to efferent signals to motor apparatus and blood vessels.

CONVERSION DISORDER

Definition A conversion disorder is a disturbance of bodily functioning that does not conform to current concepts of the anatomy and physiology of the central or the peripheral nervous system. It typically occurs in a setting of stress and produces considerable dysfunction.

Many conversion disorders simulate acute neurological pathology (e.g., strokes and disturbances of speech, hearing, or vision). However, conversion disorders are not associated with the usual pathological neurodiagnostic signs or the underlying somatic pathology. Conversion symptoms (e.g., anesthesias and paresthesias produced by a conversion disorder) do not conform to usual dermatomal distribution of the underlying peripheral nerves; rather, the signs and symptoms of a conversion disorder typically conform to the patient's concept of the medical condition.

Conversion disorders seem to change or convert the psychic energy of the turmoil of acute conflict into a personally meaningful metaphor of bodily dysfunction. Turbulence of the mind is transformed into a somatic statement, condensing and focusing concepts, role models, and communicative meanings into one or several physical signs or symptoms of dysfunction. These somatic representations often simulate an acute medical calamity; initiate urgent, sometimes expensive medical investigation; and produce disability. In primitive settings, however, certain conversion symptoms have been taken as tokens of religious faith and even as expressions of witchcraft.

Although most conversion reactions are transient (hours to days), some can persist. Chronic conversion disorders can actually produce permanent conversion complications, such as disuse contractures of a “paralyzed” limb that remains long after the psychic strife that prompted the conversion has been resolved. In many cases a chronic conversion disorder serves to help stabilize an otherwise dysfunctional family. In addition to sensorimotor symptoms, marked autonomic disturbances such as protracted (psychogenic) vomiting, hyperemesis gravidarum, urinary retention, and pseudocyesis are also seen, although less commonly. Conversion

disorders challenge the diagnostic competence of internists, neurologists, otolaryngologists, ophthalmologists, and psychiatrists.

Like the other somatoform disorders, conversion disorders are not volitional. Rather, ego defense mechanisms of repression and dissociation act outside of the patient's awareness. Many patients with conversion disorders experience *la belle indifference*, an emotional unconcern or even flatness in a setting of catastrophic illness; but some patients do experience considerable anguish over their new symptoms.

A conversion disorder can be considered when a patient manifests a loss or alteration in physical functioning suggesting a medical or neurological disorder and the condition cannot be explained by any other known medical disorder or pathophysiological process. A conversion disorder cannot be diagnosed just because a medical disorder cannot be ruled in. Failure to prove a physical illness is a necessary but not sufficient condition for making the diagnosis of conversion disorder.

HISTORY

Until the middle of the nineteenth century, somatization disorder and conversion disorder (which often travel together) were considered to be one condition called *hysteria.* The term *hysteria* was derived from the Greek word *hystera*, meaning uterus. Descriptions of conversion disorders appeared as far back as 1900 BC when multiple symptoms were attributed by Egyptian physicians to a wandering of the uterus within the body.

In the middle of the century, Pierre Briquet originated the modern concept of conversion disorder. He considered the disorder to result from a dysfunction of the central nervous system (CNS). He proposed that conversion symptoms occurred in those with a constitutional predisposition when a receptive part of the brain was impacted by extreme stress. Later, Russel Reynolds described clinical cases in which the loss of function or the persistence of severe pain could be attributed to an idea that the patient had about the body.

Jean-Martin Charcot then expanded on the biological concepts of Briquet and the psychological constructs of Reynolds, adding heredity to factors that influence predisposition. Moreover, Charcot suggested that a traumatic event gave rise to the idea, which then led to the brain's dynamic dysfunction; Charcot also suggested that the idea could be produced in the brain by hypnosis.

The term *conversion* was first used by Sigmund Freud and his associate Josef Breuer. It was used to describe the clinical case of Anna O., whose undischarged psychic energy was bound in a somatic symptom. This symptom represented the unconscious conflict. That is, a repressed thought was converted to a somatic symptom. Freud then worked out his concept of talking therapy as a catharsis through which unconsciously repressed material might become conscious. With catharsis in psychotherapy and with hypnotic suggestion, somatic conversion symptoms were shown to diminish and even disappear.

In 1929, following from Charcot, Pierre Janet observed that conversion disorders were preceded by a lowering of conscious threshold and were associated with dissociation. He recognized that a constitutional weakness in an individual might be accentuated by shock or fatigue, resulting in aspects of consciousness being split off. His concept of what is now considered to be conversion disorder did not, however, include the concept of repression; thus, he was not concerned with the significance of the dynamic unconscious as Freud was.

COMPARATIVE NOSOLOGY

In 1952 the American Psychiatric Association's first edition of DSM (DSM-I) used the diagnostic term “conversion reaction,” stressing (1) the reactive part of the disorder, (2) issues of symbolism—symbols or ciphers from the individual's unconscious that relate to significant life experiences, and (3) secondary gain—tangible benefits that accrue to the individual upon assumption of the sick role. In 1967 the second edition of DSM (DSM-II) changed the diagnostic term to “hysterical psychoneurosis, conversion type.” Important in this formulation was *la belle indifférence.* Follow-up studies of specific phenomena associated with conversion disorder were constructed by assigning relative weights to certain features associated with conversion studies. These studies indicated, however, that there is no pathognomonic validity (using outcome as a gold standard) to symbolism of the symptom, secondary gain, hysterical personality, and *la belle indifférence.*

In 1980 DSM-III revised the diagnostic term again to *conversion disorder.* Removed from the cluster of symptoms was pain disorder, a symptom-based pain disorder with criteria otherwise comparable to that of conversion disorder. DSM-III and the revised third edition of DSM (DSM-III-R) required conversion disorder to be judged by the clinician to be etiologically related to the conversion symptom because of a temporal relationship between it and a significant psychosocial stressor or else a demonstrated coupling of conflict and psychological need and the initiation or the exacerbation of a preexisting symptom. That is, it was one of the few diagnoses where the judgment of the clinician was explicitly sought in the making of a diagnosis based on psychodynamic mechanisms. A subjective rather than an objective component was written into the diagnostic criterion; this raised the issue of inter-rater reliability in the diagnostic process.

One of the major changes from DSM-III and DSM-III-R to DSM-IV has been the further removal of the etiological inference of unconscious mechanisms and psychodynamics involved in the productions of symptoms, with the statement that “psychological factors are judged to be associated with the symptom or deficit because it was preceded by conflicts or other stressors.” That is, since diagnosticians are not mind readers, the role of unconscious motivation must be inferred.

A second difference in DSM-IV from DSM-III-R is in the exclusion category associated with the concept of “not fully explained by a known physical disorder.” This was broadened to include culturally sanctioned behavior or experience, general medical condition, and the direct use of a substance.

A third change came in the distress-disability category, in which the concept has now been broadened to include important areas of functioning to the individual other than just social and occupational and the phrase “warrants further medical attention” has been added (e.g., distress to family or physician because of potential medical implications associated with the symptom or deficit).

A fourth change focused on the wording used to eliminate factitious disorder and malingering. The words “not conscious of intentionally producing the symptom” have been removed in favor of the simple concept “not intentionally produced or feigned.”

In 1978 the ninth revision of *International Statistical Classification of Diseases, Injuries, and Causes of Death* (ICD-9) used the term “hysteria” to include conversion disorder and dissociative phenomena. Both conditions were defined as mental disorders in which a mechanism beyond the patient's awareness produced either a restriction of the field of awareness or a disturbance of motor or sensory function. Hysteria was associated with psychological advantage or symbolic value. Conversion symptoms involved the body's function, whereas dissociative symptoms involved the mind's function.

When ICD-10 considered the somatoform disorders, it listed somatization disorder and its subthreshold companion diagnosis, undifferentiated somatoform disorder, plus hypochondriacal disorder, persistent somatoform pain disorder, autonomic (psychogenic aerophagia) and nonautonomic (psychogenic pruritus) somatoform disorders as part of the group of the somatoform disorders. However, ICD-10 assigned conversion disorder to the dissociative disorders. Presumably this ICD-10 change was made because conversion disorders, like dissociative disorders, typically have a sudden onset and a short duration whereas the other somatoform disorders have a gradual onset and a much more chronic course. Thus, the term *conversion hysteria*, coupled loosely and interchangeably over centuries now disappears whereas *dissociative (conversion) disorders* appear in ICD-10 with separate codings for dissociative disorders of movement and sensation, dissociative motor disorders, dissociative convulsions, and dissociative anesthesia and sensory loss.

EPIDEMIOLOGY

Conversion disorders are the most frequently occurring of the somatoform disorders. Affected persons can range in age from early childhood into old age. The annual incidence of conversion disorders seen by psychiatrists in a New York county has been estimated to be 22 cases per 100,000 population. In a general hospital setting 5 to 16 percent of all psychiatric consultation patients manifest some conversion symptoms. In a study of a rural Veterans Administration general hospital, 25 to 30 percent of all male patients had a conversion symptom at some time during their admission. By contrast, in a psychiatric emergency room or psychiatric clinic, the incidence of conversion disorder is far lower (1 percent of all psychiatric admissions), as different selection factors supervene. Lifetime figures for ever having any conversion symptom, even if only on a transient basis, are far higher, with some studies reporting a 33 percent prevalence rate. Conversion disorder occurs mainly in women, with a ratio of 2 to 1 up to 5 to 1 in some studies. However, there does not seem to be an overrepresentation of conversion disorders in female children.

The prevalence of the disorder is highest in rural areas and among the undereducated and the lower socioeconomic classes. It is more prevalent in military populations, especially in those exposed to combat. It is also more common in underprivileged persons, in those of subnormal intelligence, and in industrial settings

where compensation neurosis may become an issue. There may be a tendency for familial aggregation and for the patient to be the youngest sibling in the family. The incidence of the disorder may be on the decline.

Clinicians frequently involved with these patients in general hospital settings contend that conversion disorders are more likely to be seen in individuals who are psychologically naive, who are not particularly introspective, and who are disinclined to believe that psychic factors can affect physical processes than in individuals who are psychologically sophisticated.

Comorbidity Medical and especially neurological disorders occur frequently among patients with conversion disorders. Indeed in some series the majority of conversion patients have a well-documented neurological condition. What is typically seen in these comorbid neurological or medical conditions is an elaboration of symptoms stemming from the original organic lesion. Whether this tells the clinician something about the nature of the sick role or about the nature of the brain with compromised functioning and an altered state of consciousness remains an open question.

Preexisting or emerging psychopathology also seems to predispose an individual to the development of a conversion. Among the Axis I psychiatric conditions, depressive disorders, anxiety disorders, and somatization disorders are especially noted for their association with conversion disorder. Conversion in schizophrenia is reported but is very uncommon. Studies of patients admitted to a psychiatric hospital for conversion disorder reveal that, on further study, one quarter to one half have a clinically significant mood disorder or schizophrenia.

Axis II personality disorders also frequently accompany a conversion disorder, especially the histrionic type (in 5 to 21 percent of cases); the passive-dependent type (9 to 40 percent of cases), and the passive-aggressive type of personality disorder. However, conversion disorders can occur in persons with no predisposing medical, neurological, or psychiatric disorder.

ETIOLOGY

Biological Factors Conversion disorders represent pathology in the mind as well as dysfunction within the brain. Recent etiological research on conversion disorder has involved event-related potentials, structural and functional brain imaging, and neuropsychological testing to investigate aspects of corticofugal inhibition of afferent stimuli.

Imaging Pierre Flor-Henry's important work on the etiopathology of conversion disorder has used bipolar derivations of the electroencephalograph (EEG) with measures of coherence to reflect synchrony, not between individual electrode sites but between regions of the brain. His findings emphasize (1) hypofunction of the dominant hemisphere systems, (2) a consequent dysfunctional overactivity of the nondominant hemisphere, and (3) abnormal interhemispheric relations. Defects in processing endogenous somatic signals and integrating sensorimotor signals appear to be the consequence of altered dominant hemispheric systems. Particularly in women there seems to be a secondary disorganization of the contralateral hemisphere that in turn is capable of producing the characteristic somatic symptoms seen in a conversion reaction. An EEG study of a woman with a left-sided paralysis as a conversion disorder has proved most illuminating. The attempt to move the paralyzed leg failed to activate the right primary motor cortex. Instead, the right orbito-frontal and right anterior cingulate cortex were significantly activated, suggesting these two areas inhibit the prefrontal (willed) effects on the right primary motor cortex when the patient tries to move her left leg.

NEUROPSYCHOLOGICAL TESTS

Impaired vigilance-attention and short-term memory have been demonstrated. Localizing studies using the Halstead-Reitan Battery and other neuropsychological tests have manifested dysfunction of both nondominant right and especially dominant left hemispheres. Increased field dependency and heightened suggestibility is also present.

Unilateral Symptoms and Localization Taken together, clinical and research findings could suggest that patients with conversion disorder under extraordinary circumstances experience impaired intercortical communication and blockade of ordinary channels of verbal associations. The preponderance of left-sided, unilateral symptoms seen in conversion disorder plus the strong association of conversion disorders with depressive disorders could be used as evidence of a nondominant right-hemispheric vulnerability. Additional complementary evidence for localization comes from the fact that the left hemisphere is phylogenetically associated with inhibitory influences. Thus, the motor and sensory symptoms of conversion suggest defects in processing and in analysis of sensorimotor signals, which leads to a failure in the integration of endogenous somatic signals. The proposed defect in understanding the signals in a conversion disorder is in some ways analogous to the failure of comprehension in a stroke (i.e., with receptive and expressive aphasia when acoustic-motor coordination of auditory signals involving language fails to occur).

Sex and Brain Localization The fact that conversion disorders occur mainly in women is another piece of evidence used to support a theory of brain localization. Studies from a variety of sources indicate that women have greater instability of right-hemispheric organization. Thus, it has been proposed that a primary defect in the left hemisphere interferes with the normal transcallosal inhibitory stabilizing functions of the unstable contralateral right hemisphere. These circumstances could account for the symptoms of conversion disorder and for its almost exclusive restriction to the female pattern of cerebral organization.

Much more clinical and experimental work remains to be done if these heuristic hypotheses are to have widespread clinical relevance. The phenomena of conversion disorder and hypnosis have both been considered to result from blockade of corticofugal impulses induced by emotional rapport or intense emotional experience. Both conditions can lead to selective diminution of awareness of a bodily function. Interestingly, hypnosis can bring about temporary remission of conversion symptoms and can also produce a mimicry of conversion symptoms in those not afflicted with the condition.

These biomedical theories account for the *how*, but not the *what* or the *why* of conversion disorder. Obviously a multifactorial explanation is needed to render an understanding of the patient's plight and to serve as a framework for testing the most effective and efficient methods of treatment. Conversion symptoms represent a common pathway for the expression of a complex biopsychosocial event. A patient with conversion disorder, having a specific diathesis, experiences and creates (outside of his or her level of awareness) an illness in a setting of stress that is shaped to some extent on his or her model of disease.

PSYCHOSOCIAL FACTORS

Long before neuropsychological, neurophysiological, and imaging evidence was available to contribute to an understanding of symptoms of conversion, astute nineteenth-century clinicians focused their attention on the psychological aspects of their patients' internal and external worlds. Sigmund Freud and Josef Breuer carefully studied the ongoing emotional struggles and the relevant life circumstances immediately antecedent to conversion symptoms in patients with neuroses. In such a fashion the context of the acute psychic trauma and other aspects of the patient's life story often could be coupled meaningfully to the development and maintenance of the patient's conversion symptoms. Moreover, psychoanalytic and hypnotic techniques sometimes produced dramatic and sometimes permanent remission of the patient's symptoms.

Psychodynamic Factors According to psychoanalytic theory a conversion reaction results when the anxiety of unconscious intrapsychic conflict is converted into somatic symptoms. When aggressive or sexual impulses emerge in a field of strong inhibition of their expression, the resultant intrapsychic conflict overwhelms the person's ordinary ego defense mechanisms. In such a setting unconscious mechanisms facilitate a compromise as conversion symptoms emerge. The settlement allows a partial expression of the primitive impulse but disguises it so that the individual is unaware of the unconscious wish and the unacceptable desire. However, the symptom formation may impose a considerable price. Suffering and disability then serve as atonement for having had the unacceptable wish or impulse.

The decrease in anxiety and psychological distress after formation of the conversion symptom is the primary gain. Benefits that also accrue to the individual after the sick role is assumed are the secondary gain. Both primary and secondary gain are typically part of the syndrome associated with conversion disorder. Its permanence and severity can be reinforced by patients being enmeshed in irresolvable conflict for which they feel no responsibility.

In psychodynamic terms conversion symptoms represent a solution to an unconscious conflict between instinctual drives and superego prohibitions to their expression. The conversion symptom emerges when a latent conflict is activated by an event unconsciously perceived as related to the conflict. The specific meaning of the precipitating event resonates with the personal vulnerability of the patient and the patient's life experiences. Thus the formation of the conversion symptom embodies a symbolic aspect of the intrapsychic conflict. The conversion symptoms may derive from identification with a significant individual, often someone whom the patient associates with loss and who has also experienced such a symptom (a conversion model). Sometimes the conversion model is the patient's own somatic

ailment, with symptoms now called forth in an effort to resolve some intrapersonal or interpersonal crisis.

Sociocultural Theory Viewed alone or as complementary to psychoanalytic theory, conversion symptoms can be understood in sociocultural terms as a form of communication concerning an emotionally charged feeling or idea blocked from expression by personal or cultural restraints. Conversion symptoms can express the forbidden, using mimicry or pantomime instead of words. Moreover, the symptoms of a conversion disorder allow the individual to enter into the sick role, avoiding certain responsibilities or noxious situations. As such, the patient can control or otherwise manipulate the behavior of others. However, it is most likely that clinicians who view conversion disorder only as a nonspecific organic response to stress and merely as a manifestation of illness behavior have: (1) had difficulty obtaining clinical data from or about the patient; (2) have failed to engage the patient from a psychodynamic perspective; or (3) have not used an amobarbital (Amytal) or other drug-assisted interview.

Learning Theory In terms of conditioned learning theory a conversion symptom can be seen as a piece of classically conditioned learned behavior; symptoms of illness, learned in childhood, are called forth as a means of coping with an otherwise impossible situation.

DIAGNOSIS AND CLINICAL FEATURES

A frequent but not invariable common denominator of conversion disorder is the pseudoneurological nature of the symptom. Common types of conversion symptoms are listed in Table 16-3.

Motor Symptoms	Sensory Deficits
Involuntary movements	Anesthesia, especially of extremities
Tics	Midline anesthesia
Blepharospasm	Blindness
Torticollis	Tunnel vision
Opisthotonos	Deafness
Seizures	**Visceral Symptoms**
Abnormal gait	Psychogenic vomiting
Falling	Pseudocyesis
Astasia-abasia	*Globus hystericus*
Paralysis	Swooning or syncope
Weakness	Urinary retention
Aphonia	Diarrhea

Table 16-3 Common Symptoms of Conversion Disorder

Motor symptoms—Abnormal gait, weakness, and paralysis may occur. There can be involuntary movements, rhythmical tremors, episodic jerks, tics, seizures, and falling. Yet when patients with conversion symptoms fall, they rarely are severely hurt. Blepharospasm, torticollis, and opisthotonos may also occur. All such symptoms tend to grow more intense when observed. Many neurological symptoms of patients with a known pathophysiological basis, such as Parkinson's disease, also tend to intensify when the individual experiences increased anxiety. The DSM-IV criteria for conversion disorder are listed in Table 16-4.

A. One or more symptoms or deficits affecting voluntary motor or sensory function that suggest a neurological or other general medical condition.
B. Psychological factors are judged to be associated with the symptom or deficit because the initiation or exacerbation of the symptom or deficit is preceded by conflicts or other stressors.
C. The symptom or deficit is not intentionally produced or feigned (as in factitious disorder or malingering).
D. The symptoms or deficit cannot, after appropriate investigation, be fully explained by a general medical condition, or by the direct effects of a substance, or as a culturally sanctioned behavior or experience.
E. The symptom or deficit causes clinically significant distress or impairment in social, occupational, or other important areas of functioning or warrants medical evaluation.
F. The symptom or deficit is not limited to pain or sexual dysfunction, does not occur exclusively during the course of somatization disorder, and is not better accounted for by another mental disorder.
Specify type of symptom or deficit: **With motor symptom or deficit** **With sensory symptom or deficit** **With seizures or convulsions** **With mixed presentation**

Table 16-4 DSM-IV Diagnostic Criteria for Conversion Disorder

Astasia-Abasia A staggering, ataxic gait with gross jerks and thrashing or wild waving of the upper extremities, often with an inability to stand without support, is called *astasia-abasia.* Surprisingly, such patients sometimes can dance to music after the clinician suggests that the ability to successfully perform a dance such as the fox trot or the Texas two-step is not impacted by the patient's inability to stand or walk.

Pseudoseizures *Pseudoseizures* are paroxysmal episodes of altered behavior resembling epileptic attacks but devoid of the characteristic clinical epileptic and electrographic features. Convulsive behaviors identified as a conversion disorder often take place when the clinician walks into the patient's room or when the family visits. Variously termed *psychogenic* or *hysterical seizures* in the past, these clinical episodes terminate without the patient having a period of sluggishness, sleepiness, or confusion (as might be seen following a true convulsion). Pseudoseizures, but not complex partial seizures, tend not to manifest extreme stereotypy in the overt motor sequence and lack a neurological indicator. These patients do not evidence an elevated serum prolactin level immediately following the clinical episode, and the patient's interictal cortical EEG is normal or ambiguous. The EEG of the pseudoseizure patient during the clinical episode does not show any of the correlates of an epileptic seizure, such as increasing frequency of spike discharges, sudden onset of focal or diffuse rhythmic activity, or postictal slow waves.

Patients with pseudoseizures tend to have a history of psychiatric treatment, suicide attempts, and borderline personality disorder. However, the Minnesota Multiphasic Personality Inventory-2 (MMPI-2) in one study demonstrated an overall accuracy rate of 67 percent (correctly identifying 71 percent of the group with pseudoseizures and 65 percent of the patients with epileptic seizures) using the video-monitored EEG as the gold standard. Families of pseudoseizure patients had considerably more health problems, distress, and criticism than families of patients with epilepsy. There have now been a number of reports linking an increased incidence of childhood sexual abuse with the initiation, precipitation, or exacerbation of symptoms in patients with pseudoseizures. A diagnosis of pseudoseizures is also more likely if there is a financial incentive. Pseudoseizures can also be seen as a form of chronic maladaptive behavior utilizing the benefits of the sick role.

The induction of a seizure by suggestion, formerly considered a hallmark of hysterical seizures, is also seen in complex partial seizures when there is elevated electrical lability. Semi-purposeful movements, thrashing and pelvic thrusting, often considered to be the hallmarks of pseudoseizures, can be seen with direct stimulation of the cingulate region and are common correlates of complete partial seizures with frontotemporal foci. Moreover, more than 70 percent of patients with pseudoseizures without documented bona fide seizures show interictal EEG abnormalities, neuropsychological impairment, or abnormalities on magnetic resonance imaging (MRI) and computed tomography (CT) scans.

Although tongue-biting, urinary incontinence, injury during falls, and seeming loss of consciousness do not usually occur with a pseudoseizure, all of these can occur. However, the preservation of corneal, pupillary, and gag reflexes, plus the absence of extensor plantar responses and the preservation of normal color during the attack all suggest a pseudoseizure. The eyes of a patient in a pseudoseizure reportedly deviate toward the ground when the patient is placed on his or her side.

The proportion of pseudoseizures in a given study typically reflects the nature of the referral source and their relationship with the evaluation. From a clinician's perspective about one third of patients evaluated for a pseudoseizure do not have a convulsive disorder or pseudoseizures but rather have some other neurological condition, another third of patients have true convulsions as well as pseudoseizures, and another third have just pseudoseizures. From a treatment perspective it is imperative to know the correct diagnosis so as to avoid polypharmacy and toxicity, hazardous diagnostic interventions, and neglect of underlying psychological distress. Although patients with pseudoseizures typically are psychologically naive, their very lack of sophistication may make them more respectful of the power of

the physician's authority. They may be more suggestible and easier to manipulate, which may be effectively utilized in the service of their treatment.

Other Common Motor Symptoms Other symptoms include paralysis or paresis, more frequently on the patient's nondominant side (i.e., on the left side if the patient is right-handed). Paralyses can occur in one, several, or all limbs. In contrast to a patient with neuropathy, the reflexes in a patient with conversion disorder with anesthesia or paralysis remain normal. There is no fasciculation, no other electromyographic abnormality, and no atrophy. However, in cases of longstanding pseudoparalysis, disuse atrophy and even contractures can occur as a complication of conversion.

Sensory Symptoms Anesthesias, hypesthesias, and paresthesias are common conversion symptoms, especially in the extremities (Table 16-3). The pattern of distribution of the anesthesia does not conform to the underlying central or peripheral nerve distribution. Typical are glove or stocking and strict midline anesthesias. Despite a claimed loss of total sensation in the legs and feet, for example, conversion patients can walk in the dark without stumbling (unlike those with tabes dorsalis who lack position sense). Conversion patients told to answer “yes” if they can feel anything when pricked with a pin in the anesthetic zone often will respond “no” when pricked, even when they are not looking at the area being tested.

Hysterical Blindness Other sensory modalities can also be affected. Patients with hysterical blindness typically do not hurt themselves seriously when they bump into stationary objects. Despite their “lack” of vision, their pupils react to light and their visual evoked potentials on the EEG are consistent with those of normal vision. Some of the other findings in monocular and binocular blindness associated with conversion are shown in Table 16-3.

Hallucinations Patients with conversion disorder can have positive or negative hallucinations. Patients who have positive hallucinations perceive an image or hear a sound that is not there. Hallucinations in conversion disorder are usually associated with intact insight, and the hallucinations are often visual, auditory, and tactile. They tend to be described by the person as part of an interesting story. Conversely, with a negative hallucination the patient with an intact nervous system does not see an object that others can see or does not hear a sound that others can hear. When generalized to more than a specific object that is not seen, the individual seems to be blind even though the visual apparatus is still working.

Visceral Symptoms Psychogenic vomiting can occur as a conversion disorder (Table 16-3). Typically such a patient will not suffer significant weight loss when observed for a week on an inpatient medical service; gastrointestinal workup will show no significant disease or disorder. Another visceral conversion disorder is urinary retention. On urological workup, conversion patients show normal intracystometric dynamics. Conversion as pseudocyesis manifests as a cessation of menses, a protuberant abdomen, and an elevation of serum hormones seen in early pregnancy. Other visceral conversions include globus hystericus, syncope, and diarrhea.

Important Caveats As with all disorders with a low specificity and no confirmatory laboratory test, substantiation of the diagnosis is facilitated by the passage of time with no other countervening diagnosis evolving. Also helping to confirm the diagnosis of conversion disorder is the development of another bout of conversion symptoms. About 25 percent of patients with conversion disorder will develop another episode during the following 1 to 6 years.

The diagnosis of a conversion disorder is made more secure if details of a prior set of conversion symptoms can be elicited. However, complicating the collecting of the past medical history in many patients with somatoform disorders is their frequent use of repression. Such patients thus may not recall important pieces of historical data. In adding collateral information a review of the patient's old clinical chart can be very helpful.

Another important caveat is that the diagnosis cannot be based solely on inexplicable neurological findings accompanied by relevant psychological factors. Patients with lesion-based neurological disorders also wrestle with the sick role. Moreover, although suggestibility is often seen in patients with conversion, some patients with organic disorders can also respond to suggestion, briefly altering their symptoms. It is not uncommon to find neurological disease coexisting with a conversion disorder.

Critical review of the literature finds little or no empirical support for the necessity of a number of previously widely accepted classic accompaniments of conversion disorder including: *la belle indifférence*, hysterical personality, the presence of secondary gain, the symptom as symbolism, sibling position, disturbed sexuality, and conversion V pattern on the MMPI-2 (elevated hysteria and hypochondriasis scales, even higher than the depression scale).

Suggestibility, with a patient seizing on command (or when induced in a particular situation), used to be considered a sign that a convulsion was a pseudoseizure. However, recent clinical and EEG evidence indicates that the precipitation of overt, nonstereotyped seizures by instruction may not be a reliable diagnostic method when an insidious process is slowly elevating temporal and limbic lobe lability. When taken by itself, no single associated finding is pathognomonic for the diagnosis of conversion disorder. However, a number of features taken together help the clinician to determine the likelihood (i.e., possible, probable, definite) of a conversion disorder.

Setting Marked psychological stress is almost always present. Precipitants typically may have been acute rage, truncated grief, sexual abuse, or physical abuse. Somatic symptoms may develop abruptly following a dramatic psychological blow, mechanical trauma, or a life-threatening experience. However, studies on patients with conversion disorder demonstrate that their life experiences are not more extreme than those with other types of psychiatric disorders.

The initial mental status examination of the patient with conversion disorder may prove to be quite unremarkable: a calm person who may or may not be troubled by a new somatic symptom may have no insight into the symptom's underlying dynamics. At first glance the patient's family may appear to be happy and integrated, with the family predicament (if present) being covert. Family difficulties are common in patients with conversion disorders, but not more so than for families of patients who attend a psychiatric clinic for other psychiatric disorders.

> Mrs. A. was a 22-year-old right-handed fundamentalist farmer's wife, homemaker, and mother of three from a sparsely settled Western state. Her past medical history was benign except for a motor vehicle accident 2 years previously that produced a sharp blow to the right temporal area, resulting in several hours' loss of consciousness. She had an unremarkable behavioral history without substance abuse, prolonged depressions, or unexplained somatic symptoms. Her demeanor had always been placid and unassuming. There was no family history of antisocial behavior or substance abuse.
>
> On Thanksgiving Day, while taking her usual solitary afternoon walk along the creek behind the kitchen, she came upon the floating, lifeless bodies of two of her children. She shrieked, swooned, and fell to the ground. Relatives in the house rushed out to assist but were unable to revive the children. When she was helped up, she asked that her husband guide her back to her room. Later that afternoon she seemed calm, even detached, as others scurried about making arrangements. She admitted to a visitor that she seemed to have lost the gift of sight.
>
> That evening the family physician was called to examine the newly sightless woman. He noted that her pupils were round, equal, and constricted briskly with a bright light; she was unable to touch the tips of her index fingers together in front of her; she failed to look at her own hands when instructed to do so; and she had no other neurological abnormalities, asymmetries, or complaints. The physician explained to the gathered family and patient that the woman was suffering from nervous shock, needed kind and quiet support, and should refrain from routine household chores for the moment. The physician also suggested that her eyesight would gradually return over the next week or so, perhaps following the funerals of her children. The patient's vision did slowly return over the next days and she gradually resumed her usual level of care for the home, her surviving child, and other members of the family.

PSYCHOPATHOLOGY AND LABORATORY EXAMINATION

Diagnostic workup is a multistep process that begins with a very thorough history and physical examination. There are a number of simple but specialized examinations that can be worked into a seemingly routine physical examination. Although some diagnoses can be made from the foot of the bed, chair, or stretcher with substantiating data collected in just a few minutes, it is not infrequent for an initial workup of a patient with a conversion disorder to take many hours even when conducted by a skilled clinician. Collateral sources need to be included to build a case based on circumstantial evidence of what was going on in the patient's life at the time of the acute shock. Table 16-5 lists examples of important tests that are relevant to conversion disorder symptoms.

Condition	Test	Conversion Findings
Anesthesia	Map dermatomes	Sensory loss does not conform to recognized pattern of distribution
Hemianesthesia	Check midline	Strict hall-body split
Astasia-abasia	Walking, dancing	With suggestion, those who cannot walk may still be able to dance; alteration of sensory and motor findings with suggestion
Paralysis, paresis	Drop paralyzed hand onto face	Hand falls next to face, not on it
	Hoover test	Pressure noted in examiner's hand while paralyzed leg when attempting straight leg raising
	Check motor strength	Give-away weakness
Coma	Examiner attempts to open eyes	Resists opening, gaze preference is away from doctor
	Ocular cephalic maneuver	Eyes stare straight ahead, do not move from side to side
Aphonia	Request a cough	Essentially normal coughing sound indicates cords are closing
Intractable sneezing	Observe	Short nasal grunts with little or no sneezing on inspiratory phase; little or no aerosolization of secretions; minimal facial expression; eyes open; stops when asleep, abates when alone
Syncope	Head-up tilt test	Magnitude of changes in vital signs and venous pooling do not explain continuing symptoms
Tunnel vision	Visual fields	Changing pattern on multiple examinations
Profound monocular blindness	Swinging flash light sign (Marcus Gunn)	Absence of relative afferent pupillary defect
	Binocular visual fields	Sufficient vision or "bad eye" precludes plotting normal physiological blind spot in good eye
Severe bilateral blindness	"Wiggle your fingers, I'm just testing coordination"	Patient may begin to mimic new movements before realizing the slip
	Sudden flash of bright light	Patient flinches
	"Look at your hand"	Patient does not look at them
	"Touch your index fingers"	Even blind patients can do this by proprioception

Table 16-5 Distinctive Physical Examination Findings in Conversion Disorder

There are also a few specialized laboratory-based procedures that can assist in the diagnostic workup of some patients with conversion disorder. Helpful in specific instances are simultaneous EEG and videotaping of behavior along with lack of elevation of serum prolactin levels in pseudoseizures; optokinetic drum test in conversion blindness; cortical evoked potentials for auditory and visual deficits; and electromyogram for fasciculation in lower motor neuron paralysis.

DIFFERENTIAL DIAGNOSIS

Almost any neurological symptom can have a conversion basis. Many serious neurological diseases can be mistaken for the conversion disorders (Table 16-6), and a number of psychiatric conditions need to be considered in the differential diagnosis of conversion disorder (Table 16-7). Until the diagnosis is clarified, ongoing evaluation by a psychiatrist and a neurologist may be useful; premature closure obviously aborts further diagnostic consideration.

Myasthenia gravis
Periodic paralysis
Brain tumor
Multiple sclerosis
Optic neuritis
Partial vocal cord paralysis
Guillain-Barré syndrome
On-off syndrome of Parkinson's disease
Degenerative diseases of basal ganglia and peripheral nerves
Acquired myopathies including polymyositis
Subdural hematoma
Acquired and hereditary dystonias
Drug-induced dystonia
Creutzfeldt-Jacob disease
Early manifestations of acquired immune deficiency syndrome (AIDS)

Table 16-6 Neurological Conditions in the Differential Diagnosis of Conversion Disorder

Major depressive episodes	Histrionic personality disorder
Catatonic schizophrenia	Adjustment disorder
Pain disorder	Posttraumatic stress disorder
Somatization disorder	Malingering

Table 16-7 Psychiatric Conditions in the Differential Diagnosis of Conversion Disorder

COURSE AND PROGNOSIS

Course Most patients diagnosed with conversion disorder experience a quick symptomatic recovery. Rapid improvement is especially seen in cases where symptoms are of recent onset, suggestive of voluntary control, inconsistent or variable, and of obvious immediate benefit.

Follow-up studies in the literature from the 1960s demonstrated multiple diagnostic errors in series of conversion patients followed for 2 to 20 years because clinicians, using subjective criteria, proved to be too liberal in their use of the diagnosis. Some long-term follow-up studies have shown that 25 percent of conversion disorder patients on psychiatric wards who subsequently died had inaccurate initial psychiatric diagnoses of conversion disorder. Long-term follow-up studies using selection criteria heavily weighted to psychodynamic issues (symbolism, secondary gain, *la belle indifférence*) from DSM-I, DSM-II, ICD-9, and even DSM-III have shown an appalling lack of diagnostic consistency. A frequently quoted British inpatient study reported that over half of the patients had an organic disease 7 to 11 years later that accounted for the symptoms of the supposed conversion disorder. Of note, however, two thirds of the patients in that series were not diagnosed as having conversion disorder by a psychiatrist before they were accepted into the series. Many cases from that inpatient study who did not develop neurological disease instead developed or were discovered to have some other type of disabling psychiatric disorder.

An American study found that neurological disease explained the original conversion symptoms in only one fifth of the cases. The emergence of neurological disease was more frequent in conversion patients who did not have somatization disorder as a comorbid condition. Another study with a 20-year follow-up noted that fully one third of patients later experienced a psychotic illness, often paranoid schizophrenia. In that sample central nervous system disease, especially epilepsy, was often mistaken for hysteria. A third major study with a 10-year follow-up noted that a quarter of patients developed organic disorders over time that accounted for the presenting conversion symptoms: mainly degenerative diseases of the spinal cord, peripheral nerves, bones, muscle, and connective tissue.

Thus, follow-up studies from tertiary medical centers show that there is a distinct possibility of the emergence of other medical, neurological, or disabling psychiatric disorders to account for the original conversion symptoms. Thus, one can conclude from the older literature that either the inclusion criteria used for the initial diagnosis of conversion disorder were far too inclusive, or else that the diagnosis of conversion disorder must be made more cautiously.

Conversion disorder has been imprecisely and improperly diagnosed when clinicians used it as a diagnosis of exclusion in the face of the neurological examination not being consistent with full-blown neurological disease. Clinicians needs to be wary that they do not erroneously think the patient has a psychiatric illness such as conversion disorder because of inexplicable neurological signs and the coincidence of emotional conflict.

Prognosis A favorable prognosis of conversion disorder is associated with sudden onset; readily identifiable stressful events; good premorbid health with no comorbid psychiatric, medical, or neurological disease; and no ongoing compensation litigation.

In a retrospective American study of patients with conversion disorder without comorbid neurological or medical disorders, 90 of 100 patients recovered by the time of

psychiatric hospital discharge; on follow-up 5 years later, 75 percent remained well. Another general hospital study demonstrated that half of patients on a medical surgical unit found to have a conversion disorder during a psychiatric consult experienced remission of their conversion symptoms by the time of medical discharge. Another study of conversion patients successfully treated with a 1-year follow-up, only one fifth had relapsed; symptom substitution was minimal.

Patients with chronic conversion disorders, however, do not have a good prognosis. In a recent 10-year British follow-up study of 56 patients hospitalized and well studied for their pseudoneurological symptoms, 30 had no relief from their original symptoms. Additionally, 11 patients had neurological findings, tentatively considered at symptom onset, which in retrospect accounted for their conversion symptoms.

TREATMENT

Most conversion symptoms remit spontaneously or after behavioral treatment, suggestion, and a supportive environment. Thus, for symptoms of very recent onset a variety of other therapies have also been utilized successfully. In practice clinicians tend to choose therapies that reflect their training. Irrespective of the technique used, most approaches seem to work when symptoms are not reinforced, when an authoritarian approach is used, and when the patient's psychosocial plight is the focus of attention.

Common Denominators of Success What seems least likely to be effective is trying to get the newly afflicted patient to accept the therapist's opinion that the somatic symptom is a direct manifestation of a psychosocial problem (e.g., that the physical disability is the representation of a psychiatric problem). Rather, the common denominator of successful treatment (irrespective of the clinician's theoretical framework) is the building of a caring, authoritative relationship. It is important to provide the patient with a safe environment to facilitate the gradual decrease in symptoms. The clinician can then deal indirectly with interpretations of the conversion symptom while trying to minimize or eliminate the symptom. It is not helpful to argue with the patient about the cause of the conversion disorder.

A multiplicity of types of therapies have their adherents (Table 16-8). When successful, some common elements in many of these treatments are the following: (1) a nonconfrontational approach, (2) discouraging retention of symptoms, and (3) manipulating the environment.

Faradic stimulation	Hypnosis and other suggestive techniques
Physical therapy	Behavioral approach to symptom elimination
Electrosleep	Family therapy
Inexact interpretations	Long-term insight-oriented psychotherapy

Table 16-8 Therapies Used in Conversion Disorder

Psychodynamic techniques and insight-oriented intensive psychotherapy may need considerable modification with psychologically naive patients. At times placing patients in a double bind by telling them that full recovery constitutes proof of an organic cause and failure to recover constitutes proof of nonorganic or psychiatric etiology, facilitates rapid recovery. For example, when the patient is failing to progress, three possible explanations can be made for the lack of progress: (1) the patient has psychological problems that will necessitate long-term self-examination in treatment; (2) the patient is not trying, which constitutes grounds for dismissal; or (3) the symptoms are caused by excessive overstimulation and fatigue, which would necessitate periods of deep rest without stimulation of any kind. Patients usually choose this latter option as the most likely explanation. Therapy would then begin with behavioral goals augmented daily and deep rest if the patient fails to meet those goals. Deep rest precludes reading, watching television, and socializing with staff members or other patients until the next therapy session. This precaution should be presented as an expression of concern about the patient's level of fatigue and as a means of preventing overstimulation. This behavioral paradigm must be seen not as punitive but as very supportive. In this way, patients rapidly lose symptoms and gain discharge; however, each behavioral intervention needs to be tailored to the specifics of the case.

If combined with a supportive and problem-solving approach, hypnosis may be helpful. On some occasions parenteral injections of amobarbital or lorazepam (Ativan) have also been seen as helpful. For example, 50-mg doses of amobarbital from an intravenous infusion in 5 percent dextrose could be administered until the patient feels sleepy. An interview might require a total of 200 to 700 mg of amobarbital. A nurse should always be present as witness and a crash cart must be available lest there be respiratory failure or cardiac arrest. Videotaping the interview can be a powerful tool to allow later feedback to the patient under the supervision of the therapist. This gives patients the opportunity to see how their unconscious works; however, it is the physician's responsibility to help the patient integrate this information.

Oral anxiolytic medications also may reduce anxiety and allow the patient to engage in a psychotherapeutic process that might otherwise be too overwhelming to handle. Decreasing the need for secondary gain by opening up other channels of communication seems to help. Eventually the more emotionally healthy patients seem to be able to gain insight into the meaning of their symptoms. Using a variety of techniques to work at resolving the patient's problems as well as eliminating the conversion symptom seems to be the best approach. Symptom substitution may occur if the patient still needs the conversion symptom, but most authors believe that substitution is usually not seen if one works patiently and with tact, allowing patients to save face and to accomplish some of their covert goals.

Poor Outcomes Not all symptoms remit in hours or days; some linger tenaciously despite skilled inpatient treatment. In such instances other psychopathology and immutably malignant social pathology are often present. The presence of a conversion disorder in one member of a family, the putative patient, may well serve as a beneficial cohesive factor in an otherwise chaotic dysfunctional family. Symptom removal and clinical remission seems to be least successful if compensation is at issue.

SOMATIZATION DISORDER

Definition The essential feature of somatization disorder is recurrent, multiple somatic complaints requiring medical attention but not associated with any physical disorder. Somatization disorder is the expression of personal and social distress in a deeply ingrained idiom of bodily complaints linked with medical help-seeking behavior. The diagnosis requires a history of many physical complaints of several years' duration and a lifetime history, beginning before age 30, which result in medical treatment or alteration in life-style. The symptoms must not be fully explained by a known nonpsychiatric medical condition, or the resulting complaints or impairment must be excessive. Typically these symptoms, coupled to persistent complaints plus demands placed on caregivers and medical services, result in gain to the patient through relief from responsibilities, through caring responses and attention from others, or both.

The diagnostic syndrome of somatization disorder has been evolving since the 1950s with various refinements and simplifications in criteria of a disorder that has the same stable, chronic course. Like a personality disorder, somatization disorder begins at an early age, is chronic and unremitting and appears to be a deeply ingrained adaptation to life. Currently, eight symptoms are required, which must meet a specific pattern: four different sites of pain; two different gastrointestinal symptoms; one sexual or reproductive system symptom other than pain; and one neurological symptom. The subjective severity of the symptoms must be sufficient to lead the patient to consult a physician, take medicine, or make life-style changes.

History The history of somatization disorder is complex. Essentially, over the centuries two complementary syndromes have been described: one monosymptomatic and the other polysymptomatic. The monosymptomatic syndrome is currently recognized as conversion disorder whereas the polysymptomatic syndrome has become known as somatization disorder. Historically, the two disorders have often been interrelated and commingled.

Hysteria Somatization disorder has had many names and many antecedents; one such predecessor has been referred to in older texts as *hysteria*, first recognized by the ancient Egyptians who believed that hysteria was caused by upward dislocation of the uterus and displacement of other organs. Migration of the uterus throughout

the body thus provided the basis for the multiple symptoms. Doubts about the uterine origin of hysteria began in the seventeenth century. Thomas Syndenham dissociated hysteria from the uterus and linked it with a psychological disturbance known at that time as “antecedent sorrows,” therein recognizing the emotional origin of the disorder. Further, Sydenham was also the first to recognize the disorder in men.

In 1859 Briquet emphasized the multisymptomatic aspects of the disease and its protracted course. His report of the 430 cases observed at the Hospital de la Charité in Paris focused on polysymptomatic aspects of the disorder. Briquet also recognized hysteria in men and attributed the disorder to emotional causes.

Modern Era An important series of papers published between 1951 and 1953 presented the first modern conceptualization of the multisymptomatic concept of hysteria. The Washington University group in St. Louis concluded that hysteria is a definable syndrome with a characteristic clinical picture that begins before the age of 35. Using objectifiable criteria, they defined a prevalence of the multisymptomatic disorder in the general hospital of 2.2 percent of all admissions. While noting the similarities of their work to Briquet's, they initially deviated by suggesting that men did not have the disorder.

In the early 1960s two studies confirmed the original findings of a definable clinical syndrome, demonstrating diagnostic stability of the multisymptomatic concept of hysteria. In 1970 the eponym *Briquet's syndrome* was proposed to denote multisymptomatic hysteria. The disorder, characterized by at least 25 symptoms from 10 symptom groups, was known as *Briquet's syndrome* until the publication of the DSM-III. Ironically, after the decision was made to incorporate Briquet's syndrome as part of the new diagnostic nomenclature, an unrelated decision was made to drop all eponyms. Hence a new name—*somatization disorder*—had to be created.

DSM-III streamlined the criteria to 14 lifetime symptoms in women (12 in men) from a list of 37 symptoms; moreover, a requirement for symptom grouping by organ systems was dropped. With the advent of DSM-III-R and further time for detailed follow-up studies, the number of symptoms required for men and women were both changed to 13.

Comparative Nosology There have been multiple predecessors to the current diagnosis of somatization disorder, the best validated of which has been Briquet's syndrome. Later studies have demonstrated only a moderate degree of diagnostic concordance between Briquet's syndrome and somatization disorder. In spite of these limitations, in most situations it appears reasonable to apply the findings from the literature on Briquet's syndrome and somatization disorder. Somatization disorder did not appear in DSM-I or DSM-II; it first appears in DSM-III and later in DSM-III-R. For DSM-IV the diagnostic criteria were simplified to require one or more symptoms from each of four symptom groups. The ICD-10 criteria for somatization disorder require (1) at least 2 years of multiple and variable physical symptoms with no adequate physical explanation; (2) persistent refusal to accept advice; and (3) some degree of impairment of functioning. There must be a total of 6 or more from a grouping of 14 symptoms in 2 of the 4 different areas (gastrointestinal, cardiovascular, genitourinary, plus skin and pain). There are no pseudoneurological symptoms in ICD-10 and DSM-IV has different gynecological and sexual symptoms from those found in ICD-10. Moreover, ICD-10 requires at least 6 symptoms from 4 groupings whereas DSM-IV requires 8 symptoms from its 4 groupings. Finally, ICD-10 is specific about duration of the disorder—2 years—whereas DSM-IV requires that some of the physical complaints have their beginnings before age 30.

Epidemiology Several studies based on large populations have estimated the lifetime prevalence of somatization disorder as 0.13 percent of the general population. Other community-based surveys estimate the lifetime prevalence to be 0.2 to 2 percent in women and less in men. Because patients with somatization disorder believe themselves to be medically ill, they can be assumed to frequent physicians' offices. Recent work indicates that as many as 5 percent of patients seen in family practice settings meet criteria for the disorder whereas 9 percent in a general hospital population and 12 percent in a group of patients with chronic pain met criteria for somatization disorder. In a group of patients with irritable bowel syndrome in a private outpatient clinic, 17 percent of patients met the criteria. In one random selection of 49 women who underwent hysterectomy for noncancerous reasons, 27 percent were diagnosed with somatization disorder.

Persons that meet the full criteria for somatization disorder are typically unmarried, nonwhite, poorly educated, and from rural areas. In families with somatization disorder, children have 11.7 times as many emergency room visits as families less afflicted with somatizing. Moreover, children's somatization is predicted by parental somatization, substance abuse, and antisocial symptoms.

Although there may not be a large number of these patients in the general population that meet full-blown criteria, individually they are expensive to care for. Recent studies estimate that somatization disorder patients incur 6 times the national average of per capital expenditures for hospitals and 14 times the national average of per capital expenditures for physician services. Moreover, there may be thirty times as many patients with subthreshold somatization, that is, those that meet partial criteria for somatization disorder (i.e., undifferentiated somatoform disorder).

Sex Early reports found somatization disorder exclusively in women. However, it is now recognized that somatization disorder afflicts men, but less commonly than women. Men comprise 5 to 20 percent of those with somatization disorder.

Comorbidity As the severity, chronicity, and invalidism of somatization increase, so does the likelihood of a major psychiatric disorder. Frequent concomitants of somatization disorder are major depressive disorder, anxiety disorders, and personality disorders. Over half of somatization disorder patients from a primary care sample were found to have a lifetime history of a major depressive episode in addition to their somatization disorder. Several recent studies using structured diagnostic interviews in patients from primary care settings found that 61 to 72 percent of patients with somatization disorder also have co-occurring personality disorders. This rate would seem to be 2.5 to 11.6 times more common in somatization disorder patients than in general medical patients.

Somatization disorder does not seem to be associated with any one or any combination of currently defined personality disorders. In one study, the most frequent types in order were avoidant, paranoid, self-defeating, obsessive-compulsive, schizotypal, and histrionic personality disorders. Earlier studies from patients attending psychiatric clinics had only reported an association with histrionic personality disorder and antisocial personality disorder. Many patients with somatization disorder also have conversion symptoms.

Anxiety disorders, especially phobias, panic disorder, and generalized anxiety disorder, are also present in patients with somatization disorder. Suicide threats are common in patients with somatization disorder, as are suicide gestures; however, suicide attempts rarely are lethal or near-lethal. Doctor shopping is frequent, with patients moving from one doctor to another. Typically, somatization patients have very chaotic social lives with frequent divorces, separations, and remarriages; similarly, they have trouble maintaining jobs and often become too disabled to hold gainful employment.

Etiology Numerous theories have been advanced to explain the psychosocial mechanisms involved in the process of somatization. By contrast few theories have been yet proposed to account for the biological basis of somatization disorder. The act of somatization can be understood as social and emotional communication. It can also be explained as the result of an intrapsychic dynamic, with somatization carried to an extreme.

Social Communication Somatization as social communication includes the use of bodily symptoms to manipulate or control relationships (e.g., an adolescent girl's developing unexplained abdominal pain to prevent her parents from going away for the weekend). Somatizing also can serve as emotional communication. Patients may be unable to verbally express their emotions; therefore, they may use somatic symptoms and somatic complaints to express their emotional state. Symptoms may be used to symbolically communicate emotions, as they are in conversion disorder. Some patients also use medical complaints as a coping device to deal with stress. Finally, physical symptoms may be used as a solution to an intrapsychic conflict, again as in conversion symptoms. Studies of psychological tests in somatization disorder have reported that compared to sex- and age-matched controls these patients have significantly more scale elevations on the MMPI-2.

Psychodynamic Factors Classical psychoanalytic theory has held that hysteria represents a substitution of somatic symptoms for repressed instinctual impulses. Freud postulated that the conflict was a phallic Oedipal one. However, more recent articles in the analytic literature emphasize a pregenital conflict as well.

Biological Factors Interesting preliminary data are now finally available concerning the biomedical underpinnings of somatization disorder. Neuropsychological testing demonstrates equal bifrontal impairment of the cerebral hemispheres and nondominant hemispheric dysfunction in patients with somatization disorder. However, some reports indicate that symptoms referable to the left side of the body may indicate that the right hemisphere of the brain is more involved than the left side. Preliminary evidence indicates that patients with somatization disorder may have an abnormality in cortical functioning, as evidenced by abnormal auditory-evoked potentials. In contrast to controls, patients with somatization disorder responded similarly to relevant and irrelevant stimuli, suggesting an impairment in selective attention. The data require much more extensive follow-through, without the confound of comorbid personality disorders influencing findings.

Christopher Bass at Oxford University is leading an effort to define the pathophysiology of symptoms experienced by patients with somatization disorder because not all patients with unexplained medical complaints have emotional disorders. The awareness, reporting, and seeking of medical help is complex and involves biopsychosocial processes. From a perceptual perspective, awareness of symptoms varies with the attention paid to them. Symptom reporting is elevated among

individuals who live alone or work in unstimulating settings. The awareness of symptoms and of disease is increased by reading about or observing medical disorders. Depressed and anxious moods are associated with greater reporting of bodily symptoms. Personality traits, neuroticism, and negative affectivity with introspective characteristics all tend to lower the threshold for noticing and reporting bodily sensations. Muscular tension, hyperventilation, sleep, and inactivity are all conditions that could contribute to the symptoms experienced by patients who have somatization disorder.

Considerable evidence now also points to familial and genetic associations in somatization disorder. Some data support the findings that groups of patients with somatization disorder have a higher-than-expected prevalence of antisocial personality disorder or manifest several traits of antisocial personality disorder. Other data, however, do not support such a strong association. One theory holds that antisocial personality disorder and somatization disorder may have a common genetic background. Some scholars consider somatization disorder to be the female expression of a genetic tendency, with antisocial personality disorder being its male counterpart.

Recent data is now emerging from a number of studies on families of patients with somatization disorder. In comparison to control families, those of patients with somatization disorder have had more physical and sexual abuse, and more disabling medical illnesses in one or both parents—all severe socio-environmental challenges. Thus somatizing behavior in many patients with somatization disorder seems often to emerge against a backdrop of emotionally disturbed or impoverished family life lacking in ordinary parental care in which physical symptoms had established meanings. Indeed Christopher Bass has argued that somatization disorder should be classified as a developmental personality disorder because of its patients' characteristic lifestyles and modes of relating to self and others. Relevant to this argument is evidence of persistent impairment associated with an illness-shaping background in an individual's formative years.

Diagnosis and Clinical Features Table 16-9 presents the DSM-IV diagnostic criteria of somatization disorder. It is important to note that specific symptoms do not need to be considered legitimate by the clinician. Rather, patient's reports that they have the symptom is sufficient as long as the symptom meets the severity criteria. A patient can have somatization disorder even if a current or presenting symptom did not begin before the age of 30 years. A careful review for an early onset of any of the unexplained symptoms for which the patient has had problems is necessary to make the diagnosis and at least one of these symptoms must begin before age 30.

Table 16-9 DSM-IV Diagnostic Criteria for Somatization Disorder

Patients with somatization disorder consider themselves to be severely ill. They report their health is worse than those with chronic, lesion-based medical conditions. In contrast, the mortality rate of somatization patients is similar to that of the general population and is substantially less than patients with major depressive disorder.

Ms. D. is a 52-year-old white woman who was referred to a general internist in the city for evaluation of persistent back pain and multiple other complaints. At hospitalization it was noted that the patient was disabled from her job as a machine operator at a shoe factory. Ms. D. gave a history of 10 operations: removal of a tumor from her right wrist, a dilation and curettage, a hysterectomy, three abdominal gastric operations, three breast biopsies, and leg surgery. She had received care from five different hospitals and seven different physicians in the past 2 years.

On physical examination, Ms. D. was an obese, chronically ill-appearing woman who came to the hospital wearing her transcutaneous electrical nerve stimulation unit. She was cooperative and showed her various scars with a certain amount of enthusiasm. The remainder of her physical examination was within normal limits except for a decreased range of motion in the area of her lumbar spine and local muscle guarding, with some tenderness. Spinal radiographs revealed some degeneration of vertebral bodies L2 to L5. On mental status examination she was cooperative and pleasant, and her behavior was somewhat seductive. There was no pressure or eccentricities in her speech. She showed little hesitation in discussing intimate details of her life. Her mood was euthymic; her affect was appropriate to mood but possibly a little shallow. The remainder of her mental status examination was within normal limits.

Disallowing all back-related symptoms, Ms. D. was positive for eight pain symptoms: four gastrointestinal symptoms, two sexual symptoms, and two pseudoneurological symptoms with an age of onset of 26 years. During the previous 12 months, Ms. D. reported that she had been in bed 21 days, had made seven office visits to four physicians, and had been hospitalized for a total of 52 days.

Ms. D.'s case illustrates that the diagnosis of somatization disorder can and should be made in the presence of comorbid medical conditions. Patients with somatization disorder do become ill, and their problems need to be appropriately diagnosed and treated. However, the management of somatization disorder should continue unchanged.

Pathology and Laboratory Examination There are no known neuropathological or routine laboratory findings specific for somatization disorder.

Differential Diagnosis An important aspect of the differential diagnosis is distinguishing a somatic symptom secondary to another psychiatric disorder from a symptom of somatization disorder. Table 16-10 explains how somatic complaints in other disorders differ from those found in somatization disorder.

Anxiety or depressive disorders	Usually one or two somatic symptoms of acute onset and short duration
Panic disorder	Somatic symptoms experienced only during panic episode
Hypochondriasis	Patient's focus is on fear of disease, not focus on a symptom
Conversion disorder	Only one or two complaints
Pain disorder	One or two unexplained pain complaints, not a lifetime history of multiple complaints

Table 16-10 Nonsomatization Somatic Symptoms

Hypochondriasis can sometimes be difficult to distinguish from somatization disorder. Hypochondriasis is more likely to begin at a later age than somatization disorder whereas the latter is more likely to occur in women than in men. Hypochondriacal patients often misinterpret normal bodily sensations as an indication of a pathological process. They believe that they harbor a specific lethal disease whereas somatization patients focus on complaints about multisystem symptoms that

lead them to have an inordinately high number of surgical procedures and consume an excessive amount of health care.

Course and Prognosis By definition, somatization disorder is a chronic relapsing condition with no known cure. It usually begins in middle to late adolescence, but may start as late as the third decade of life.

Typically, patients develop a new symptom, or symptoms, during times of emotional distress. No research data are yet available as to how long a modal episode of illness lasts. Clinical wisdom indicates that a typical episode lasts 6 to 9 months, with quiescent periods lasting from 9 months to a year. It is unlikely that patients with somatization disorder can go for more than a year without developing a new symptom and seeking some type of health care. Periods of psychosocial distress seem to coincide either with the onset of new symptoms or with increased health—care-seeking behavior associated with some preexisting symptom. Although no research data exist on whether stress precipitates the relapse, anecdotally there does seem to be an association. This association is especially problematic for patients because somatization disorder considerably disrupts social aspects of living.

Poor Long-Term Health Somatization disorder patients typically consider their health to be poor. When standard measures for health status are applied, the patients report that all aspects of their health—physical, social, and mental—as well as their general health perceptions are severely impaired. Patients with somatization disorder report worse health than do those with chronic medical conditions. Further, because patients who have somatization disorder perceive themselves to be sicker than the sick, it is not at all incongruous that they usually deem themselves disabled from work.

Treatment Because the cause of somatization disorder is unknown and no curative or ameliorative treatment has been found, the clinician needs to focus on management rather than treatment, on coping rather than curing (care rather than cure).

General Management Strategies While taking the medical history, physicians should take note of and store away for future use psychosocial material that it brought up spontaneously by the patient: references to personal difficulties and life events that cause distress. These matters can be explored at a later time after the relationship with the patient is more developed. It is important initially to avoid confrontations or to alienate the patient in other ways. The physical examination is an opportunity for discussing symptoms and providing clear information about clinical findings.

Information to the patient must be clear and unambiguous. During regularly scheduled repeat visits, as the patient endlessly drones on about physical symptoms, the clinician should gradually change the agenda to inquire about psychosocial issues in an empathic manner. In actual practice, this type of inquiry does not consume inappropriate amounts to time, contrary to clinicians' fears. Limits also need to be placed on the numbers and types of investigations that the patient requests. Crises in the patient's life, provoked by psychosocial stresses, are often accompanied by an increase in somatic symptoms. At such times the physician may be more able to draw the patient's attention to the relationship between emotional and physical suffering.

Best practice would indicate that the patient's primary care physician follows the patient closely and treats, or refers for treatment, any complicating comorbid psychiatric condition, such as a mood disorder. When ordering laboratory studies, the physician should order for the patient the same set of tests as if the patient were not a somatizer. If called into the case after all medical evaluations have been completed, the psychiatrist is advised to inquire about symptoms and the patient's medical odyssey, avoiding the temptation to express any opinions prematurely and maintaining a position of empathic curiosity during the initial intake in an effort to understand the patient's experiences.

Several types of treatment techniques have been advocated, including behavioral (avoid prolonged bed rest, which only increases weakness and encourages the patient to focus on symptoms); cognitive (avoid catastrophizing); and interpersonal (elucidate and deal with family conflicts). Progress should be aimed at improving functional capacity and the patient's progress will typically be very gradual.

Management of somatization disorder has only been tested empirically in several studies, findings from which revealed that when certain specific management strategies were undertaken by the primary care physician, patients with somatization disorder improved their physical functioning; their health care utilization decreased at the same time too.

Cost estimates of the savings of a simple consultation letter to these patients' primary care physicians about specific principles was associated with a 12 percent decrease in per-patient annual health care cost. Net annual cost savings were $295. Improvement to the patient is best reflected in the ability to perform the activities of daily living. Patients whose physicians received a simple consultation letter from a psychiatrist were significantly clinically improved in this domain compared to patients whose primary care physician did not receive such a consultation letter. Table 16-11 presents helpful management strategies for somatization disorder.

Establish primary care physician as patient's main and (if possible) only physician
Set up regularly scheduled visits every four to six weeks
Keep outpatient visits brief
Perform at least a partial physical examination during each visit directed at the organ system of complaint
Understand symptoms as emotional communication rather than the harbinger of new disease
Look for signs of disease rather than being symptom focused
Avoid diagnostic tests, laboratory evaluations, and operative procedures unless clearly indicated
Set a goal of getting at least selected somatization disorder patients referral-ready for mental health care

Table 16-11 Helpful Management Strategies for Somatization Disorder

There is little data on the treatment of depression in patients with somatization disorder, but what evidence there is suggests that depression can be successfully treated; when it is treated successfully, the somatization itself may also improve.

Doctor-Patient Relationship The cornerstone for successful management of the patient with somatization disorder is establishing a trusting relationship between the patient and one community physician. The doctor-hopping that frequently occurs in these patients is both frustrating and countertherapeutic.

Recently a form of group treatment was shown to be effective in somatization patients. The intervention tested was a time-limited, behaviorally oriented group with a structured protocol. The overall goals of the group were to be a source of peer support, to share methods of coping, to increase the ability to perceive an expressed emotion, and to allow the patient to enjoy the group experience. The study demonstrated that in the year following treatment the experimental group of patients with somatization disorder demonstrated better physical and emotional health and evidenced decreased health care charges than untreated controls with the same disorder. Moreover, the more group sessions the subjects attended, the greater their sense of well-being and the lower their net health care costs. Other studies using short-term cognitive-behavioral therapy, individually or in groups, for somatizing or somatization disorder patients have demonstrated decreased somatic preoccupation, anxiety, depression, and medication usage.

UNDIFFERENTIATED SOMATOFORM DISORDER

Definition Undifferentiated somatoform disorder is characterized by one or more unexplained physical complaints of at least 6 months' duration. These symptoms impair the patient in some domain and are temporally associated with a stressor. Psychological factors are assumed to be associated with the symptoms or complaints because of a contemporaneous relationship between the initiation or exacerbation of the symptoms and stressors, conflicts, or needs. The complaint must be unattributable to any other known psychiatric condition or pathophysiological mechanism or, when it is related to a nonpsychiatric condition, the physical complaints or resulting social and occupational impairments must be grossly in excess of what would ordinarily be expected from the findings.

History and Comparative Nosology Many who work in the general medical setting find the diagnosis of undifferentiated somatoform disorder helpful. Research indicates the validity or distinguishing undifferentiated somatoform disorder from somatization disorder. There appears to be a dimensional or quantitative difference

between undifferentiated somatoform disorder and somatization disorder rather than a qualitative difference between the two. However, the natural history of both disorders seems to be similar. The disorder was not included in DSM-I, DSM-II, and DSM-III; it was first introduced in DSM-III-R and remains unchanged in DSM-IV. Undifferentiated somatoform disorder was introduced to the psychiatric lexicon in DSM-III-R because somatization disorder was considered to be too restrictive by primary care providers to provide adequate coverage for many patients with significant somatoform complaints. Thus the subsyndromal grouping was formalized to facilitate learning about the natural course of a large cluster of patients. The criteria for undifferentiated somatoform disorder in ICD-10 are similar to the diagnostic criteria in DSM-IV.

Somatizing Syndrome This disorder, characterized by a lifetime history of four unexplained somatic complaints for men and six for women, has been called various names. It forms a subset of patients with undifferentiated somatoform disorder. All research data so far have used the term *somatization syndrome* rather than the broader term *undifferentiated somatoform disorder.* The remainder of this section refers to data from research on somatizing syndrome.

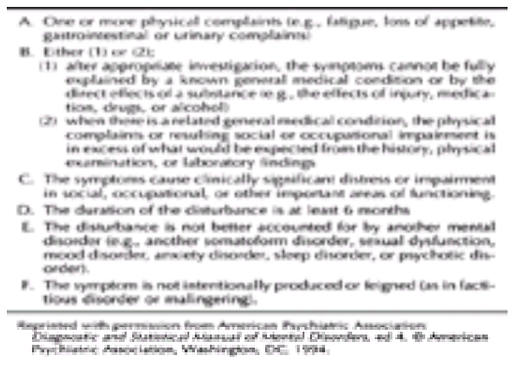
Epidemiology The importance of undifferentiated somatoform disorder comes from the fact that it may be 30 to 100 times more prevalent than full-blown somatization disorder. Undifferentiated somatoform disorder has an estimated lifetime prevalence in the general population of between 4 and 11 percent with an estimated 1 percent 6-month prevalence. Javier Escobar has described a group of patients with this disorder who have six unexplained symptoms for women and four for men; these patients have many of the same socioeconomic and clinical manifestations of somatization disorder.

Undifferentiated somatoform disorder typically affects women. It has also been shown in some reports to be associated with lower socioeconomic status, older age, and Hispanic or African-American origin. One study found a slight association with antisocial personality disorder; however, other studies have not confirmed this. One recent study reported these patients had higher warning salivary cortisol concentrations and higher heart rates under the stress of a mental task and less habituation than controls. Presumably, those with undifferentiated somatoform disorder are comorbid with at least one other lifetime psychiatric disorder, but this has not yet been firmly established.

Approximately 50 percent of patients with the disorder have comorbid psychiatric conditions (e.g., depression, anxiety, personality disorders) compared with 7 percent in the general population.

Etiology There are multiple theories about the process of somatization; none of which is specific to undifferentiated somatoform disorder.

Diagnosis and Clinical Features The DSM-IV diagnostic criteria are listed in Table 16-12. Patients with undifferentiated somatoform disorder have more comorbid psychiatric diseases than do general medical patients without the disorder. These comorbid conditions are primarily depressive disorders, anxiety disorders, and personality disorders.



A. One or more physical complaints (e.g., fatigue, loss of appetite, gastrointestinal or urinary complaints)
B. Either (1) or (2):
   (1) after appropriate investigation, the symptoms cannot be fully explained by a known general medical condition or by the direct effects of a substance (e.g., the effects of injury, medication, drugs, or alcohol)
   (2) when there is a related general medical condition, the physical complaints or resulting social or occupational impairment is in excess of what would be expected from the history, physical examination, or laboratory findings
C. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The duration of the disturbance is at least 6 months
E. The disturbance is not better accounted for by another mental disorder (e.g., another somatoform disorder, sexual dysfunction, mood disorder, anxiety disorder, sleep disorder, or psychotic disorder).
F. The symptom is not intentionally produced or feigned (as in factitious disorder or malingering).

Table 16-12 DSM-IV Diagnostic Criteria for Undifferentiated Somatoform Disorder

Many patients with this disorder have illnesses that wax and wane but continue to play a persistent role in their lives. In a study of 46 patients with chest pain, those without coronary artery disease had a higher rate of anxiety disorders than those with coronary artery disease. Eleven years later, those with chest pain but without coronary artery disease were found to have led lives of disability and chronic distress. They had had repeated interruptions in their lives associated with functional symptoms. Those in the study with chest pain without coronary disease also had higher research scale ratings for depression and anxiety and reported more physical symptoms.

Pathology and Laboratory Examination There are no specific pathological or routine laboratory features for undifferentiated somatoform disorder.

Differential Diagnosis In the differential diagnosis of undifferentiated somatoform disorder care must be taken to differentiate somatic symptoms that could be a part of many other psychiatric disorders. For example, somatic symptoms frequently occur in major depressive disorder. Similarly, the somatic delusion of schizophrenia and major depressive disorder also needs to be differentiated from undifferentiated somatoform disorder.

Several other psychiatric disorders need to be differentiated from undifferentiated somatoform disorder. Somatization disorder is a more severe disorder characterized by a chronic history of multiple unexplained somatic complaints that fit a specific pattern and begin before the age of 30. Adjustment disorder with physical symptoms may also evidence unexplained somatic complaints; however, the duration of this disorder is by definition less than 6 months. Finally, the diagnosis of psychological factors affecting medical condition may at first appear similar; however, the disorder affects a known Axis III disorder rather than mimicking an Axis I disorder.

Course and Prognosis The course of undifferentiated somatoform disorder is generally chronic and relapsing; however, little systematic research on the disorder has been accomplished to date. It is likely that some cases of the disorder can resolve after a single episode. There is substantial disability, work impairment, and excessive health care utilization in undifferentiated somatoform disorder. The dysfunction is not seen to the same extent as in somatization disorder. Extensive comorbidity has been shown for somatization disorder with depressive, anxiety, and personality disorders. With the less restrictive criteria for undifferentiated somatoform disorder, there is also considerable comorbidity, although the rates are not quite as high.

Treatment Recent studies have indicated that patients with undifferentiated somatoform disorder respond to the same treatment or management approach as patients with somatization disorder.

One recent study indicates that somatizing syndrome patients of physicians who received a simple psychiatric consultation letter explaining management principles of intervention were able to lower the annual medical care charges of these patients by $289 (in constant 1990 dollars), which equals a 32.9 percent reduction in the annual median cost of their medical care. In addition, these atients experienced clinically significantly improved physical functioning after the intervention.

HYPOCHONDRIASIS

Definition Hypochondriasis is a disorder characterized by preoccupation with the fear of developing a serious disease or the belief that one has a serious disease. The fear is based on the patient's interpretation of physical signs or sensations as evidence of disease even though the physician's physical examination does not support the diagnosis of any physical disorder. The unwarranted fear of or belief in a diseased state persists in spite of medical reassurance. However, the belief does not have the certainty of delusional intensity.

History The concept of hypochondriasis has been a part of medical lore since ancient times. Prior to the early nineteenth century the area of the body below the rib cage, the abdomen, was called the hypochondrium. Thus, hypochondriasis referred to somatic complaints occurring in the abdomen. In the late 1920s, R.D. Gillespie provided the first modern description of the disorder.

Comparative Nosology Hypochondriacal symptoms can be a part of another disorder such as major depressive disorder, dysthymic disorders, generalized anxiety

disorder, or adjustment disorder. However, primary hypochondriasis or hypochondriacal disorder is a chronic and somewhat disabling disorder with hypochondriacal symptoms, not merely a part of another psychiatric condition.

Hypochondriasis was included as a diagnostic entity in DSM-I. The diagnostic criteria continued to be revised in DSM-II, DSM-III, and DSM-III-R; however, the changes have been primarily linguistic, not substantive. The only change between DSM-III-R and DSM-IV is the addition of a specifier to note that the patient has poor insight during the current episode. The ICD-10 criteria for hypochondriasis are essentially the same as those of DSM-IV.

Epidemiology Hypochondriasis is rather common in primary care settings. In various settings, the prevalence has varied from 3 to 14 percent. Recent work indicates that in a 6-month period of observation, 4 to 6 percent of the general medical population meet the specific criteria for this disorder. The prevalence in either sex is comparable to that within the general medical population. There are no specific tendencies for overrepresentation based on social position, education, marital status, or other sociodemographic descriptors. There is a wide range of ages at onset. Although the disorder can begin at any age, onset is thought to be most common between 20 and 30 years of age. A preliminary family study of 19 cases and their 72 first-degree relatives demonstrated no increase in the rate of hypochondriasis among their relatives compared with a control group.

Comorbidity with other psychiatric disorders is common with hypochondriasis, and must be treated accordingly. As an example, when case-matched controls and 42 hypochondriasis patients from a medical clinic were evaluated psychiatrically, the hypochondriasis patients had twice as many lifetime Axis I disorders and three times the number of personality disorders. Of the hypochondriasis patients in the study, 88 percent had one or more additional Axis I disorders, the overlap being greatest with depressive and anxiety disorders. Depression only accounts for a minor part of the total picture in hypochondriasis, so it is a mistake to think that all hypochondriasis is the result of some other Axis I disorder.

Etiology There are four major etiological theories concerning hypochondriasis: (1) amplification of normal bodily sensations; (2) psychodynamic formulations; (3) social learning concepts; and (4) syndromic variant of some other psychiatric condition, such as a mood or an anxiety disorder.

Amplification The amplification hypothesis posits that hypochondriasis results from the augmentation of normal bodily sensations. Of the four hypotheses it has the most research interest: hypochondriacal patients might amplify their normal somatic sensations and then attribute them to some sort of pathological condition. For instance, a change in a patient's perception of peristalsis might be interpreted as abnormal, hence representing disease. However, studies of hypochondriacal patients' awareness of their own normal heart-beat now shows that they are no more accurate than are a comparison group of nonhypochondriacal patients. Moreover, in a test of tactile sensitivity, patients with hypochondriasis did not have a greater ability to discriminate on two-point touch. Yet hypochondriacal patients consider themselves to be more sensitive to benign bodily sensations and certainly report more functional somatic symptoms. When hypochondriacal patients develop clinical arrhythmias, they are not more sensitive to or more accurately aware of subtle changes in cardiac activity than nonhypochondriacal patients. A hypochondriacal patient's behavior would seem to indicate a response bias toward reporting somatic and physiological distress with an attributional tendency to invoke somatic pathology.

Psychodynamic Factors A variety of hypotheses purport that intrapsychological factors are responsible for hypochondriasis. These factors run the gamut from Freud's early theories about disturbed object relations and intense preoccupation with the self to the concept of hypochondriasis as ego defense mechanisms against guilt.

Other theorists advocate that in hypochondriasis aggressive and hostile wishes toward others are transferred into physical complaints via repression or displacement. The frustration or anger that these patients often express can be theorized to be caused by past losses, rejections, or disappointments. Sometimes these patients express anger by first soliciting and then rejecting the help and concern of others. Alternatively, hypochondriasis may be viewed as a defense against guilt, a result of low self-esteem, or a sign of excessive self-concern. Pain and somatic suffering then symbolically become a means of atonement or can be experienced as deserved punishment for past real or imagined wrongdoing.

Learning Theory Learning theory postulates that psychosocial learning has a strong etiological component in hypochondriacal disorder. The concept contends that a patient learns the sick role and that role is sufficiently reinforced through either social contact or some need gratification. Interestingly, when compared to case-matched controls, patients with hypochondriasis believe that to be in good health means to be relatively symptom free, and they consider the presence of symptoms as indicative of sickness. Hence, personal theories of attribution, when coupled to a catastrophizing cognitive style, may be relevant to the focus on illness. The sick role then becomes a means of receiving caretaking from others.

Variants The variant theory holds that hypochondriasis is a modification of some other psychiatric disorder, such as depressive disorders, anxiety disorders, and certain personality disorders, such as obsessive-compulsive personality disorder. Although some scholars have maintained that hypochondriasis is a variant of a depressive condition, current research has not supported this hypothesis. Some theorists believe that hypochondriasis is a variant of an anxiety disorder, such as obsessive-compulsive disorder or a panic disorder, but the research data on this is not yet compelling.

Diagnosis and Clinical Features Table 16-13 lists DSM-IV criteria for the diagnosis of hypochondriasis. The developmental background of hypochondriacal patients is of interest in that significantly more of these patients than matched controls report traumatic sexual contacts, physical violence, and major parental upheaval before the age of 17. Significantly more hypochondriacal patients also report being sick as children and missing school time for health reasons; thus, they recall more childhood trauma and illnesses even though they are not currently more medically sick.

A. Preoccupation with fears of having, or the idea that one has, a serious disease based on the person's misinterpretation of bodily symptoms.
B. The preoccupation persists despite appropriate medical evaluation and reassurance.
C. The belief in criterion A is not of delusional intensity (as in delusional disorder, somatic type) and is not restricted to a circumscribed concern about appearance (as in body dysmorphic disorder).
D. The preoccupation causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
E. The duration of the disturbance is at least 6 months.
F. The preoccupation is not better accounted for by generalized anxiety disorder, obsessive-compulsive disorder, panic disorder, a major depressive episode, separation anxiety, or another somatoform disorder.

Specify if:
With poor insight: if, for most of the time during the current episode, the person does not recognize that the concern about having a serious illness is excessive or unreasonable

Table 16-13 DSM-IV Diagnostic Criteria for Hypochondriasis

Patients typically present for the first time with the complaint of a symptom, pain, or sensation. With some gentle questioning they quickly move from concern about the symptom to fear of a disease. Almost uniformly these patients are not concerned transiently about a minor disease, but rather are persistently worried about a serious disease. The specific disease may change from over time. The duration of an episode of a feared disease may run from months to years; alternatively, the feared disease may not change at all throughout the course of the disorder.

Pathology and Laboratory Examination At present there are no known pathological somatic features of the disorder nor are there known routine laboratory or electrophysiological tests that help to elucidate this disorder.

Differential Diagnoses Essential to the process of differential diagnoses is ruling out underlying organic disease. In the vast majority of cases this can be completed by the primary care physician without referral to a specialist. The workup is usually a straightforward process and typically focuses around the disease that the patient is concerned about.

Somatization disorder is the main somatoform disorder that needs to be differentiated from hypochondriasis. Although there are numerous differences between somatization disorder and hypochondriasis, the major distinction is that patients with somatization disorder are concerned about their symptoms, even dramatizing them, and are relatively indifferent to concerns about underlying disease. Patients with hypochondriasis have an exactly opposite preoccupation; they fear an

underlying disease and concern about symptoms quickly fades. Typically, hypochondriacal patients do not have the plethora of symptoms present in somatization disorder patients. Hypochondriasis needs to be distinguished from factitious disorder with predominantly physical signs and symptoms and from malingering. In hypochondriasis, patients actually experience the symptoms they report rather than simulating them.

Patients with psychotic disorders, particularly major depressive disorder and schizophrenia, may have somatic delusions or concerns about the presence of a disease. Hypochondriacal concerns secondary to major psychiatric disorders are categorized with the more serious disorders. Candidate conditions include major depressive disorder, dysthymic disorder, generalized anxiety disorder, obsessive-compulsive disorder, and panic disorder.

Course and Prognosis Hypochondriasis is a chronic, relapsing condition with waxing and waning symptoms. The disorder is usually longstanding, frequently over several years. Episodes typically last months and even a few years. There are often quiescent periods between episodes; however, frequently there are recurrences during times of psychosocial distress.

Symptom severity of the disease is such that some degree of psychosocial impairment occurs. Typically, familial and spousal relationships become strained by living with a patient who persistently fears disease. The individuals ability to work may or may not be affected.

Historically hypochondriasis has been given a pessimistic prognosis; however, that reputation may be exaggerated. Some authors now state that approximately 50 percent of patients show improvement; the remainder show a chronic, fluctuating course. A recent case-matched study to examine diagnostic stability and outcome of 50 cases meeting DSM-III-R criteria indicated that after 1 year two thirds of the subjects continued to meet criteria for hypochondriasis and the remaining one third had persisting hypochondriacal symptoms. The hypochondriacal subjects were improved on most measures. However, severe symptoms, longer duration of illness, and coexisting psychiatric illness were predictive of a worse outcome. In a 2-year follow-up study of 24 patients with transient hypochondriacal symptoms that did not meet DSM-III-R criteria for hypochondriasis, these patients continued to have their hypochondriacal symptoms with only one patient going on to meet full DSM-III-R criteria of the full-blown disorder. These patients continued to magnify the importance of their physical symptoms, had more functional disability, and utilized more medical care than case-matched controls. Thus, recent research has validated the clinical view that the diagnosis of hypochondriasis appears to be stable over time, with symptoms waxing and waning. Hypochondriasis carries a very substantial, long-term burden of morbidity, functional impairment, and personal distress.

The following characteristics, which bode well for a patient's general health status, bode well for patients with hypochondriasis as well: a high socioeconomic status; the presence of other treatable conditions, such as an anxiety or depressive disorder; a sudden onset; an absence of a personality disorder; and the absence of comorbid medical disease.

Treatment To date there are no controlled clinical trials on which to base rational treatment, therefore inferences have to be made from the treatment of other disorders and from clinical lore used in treating hypochondriasis. The simplest treatment approach is to look for and treat any comorbid psychiatric conditions, such as obsessive-compulsive disorder, panic disorder, and depressive disorder. When these conditions are treated pharmacologically and with appropriate therapy, the hypochondriasis often will improve.

A recent open trial of high dosages of fluoxetine (Prozac) on hypochondriasis patients not meeting criteria for comorbid depressive disorders showed much promise, with 10 of 16 patients much improved at the end of a 12-week trial. Several other trials with selective serotonin reuptake inhibitors (SSRIs) with primary hypochondriasis have also shown some positive results. Previously this group of patients had been regarded as refractory to all psychopharmacological treatment.

The management of hypochondriasis has typically been in the domain of the primary care physician. At least initially, these patients strongly resist psychiatric referral. Their mental model of the problem is that they have a covert physical illness and so they do not believe they need to see a psychiatrist. Secondly, psychiatry's track record using traditional psychotherapies for these patients has been rather dismal. Psychoanalytic treatment and sometimes even psychodynamically oriented therapy of patients with full-blown primary hypochondriasis have been unsuccessful in removing symptoms and improving the function of these patients. One pragmatic approach that has heuristic merit is the use of paradoxical intention, telling the patient that you recognize the suffering but that you are not certain that you can help very much. When little is expected, sometimes small gains are appreciated and there is some improvement.

Another approach that may possess merit is group treatment. A cognitive-educational group treatment has recently been proposed that at face value appears to have validity, especially given the success demonstrated by a similar approach in patients with somatization disorder. Currently several trials of cognitive-behavioral treatment, both in groups and individually, are ongoing.

Hypochondriasis patients usually accept referral for treatment of a comorbid psychiatric condition, and such conditions are not rare for them. Finally, management suggestions that have been shown to be effective in somatization disorder should be tried in patients with hypochondriasis.

PAIN DISORDER

Definition With their expertise in the use of psychoactive medication plus their interest in the personal and family dynamics of patients, psychiatrists have the capacity to be involved in the treatment of patients with chronic pain. Astute clinicians have long known that some patients use their pain as a way of seeking human relationships; the secondary gain they receive from their infirmity then can be reinforced, maintaining the pain.

Co-occurring psychiatric disorders are not rare when pain is severe. It is always gratifying when a pain syndrome dissipates as an accompanying psychiatric disorder is treated, both receding together. However, the clinical question remains: was pain the cause of a coexisting psychiatric disorder or was pain the consequence of another psychiatric syndrome? One study found that in 89 percent of one clinic's patients who had both depression and pain, there was no antecedent history of depressions. This data would be consistent with the hypothesis that pain often causes depression rather than vice versa.

Pain is a highly subjective matter and is extremely difficult to quantify. For example, it has always been difficult to specify just how much chronic pain ought to be associated with a given lesion. Assessing the degree to which emotional factors are intensifying the patients' complaints is also complicated. Moreover, patients with chronic pain are not always immediately motivated to give an intricate personal and family history because they fail to see its relevance to their pain.

There is no accepted objective way to measure pain, and a variety of different measures of pain intensity and severity are currently used in the field, which makes it difficult to compare different clinical studies. Finally, many studies in the pain literature have demonstrated considerable differences in study populations, with different personalities and different cultures experiencing and expressing themselves in divergent fashions.

Wilder Penfield's clinical wisdom about patients with chronic pain has now become rather widely accepted in the field: if the patient is not a malingerer, the complaints about the extent of the pain are to be believed. The issues that need to be explored clinically are: (1) how disabled by the pain is the patient and (2) to what extent are there complicating emotional factors and comorbid psychiatric conditions. The physician attendant to the suffering of a patient with chronic pain needs to render a diagnosis that communicates important underlying aspects of the case and leads to a treatment plan that encompasses the patient's emotional needs.

Comparative Nosology There have been a variety of informal and formal diagnostic terms associated with pain. For example, the euphemistic term *atypical* has been used, as in *atypical facial pain*, or *atypical pelvic pain*, to indicate that psychiatric issues needed to be considered in the cause or the maintenance of the severe pain syndrome. ICD-9 used the term *psychalgia* and DSM-III incorporated the term *psychogenic pain.*

Previous terms such as *chronic pain syndrome, psychogenic pain*, and DSM-III-R's *somatoform pain disorder* were used as psychiatric diagnoses for patients in pain wherein psychological factors have played a pronounced role. DSM-III-R required preoccupation with pain for at least 6 months and either no organic pathology or no pathophysiological mechanism found after appropriate evaluation; if organic pathology is present, the extent of the complaints about the pain or the degree of social-occupational disability should be greater than could be expected by the examiner based on the physical findings.

Applying the diagnostic terminology of DSM-III and DSM-III-R, however, has proved difficult. Even when diagnostic criteria required only no organic pathology or impairment in excess of what would be expected, precise application of criteria was problematic. Judging whether the amount of a patient's subjective pain is excessive became a daunting task and lacked validity and reliability studies. Furthermore, these diagnoses failed to adequately describe persons who have a physical cause for pain but react to their pain in a dysfunctional manner.

DSM-IV provides a more focused approach, not relying on the extent of the pain as a criterion but asking the clinician to make a judgment as to whether psychological factors have a major role in the onset, severity, exacerbation, or maintenance of the pain, and as to whether or not there are factors from the general medical condition that also make a major contribution to the symptoms.

DSM-IV divides pain disorder into *acute* and *chronic* subsets. Another new feature of DSM-IV is that it splits pain disorders into three subtypes: pain disorder associated with psychological factors, pain disorder associated with both psychological factors and a general medical condition, and pain disorder associated with a general medical condition (which is not considered to be a mental disorder but is included to help in the differential diagnosis). Patients with chronic pain do not readily fall into dichotomous roups, those either with physical or with mental illness. According to one student of chronic pain, “Many patients have both; a few have neither.”

ICD-10 labels pain disorder as “persistent somatoform pain disorder.” ICD-10 does not subdivide pain into subtypes in which psychological factors play a major role along with a general medical condition and in which psychological factors are the determinant of pain. ICD-10 excludes backache not otherwise specified, tension headache, muscle tension, and migraine. Additionally, ICD-10 retains more of a DSM-III-R approach regarding emotional factors involved in the cause of the pain, indicating that “persistent somatoform pain occurs in association with emotional conflict or psychosocial problems that are sufficient to allow the conclusion that they are the main causative influences.” ICD-10 is inconsistent in that it does not specify, as DSM-IV does, that emotional factors can impinge on certain aspects of the pain condition (onset, severity, exacerbation, or maintenance). Finally, ICD-10 goes beyond DSM-IV's statement that “pain... is the predominant focus of clinical attention and is of sufficient severity to warrant clinical attention” when it describes the outcome of persistent somatoform pain disorder in this way: “Usually [there is] a marked increase in support and attention, either personal or medical.”

Epidemiology Pain of one sort or another is among the most frequent reasons that patients consult their physician. One study found that 13 percent of patients in a private internal medicine practice suffered from chronic pain. In one sample of health maintenance organizations, 8 percent of patients had severe persistent pain and 2.7 percent had severe persistent pain with at least 7 or more days of pain-related activity restriction in the past 6 months. Most pain is remediable, but chronic pain carries with it a high price: more than $10 billion was spent in 1980 in disability payments for chronic pain problems. Recent data from numerous local and regional surveys leads to a yearly estimate of $60 billion as the annual cost to the nation from health care costs and loss of work from patients of chronic pain. Low back pain alone currently affects more than 7 million Americans. Another cost of pain disorders is suicide, with one report stating that the suicide rate among pain sufferers is 9 times that of the general population.

Because diagnostic criteria for the disorder have been changing (from DSM-III to DSM-III-R to DSM-IV), detailed investigations that pull together the databases are still lacking. Studies seem to indicate that there are twice as many women as men with pain disorder, with peak incidence in the fourth and fifth decades, especially in those in blue-collar jobs. There is also some tendency for familial aggregation, along with more depression and more chemical dependency use disorders in those families.

Comorbidity There is a high frequency of comorbid psychiatric diagnoses in most groups of chronic pain patients. One study reported that 56 percent of their sample of 283 chronic pain patients suffered from one of the depressive disorders and that alcohol or drug dependence occurred in 15 percent. Finally, 58 percent met criteria for a personality disorder (most frequently dependent, passive-aggressive, or histrionic). Since these studies of personality disorder are retrospective, it remains unclear whether the pain itself has caused the patient's personality traits to become a personality disorder, or whether having a personality disorder predisposes one to developing a pain disorder.

Etiology Pain comes from many sources, but the peripheral afferent nerves, central nervous system processing, and central nervous system interpretation of the localization and the severity of the pain are almost always involved. In some cases of pain disorder of the psychological or the combined type, a purely neurosurgical approach (eliminating a painful lesion and its connectivity) can successively chop away at parts of a person's peripheral and central nervous system until the cortex is no longer in contact with the relevant nerves or with the involved spinal cord from an afflicted area. In some cases the pain can still continue.

No adult registers an experience on a tabula rasa; rather, persons all encounter life happenings in a context of (1) personal training based on critical developmental incidents; (2) family-centered culture transmitted early in life; and (3) societal values about appropriate behaviors, including the expression of feelings. These past experiences all interact with a person's constitutional hardwiring, including preprogrammed response modes.

Chronic pain syndromes are among the most frustrating conditions in all of medicine for patients and physicians. To even have a chance at being successful in dealing with patients in pain clinicians need to be able to appreciate the patient in a biopsychosocial context. Successful academic pain clinics have discovered the necessity of a multidisciplinary approach. Indeed, physicians caring for such a patient need to do more than just take a detailed history; they also need to understand the patient's life from the patient's as well as the family's perspective.

For reasons they may or may not be aware of, some individuals magnify a given pain; others pay little attention to it, diminishing their response to a lesion that might otherwise cause great discomfort. Pain thresholds, which can be clinically measured, vary from person to person. Pain tolerance, likewise, has considerable latitude. Moreover, there is a broad range of ways in which individuals express their discomfort or even their agony. Some with a broken ankle will be stoic; others with the same fracture will scream out in agony, facies pinched, arms flailing.

Although there are conditions in which persons do not have pain fibers (familial dysautonomia), this is so rare that they are not a factor in everyday practice. It is easier to divide the discussion of issues in pain into four categories: intrapersonal factors, interpersonal factors, ethnic factors, and biological factors.

Intrapersonal Factors Intrapersonal factors can impact how pain is experienced. Psychodynamically formative events in the early years can carry over later into how one processes illness and other types of distress. One psychodynamically oriented theory is that having pain and expressing distress attracts others to deliver needed attention. In later years the experience of pain can be associated with obtaining love from an otherwise absent significant caregiver.

Another psychodynamically oriented theory holds that painful experiences, such as repeated severe corporal punishment from an abusive parent, can set the stage many years later for the person's response to a wrongful piece of behavior with self-imposed retribution. In this way a pain disorder may be used to pay for some self-perceived sin or transgression. However, simple interpretation (illuminating the repressed, suppressed, or even grudgingly embellished facts) rarely serves to remove the pain dramatically.

Recent research data suggests that pain patients have a background of past sexual abuse or trauma and the resultant posttraumatic stress disorder. Some patients can be vaguely or poignantly aware of the associations between past life events and being pain prone or even being overresponsive to a painful experience. For other pain patients, the associated early-life experiences of pain are deeply buried and emerge only through a lengthy process of free association, dream work, or psychological testing.

Not every one with severe pain and unusual pain behavior has had dysfunctional early-life experiences that caused a psychopathological organization of the character structure. However, astute clinicians are always alert to the possibility that there may be important masochistic, dependent, or narcissistic features to the personality, or traumatic life experiences that impact how a given patient handles pain.

No one psychological test can accurately delineate the extent of the psychological component in a pain syndrome. Any painful chronic disease highlights and even changes certain components of personality. Psychological testing and patient interviews can yield clear evidence that some patients with considerable emotional overlay to their pain are at least initially resistant to suggestions that their pain symptoms are caused by anything other than physical factors.

Finally, it is likely that intense pain affects attitudes and emotions, and that attitudes and emotions influence the reported perceptions of pain intensity.

Interpersonal Factors Interpersonal factors may also impact on the pain experience and behaviors can be reinforced or inhibited. For example, reinforcements given by others important to the pain-afflicted person can play a major role in day-to-day and even second-to-second experiences. Lavishing attention on an individual when chronic pain intensifies creates a different inner and outer world for the patient than when the pain is either ignored or treated with additional painful experiences.

Some persons use their pain to manipulate others. Clinicians often observe this when there is a chaotic and otherwise inattentive family or in the case of a dysfunctional marriage that becomes reorganized around the continued crisis of chronic pain. Surprisingly, in some persons the persistence of pain is far less

important than what it is traded for: a relationship that is far more to the patient's liking.

The consequences of pain are often gain. Secondary gains, such as monetary rewards or avoidance of distasteful activities, are not an unusual consequence of having prolonged pain. It is only when interpersonal and other rewards are stripped away from the pain experience and its attendant disability that the individual with pain can develop a more normal life.

Like a somatization disorder, a pain disorder can become a way of life that alters the behavior of other people. The caring physician must always be aware of interpersonal factors. Family, financial, and legal dynamics of a situation can have a dramatic influence on the patient's pain experience and pain behavior.

In one study, male patients with chronic pain who received financial compensation following injury at work showed a particularly high rate of personality disorder (83 percent) which supports a contention in the literature that patients with “compensation neurosis” were frequently passive-aggressive, hostile, and inadequate.

Ethnic or Cultural Factors Quantitative and qualitative research projects of chronic pain sufferers in New England and Puerto Rico by the same investigators reinforce what astute clinicians have known all along—that similar lesions in patients from different backgrounds can produce profound variations in pain experience and pain intensity. The style of the typical taciturn “old Mainer” is quite different from the emotionally labile and highly expressive native Puerto Rican. Despite higher pain intensity and more emotional responses among Puerto Ricans, there was no significant difference between the two groups regarding interference in daily activities. Attitudes, beliefs, and emotional and psychological states can differ according to ethnic group affiliation. Moreover, the individual's psychological coping style and internal or external locus-of-control style, which are important determinants of how an individual handles the pain, are to a considerable extent culturally determined.

Biological Factors Biological factors also play a large role in the onset and perpetuation of chronic pain. Cortical and subcortical centers process and filter afferent impulses. Sensory and limbic structural abnormalities can determine the severity of a pain experience. Neural pathways serving pain are not “hard wired,” but demonstrate considerable plasticity in response to injury. After an injury, changes occur in the sensitivity of the pain receptors themselves and also in the excitability of neurons in the dorsal horn of the spinal cord. Thus symptoms of chronic pain following injury may have a physiological basis in changes in the brain, spinal cord, and peripheral nerves.

Neurological changes resulting from recalibration of pain thresholds may be the result not of gross external injuries but rather of nonobvious injury resulting from mechanical stresses such as increased muscle tension (associated with anxiety or depression), and mechanical stresses of the lumbar spine. Additionally, there could be an associated muscular ischemia with the release of pain-producing substances such as substance P and histamine that alter the pain threshold.

The gate control theory purports that a gating mechanism in the dorsal horn of the spinal cord handles afferent pain signals; competing signals as well as neurotransmitters then can open or close the gate on painful perceptions. Endorphin deficiency seems to correlate with the augmentation of afferent stimuli. Serotonin, presumably relatively diminished in some forms of depression, has now been implicated as the main neurotransmitter in descending inhibitory pathways. Such mechanistic studies still remain preliminary but offer interesting explanations into a patient's plight when pain is burdensome but organic lesions do not appear major.

Thus, the underlying psychodynamic and neurobiological framework can impact on the complex ways a given person experiences and re-experiences pain. Pathophysiology and psychopathology may well be reciprocally linked in self-perpetuating cycles.

Diagnosis and Clinical Features Pain disorder as a psychiatric condition is diagnosed when a patient's preoccupation with pain is consuming and to some extent disabling. That is, pain becomes the predominant focus of the clinical presentation and the pain itself causes clinically significant distress or impairment and the patient's life becomes organized around the pain; also, psychological factors are judged to play a role in this disorder. Table 16-14 lists the diagnostic criteria for pain disorder.

Table 16-14 DSM-IV Diagnostic Criteria for Pain Disorder

Pain disorder patients make repeated visits to physicians, often successively or even concomitantly and doctor “shopping” is very common. There is a risk of excessive use of narcotic or sedative hypnotic agents because the patient is enveloped by pain and often has associated complaints of anxiety, depression, and insomnia. Thus, any related comorbid psychiatric conditions must also be treated to alleviate the patient's pain.

The major feature of pain disorder is an all-encompassing focus on the pain such that any other concern takes on less than its ordinary significance. The pain is believed by the patient to be the source for all the patient's misery.

If the patient is depressed, anxious, or has insomnia, those symptoms are almost always considered by the patient to be secondary to the pain. Other frequent ancillary symptoms include changes in appetite, loss of energy, decreased interest in social activities, decline in sexual interest, diminished physical exercise, and even diminished exertion. Also often noted are a change in normal recreational pursuits, a breakdown in family relationships, an increased amount of time spent in bed or lying down, an increased amount of self-absorption (including hypochondriasis), and multiple drug use or abuse. Frequent visits to physicians and requests for medical or even surgical approaches to obtain pain relief are commonplace.

One of the possible predisposing factors for handling pain poorly is childhood sexual abuse, for example, in patients with chronic pelvic pain. Another predisposing factor is pending litigation, as in the case of whiplash injury. Here the personal meaning of a symptom can mitigate or increase the pain's intensity and the severity of the incapacitation.

By contrast, sometimes refractory pain with a presumed strong psychogenic component turns out to be a treatable neurological or orthopedic condition that has been missed by the referring clinician. In one report from a multidisciplinary pain clinic keeping tally on these matters for 120 patients with chronic pain, the overall rate of inaccurate or incomplete diagnosis at referral was 40 percent. Commonly missed diagnoses were myofascial disease, facet disease, peripheral nerve entrapment, temperomandibular joint disease, thoracic outlet syndrome, and herniated discs. After comprehensive workup, an organic origin for the pain was found in 98 percent of these patients.

Sites of Pain Typical sites and types of pain involved in pain disorder are headache, atypical facial pain, low back pain, and chronic pelvic pain; however, any site is a potential target. Pain can emanate from almost any point source in the body or it can be a conversion symptom involving just pain, using a previous pain pattern from organic disease as a conversion pain model. If the pain is used as a metaphor for psychic turmoil converted into a somatic form, it may bring to the afflicted person primary and secondary gains that reinforce the initiation, maintenance, and even exacerbation of pain symptoms for psychological purposes. When pain is a conversion, its distribution may not conform to known anatomical patterns. From a diagnostic perspective, pain cannot be diagnosed as a conversion disorder according to DSM-IV.

Mr. L., a 72-year-old married, Ukrainian-born, pious, wealthy retailer and father of a large family from an east coast city was admitted to the orthopedic service of a general hospital for evaluation of unbearable pain in the arches of his feet. He had fled his native country following a pogrom when he was 9. During the year of flight he had endured enormous physical hardships, starvation, and beatings until the surviving family members finally were able to emigrate to the United States. With incessant hard work, he had prospered economically; married a patient, supportive wife; and witnessed his six children develop promising careers. He became the major contributor to his temple and gave unstintingly to local charities for the needy and unfortunate. He had little time for personal enjoyment. Over the years each time he and his wife had time alone together and she had been affectionate with him, he would develop some excruciating bodily pain shortly thereafter: blinding headache, severe back spasm, abdominal pain, facial pain, or pelvic pain. These pains usually receded several days after the weekend was over or the trip was completed. Some pains occurred more frequently than others. He sought medical attention rarely except for these pains, which occurred every few months. His mood varied from glum to gloomy but he denied that he was depressed. He often claimed to have been blessed with good fortune. He led a temperate life, drank little, and had relatively good health between these episodes of pain.

Over the four decades that his physicians cared for him, they had become frustrated with this unassuming and humble man; his ardent complaints of pain were always so nonspecific and fluctuating in nature that they could not describe adequately for themselves any pathophysiological mechanisms to account for his pain. Their diagnostic tests were not revealing and Mr. L. usually refused their offers of narcotic or other analgesic relief. Laboratory workup for pains in the arches was noncontributory, and he was discharged when his symptoms cleared in 3 days. Four months later he was readmitted to the surgical service of the general hospital with severe, unrelenting, left-side upper abdominal pain. This time Mr. L. described this new pain in meticulous detail. A brief workup revealed very advanced carcinoma of the tail of the pancreas. He took the news from his physician stoically and asked to be discharged home that day.

Differential Diagnosis All pain is subjective and only obvious if the patient tells the physician about it. Acute pain tends to distort the facies in a grimace, causing muscle tightening and elevation of autonomic measures, such as pulse and blood pressure. Chronic pain, however, produces none of these signs. Clinicians trying to explore the extent of psychiatric involvement have used a number of clues, the validity of which still remains to be proved (Table 16-15). Those are the underlying dynamics and the presence or absence of conflicts and stressors are open to multiple interpretations; only careful long-term follow-up studies of large series of patients will help increase validity.

Antecedent history of poor premorbid adjustment: alcohol or drug abuse, sexual difficulties, multiple marriage, inability to hold a job
Temporal relationship between an environmental stimulus, relevant intrapsychic conflict, and pain
Utility of pain in either gaining compensation or avoiding situation deemed noxious by the patient
Lack of variation in the amount of pain from distraction, suggestion, or fear

Table 16-15 Clues to Underlying Psychopathology in Pain Disorder

Patients deal with their chronic illnesses in ways characteristic of their dynamics and their own psychopathology. Those with a histrionic nature exaggerate; those who use a history of ill luck to manipulate their environment make the most of their pain for their own ends; those with a need for punishment for real or imagined sins may fulfill their needs for atonement.

Both acute and chronic pain tend to be very field dependent. For example, soldiers who have survived fierce fighting on the battlefield typically need far less morphine for relief than their civilian counterparts with the same degree of tissue injury. Absolute pronouncements about no somatic pathology or no emotional components to the clinical picture must be viewed with skepticism. A positive response to a trial of placebo medication does not indicate anything about the organic nature of the patient's pain or the extent of the underlying psychopathology. The placebo response is positive in about one third of whatever population is tested. Pain associated with both melancholia and metastases can respond to placebo. Patients and their clinical syndromes need to be treated without too much loss of time deliberating about whether the pain caused the depression or the depression caused the pain. Individuals with personality disorders and chronic pain tend to have a more difficult time coping with any type of difficulty, both in the hospital and at home, and they are a challenge to their physicians. Fortunately, intensive inpatient treatment of refractory chronic pain has had some success.

Depressive Disorder Of the psychiatric diseases, depression presents most often as a pain disorder. At times the individual will have had previous depressive episodes with an altogether different clinical presentation and with no associated pain. Sometimes the best clue to the presence of a mood disorder is just the family history of severe depression, with or without pain being part of the clinical picture. There is no specific type of pain picture to alert the clinician to the presence of depression. Moreover, the sadness accompanying the pain disorder can almost always be ascribed to the pain.

Supporting the diagnosis of a mood disorder are the vegetative signs of depressive disease, especially sleep and libidinal disturbances. Cognitive signs of an accompanying depression include apathy, decreased interest in work, suicidal ideation, and a preoccupation with death. Collaborative sources of information are often needed to fully understand the patient's level of functioning.

Sometimes the best way to make the diagnosis of depressive disorder in a patient presenting with pain is simply to initiate a treatment trial of an antidepressant medication in addition to nonspecific modalities. Dramatic clinical relief of both the pain and the vegetative signs of depression provides the answer to the clinical question. Suicide in chronic pain patients must always be kept in mind, especially during the first 10 days of treatment with an antidepressant when the patient begins to look better and has more energy; such a state often occurs before the feeling of despair has lifted.

Conversion Disorder When a conversion mechanism is involved in the pain disorder, the clinician determines that (1) details of the pain picture have a symbolic or other specific meaning for the patient; (2) there is a conversion model, often a parent or other close family member; and (3) the pain follows no known anatomical pathway. By convention, pain involving a conversion mechanism is diagnosed as a pain disorder, not as a conversion disorder.

Treatment for this is similar to the psychotherapy of a patient with a conversion disorder. In addition, the clinician will use the same nonspecific treatment meted out to many or all pain disorder patients: physiotherapy, water pool massage, infrared heat, nonsteroidal anti-inflammatory agents, and other such modalities.

Psychosis When a psychosis associated with schizophrenia, medical disorder, or a dementing illness presents with pain, the pain itself is delusional and the pain pattern is atypical in quality and in distribution. Treatment must relieve the underlying psychiatric disorder. Delusional beliefs, however, may prevent the patient from cooperating with the treatment plan.

Malingering When someone is purposely lying about pain, the pain is hard to detect. Such individuals are not interested in the same outcome as the physician, which is relief of pain. Sometimes old records betray that the patient has tried to malinger in other settings and in other ways. Unlike the patient with Munchausen syndrome (facticious disorder with predominantly physical signs and symptoms), who is interested in staying in the sick role, the malingerer is consciously interested in some other benefit. Some clinicians have found that Munchausen syndrome patients will willingly agree to painful procedures whereas the malingerer will not.

Emotional Overlay Determining the extent of the emotional component of chronic pain is helpful, and care plans could then be effected, along with appropriate expectations and appropriate treatment. The well-known MADISON scale (Table 16-16) has not been rigorously validated but has been of considerable help to those working in the field. Another instrument that has proven to be clinically valuable in assessing whether a patient has an organic lesion that potentially amenable to a corrective surgical approach is the Mensana Pain Test, a 10-minute structured medical interview.

M =	**Multiplicity:** Pain is either in more than one place or of more than one variety; when treated, may recur elsewhere.
A =	**Authenticity:** More interested in clinician's acceptance of pain as genuine than in a cure.
D =	**Denial:** Especially exaggerated marital or family harmony; when admitting depression or anxiety, no impact on pain is admitted.
I =	**Interpersonal relationship:** Although the connection to the presence of any particular person's company as worsening the pain may be denied, observation of the patient's nonverbal and interactive behavior indicates otherwise.
S =	**Singularity:** When the pain is described as unlike that of anyone else, ever.
O =	**"Only you":** When the patient immediately idealizes the physician as savior, despite numerous failures by other competent experts.
N =	**Nothing helps, or no change:** When there is no relief whatsoever from any type of intervention, although all are tried (including narcotics) and there is no hour-to-hour or day-to-day fluctuation under a variety of circumstances.

Tabby adapted from Hackett TP, Cassem NH: *Massachusetts General Handbook of General Hospital Psychiatry*., St. Louis, 1978.

Table 16-16 MADISON Scale for Markers of Considerable Emotional Overlay

Course and Prognosis Once diagnosis is complete, treatment on an outpatient basis can be carried out by concerned physicians who will see the patient on a regular basis, be interested in the patient's complaints, and assure the patient that treatment will continue if there is some improvement. Pain disorder patients with pending litigation often attain no, or only minimal, relief until after the legal proceedings are finished.

Pain-Prone Individuals Persons who are painprone often experience pain in response to losses or other stresses, presumably as a way of dealing with unresolved guilt. Outcomes from treating the pain-prone are typically described as transient or poor. Techniques that are most promising are supportive therapy, a modicum of insight, and, when indicated, antidepressant medication.

Treatment Many patients, especially those with depression, can be considerably helped. The key to dealing with the pain disorder patient is accurate diagnosis and focus on the patient's level of functioning. The role of the family in the pain patient's life must be determined and efforts must be made to intervene in the dysfunctional components of family life. The patient's pain and predicament are always acknowledged at each visit, but the major focus is in moving on and regaining function. Pain clinics and inpatient pain treatment units both have had their share of success.

Treatment of the patient with any of the pain disorder subtypes needs to be multidisciplinary and multidimensional. Controlled trials seem to indicate that group therapy with antidepressant medication seems to have an advantage over individual therapy with antidepressant agents.

Treatment programs need to be culturally sensitive in terms of intake procedures and treatment planning. Treatment teams need to be aware of the potential effect of ethnic background on the communication, concerns, and coping styles related to the chronic pain experience of these patients.

Treatment team planning is important from the onset, coordinated as needed on a periodic basis. Multiple regimens often help in reducing pain intensity. Tailored to the patient, options include nonsteroidal anti-inflammatory agents, tricyclic medications, selective serotonin reuptake inhibitors, nerve blocks, localized electrical stimulation, visual imaging, relaxation, physical therapy, hypnosis, counseling, cognitive behavioral therapy, and supportive psychotherapy. Currently the choice of which form of psychotherapy to use is based on empiric grounds and personal preference because no case-matched studies have yet been performed. Research data is clear, however, that success in treatment result in a decrease in the patient's catastrophizing and an increase in the patient's perceived control over the pain.

If opioids have been used for chronic refractory pain, they should be tapered and discontinued because obviously they were not helping and may have been interfering with the patient's progress. Abuse of anti-anxiety medications may also be present in patients with chronic pain and must be dealt with. Antidepressant medications often play an important role in decreasing pain, even in the absence of a frank depressive syndrome. The possibility of a chronic sleep disorder must be investigated and appropriately treated, if present.

Price of Chronic Pain The clinician needs to be aware that any type of chronic pain can alter the patient's personality and family dynamics. Pain can also alter the way the patient relates to the environment and perhaps also the patient's internal locus of control style. At the onset of treatment the clinician needs to set guidelines for continuing and discontinuing treatment. No improvement in any way after 6 months is grounds for termination of treatment. If improvement is shown, the patient will need continued support. Often the patient's objective improvement far exceeds the subjective improvement.

BODY DYSMORPHIC DISORDER

Definition Body dysmorphic disorder focuses on the patient's feelings of dislike or even loathing for some aspect of the body's appearance. Despite the starkness of the complaint, few empirical data about the condition have been gathered although clinical investigations into this disorder are greatly increasing.

Patients with body dysmorphic disorder have a pervasive subjective feeling of ugliness of some aspect of their appearance despite a normal or nearly normal appearance. The core of the disorder is the person's strong belief or fear that he or she is unattractive or even repulsive. This fear is rarely assuaged by reassurance or compliments even though the typical patient with the disorder is quite normal in appearance. Although a minority of patients with the disorder do have a minor defect, the patient's concern is disproportionate to the degree of defect. So great is the individual's preoccupation that there is significant impairment in social or occupational functioning, or there is marked personal distress. All other problems are illogically attributed to the perceived cosmetic defect, accompanied by the unrealistic expectation that surgery will correct the defect and the patient's deficient life. Finally, the preoccupation is not better accounted for by any other mental disorder.

History Body dysmorphic disorder has been described in the European, Japanese, and Russian psychiatric literature for almost a century with various names. Emil Kraepelin considered it to be a compulsive neurosis. Pierre Janet called it an obsession of shame of the body, and Freud's famous Wolf-Man case was obsessively concerned about the size of his nose. In the United States this disorder was initially classified as an atypical somatoform disorder, labeled first as *dysmorphophobia*; however, until the late 1980s it has been little used and little studied in the United States.

Comparative Nosology In the United States body dysmorphic disorder first appeared in DSM-III with the term “dysmorphophobia” in the residual category of atypical somatoform disorder. Because dysmorphophobia inaccurately implied the presence of a behavioral pattern of prominent avoidance of the body, the term “body dysmorphic disorder” was introduced in DSM-III-R as a nondelusional somatoform disorder of undue preoccupation with imagined defects of appearance. Clinicians have wrestled over whether a patient's strong conviction about a feature of appearance was or was not of delusional intensity (i.e., whether the patient had a somatoform disorder or a delusional disorder with somatoform features). DSM-IV resolves that issue by not requiring that the conviction be defined in intensity as a criteria for inclusion. Delusional body dysmorphic disorder can be double coded as both a delusional disorder and as body dysmorphic disorder—a compromise that underscores the uncertainty about whether they are the same or different disorders. The delusional form of the illness may be a more severe type of the disorder. It was first incorporated into ICD-9 with the somatoform disorders and is grouped with them in ICD-10.

Epidemiology Accurate prevalence data for this disorder in the general population are not available. From the clinician's perspective, the full-blown syndrome is uncommon. Concern over appearance is culturally determined and dissatisfaction of a transient nature is particularly high in adolescents. However, to justify the diagnosis the individual must have clinically significant distress or impairment, which is not often found in teenagers.

The largest series to date, with 188 cases, had an equal balance of men and women. The average age of patients first diagnosed with body dysmorphic disorder is 30 years, and a high percentage have never married and are unemployed. Patients with the disorder first develop symptoms in adolescence or young adulthood. Typically they come from middle-class families and constitute a small, underrecognized and distinct group of patients in the general population. Only about 2 percent of those attending a university hospital plastic surgery clinic meet criteria for the disorder.

Body dysmorphic disorder is not uncommon as a comorbid condition in patients with major depressive disorder (current rate of 60 percent; lifetime rate of 80 percent), obsessive-compulsive disorder, and social phobia. Indeed in one study of 30 patients, all met DSM-III-R criteria for at least one other psychiatric diagnosis at some point in their lives, and usually concurrently.

Etiology The cause of body dysmorphic disorder is unknown. The high comorbidity with depressive disorders, a higher-than-expected family history of mood disorders and obsessive-compulsive disorder, and the reported responsiveness to SSRIs indicates that, in at least some patients, the pathophysiology of the disorder may involve serotonin and may be related to other disorders. There may be significant cultural or social effects on patients with body dysmorphic disorder because of the emphasis on stereotyped concepts of beauty that may be emphasized in certain families and within the culture at large. In psychodynamic models body dysmorphic disorder is seen as reflecting the displacement of a sexual or an emotional conflict onto a nonrelated body part; such a putative association occurs through the defense mechanisms of repression, dissociation, distortion, symbolization, and projection.

Diagnosis and Clinical Features There are several likely places to find patients with this uncommon disorder: in a mood disorders clinic, in a plastic surgery clinic, and in a dermatology clinic. A patient with a body dysmorphic disorder might request rhinoplasty; removal of facial sags, jowls, wrinkles, or puffiness; or breast reduction or augmentation. In a clinic for refractory and recurrent depression a patient with the disorder might request relief from a depression caused by an imagined but burdensome bodily defect, but because of embarrassment or shame might not reveal the self-loathing of a body part. In a dermatology clinic, the concern could be acne, scarring, or blemishes. It is a secret disorder, often not admitted to, yet it is often a time-consuming one that engages the patient for many hours during the day with activities such as excessive checking of the defect in mirrors or other reflective surfaces, skin picking, hair combing, or frequently asking others for reassurance. Frequent accompanying symptoms, presumably related to suffering from discomfort about appearance in social situations, are insomnia, depression, and anxiety. Social isolation, dissatisfaction with relationships, shame, and low self-esteem are also common.

Facial flaws are the most common defect in body dysmorphic disorder. Other body parts that sometimes become a focus include hair, breasts, and genitalia. Commonly associated with the distorted belief about appearance is an unrealistic concept of how much one's image can be improved by surgical intervention. Some clinicians report that these patients, for all their preoccupation with their defect, still are vague or inconsistent in the description of it.

Family histories of substance abuse and mood disorder are common in reported cases. Also predisposing to the disorder may be certain types of personality characteristics, especially a mixture of obsessional and avoidant traits, but no single personality pattern predominates. Reportedly the patients are shy, self-absorbed, and overly sensitive to their imagined defect as a focus of notice or criticism. As adolescents, some reports hold that they had few friends and seldom dated. There may be some ideas of reference related to the body dysmorphic disorder, but otherwise there is no formal thought disorder. The major abnormality on mental status examination is the lack of insight into the nature of the problem. Table 16-17 lists the DSM-IV criteria for body dysmorphic disorder.

A. Preoccupation with an imagined defect in appearance. If a slight physical anomaly is present, the person's concern is markedly excessive.
B. The preoccupation causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
C. The preoccupation is not better accounted for by another mental disorder (e.g., dissatisfaction with body shape and size in anorexia nervosa).

Table 16-17 DSM-IV Diagnostic Criteria for Body Dysmorphic Disorder

Differential Diagnosis Body dysmorphic disorder patients have an overvalued idea about their defective appearance. A number of other psychiatric disorders are also accompanied by odd or unusual ideas about the body. In general such patients are best accounted for diagnostically by considering other major psychiatric disorders as primary, and adding that body dysmorphic symptoms are also present. For example, especially in the early phases of schizophrenia some patients may have somatic delusions for which they seek correction by cosmetic surgery. In such cases there is an absolute conviction of ugliness as well as other bizarre delusions and perhaps even hallucinations.

Other disorders with body dysmorphic symptoms include mood disorder, narcissistic personality disorder, and anorexia nervosa; in such instances, both diagnoses should be made. Melancholically depressed patients often have additional delusions about some aspect of their body's inadequacy or defect. The presence of a mood disorder, if suspected, can be further elucidated through the taking of the appropriate medical history. Patients with narcissistic personality disorder have a continual interest in their appearance and a long history of interpersonal difficulties that overshadows the body image problem. Constant preoccupation with feared obesity and inadequacy in an obviously malnourished person may be best classified as anorexia nervosa.

A certain proportion of patients with obsessive-compulsive disorder also have body dysmorphic disorder, in which case both disorders should be diagnosed. If the patient has obsessions about appearance and associated compulsive behaviors (such as mirror-checking), the diagnosis of obsessive-compulsive disorder is not made if the obsessions only concern aspects of appearance.

Isolated somatic delusions unrelated to appearance and accompanied by absolute certainty without other evidence of thought disorder are best classified with the delusional disorders. The belief that one's gender is not rightly assigned (according to the appearance of the external genitalia at birth) is better accounted for by a diagnosis of gender identity disorder. Opinions still vary as to whether monosymptomatic hypochondriacal psychosis (a delusion about a disease or disfigurement in a body part) and body dysmorphic disorder are one or two disorders. DSM-IV allows for double coding if it seems relevant to the clinician.

Course and Prognosis Onset of the disorder may be gradual, during childhood, adolescence, or in the 20s. Discontentment may build for several years before the person considers some type of definitive surgical correction; however, surgical treatment produces no relief. Several long-term follow-up series of patients who have undergone cosmetic surgery have indicated the frequent later emergence of even more severe psychopathology.

Treatment Neither surgical nor psychotherapeutic intervention has had any significant long-term impact on decreasing the preoccupation with defective bodily appearance in most patients with body dysmorphic disorder. There are case reports that psychotherapy alone has helped some patients with this disorder: presumably those helped most by this treatment modality are more emotionally intact, but current thinking in the field is that psychotherapy and medication are both indicated.

Case reports note positive effects from tricyclic drugs, monoamine oxidase inhibitors (MAOIs), and pimozide (Orap), a dopamine-receptor antagonist. Recent preliminary data now support the efficacy of SSRIs and cognitive-behavioral therapy. Moreover, the efficacy of SSRIs appears to be greater than that of tricyclic drugs, which in turn are more effective than the MAOIs. Augmentation of SSRIs with buspirone (BuSpar) and antipsychotic agents, as well as the combination of SSRIs also appears to be promising. However, to date there have been no controlled pharmacotherapy trials.

Some patients refractory to the tricyclics and MAOIs have recently been shown in open trials to respond to antidepressant and antiobsessional agents with potent serotonin receptor blockade, such as fluoxetine (Prozac) and clomipramine (Anafranil).

After maximal treatment response, some patients with body dysmorphic disorder may still retain remnants of their bodily preoccupation, but symptom intensity is often diminished enough to allow patients to resume full social and personal lives. However, relapse when patients are taken off medication is common.

SOMATOFORM DISORDER NOT OTHERWISE SPECIFIED

This is the second of the residual categories for the somatoform disorders. Like the first residual category, undifferentiated somatoform disorder, this category was created in order to classify certain somatoform disorder patients whose symptoms and associated disability do not fit the full criteria for other somatoform disorders. The diagnostic criteria for somatoform disorder not otherwise specified are presented in Table 16-18. Patients with this disorder have clinically significant distress or

disabilities in social, occupational, or other important areas of functioning.

This category includes disorders with somatoform symptoms that do not meet the criteria for any specific somatoform disorder. Examples include:

1. pseudocyesis: a false belief of being pregnant that is associated with objective signs of pregnancy, which may include abdominal enlargement (although the umbilicus does not become everted), reduced menstrual flow, amenorrhea, subjective sensation of fetal movement, nausea, breast engorgement and secretions, and labor pains at the expected date of delivery. Endocrine changes may be present but the syndrome cannot be explained by a general medical condition that causes endocrine changes (e.g., hormone-secreting tumor).
2. a disorder involving nonpsychotic hypochondriacal symptoms of less than 6 months' duration.
3. a disorder involving unexplained physical complains (e.g., fatigue or body weakness) of less than 6 months' duration that are not due to another mental disorder.

Table 16-18 DSM-IV Diagnostic Criteria for Somatoform Disorder Not Otherwise Specified

NEURASTHENIA

Neurasthenia, literally a lack of nerve energy, was described by George M. Beard at the end of the nineteenth century to account for the physical and mental exhaustion arising from the depletion of nervous resources. This finding has given rise to numerous theories but little controlled research. The diagnosis is not included in DSM-IV, nor was it included in DSM-III or DSM-III-R. In DSM-I the condition was called *psychologic nervous system reaction* and in DSM-II it was called *neurasthenic neurosis.*

Neurasthenia is still diagnosed with some frequency in Asia and Russia but not the United States. Particularly in Asia, researchers have found neurasthenia to be a culturally sanctioned idiom of distress. In ICD-10, two main types of neurasthenia occur, with considerable overlap. One type has a predominance of increased fatigue after mental effort, thus associated with a decrease in job performance or coping with activities of daily living. Difficulty in concentration, unpleasant distracting associations or recollections, and generally inefficient thinking have all been reported. The other type has physical weakness and exhaustion after only a minimal physical effort, accompanied by muscular aches and pains and an inability to relax. Both types also have a variety of unpleasant physical feelings including dizziness, tension headaches, and feelings of general instability. Patients also worry about decreased mental or physical well-being and have irritability and anhedonia. Varying degrees of minor anxiety and depression are also common. Sleep may be disturbed with initial or middle-phase insomnia or hypersomnia.

According to ICD-10, the condition must be present for more than 3 months and have either (1) persistent and distressing complaints of feelings of exhaustion after minor mental effort or (2) persistent and distressing complaints of feelings of fatigue and bodily weakness after minor physical effort (Table 16-19). Moreover, the patient is unable to recover from the symptoms of exhaustion or fatigue by rest, relaxation, or entertainment.

A. Either of the following must be present:
   (1) persistent and distressing complaints of feelings of exhaustion after a minor mental effort (such as performing or attempting to perform everyday tasks that do not require unusual mental effort);
   (2) persistent and distressing complaints of feelings of fatigue and bodily weakness after minor physical effort;
B. At least one of the following symptoms must be present:
   (1) feelings of muscular aches and pains
   (2) dizziness;
   (3) tension headaches;
   (4) sleep disturbances;
   (5) inability to relax;
   (6) irritability.
C. The patient is unable to recover from the symptoms in criterion A (1) or (2) by means of rest, relaxation, or entertainment.
D. The duration of the disorder is at least 3 months.
E. *Most commonly used exclusion clause.* The disorder does not occur in the presence of organic emotionally labile disorder, postencephalitic syndrome, postconcussional syndrome, mood disorders, panic disorder, or generalized anxiety disorder.

Table 16-19 ICD-10 Diagnostic Criteria for Neurasthenia

Prevalence studies indicate that, using ICD-10 criteria, about 1 percent of the population have had this condition for more than 3 months and 10 percent have it for more than a month during the past 10 years. An epidemiological study of Chinese-Americans reported that 6.4 percent of the subjects had neurasthenia, and only 3.6 percent of those had no other current or lifetime psychiatric diagnoses.

The cause of neurasthenia seems to be pleomorphic, with proponents implicating mood disorders, anxiety disorders, or conversion disorders. Others propose viral sequelae while still other investigators search for trace mineral deficiencies. Obscure neuromuscular conditions, cryptic immune dysfunction, and chronic fatigue syndrome have also been implicated in the cause of neurasthenia. Despite the broad range of unproven theories, individuals can be considerably incapacitated with symptoms of fatigue and fatigability, with or without accompanying anxiety. Diagnostic workup of the fatigue syndrome by definition is unrewarding because a medical condition causing fatigue would by definition exclude the diagnosis of neurasthenia.

There is no best treatment for neurasthenia. Randomized controlled trials have not been completed. In clinical practice, trials on antidepressant agents such as the activating selective serotonin reuptake inhibitors and psychostimulants such as methylphenidate (Ritalin) or amphetamines have been tried. It may be that sleep, tincture of time, and empathic support are the best treatment modalities, but this has not been proven.

Mrs. B. is a 45-year-old married accountant who had an especially promising career with a large national firm for 5 years until, 10 years ago she developed the gradual onset of neurasthenic symptoms of fatigue, diffuse muscle aches, and fitful sleeping following a series of major psychological stressors including a secret extramarital affair. Her primary care physician prescribed nonspecific treatments including nonsteroidal anti-inflammatory agents and rest, all to little avail.

Two years after the onset of her neurasthenia, she developed an acute depressive episode with multiple somatic complaints. She was referred to a psychiatrist who also noted that her mother had multiple sclerosis, requiring considerable physical care from all her children as they grew up.

During treatment for this major depressive episode, Mrs. B.'s depression and neurasthenia improved gradually, but she experienced multiple side effects from fluoxetine, cyclobenzaporine (Flexeril), and even the low-impact swimming program. In addition to medication, she was treated with behavioral therapy that focused on diminishing her catastrophizing about her bodily sensations. In supportive psychotherapy she benefitted from working through both some of her insoluble family conflicts and her grief about letting go of her high career aspirations.

Her energy gradually increased toward normal. Her sleep pattern of multiple interruptions and early-morning awakening improved considerably. Her overall outlook on a life of diminished expectations ameliorated markedly.

Now 10 years since the onset of her neurasthenia, she still has mini-relapses of persistent and vexing exhaustion; when others see her faring better, they make demands on her for emotional or physical support that she can not directly refuse. She has not returned to gainful employment.

CHRONIC FATIGUE SYNDROME

Fatigue is one of the most common symptoms in all of medical practice. The nature of chronic fatigue syndrome, however, remains very controversial. This syndrome has been defined by the Centers for Disease Control (CDC) in 1988 as a disabling disorder with a combination of a certain number of nonspecific symptoms such as fluctuating levels of fatigue, various combinations of neuromuscular and neuropsychological symptoms, chronic pain, malaise, mild fevers, and anxiety. According to the latest CDC criteria, it is a condition that has been clinically evaluated and still remains as an unexplained, persistent, or relapsing chronic fatigue that is of new or definite onset in a previously healthy person; is not the result of exertion; is not substantially alleviated by rest; and results in substantial reduction in previous levels of occupational, educational, social, or personal activities (Table 16-20).

A. Severe unexplained fatigue for over 6 months that is:
(1) of a new or definite onset
(2) not due to continuing exertion
(3) not resolved by rest
(4) functionally impairing
B. The presence of four or more of the following new symptoms:
(1) impaired memory or concentration
(2) sore throat
(3) tender lymph nodes
(4) muscle pain
(5) pain in several joints
(6) new pattern of headaches
(7) unrefreshing sleep
(8) postexertional malaise lasting more than 24 hours

Table 16-20 1994 CDC Criteria for Chronic Fatigue Syndrome

Since the time of the original CDC definition there have been a few minor revisions in criteria. The debate continues on whether chronic fatigue syndrome is a psychiatric illness or a somatic one with emotional components.

The prevalence of chronic fatigue syndrome is yet to be determined. In one recent primary care clinic study, of 686 patients specifically examined for fatigue, 77 patients were identified as having chronic fatigue and 17 cases met criteria for chronic fatigue syndrome. To date, there has been no community-based epidemiological investigation of this condition, only studies from primary-care practices. Hence there is no data of this condition that is not biased by help-seeking and access to health care.

In the absence of a clear cause, chronic fatigue syndrome has been disparagingly called “the yuppie flu,” neurasthenia, and masked depression. Viral or postviral etiologies have also been considered, with diagnoses such as myalgic encephalomyelitis and chronic Epstein-Barr virus disorder being in vogue for a while. Studies of these viral etiologies have not seemed to be relevant to a large segment of those with chronic fatigue syndrome, but recent studies note a persistent enterovirus or herpes virus 6 in some cases. An overlap with fibrositis or fibromyalgia has also been considered, but this is not particularly illuminating because it only links a poorly understood rheumatic condition with another even less clearly defined, fatigue-defined condition of unclear etiology.

Medical anthropologists have seen chronic fatigue syndrome as a vehicle for negotiation of change in interpersonal worlds. A physiologist recently suggested that there might be a nasal fatigue reflex, akin to the atavistic but well-documented diving reflex. According to this hypothesis, the nasal fatigue reflex could produce the debilitating fatigue that would in turn give the afflicted individual the time to heal before having to face a hostile environment. Brain magnetic resonance imaging (MRI) studies of 43 patients with chronic fatigue syndrome, compared to controls, demonstrated that no MRI pattern of white matter abnormalities is specific.

Psychiatric factors have been strongly associated in the etiology of chronic fatigue syndrome. For example, certain clinical samples have reported that almost half of their cases have had antecedent psychiatric disorders such as depression, phobias, or other anxiety disorders. In a recent matched study of 214 subjects with chronic fatigue syndrome from a nonspecialist, nonreferral setting, most of the index subjects were at considerably greater risk of current psychiatric disorder than were control subjects. The likelihood of psychiatric disorder was six times greater in these chronic fatigue syndrome patients than in the matched controls when evaluated either by interview or by questionnaire. Other studies of subjects who have undergone neuropsychological testing indicate that at least a subset of patients with chronic fatigue syndrome experience significant impairments in learning and memory. However, a primary psychiatric etiology for chronic fatigue syndrome is typically stoutly denied by patients with this syndrome, especially by those who are members of the chronic fatigue syndrome national peer support groups.

Chronic fatigue syndrome is most likely to be a heterogenous condition, with fatigue being only a final common pathway. At this phase of research on the condition, it is not possible to speak with certainty about the etiology of this complicated condition.

Whether chronic fatigue syndrome should be considered as a special class of mood disorder with somatic symptoms (specifically fatigue), or a somatoform disorder not otherwise specified, or a combination of a psychiatric disorder with an unidentified infectious agent, or even some combination of these conditions, remains to be clarified. Using strict DSM-III-R criteria, a recent study demonstrates that very few chronic fatigue syndrome patients have somatization disorder.

Treatments for a presumably heterogenous condition with an unknown cause typically should involve a multidisciplinary approach involving psychological, physiological, and social factors. Possible concomitant psychiatric disorders could most likely benefit from a psychopharmacological trial. Many other types of treatments are being used for this debilitating illness, with even electric plum blossom needle therapy having its adherents in the literature. Two randomized controlled trials of cognitive-behavioral therapy (compared with relaxation therapy or routine practitioner care) indicate that cognitive behavioral therapy has substantial impact on the disability and symptoms of patients with this disorder.

Miss J. was a 35-year-old single white librarian with a benign medical past and no psychiatric symptoms prior to developing a flu-like illness. After 10 days the acute episode passed, but she continued to feel lethargic and readily fatigued. Two weeks after the onset of this illness, she returned to work but was unable to complete her usual 8-hour days because of increasing exhaustion and a newly developed set of symptoms: gradually evolving, diffuse muscle and joint pain.

Her primary care physician suggested naproxen (Naprosyn) and gave her encouragement while counseling patience. The physician noted nothing unusual about her mood, and prescribed hypnotic agents to improve her sleep. There was no improvement, however, on 10 mg of zolpidem (Ambien). She then started having squeezing bitemporal headaches. After 3 months, she was referred to a rheumatologist who tried to start her on amitriptyline (Elavil) 50 mg at night. The patient protested vehemently, denying that she was depressed, just in pain.

Previously she had been a conscientious employee and had rarely taken leave or missed work because of illness. After 3 months of this illness, however, she was forced to take a leave of absence, returning to live with her mother since she no longer had any income. She continued to “hurt all over,” was lethargic and irritable, and slept poorly because of pain. When she slept, she reported that she no longer awoke refreshed.

Six months after the onset of her original symptoms, she self-referred to an academic health center's rheumatology clinic where she presented as an afebrile and otherwise healthy woman who was angry about her protracted illness and her living situation. She admitted to difficulty with concentration. Joint examination revealed full range of motion with no red, hot, or swollen joints; tender points were present at all 18 sites.

Her rheumatologist prescribed amitriptyline 25 mg at night for 4 days and then told to increase the dose by one tablet until she achieved better sleep or reached a dosage of 150 mg. Still protesting that she was not depressed, she took the antidepressant medication because she was desperate for relief. A month later she returned to the rheumatology clinic, still hostile and impatient, with little change, and she was then prescribed 20 mg of fluoxetine in the morning in addition to the amitriptyline at night.

Within a month of this regimen, she was somewhat improved in her mood, sleep, and joint symptoms. However, she still continues to have episodes of fatigue, usually related to stressful life events. She had not yet returned to the work force.

SUGGESTED CROSS-REFERENCES

Related disorders are discussed in Chapters 17 on factitious disorders and Chapter 18 on dissociative disorders. Section 25.12 on consultation-liaison psychiatry, Section 27.1 on noncompliance with treatment, and Section 27.2 on malingering also have information relevant to somatoform disorders. Chronic pain is presented in Section 28.6.

CHAPTER 17. FACTITIOUS DISORDERS

MARC D. FELDMAN, M.D., AND CHARLES V. FORD, M.D.

Factitious disorders are among the most challenging phenomena in clinical practice. They involve efforts to garner gratifications intrinsic to the sick role through the simulation, exaggeration, aggravation, or induction of physical or psychological signs and symptoms. Factitious disorders can be conceptualized to fall within a continuum of "abnormal illness behavior," in which individuals create or amplify medical signs or symptoms. Somatoform disorders, factitious disorders, and malingering represent various points on the continuum, with the respective goals traversing the spectrum from fully unconscious and nonvolitional to exclusively conscious and willful. Commenting upon the "purloined sick role" in *The Spectrum of Factitious Disorders*, Don R. Lipsitt writes,

> In all likelihood, factitious disorder is both disease and deception, presenting one of the most challenging (and potentially vexing) variants of psychopathology in medical experience. If we impute a conscious motive to the wish to be sick, we regard this as strange behavior indeed; only in the case of the true malingerer, whose behavior is quite transparently designed for some personal gain, does logic prevail. If we can detect no reason for such a desire, our preference is to assume that there must be strong propulsion from deeply unconscious and complex roots.
>
> Such behavior lies outside the parameters of the 'sick role' as defined by Talcott Parsons in 1951. In this role, sick individuals are excused from social responsibility, are expected to perceive their condition as undesirable, lack voluntary control over it and therefore are not considered at fault, and are expected to seek competent help in ameliorating or curing the condition . . . . The concept of 'abnormal illness behavior' . . . can be extended emphatically to the voluntary induction of illness, whether for primary or secondary gain.

Not surprisingly, clinicians confronted by factitious disorders often find themselves frustrated and bewildered by individuals who ostensibly present for thorough medical care but simultaneously conceal the cause of the malady, thus making definitive care impossible.

DEFINITION

The fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) contains a single set of criteria for factitious disorder, but delineates three subtypes: factitious disorder with predominantly psychological signs and symptoms, factitious disorder with predominantly physical signs and symptoms, and factitious disorder with combined psychological and physical signs and symptoms. The diagnostic criteria for factitious disorder and explanations of the subtypes appear in Table 17-1. The category of factitious disorder not otherwise specified includes disorders with factitious symptoms that do not meet the criteria for the other factitious disorders. The DSM-IV diagnostic criteria for factitious disorder not otherwise specified are outlined in Table 17-2.

A. Intentional production or feigning of physical or psychological signs or symptoms.
B. The motivation for the behavior is to assume the sick role.
C. External incentives for the behavior (such as economic gain, avoiding legal responsibility, or improving physical well-being, as in malingering) are absent.

Code based on type:

With predominantly psychological signs and symptoms: If psychological signs and symptoms predominate in the clinical presentation

With predominantly physical signs and symptoms: If physical signs and symptoms predominate in the clinical presentation

With combined psychological and physical signs and symptoms: If both psychological and physical signs and symptoms are present but neither predominates in the clinical presentation

Table 17-1 DSM-IV Diagnostic Criteria for Factitious Disorder

This category includes disorders with factitious symptoms that do not meet the criteria for factitious disorder. An example is factitious disorder by proxy: the intentional production or feigning of physical or psychological signs or symptoms in another person who is under the individual's care for the purpose of indirectly assuming the sick role.

Table 17-2 DSM-IV Diagnostic Criteria for Factitious Disorder Not Otherwise Specified

DSM-IV illustrates factitious disorder not otherwise specified with the example of factitious disorder by proxy. However, the DSM-IV Task Force determined that there was insufficient information about factitious disorder by proxy to warrant its inclusion as an official category, and so research criteria for this disorder are consigned to Appendix B, "Criteria Sets and Axes Provided for Further Study." Factitious disorder by proxy includes situations in which one person produces symptoms in another for the purpose of assuming the sick role indirectly (i.e., by proxy). In representative cases, a mother fabricates illness in her child, then presents the child for medical treatment while disclaiming knowledge of the origin of the problem. Risks to the health of these children stem from diagnostic maneuvers and treatments as well as actual illness induced by the parent. The research criteria for factitious disorder by proxy are presented in Table 17.3.

A. Intentional production or feigning of physical or psychological signs or symptoms in another person who is under the individual's care.
B. The motivation for the perpetrator's behavior is to assume the sick role by proxy.
C. External incentives for the behavior (such as economic gain) are absent.
D. The behavior is not better accounted for by another mental disorder.

Table 17-3 DSM-IV Research Criteria for Factitious Disorder by Proxy

Patients with factitious disorders consciously perpetrate their deceptive behaviors although their underlying motivations may be unconscious. By convention, individuals who readily acknowledge that they have produced their own medical signs (e.g., patients who self-mutilate) are not diagnosed with factitious disorders.

HISTORY

Although reports in the professional and lay literature have flourished during the past several decades, the phenomenon of falsified physical or psychological ailments is hardly unique to modern medicine. The Bible (1 Samuel 21:11–15) describes King David's feigning of madness before Achis, the King of Geth. Facing Achis's servants,

> [David] changed his countenance before them, and slipt down between their hands. And he stumbled against the doors of the gate; and his spittle ran down upon his beard.
>
> And Achis said to his servants: You saw the man was mad. Why have you brought him to me?
>
> Have we need of madmen, that you have brought in this fellow to play the madman in my presence? Shall this fellow come into my house?

In the second century AD, Galen wrote a treatise on the subject, listing medical signs and symptoms that people had self-induced or simulated, including vomiting and rectal bleeding. In the first half of the nineteenth century, several treatises on feigned insanity appeared; late in this period, authors such as Isaac Ray disputed earlier writers who had maintained that falsified insanity was difficult to detect. In 1838 the British physician Hector Gavin published an essay, “On Feigned and Factitious Diseases,” on the array of medical and psychological ruses plied by soldiers and seamen. Gavin recognized that while most of these errant conscripts sought to procure discharge or evade unpleasant duties, others seemed driven by a less concrete goal: they wished simply “to excite compassion or interest,” a motivation that is often the basis for contemporary cases of factitious disorder. In his book *Hysteria* (1853), Dr. Robert Carter coined the term “tertiary hysteria” to refer to those who would bask in the “fuss and parade of illness” to elicit sympathy. Speculation about the psychodynamic underpinnings of factitious behavior was advanced in 1934 when Karl Menninger described “polysurgical addiction.” He postulated an intrapsychic struggle in these patients characterized by intense aggression both toward themselves and their physicians, the latter representing the “perceived sadistic parent.”

Perhaps the most influential article to date on the subject appeared in *Lancet* in 1951. In this work of whimsical medical literature, Richard Asher coined the term “Münchausen syndrome” to refer to a pattern of factitious disorder “which most doctors have seen, but about which little has been written.” Recounting several brief case reports, Asher distinguished Munchausen syndrome by the chronic use of fabricated symptoms to gain hospital admission, embellishment of the personal history, and migration from hospital to hospital. Asher named the syndrome after Baron Hieronymus Karl Friedrich Freiherr von Münchausen (1720–1791), a retired German cavalry officer and raconteur who had been ruthlessly parodied by R. E. Raspe in an immensely popular book first published in 1785 (Fig. 17.1). Asher advised physicians to be alert to the possibility of Munchausen syndrome if a patient (1) exhibited numerous surgical scars, usually in the abdominal area; (2) displayed a truculent and evasive manner; (3) recounted a medical history fraught with harrowing episodes of dubious veracity; and (4) attempted to conceal documents such as hospital discharge forms or insurance claim filings. In 1962 J. C. Barker argued that the fascinating but false stories of personal triumph and tragedy these patients told were not simply an intriguing feature, but instead a cardinal feature of the diagnosis. Barker referred to these tales as “pseudologia fantastica,” a term included in DSM-IV as a common feature of factitious disorder but one that is not essential for the diagnosis. *Pseudologia fantastica* is typified by stories that are not entirely improbable and that often contain a matrix of truth and falsehood. The stories are enduring and have a self-aggrandizing component.

FIGURE 17-1 A commemorative stamp issued by Germany in 1970 to mark the two hundred and fiftieth anniversary of Baron von Münchausen's birth. The Baron is depicted riding a severed horse into battle.

Asher suggested that Munchausen syndrome patients “desire to be the centre of interest and attention,” but still found himself unable to explain their often-startling behavior: “The most remarkable feature of the syndrome is the apparent senselessness of it. Unlike the malingerer, who may gain a definite end, these patients often seem to gain nothing except the discomfiture of unnecessary investigations or operations.” The resolution to this apparent paradox—one that tends to trouble observers but not the patients themselves—has remained a source of speculation. For example, in 1968 H.R. Spiro expanded upon Menninger's psychodynamic formulation and invoked disturbed early parent-child relationships as a critical etiological factor. He suggested that factitious behaviors were the consequence of early deprivation, an incomplete self-identity, superego defects, and abortive attempts at mastery of early trauma. He further noted that hospitals are a natural setting in which such unresolved issues could be reenacted because, like parents, medical professionals bestow caretaking even as they exert control over their charges. Spiro also chronicled one of the legacies of Asher's often-whimsical article, the ever-evolving and vaguely pejorative lingo used to describe factitious disorders. Terms such as “hospital hoboes” often seemed to reflect the authors' feelings of both bemusement and betrayal. Refuting the implication that these patients were mere “tricksters, liars, and swindlers,” Spiro advocated a more “impersonal nomenclature.” He suggested that, rather than “epithets,” these patients receive primary psychiatric diagnoses qualified with the phrase “with chronic factitious symptomatology.” Despite the 1980 introduction of the term “chronic factitial disorder” into the third edition of DSM (DSM-III), its retention in the revised third edition of DSM (DSM-III-R) and DSM-IV as “factitious disorder,” the appeal of the colorful *Munchausen* eponym has remained. “Munchausen syndrome” is mentioned only parenthetically in DSM-IV as a severe subtype involving repeated hospitalization, but the terms “factitious disorder” and “Munchausen syndrome” are often used interchangeably, especially by nonpsychiatrists. As a result, health care professionals often experience a reflexive therapeutic nihilism whenever a patient is determined to have feigned or induced an ailment, no matter the severity or chronicity.

The term *Munchausen syndrome by proxy* was coined in 1976 by John Money and June Werlwas to refer to psychosocial dwarfism, but came into broad use only as a result of its having been applied by Roy Meadow in a 1977 article. Consistent with a move in the official nomenclature away from eponyms, the syndrome entered

DSM-IV as “factitious disorder by proxy.”

COMPARATIVE NOSOLOGY

Arising from the Munchausen archetype, DSM-III emphasized chronic factitious disorder with physical symptoms. DSM-III-R offered an expanded nomenclature that reflected emerging evidence that factitious disorders may occur briefly or episodically, and that patients sometimes manifest mixed or exclusively psychological symptoms. It outlined distinct criteria sets for factitious disorder with physical symptoms and factitious disorder with psychological symptoms, and required the use of the not otherwise specified category for persons who presented with mixed symptom pictures. DSM-IV has merged the criteria sets into a single one, labeled *factitious disorder*, but has delineated the three subtypes described. In contrast, the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) lists factitious disorder within the category of disorders of adult personality and behavior under the name of “intentional production or feigning of symptoms or disabilities, either physical or psychological.” The diagnostic criteria in ICD-10 are listed in Table 17-4. Similar to DSM-IV, ICD-10 criteria imply that the demarcation between “internal” motivation (factitious disorder) and “external motivation” (malingering) is clearcut. In practice, a given patient's dissimulation may stem from a combination of incentives, both internal and external, which vary over time and even coexist; for example, a patient may feign severe pain both to acquire opioids and to obtain nurturance from a solicitous nursing staff. Despite this shared limitation, the DSM-IV entry appears more clinically useful for a number of reasons. First, ICD-10 goes further than DSM-IV in proposing that even the motivation of accessing “more medical care” is “external” and therefore suggests malingering; the task of differentiating the pursuit of the sick role from the pursuit of more medical care is taxing and speculative at best. Second, the ICD-10 criteria do not differentiate self-mutilation (as in borderline personality disorder) from the self-harm that can occur in factitious disorder; however, the latter but not the former typically involves deception about the cause of the injuries. Third, in the preamble to the criteria, the authors of ICD-10 select for inclusion two of the pejorative terms formerly applied to factitious disorder patients (“hospital hopper syndrome” and “peregrinating patient”); they also choose to list, without definition, the term “Münchhausen's syndrome” although this phrase is accurately applied only to a small subset of patients with factitious disorder. Other differences are that ICD-10 arbitrarily excludes factitial dermatitis and categorizes “Münchhausen by proxy” as a form of child abuse but not of factitious disorder.

Elaboration of physical symptoms for psychological reasons

A. Physical symptoms originally due to a confirmed physical disorder, disease, or disability become exaggerated or prolonged in excess of what can be explained by the physical disorder itself.

B. There is evidence for a psychological causation for the excess symptoms (such as evidence fear of disability or death, possible financial compensation, disappointment at the standard of care experienced).

Intentional production or feigning of symptoms or disabilities, either physical or psychological [factitious disorder]

A. The individual exhibits a persistent pattern of intentional production or feigning of symptoms and/or self-infliction of wounds in order to produce symptoms.

B. No evidence can be found for an external motivation such as financial compensation, escape from danger, or more medical care. (If such evidence can be found, the category malingering, should be used.)

C. Most commonly used exclusion clause. There is no confirmed physical or mental disorder that could explain the symptoms.

Other specified disorders of adult personality and behavior. This category should be used for coding any specified disorder of adult personality and behavior that cannot be classified under any one of the preceding headings.

Table 17-4 ICD-10 Diagnostic Criteria for Other Disorders of Adult Personality and Behavior

EPIDEMIOLOGY

Because factitious disorders always involve willful deception and sometimes involve itinerancy as well, standard epidemiological techniques are not applicable. Information must be inferred from individual case studies, a few reported series, and referral patterns, typically within university medical centers. For example, at a large teaching hospital in Toronto, factitious disorders were diagnosed in 10 out of 1288 (0.8 percent) patients referred consecutively to the psychiatric consultation-liaison service. At a New York City medical center, a comparable proportion of psychiatric consultation patients—1 percent—were diagnosed with factitious disorders. In one general hospital setting, 3.5 percent of fevers of unknown origin proved to be factitious, a rate higher than that of drug-related fevers. Since primary treating physicians often do not detect psychiatric illness in patients with physical complaints, these identified cases probably represented only a fraction of the actual prevalence of factitious disorders at these sites. Factitious disorders were identified in 32 of 343 patients (9.3 percent) referred for evaluation of fever of unknown origin in a report from the National Institute for Allergy and Infectious Disease in which nonpsychiatric physicians explicitly considered the diagnosis. Five of 1538 patients (0.3 percent) who were treated for ostensible neurological disorders at a Berlin hospital had an ultimate diagnosis of factitious disorder. Finally, 3 percent of the “kidney stones” submitted by patients in one report were determined to have been nonphysiological and to have represented probable attempts to deceive physicians. Experts concur that factitious psychological disorders that receive professional attention are much less frequent than factitious physical disorders. The prevalence has been estimated at 0.1 to 0.5 percent of inpatient psychiatric admissions.

In the Toronto study, factitious disorder patients had a median age of 26 years. The average age at onset of the dissimulations was 21 years, and other reports have also suggested onset in early adulthood. Overall, demographic analyses in the literature have distinguished two general patterns. Factitious disorder patients with Munchausen syndrome are typically middle-aged men who are unmarried, unemployed, and estranged from their families; the remaining patients are generally women aged 20 to 40 years. A number of reports suggest that those in the second group are commonly employed in or intimately familiar with health care occupations such as nursing and physical therapy. In a 10-year retrospective study of hospitalized patients, 28 of 41 patients with factitious disorder identified worked in medically related fields, 15 as nurses.

No genetic pattern has been established, although a large number of persons diagnosed with factitious disorders have comorbid psychiatric diagnoses (e.g., mood disorders, personality disorders, or substance-related disorders) that are genetically influenced.

Factitious disorder by proxy currently accounts for fewer than 1000 of the almost 3 million cases of child abuse reported each year in the United States, but this number may rise as mass media and professional attention increase recognition of these cases. Authors have attempted to elucidate the prevalence of factitious disorder by proxy within particular populations, such as children presenting with apnea (0.27 percent), allergy (5 percent), asthma (1 percent), apparent life-threatening episodes (1.5 percent), and life-threatening episodes treated with cardiopulmonary resuscitation (over 9 percent among children in whom final diagnoses were established). The average length of time to establish a diagnosis of factitious disorder by proxy after the initial presentation is 15 months, and often a sibling has died of undiagnosed causes before the disorder is recognized.

ETIOLOGY

Biological Factors Over the past decade, several researchers have proposed that brain dysfunction may play a role in factitious disorders, particularly the Munchausen variant. In single case reports or small series, some patients with Munchausen syndrome have displayed abnormalities on brain imaging, such as frontal temporal cortical atrophy, or on neuropsychological testing, particularly in the areas of conceptual organization, management of complex information, and judgment. It has been speculated that impaired information processing contributes to the aberrant behavior and pseudologia fantastica of Munchausen patients. Electroencephalography (EEG) studies have been small in scale, and abnormalities observed in a minority of the patients have been nonspecific.

Psychosocial Factors A number of psychodynamic causes for Munchausen syndrome have been proposed, and they appear applicable to persons with non-Munchausen factitious disorders as well. For many patients, the production of illness simultaneously meets multiple needs ranging from conscious to fully unconscious. Dependency needs are typically among the salient ones. These patients often have had emotionally deprived backgrounds with parents who were rejecting, and illness becomes a way of inducing others to gratify these needs and to satisfy the longing for nurturance. For other patients, particularly those prone to a decline in reality testing, factitious behavior organizes them, establishing a role to be played. Through this role, a helpless individual becomes a clever manipulator able to control health care providers, who may also represent surrogates of the parents. Similarly, factitious behavior also meets the need for identity. Patients with factitious disorders frequently have a poor sense of self and have failed to define their value systems and goals. By simulating or inducing disease, they assume the well-defined role of sick persons; through the pseudologia fantastica in Munchausen syndrome, they even become important and interesting people with exotic backgrounds. Another need gratified through dissimulation is the need for mastery. Individuals with poor coping skills, a limited social support system, and poor vocational skills may feel helpless. Successful appropriation of the status of “patient” stifles this weak and vulnerable feeling. In particular, the illusion of glamorous roles (e.g., professional athlete or war hero) in pseudologia fantastica provides them the vicarious pleasure of being someone who is respected and powerful. A classical psychoanalytic interpretation of the patient's eager acceptance of the sick role is underlying masochism. This theory suggests that inadequate, sometimes

abusive parenting has resulted in a distorted self-image, and that anger directed toward the child has resulted in a devalued sense of the self as one who deserves abuse. The Munchausen syndrome patient may therefore seek out situations that mix nurturing with pain, as in surgical procedures. Incorporated into this formulation is the concept of compromise formation: that a part of the body may need to be sacrificed to save the whole—that is, the sense of self.

FACTITIOUS DISORDER BY PROXY

By definition, factitious disorder by proxy requires that any external gains for the victim's fabricated or induced illnesses, such as disability payments or respite from child-rearing responsibilities during hospitalization, are incidental to the pursuit of the vicarious sick role. Several analyses have referred to a disorder of empathy among perpetrating mothers fueled by depression and isolation. With their spouses typically unavailable or uninvolved, they vitiate these painful feelings by mobilizing attention and nurturance through this disorder. A related hypothesis involves projective identification. Through this defense mechanism, the mother projects onto her child her own unconscious longings for nurturance, then ensures—through her own indefatigable attention as well as that of health care providers and others—that the child receives the attention she herself so desperately craves. Others have referred to factitious disorder by proxy as an epiphenomenon of the parent's narcissism and sociopathy, with glee arising from the capacity to dupe highly educated professionals. The perpetrator may also be displacing sadistic impulses toward herself or others onto the child. A recent theory suggests that an unsatisfactory relationship with a desired but unavailable father contributes to a perverse relationship with physicians and hospital staff members, surrogate parents whom the abusing mother simultaneously pursues and punishes. In this context the mother perceives her child as an object to be used to manipulate an intensely ambivalent relationship with the medical establishment. Concrete evidence for this last observation has been provided through covert videotapes. In contrast to the devoted, even symbiotic parenting style they reveal in public, these mothers are commonly unresponsive to their infants when their behavior is unwitnessed. Despite the perversity of their behavior, they rarely suffer from psychotic or dissociative disorders, although they often have personal histories of factitious or somatoform disorders. Although they may have been neglected or undervalued, most perpetrators did not suffer direct abuse in childhood.

DIAGNOSIS AND CLINICAL FEATURES

Factitious Disorder With Predominantly Psychological Signs and Symptoms The essential feature is a clinical presentation characterized by the intentional production or feigning of psychological signs and symptoms that suggest a mental disorder. The individual's goal is to assume the sick role, not to accrue external gain. The patient's symptomatology typically appears inconsistent with the known features of the mental disorder, responds poorly to treatments expected to be effective if the malady were authentic, and worsens when the patient is aware of being observed.

The preponderance of published cases of factitious disorder involve only physical signs and symptoms. Factitious psychological symptoms are most frequently seen in conjunction with physical complaints. In the accounts in which the factitious disorder consists exclusively of psychological symptoms, the individuals often present as the typical Munchausen syndrome patients, exhibiting peregrination, antisocial behavior, and a lack of intimate or sustained relationships. In addition, since these patients rely on verbal exchange to capture the attention of health professionals, pseudologia fantastica may be more prominent in those with factitious psychological rather than physical symptoms.

As Table 17-5 indicates, patients have displayed a formidable array of psychological manifestations. Presentations involving depression or suicidal ideation have often been linked to false claims of bereavement. In a study of 20 patients who had embellished or falsely reported the deaths of loved ones in order to procure the sick role, 15 had also feigned physical symptoms in the past. Of 12 patients in another report, 9 had claimed that they were grieving for more than one deceased family member and 5 had been hospitalized previously with factitious physical symptoms. Features commonly noted in factitious bereavement include a lack of witnesses to corroborate the patient's story and deaths of loved ones that are purported to have been especially dramatic or gruesome. Such dramatic but unverifiable events may also be reported in factitious victimization, in which an individual contrives baseless claims of rape, assault, or other crimes.

Bereavement	Eating disorder
Depression	Amnesia
Posttraumatic stress disorder	Substance-related disorder
Pain disorder	Paraphilias
Psychosis	Hypersomnia
Bipolar I disorder	Transsexualism
Dissociative identity disorder

Table 17-5 Presentations in Factitious Disorder With Predominantly Psychological Signs and Symptoms

Although evidence exists in isolated cases for feigned psychosis, some authors contend that such cases need to be examined longitudinally before a diagnosis of factitious disorder is proffered. Such patients tend to have family histories of mental illness and, over time, often develop authentic psychotic disorders, such as schizophrenia. Indeed, feigning psychosis may be a defense against the emergence of a genuine psychotic disorder. Based on these considerations, at least one researcher has questioned the diagnostic legitimacy of the entire category of factitious psychological disorders. The debate about this category is likely to grow more vigorous; the distinction between psychological and physical is becoming increasingly artificial in the face of neurophysiological advances pointing to the interplay between abnormal psychology and neurobiology. Further, almost all patients with factitious psychological disorders have comorbid personality disorders.

The Minnesota Multiphasic Personality Inventory-2 (MMPI-2) may help to confirm the diagnosis of factitious disorder with predominantly psychological signs and symptoms. An invalid test profile and elevations of all clinical scales indicate an attempt to appear more disturbed than is the case (“fake bad”). Also, patients with factitious disorders, whether physical or psychological, most often demonstrate an average or above-average intelligence quotient (I.Q.), absence of a formal thought disorder, a poor sense of identity, poor sexual adjustment, poor frustration tolerance, strong dependency needs, and narcissism.

Ms. A. was a 35-year-old unemployed woman who presented to the emergency room complaining of auditory hallucinations and both suicidal and homicidal ideation. She acknowledged 10 prior psychiatric hospitalizations and diagnoses that had included major depressive disorder, bipolar I disorder, and dissociative identity disorder. She reported that “another personality,” whom she called Krystal, would assume control at times and that Krystal was responsible for her frequent episodes of rage. In addition, the voice instructing her to harm others, which she felt increasingly unable to resist, was that of Krystal. Ms. A. added that at times she would go 8 full days without sleep because of her continual shifts in identity states.

Ms. A. indicated that she had been married and divorced four times. After receiving a Bachelor's degree in psychology, she said, she had worked as a substance abuse counselor but had recently had to quit her job. The limited records available showed that she had been detoxified from benzodiazepines at age 18 and cocaine at age 28 and had attempted suicide on multiple occasions.

Following admission, Ms. A. abruptly dropped her complaints of hallucinations and disclaimed further suicidal or homicidal ideation. She was noted by the staff to socialize freely with other patients, but abruptly to assume a demeanor of perplexity or intense preoccupation when she was aware of being observed. Shortly after the attending psychiatrist began discussions with her about discharge planning, Ms. A. began to speak unintelligibly and wander seemingly aimlessly into other patient's rooms. However, her behavior normalized almost immediately after she was transferred to a more secure, notably less plush unit, and she insisted upon a return to the original ward. She later blamed Krystal for the uncontrolled behavior. Psychological testing indicated severe borderline personality disorder. Telephone calls to a family member and a former psychiatrist revealed that Ms. A. had never exhibited an alternate identity state. It was also learned that she had neither received a degree in psychology nor had she worked as a substance abuse counselor.

Ms. A. was discharged to the care of a local psychiatrist. Two weeks later, she was readmitted for less than 48 hours with complaints of suicidal intent. Her suicidal ideation promptly resolved when she learned that transfer to the secure unit was again being arranged, and she returned to the local physician.

Discussion Ms. A.'s diagnoses were factitious disorder with predominantly psychological signs and symptoms, and borderline personality disorder. Her apparent dissociation in the hospital appeared contrived and resolved almost instantly when she was transferred to a less desirable ward; this degree of control is absent in authentic dissociative identity disorder. Similarly, she abandoned the claim of suicidal and homicidal ideation as soon as admission was assured. No history of additional identity states could be culled from the records of a former treating psychiatrist, and a relative stated that any claim of dissociative identity disorder was spurious. Ms. A. did not solicit medications, disability payments, or other external gains with her fallacious dissociative history, but instead primarily seemed to be seeking the sick role. Ms. A.'s willful creation of Krystal may also have served as a ready explanation for the rage and impulsivity that were in reality attributable to her personality disorder. She gratuitiously enhanced her educational and work histories, and her relaxed sociability when she was not aware of being observed supported the impression of factitious disorder. She tailored her presentation to the settings and people around her and, in so doing, diverted attention from and impeded potential assistance with her actual emotional problems.

Factitious Disorder With Predominantly Physical Signs and Symptoms The essential feature is the intentional production or feigning of physical signs and symptoms, motivated solely by a psychological need to assume the sick role. The presentation of factitious physical symptoms spans a considerable range. Individuals may engage in: (1) total fabrications (e.g., asserting falsely that one is infected with the human immunodeficiency virus [HIV]), (2) simulations (e.g., mimicking a grand mal seizure); (3) illness aggravations (e.g., manually manipulating a preexisting wound so it will not heal); or (4) illness inductions (e.g., injecting oneself with fecal bacteria to cause sepsis). The specific examples in the literature are as varied and intricate as the human imagination, and are constrained only by the limitation of the particular individual's creativity and motivation. The maladies may be relatively common (e.g., urinary tract infections) or so esoteric that most physicians would have only a passing familiarity with them (e.g., intermittent Mediterranean fever; necrotizing fasciitis). The potential sophistication and multiplicity of the deceptions is well illustrated by five patients in a German report who feigned neurological syndromes: they had enacted meningoencephalitis, grand mal seizures with postictal agitated states, sudden loss of consciousness, progressive brainstem syndrome, status epilepticus, dysarthria, spastic paraparesis, hemiparesis, and paresis of one arm. The most common factitious physical signs, symptoms, and diseases reported in the literature include iron deficiency anemia, rash, chronic diarrhea, seizures, fever of unknown origin, renal stones, hematuria, hypoglycemia, cancer, and intestinal bleeding. Less frequent reports have involved every medical or surgical specialty, and have included such disparate conditions as anaplastic anemia, septic arthritis, lead poisoning, pheochromocytoma, Goodpasture's syndrome (hemoptysis and glomerulonephiritis), ectopic pregnancy, ventricular tachycardia, and torsion dystonia.

Ms. B., a 24-year-old woman, presented to a medical clinic for treatment of chronic vomiting. She described herself as having C5 quadriplegia and used a motorized wheelchair. Her limbs were markedly atrophic but she retained sufficient movement to operate her wheelchair and perform most activities of daily living. Ms. B. attributed her quadriplegia to a motor vehicle accident she had suffered at the age of 13, and she had a scar on her neck at the site of subsequent spinal fusion. Due to severe spasticity, an in-dwelling intrathecal baclofen pump had been inserted and, due to apparent bladder atony, she had had an ileal loop procedure for urine drainage. Based upon the patient's report of unremitting fecal incontinence, a colostomy had been performed 1 week prior to her presentation at the clinic.

Ms. B.'s vomiting failed to respond to dietary manipulations, and increasing dehydration and malnutrition necessitated hospitalization. She was ultimately discharged on total parenteral nutrition. A series of readmissions ensued, however, for line sepsis caused by unusual microorganisms such as *Clostridia* and fungi. It was during one of these hospitalizations that a nurse recognized Ms. B. and recalled having taken care of her after the car accident years earlier. She remembered clearly that the patient had had no lingering physical sequelae at discharge. For the first time, the diagnosis of factitious disorder was entertained.

Ms. B. was not confronted with this suspicion. Instead, she was referred for extensive neurological testing that confirmed that her spinal cord was intact and that her peripheral nerve function was normal. Although Ms. B. had consistently denied permission for the staff to speak with her parents, she finally acceded when her primary physician threatened to resign from her case. A family meeting was scheduled.

During the family session, Ms. B.'s parents stated that they had always felt badly that Ms. B. discouraged their involvement, going so far as to insist that they not visit her in the hospital. They confirmed that she had been physically normal following the accident. It was not until her senior year of high school as she was preparing for college that she developed neurological dysfunction that defied diagnosis. Her incapacity progressed until she became wheelchair-bound. Confronted in the context of the family meeting, Ms. B. acknowledged hesitantly that perhaps she did not have objective physical pathology and proposed that she had “acted quadriplegic” because her health care providers had told her she was quadriplegic.

After the meeting, a multidisciplinary treatment team was formed. The team met regularly and made it clear to Ms. B. that the goals for her were nothing short of full recovery. Within this firm and expectant context, she received physical therapy, occupational therapy, and psychological counseling supplemented by home visits by a psychiatric nurse. Regularly scheduled medical follow-up was provided, and her baclofen pump was eventually removed. She eventually became able to walk with leg braces and a walker. She regained the lost weight and has required no additional hospitalizations since the family session occurred.

Discussion Consistent with the diagnosis of factitious disorder, Ms. B. sought to assume the sick role, particularly to mobilize the attention and concern of skilled medical professionals and to gain relief from responsibilities and expectations such as establishing autonomy. Here, as in many other cases, repeated diagnostic studies, invasive procedures, and major surgical operations were performed in an effort to manage what ultimately proved to be feigned or self-induced ailments.

Ms. B.'s behavior was characteristic in that she demonstrated essentially no anxiety even when confronted with painful and disfiguring surgery. In addition, she strenuously resisted efforts to confirm the details of her stories and almost never had visitors. In this case the patient's deceptions proved so effective that the diagnosis was considered only when a nurse coincidentally recognized her from a much earlier hospitalization. Psychological testing confirmed that Ms. B. had a severe personality disorder with avoidant and dependent features. (Adapted from Feldman MD, Duval NJ: Factitious quadriplegia: A rare new case and literature review. Psychosomatics *38*:76, 1997.)

Factitious Disorder With Combined Psychological and Physical Signs and Symptoms If a patient presents with factitious disorder with both physical and psychological features and neither type of disorder predominates clinically, the appropriate diagnosis is factitious disorder with combined psychological and physical signs and symptoms. In one representative report, a patient alternated among feigned dementia, bereavement, rape, and seizures. Another patient, confronted about his factitious posttraumatic stress disorder, began to offer complaints of incapacitating pain associated with metastatic cancer that proved factitious as well (Table 17-1).

Factitious Disorder Not Otherwise Specified This category is reserved for patients who do not meet the criteria for the other factitious disorder classifications. The example provided in DSM-IV is factitious disorder by proxy. According to the research criteria for this disorder the essential feature is the intentional production or feigning of physical or psychological signs and symptoms in another person who is under the individual's care. The motivation for the perpetrator's behavior is to assume the sick role by proxy, and external incentives for the behavior (such as economic gain) are absent. In 95 to 98 percent of reported cases, the abusive individual is the mother and the victim is her own child; fewer than 20 cases have been published in which the father is the perpetrator. Typically the child is an infant or toddler, but the ages reported have varied from neonates to 14-year-olds. In extremely rare cases, an adult will produce an illness in another adult. The manufactured signs and symptoms are almost always physical, and the perpetrator creates the dissimulation through behaviors such as spurious or exaggerated symptom reports, manipulation of laboratory samples or data, or actual induction of illness through maneuvers such as surreptitious administration of drugs. Table 17-6 summarizes the most common presentations of factitious disorder by proxy. Such descriptions have been reaffirmed by hundreds of case reports in the medical literature from around the world.

Poisoning (includes Munchausen syndrome by proxy and intentional poisonings)
Seizures or vomiting
Apnea
Diarrhea
Unconsciousness
Fevers
Lethargy
Dehydration or hematemesis
Ataxia or hematuria

Adapted with permission from Schreier HA, Libow JA: *Hurting for Love: Münchausen by Proxy Syndrome.* © Guilford Press, New York, 1993; and Rosenberg DA: Web of deceit: A literature review of Münchausen syndrome by proxy. *Child Abuse Negl* 11:553, 1987.

Table 17-6 Ranking of the Most Common Bibliographic References to Signs and Symptoms of Factitious Disorder by Proxy

In a typical case of factitious disorder by proxy, the child is brought to the clinic or hospital with dramatic symptoms. The mother characteristically assists the staff and readily consents to any invasive diagnostic procedures proposed for the child, often seeming more concerned about obtaining additional tests than about the child's emotional status. Discovery of her role in the production of the child's symptoms may occur accidentally, such as finding her smothering the child with a pillow to induce hypoxic seizures. At other times, mothers have been found administering ipecac to cause vomiting or introducing feces into intravenous tubing to create sepsis. Barring such direct findings, detection can be supported by interventions such as finding toxic amounts of sodium in food items that the mother has brought for the child; drug screening tests unexpectedly indicating surreptitious administration of drugs; or anomalous, inexplicably variable, or flatly impossible laboratory results. Older siblings may have had similar findings that were medically unexplained at the time. Gross evidence of abuse—such as burns, bruises, or fractures—is uncommon in factitious disorder by proxy. Instead, clinicians should consider the diagnosis based upon the indicators that have emerged in the literature (Table 17-7).

The symptoms and pattern of illness are extremely unusual, or inexplicable physiologically.
Repeated hospitalizations and workups by numerous caregivers fail to reveal a conclusive diagnosis or cause.
Physiological parameters are consistent with induced illness; e.g., apnea monitor tracings disclose massive muscle artifact prior to respiratory arrest, suggesting that the child has been struggling against an obstruction to the airways.
The patient fails to respond to appropriate treatments.
The vitality of the patient is inconsistent with the laboratory findings.
The signs and symptoms abate when the mother has not had access to the child.
The mother is the only witness to the onset of signs and symptoms.
Unexplained illnesses have occurred in the mother or her other children.
The mother has had medical or nursing education, or exposure to models of the illnesses afflicting the child (e.g., a parent with sleep apnea).
The mother welcomes even invasive and painful tests.
The mother grows anxious if the child improves.
Maternal lying is proved.
Medical observations yield information that is inconsistent with parental reports.

Table 17-7 Clinical Indicators That May Suggest Factitious Disorder by Proxy

By 9 weeks of age, Carter C. had spent the majority of his life in the hospital for recurrent idiopathic apnea. Evaluations by multiple subspecialty teams had been unrevealing. Similarly, medical tests—which had been expanded to include lumbar puncture, EEG, continuous electrocardiogram (ECG) monitoring, upper gastrointestinal tract series, pH probe, overnight sleep study, herpesvirus culture, mandible films, chest X-ray, and numerous blood studies—were notable only for minor findings of doubtful significance. An empiric trial of metoclopramide (Reglan) was ineffective. Mrs. C. had been the only witness to the onset of the apneic spells, and her reports sometimes struck the staff as unconvincing. For example, she had claimed that the apneic episode precipitating the most recent admission had lasted less than 1 minute, but Carter's blood pH had been 6.9, suggesting that the apnea had been sustained.

These facts, combined with Mrs. C.'s eagerness to have Carter undergo invasive tests, led to a request for psychiatric consultation. Review of the records by the psychiatrist revealed that Mrs. C.'s first child, Denise, had died at 18 months of age of aspiration pneumonia. Denise had had 3 hospitalizations and 9 emergency room presentations for seizures or apnea observed only by Mrs. C. Phenobarbital had been prescribed empirically, but there were unaccountable variations in the blood concentration. During the interview, Mrs. C. disclosed that she had been unable to realize her goal of becoming a paramedic, but often accompanied her mother, a nurse, to continuing-education courses. She used medical terms freely and expressed pride in having resuscitated Carter on numerous occasions. Now divorced from Mr. C., her third husband, she lived with her sister, who was disabled.

Based upon the accumulated evidence of factitious disorder by proxy, and despite Mrs. C.'s emphatic denial, the Department of Human Resources placed Carter with a foster mother. The child remained well during this period. At the Shelter Care and Dependency trial, the medical examiner voiced concerns about Denise's illnesses and death, and noted disturbing parallels with Carter's course to date. Following the testimony of the state's psychiatric expert, and before a judgment was rendered, Mrs. C. agreed unilaterally to an award of temporary custody to Mr. C. Six months later, Carter was thriving without medical intervention, and Mr. C. was awarded permanent custody. While continuing to deny having engaged in factitious disorder by proxy Mrs. C. stated that she would “acquiesce” to this arrangement. The State elected, without explanation, not to pursue an inquiry into Denise's death.

Discussion In DSM-IV, factitious disorder by proxy is a diagnosis that accrues to the abusive caretaker. The victim is not given a psychiatric diagnosis, but is identified with a V code, “physical abuse of child” (or in rare cases involving an adult victim, “physical abuse of adult”).

This case was typical in that the conclusion that the mother actually produced the symptoms in the child was based on an accumulation of circumstantial evidence. In cases of factitious disorder by proxy the mother almost never acknowledges her role in the dissimulation. This denial complicates detection and management, although intervention, as in this example, must focus on ensuring the safety of the child regardless of the caregiver's response. Mrs. C. appeared to be motivated by the desire to experience the sick role indirectly through her child and to realize her unfulfilled goal of becoming part of the health care system.

Like most cases of factitious disorder by proxy, Mrs. C. appeared superficially quite normal; in fact, this diagnosis is not an “attribute” of an individual that can be elicited during an interview. Psychiatric evaluations and psychological testing do not enable an examiner to confirm or disprove the diagnosis, although one report claims that many of these parents display nonspecific features such as limited stores of information (except in the medical arena); poor abstract conceptual abilities; superficial social skills; outgoing behavior; rigid, defensive styles that mask rebelliousness; emotional immaturity; self-centeredness; a lack of social conformity; and intense passive resentment.

DIFFERENTIAL DIAGNOSIS

Factitious Disorder With Predominantly Physical Signs and Symptoms

True Physical Illness An important item in the differential diagnosis is an authentic physical illness. A true disease may account for the clinical presentation, as in the report of a patient who died of encephalitis after having been spurned by the staff as having feigned her presentation. The complexity of the challenge to the diagnostician is heightened by the fact that patients may self-induce ailments such as sepsis, conditions that are life-threatening and require vigorous medical intervention despite being manifestations of factitious disorder. As another example, the history of numerous abdominal surgical procedures in many cases of Munchausen syndrome predisposes the patient to actual intestinal obstruction, necessitating even further surgery.

Somatoform Disorders In somatoform disorders, such as conversion disorder, somatization disorder, and hypochondriasis, the patient reports or manifests physical symptoms that suggest a general medical condition but are not fully explained by a medical ailment, the direct effects of a substance, or another mental disorder. Unlike patients with factitious disorders, those with somatoform disorders do not intentionally produce their somatic symptoms. However, the presence of factitious or malingered symptoms mixed with other nonintentional symptoms is not uncommon, particularly in somatization disorder.

Personality Disorders Patients with Munchausen syndrome frequently meet criteria for antisocial personality disorder as well, but this comorbidity is not invariable. Like the patient with Munchausen syndrome, individuals with antisocial personality disorder alone may exhibit pseudologia fantastica, shoddy work records, substance-related disorders, and few sustained or intimate relationships, but they do not center their lives around hospitalization. Borderline and other personality disorders are also extremely common in Munchausen syndrome and factitious disorder as a whole. The diagnosis of these personality disorders is based on explicit criteria—in the case of borderline personality disorder, for example, the diagnosis is based on the person's identity disturbance, affective instability, suicidal or self-mutilating behavior, impulsivity, and chronic feelings of emptiness. If the patient meets criteria for both personality disorder and factitious disorder, the Axis II and Axis I diagnoses may be made concurrently.

Malingering In DSM-IV malingering is listed as an additional condition that may be a focus of clinical attention. In factitious disorders, the motivation is to assume the sick role, whereas in malingering, external incentives such as financial compensation, avoidance of military duty, or evasion of criminal prosecution, are apparent. However, when perceived incentives are used as a diagnostic criterion, imprecision in diagnosis is bound to occur. In addition, patients may feign illness to achieve different goals—internal or external—at different times.

Factitious Disorder With Predominantly Psychological Signs and Symptoms The patient's simulation of a mental disorder may actually represent the prodrome to an authentic mental disorder with a serious outcome. In particular, clinicians should be cautious in diagnosing factitious psychosis because in two small series a majority of these patients eventually manifested clear-cut psychotic disorders such as schizophrenia. In other cases, an ostensibly feigned condition such as depression has responded to psychotropic medications, validating at least some element of the presentation. Since virtually all patients with this type of factitious disorder have a personality disorder (usually borderline, histrionic, or antisocial), caregivers must also recognize that the simulated mental disorder coexists with an authentic one. Comorbidity with substance-related disorders and somatoform disorders has been reported as well, and dissociative disorders may result in alterations of memory and the patient's providing inconsistent factual information. In the past, Ganser's syndrome had been considered by a number of authors to fall within the realm of factitious psychological disorders, but it is classified in DSM-IV as an example of dissociative disorder not otherwise specified. The hallmark of Ganser's syndrome is approximate answers, or *vorbeireden*, to questions (e.g., Examiner: “How many legs does have a spider have?”; Patient: “Seven”). Although the syndrome has been shown to be present in some patients with impaired cognitive abilities and previous brain injury, there is clearly some conscious component to the responses provided by the patient because random answers would not be approximate, and it has been described in one patient who also had clearcut factitious disorder with combined physical and psychological signs and symptoms.

The clinician's level of suspicion that a factitious psychological disorder is present should be raised by a number of factors. At times, the symptoms are patent caricatures, reflecting a layperson's view of how those with mental disorders would behave. Cases involving feigned depression, however, may be modeled from the individual's personal experiences and thus more difficult to detect. Recognition of inconsistencies in the patient's account, or between the professed history and the patient's objective presentation, facilitates detection. For example, individuals falsely reporting posttraumatic stress disorder as a result of combat may be unmasked as a result of inherently flawed narratives or the staff's acquisition of military records or other collateral information; indeed, these patients may be discovered to have never served in the military at all. Other clues arise when the patient's symptoms are only present when observation by others is evident; when new symptoms arise that are incongruous with the condition already diagnosed; when new symptoms emerge that are similar to those exhibited by other patients on the ward; and when there is a consistent and chronic lack of response to standard treatments. In some cases, psychological testing (e.g., the Malingering/Dissimulation Scale of the MMPI-2, Structured Interview of Reported Symptoms, M Test, projective tests, or the Bender Visual Motor Gestalt Test) may aid in arriving at the correct diagnosis.

Factitious Disorder by Proxy Several categories of illness presentation can be confused with factitious disorder by proxy. First, overanxious parents may continually bring their children for medical evaluation and treatment, therefore putting them at risk for iatrogenic complications. However, this behavior is founded in a genuine belief that their offspring are ill, and they are at least transiently relieved when illness is ruled out. The signs and symptoms reported in such cases are usually not exotic and they respond predictably to medical intervention. Second, parents of children who are recovering from a documented health crisis such as prematurity may appear to overreact to mild symptoms of illness. The physician can identify these families by documenting the veracity of the previous diagnoses. Once recovery is well established, these parents will begin to attenuate their reactions to illness. Third, some parents discontinue prescribed medications because of concerns about adverse effects, not because they wish to mislead medical caregivers or worsen the child's symptoms. After they receive additional information, these parents comply or at least become more forthright in expressing their reservations about the medication regimen. Fourth, a parent's nominal exaggeration of her child's symptoms may represent an attempt to call attention to symptoms that concern her but seem not to impress the pediatrician. In contrast to cases of factitious disorder by proxy, these parents welcome recovery when it occurs and exaggeration of symptoms does not represent a pattern of behavior. Fifth, a number of illnesses, such as asthma, present with such variability that it is possible for the same child to appear remarkably different within a short period of time. An innocent parent may appear to be an illness exaggerator if she is describing a child whose symptoms no longer fit her description; independent corroboration will provide the necessary clarification. Sixth, an older child may malinger for secondary gain. The innocent parent witnesses and presents the child's symptoms to the physician, and appears to have manufactured the symptom reports when illness is disconfirmed by examination. Finally, a legitimate medical disorder occasionally presents with symptoms that can be confused with various manifestations of factitious disorder by proxy. For example, although sudden infant death syndrome is a well-described phenomenon, the absence of a clearcut marker renders parents vulnerable to charges of abuse. Guidelines are in the process of development that will help to differentiate this syndrome from induced apnea. For instance, repeated episodes of apnea culminating in the death in a child over the age of 6 months point to factitious disorder by proxy much more commonly than to sudden infant death syndrome. Covert video surveillance of mother and child in the hospital room has been used to confirm the diagnosis of factitious disorder by proxy although this method is controversial from a legal and ethical standpoint. The decision to undertake covert video surveillance should ideally involve a team comprised not only of medical personnel, but of legal, child protection, and law enforcement representatives as well. Prevailing case law in the United States suggests that the serious, potentially life-threatening nature of the abuse in factitious disorder by proxy provides a strong countervailing interest when balanced against a parent's or caretaker's right of privacy.

COURSE AND PROGNOSIS

Information concerning the course and prognosis of factitious disorder with predominantly physical signs and symptoms is limited to anecdotal case reports and small series. Patients who meet the criteria for Munchausen syndrome appear generally to have an unremitting course. Death may occur from miscalculations in disease-producing behavior (e.g., an overdose of chemotherapeutic agents that were being taken surreptitiously) or as a result of iatrogenic complications. Patients with Munchausen syndrome rarely accept psychiatric treatment; when they do, such intervention serves to ameliorate factitious behavior only transiently; the patients almost inevitably move on and resume their previous lifestyle. The course and prognosis for patients with simple (nonperegrinating) factitious disorder is more variable. When confronted with their behavior, most of these patients will deny the factitious nature of their illnesses; some will then quietly discontinue the dissimulation, some will change doctors and resume their illness-producing behavior, and a few will accept a referral for psychiatric treatment. If patients persist, they—like Munchausen patients—are at risk for a panoply of complications that include unnecessary amputations, removal of internal organs, and death. Non-Munchausen forms of the disorder appear usually to remit spontaneously after about age 40. Perhaps this remission is related to the observation that features of borderline personality disorder also tend to abate at midlife.

The literature on factitious disorder with predominantly psychological signs and symptoms is notable for the magnitude of the psychological dysfunction present in the patients. Almost all have serious personality disorders, often associated with substance abuse. Several authors have reported that there is a high rate of suicide in

this population and that factitious psychological disorders have a worse prognosis than most other Axis I disorders.

A comprehensive 1987 literature review of factitious disorder by proxy showed a 9 percent mortality rate. Although this rate was probably inflated from its having been derived only from published reports, a later study highlighted other risks. In this article, British researchers followed up 41 victims of factitious disorder by proxy an average of 5.6 years after the condition was identified. They showed that, of the moderately severe cases in which the children had been returned home, the fabrications were repeated in 33 percent. In addition to the caretaker's abuse of the child, diagnostic and treatment maneuvers in pursuit of the elusive diagnosis may also engender their own short- and long-term morbidity. Behaviorally, a range of conduct, school, and emotional disorders was observed in around half of the British children whether they had been returned home or placed with others. In a more recent study of 10 adults who identified themselves as having experienced factitious disorder by proxy in childhood, persistent insecurity, reality-testing deficits, and symptoms of posttraumatic stress disorder were uncovered. In several other reports, individuals who had been victimized by factitious disorder by proxy have had an increased likelihood of developing factitious disorder later in life although some individuals, consistent with the profile of posttraumatic stress disorder, have avoided even essential testing and procedures that remind them of the original trauma.

TREATMENT

Factitious Disorder The primary goals in treatment of factitious disorders are to reduce the patient's disease dissimulation and the overutilization of medical and surgical services. Psychiatric consultation should be initiated when the diagnosis is first seriously considered. Consultation, perhaps using the format of a task force or management team, should be pursued in conjunction with nursing, social work, and legal professionals, and should include an ethicist when available. This multidisciplinary approach can be invaluable because patients with factitious disorder often mobilize interpersonal conflicts among their caretakers, including splitting, and raise complex management issues—for example, is it legal, ethical, and medically warranted to perform a surreptitious room search based on the suspicion that a patient is self-injecting with insulin?

Although there are isolated anecdotal reports of successful treatment of factitious disorder, there is no specific treatment that has been proved to be the gold standard. Nonetheless, authorities generally advocate that, following confirmation of the diagnosis, the patient should be confronted in a supportive manner that redefines the patient's illness from that of physical disease to that of psychological distress. Rather than angrily rejecting the patient as a fraud, the psychiatrist should extend an offer of help. If the patient accedes, a careful diagnostic evaluation is then needed to determine the presence or absence of comorbidity. Although concurrent Axis I disorders are relatively uncommon, they should be vigorously treated if present. Essentially all patients with factitious disorder are comorbid for a personality disorder, and an assessment of ego strengths is mandatory because many of these patients are at risk for acting-out behaviors, including psychosis and suicide.

Pharmacotherapy of factitious disorders is largely limited to treatment of any comorbid Axis I disorders. Medications should be carefully monitored because of patients' propensity to act in self-destructive ways. The selective serotonin reuptake inhibitors (SSRIs) may prove to be of some use in reducing impulsivity. While not treating the underlying causes for an individual's factitious behavior, other somatic interventions, such as the provision of physical therapy, may provide both needed attention and a face-saving mechanism for the patient to curtail or abandon factitious behavior.

The psychotherapy of patients with factitious disorders is directed to the underlying personality disorder. Thus, the indications, techniques, and complications are similar to the those that apply to the treatment of any person with a Cluster B personality disorder. Persons with severe personality disorders, if seen in reconstructive-type therapies, are prone to intense transference responses and acting-out behaviors as a result of elicited anxiety; in this respect, the patient with factitious disorder may engage once again in disease forgery or flee treatment to resume previous behavior in a new locale. Supportive psychotherapies, although not curative, may be more effective in the containment of symptoms. Supportive techniques include the establishment of an ongoing relationship in which there is minimal confrontation of the patient's factitious behaviors or pseudologia fantastica even though the therapist does not express agreement with them. Instead, increased attention to material involving day-to-day conflicts provides a helpful reinforcement of the patient's attempt to struggle with real problems while serving also to reduce the patient's preoccupation with fantasy. Approximate or general interpretations may be particularly useful at times—for example, “You find it difficult when your mother leaves town on a business trip,” rather than “You feel abandoned and helpless when your mother leaves town and resort to factitious behavior to create a sense of power.”

The psychotherapist who treats these patients must have modest expectations, anticipating relapse and accepting periods of symptomatic relief rather than “cure.” It is the relationship itself that at least transiently serves to provide the nurturance that these patients crave.

Family intervention, especially for the younger patient, offers promise as an effective adjunctive approach (as in the case of Ms. B.). Such therapy can decrease family secrets and help the family to provide more attention that is not contingent on perceived illness, thereby diminishing the reinforcement of sick-role behaviors.

Behavior therapy has been suggested for some factitious disorder patients. The goals of such strategies are to allow face-saving ways for the patient to relinquish symptoms and learn socially appropriate techniques to have needs met.

Overall, several clinical indicators of enhanced treatment responsiveness have been elucidated. They include: (1) underlying psychiatric syndromes, such as mood, anxiety, substance-related, or conversion disorders; (2) personality traits without borderline or antisocial elements; (3) psychosocial supports, such as ongoing relationships with significant others, employment or employability, or religious affiliations; and (4) ability to establish a therapeutic alliance as characterized by the capacity to establish and maintain rapport, accept confrontation, and comply with treatment recommendations.

As suggested, clinicians should be aware of their countertransference toward patients with factitious disorders. The patient's overt behaviors, such as actual bodily damage, as well as their underlying emotional conflicts can mobilize particularly intense reactions in health professionals. These reactions may include therapeutic nihilism, anger and aversion, nonemergent breaches of confidentiality, overidentification, or feelings of personal responsibility for the patient's ongoing behavior. Identification of these countertransferential feelings will enhance the clinician's understanding of the patient.

Factitious Disorder by Proxy Authors differ in the intensity with which they have confronted the abusive parent and in the amount of supporting evidence they have produced. Categorical denial is extremely common whether a gentle suggestion is made, previously concealed medications or medical equipment are displayed, or definitive evidence from video surveillance is provided. Unless legal mechanisms to prevent it are in place, escalation of the behavior or immediate discharge of the child against medical advice is common. The management plan must therefore involve the immediate protection of the child. By law in all 50 states, health professionals who suspect or diagnose factitious disorder by proxy must alert child abuse authorities. In many situations the child's safety can be assured only by removing him or her from the home, at least temporarily. Reunification of families should be undertaken only if a plan, typically one mandated by the court system, is in place to help ensure the child's continued safety. Criminal prosecution of the mother may be indicated as well.

For the victimized child, additional medical care to address residual physical problems may be necessary; the child should also receive a psychiatric evaluation and therapy. Despite the abuse, children remain attached to their parents and suffer from the separation. If possible, perpetrating mothers and other family members should be engaged in long-term therapy. Ideally, the therapy will focus on teaching the parent adaptive ways to get her needs met, including expressing painful affects in words rather than with abusive actions. However, no author has yet described a consistently effective or specific treatment program for the factitious disorder by proxy maltreater, especially if an acknowledgment of culpability is not forthcoming. Without definitive intervention, the risk remains that the parent will relocate to an area where she is unknown and where the dissimulations can be successfully repeated. A listing of guidelines endorsed by a number of researchers and clinicians is provided in Table 17-8.

The child should generally be removed from the care of the mother, and separation should continue at least until the mother's evaluation is completed and the child's health status is clarified.
A pediatrician or family practitioner familiar with the case should become the long-term, court-ordered gatekeeper for the child's health care needs.
The gatekeeper should perform a periodic audit of the child's health and school records to help detect school absences or developmental and behavioral consequences of the disorder.
Audits of the health status of siblings should be performed for an extended period.
Individual psychotherapy is indicated for the mother and, if old enough, for the child.
Family therapy should be provided to the parents, siblings, and affected child.
If the family is reunited, supervision should be continued and arrangements made with the courts to have monitoring continue following any relocations.

CHAPTER 18. DISSOCIATIVE DISORDERS

18.1 DISSOCIATIVE AMNESIA

MARLENE STEINBERG, M.D.

Amnesia is the black hole of dissociation: neither the dead star nor the symptom can be directly observed; their existence and nature must be inferred from only the surrounding effects. Patients usually become aware of their amnesia only after it begins to disrupt their social or work environments. However, recent advancements in psychiatry—including new diagnostic tools—enable clinicians and researchers to reliably assess the severity of amnesia symptoms and to diagnose the syndrome of dissociative amnesia.

DEFINITION

The fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) defines *dissociative amnesia* as “an inability to recall important personal information, usually of a traumatic or stressful nature, that is too extensive to be explained by normal forgetfulness ... and is not due to the direct physiological effects of a substance or a neurological or other general medical condition.” DSM-IV further distinguishes between five types of memory disturbances included under the heading of dissociative amnesia: (1) *localized amnesia*, in which “the individual fails to recall events that occurred during a circumscribed period of time, usually the first few hours following a profoundly disturbing event”; (2) *selective amnesia*, in which “the person can recall some, but not all, of the events during a circumscribed period of time”; (3) *generalized amnesia*, when “failure of recall encompasses the person's entire life”; (4) *continuous amnesia*, “the inability to recall events subsequent to a specific time up to and including the present; (5) *systematized amnesia*, the “loss of memory for certain categories of information, such as all memories relating to one's family or to a particular person.” The latter three types of dissociative amnesia are more rare. When dissociative amnesia occurs recurrently, clinicians should rule out the diagnosis of more complex dissociative disorder, such as dissociative identity disorder.

HISTORY

Paul Briquet and Jean-Martin Charcot were two of the first to record and comment on the frequency of amnesia in their classic studies of hysteria. Pierre Janet, however, was the true pioneer in the field of dissociation. Demonstrating a surprising similarity to our modern conceptions, Janet's discussion of amnesia is fundamental and remains one of the most extensive in the literature. Josef Breuer and Sigmund Freud also describe dissociative amnesia in their studies of hysterical patients; many were described as experiencing blackouts and extended amnesic gaps in memory.

Although there have been a number of studies and case reports of amnesia during the twentieth century—which have been extremely influential in the formation of modern notions and texts—many of these suffer from methodological weakness. Nonetheless, most support the classic concept which notes that most patients with dissociative amnesia come from massively stressful psychosocial environments characterized by feelings of shame, guilt, desperation, and conflict. During the 1940s, a group of clinicians became interested in dissociation and published several case reports of amnesia including a series of case studies on amnesia and other disturbances resulting from combat experiences in the World War II. Modern studies have begun to address the range of amnestic experiences and the relationship between amnesia and trauma in a more systematic fashion. Research based on the analysis of 141 clinical interviews utilizing Steinberg's *Structured Clinical Interview for DSM-IV Dissociative Disorders–Revised (SCID-D–R)* indicates that amnesia occurs across a spectrum, ranging from the occasional forgetfulness of normal controls, to occasional memory difficulties of patients with a variety of psychiatric disorders, to recurrent or persistent episodes of amnesia (lasting days or longer) in patients suffering from dissociative disorders.

COMPARATIVE NOSOLOGY

Little data has accumulated suggesting that the description or diagnostic criteria of dissociative amnesia be revised since the publication of the third edition of DSM (DSM-III) in 1980. However, one noteworthy change is the disorder's name, which was changed from *psychogenic amnesia* to *dissociative amnesia* in DSM-IV. Most other changes merely reflect attempts at clarification, emphasizing the sudden nature of the condition and its relationship to trauma, and instructing the clinician to rule out *dissociative identity disorder (multiple personality disorder)* before making a diagnosis of dissociative amnesia.

The 10th revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) defines dissociative amnesia in basically the same terms: “The main feature is loss of memory, usually of important recent events, that is not due in organic mental disorder and is too great to be explained by ordinary forgetfulness or fatigue (see Table 18.5-3). The amnesia is usually centered on traumatic events” although it does not differentiate between subsets of memory disturbance, as DSM-IV does (Table 18.1-1).

A. The predominant disturbance is one or more episodes of inability to recall important personal information, usually of a traumatic or stressful nature, that is too extensive to be explained by ordinary forgetfulness.

B. The disturbance does not occur exclusively as a symptom of dissociative identity disorder, dissociative fugue, post-traumatic stress disorder, acute stress disorder, or somatization disorder and is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a neurological or other general medical condition (e.g., amnestic disorder due to head trauma).

C. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Table 18.1-1 DSM-IV Diagnostic Criteria for Dissociative Amnesia

EPIDEMIOLOGY

The epidemiology of dissociative amnesia has not been adequately examined but the few studies that have been conducted provide some data. The majority of studies, excluding those of veterans, indicated a relatively equal sex incidence. Similarly, although a wide range of ages have been reported, most studies report a peak incidence in the third and fourth decades. Although the frequency of occurrence awaits systematic research, researchers believe that dissociative amnesia may be more common than previously recognized. In modern clinical practice, dissociative amnesia most frequently presents in hospital emergency rooms, where amnesic patients are typically brought after being found on the street.

ETIOLOGY

According to the DSM-IV criteria B for dissociative amnesia, the disturbance is not due to a medical or neurological condition or to the effects of substance abuse. Thus the etiology of dissociative amnesia excludes all organic causes. Janet was one of the earliest researchers to emphasize the role of trauma in cognitive impairments. Although systematic research specific to the etiology of dissociative amnesia is limited, numerous subsequent investigators have noted a causative link between emotional trauma and dissociative amnesia. The amnestic episode is thought to be an intrapsychic defense, excluding painful memories from conscious awareness, and can result from a single overwhelming traumatic event or from a series of smaller precipitants. Commonly reported circumstances include childhood abuse, kidnapping, incest, rape, past wartime combat experience (“shell shock”), and other threats of death or physical violence, and even being a witness to violence. Intensity, duration, and age of exposure to the traumatic event seem to be critical factors in the development of dissociative amnesia; generally the stronger, longer, and earlier the exposure, the worse the amnesia. Research by the author reports that recurrent dissociative amnestic episodes often occur in individuals suffering from a range of other dissociative symptoms, and frequently occur in the most severe dissociative disorder, *dissociative identity disorder*.

The DSM-IV diagnostic criteria for dissociative amnesia are listed in Table 18.1-1.

DIAGNOSIS AND CLINICAL FEATURES

In order to systematically assess dissociative amnesia, clinicians may wish to use specialized diagnostic tools. Currently the only tool that assesses both the degree of amnesia and diagnoses dissociative amnesia is SCID-D-R. This semistructured interview evaluates the severity of five dissociative symptoms (amnesia, depersonalization, derealization, identity confusion, and identity alteration) and diagnoses the five dissociative disorders (dissociative amnesia, dissociative fugue, depersonalization disorder, dissociative identity disorder, and dissociative disorder not otherwise specified). The interview contains a total of 276 items (36 items relate to amnesia), with follow-up items if the examiner requires additional information. Particularly important in the evaluation of substance abusers, *SCID-D-R* enables the interviewer to rule out amnesia secondary to organic etiology and drugs or alcohol prior to diagnosing dissociative amnesia. Good to excellent reliability and discriminant validity have been reported for SCID-D-R in the United States and in cross-national reliability studies.

Dissociative amnesia is more likely to involve interruption of the episodic-autobiographical memory than the implicit-semantic memory. The memories unavailable for recall tend toward historical factual information (i.e., where was I; whom was I with; and what did I do, think, and feel during the unaccountable period of time?) rather than interruption of general cognitive functioning or language capacity. This period of amnesia usually centers around a traumatic event or series of events and is usually localized, occurring during a specific period of time lasting anywhere from a few hours to several years. Occasionally the amnesia may be selective or systematized, whereby it is restricted to certain memories such as those involving a particular individual. Other forms of amnesia also occur (*generalized amnesia*, when the amnesia extends over the patient's entire life, and *continuous amnesia*, when the amnesia extends from a specific time up to the present), but are much more rare and are often associated with more severe dissociative disorders.

Dissociative amnesia is one of the most difficult disorders to assess because it cannot be observed directly except in cases of global amnesia; patients rarely complain about amnesia itself. Clinically, the patient may present symptoms of anxiety, depression, confusion, difficulty concentrating, and a history of blank spells or gaps in memory. Even once amnesia is confirmed, clinicians typically find it difficult to obtain from patients reliable estimates of the frequency and extent of their amnestic episodes.

Clinicians should pay particular attention to patients' verbal responses and nonverbal behaviors because these may exhibit patterns that suggest amnesia. For example, research based on the administration of Steinberg's *SCID-D-R* notes that vagueness and inconsistency of response and difficulty in narration of past events may indicate amnesia. Other clues that suggest amnesia include a history of unexplained displacement, possession of unfamiliar objects, disavowal of confirmed actions, and any instance of identity loss. The following clinical descriptions, accompanied by actual patient quotations, should help to clarify some of the most prominent individual manifestations of dissociative amnesia.

Confabulation and Self-Monitoring Because amnesia can have a disastrous effect on a patient's day-to-day life, many people with chronic amnesia develop adaptive strategies. One such strategy is *confabulation*, the invention of false information to cover up a gap in memory. One woman with dissociative identity disorder spoke of the marital tension caused by her amnesia:

> “When Charlie and the kids were infants ... I would have to wonder if I fed them—wonder what I did with them—wonder where we went. Often, as I think of it, I couldn't figure out what we had done. When my husband would come home from work and he'd say, “Gee, what did he have for lunch? How did he eat? How many times did he eat?” I wouldn't be able to tell him ... After a while I began to lie.”

Other patients will resort to various forms of self-monitoring to protect themselves from memory loss, such as note-taking or the cessation of regular activities.

Distortions in Time Perception Episodes of amnesia are often characterized by the subject's misperception of elapsed time. The patient may have a distorted sense of the rapid passage of time from the last moment of fully remembered consciousness to the present. The following example is typical:

> “It's like I have specific things that flash on the screen, specific, I'm only talking about minutes, hours at the most. It's like my whole, from the time I was not quite 5 till not quite 13, it seems like my memory is in an hour's time. Then from the time I am like 14 through high school seems pretty ... I can remember all that. In between like from the time I'm through high school till I'm 21 that seems pretty clear. And from the time I am 21 forward there sometimes seems to be entire years like I arrived, I feel like I arrived at this age.”

Amnesia and Memories of Abuse Patients are often amnestic for traumatic experiences. Research investigations found that 59 percent and 64 percent of the study sample were amnestic for having been sexually abused prior to the age of 18. Independent corroboration was reported of 74 percent of subjects' reports of abuse. However, a person may also experience intrusive traumatic memories during stressful periods or following exposure to a sensory trigger. Sometimes a consciously unretrievable memory can cause anxiety without the patient's recollection of any historical connection, as in the following example:

> “I'm paranoid of handkerchiefs. I was scared to death ... I was afraid of a handkerchief. When I finally traced my mind and forced myself to remember and everything else, I remember why now. At, I don't know, I guess 4 years old, a babysitter used to gag me with a handkerchief, shove it down my throat, and rape me... . It's like after a while you learn to remember it. I don't want to remember it, but in order to help myself I knew I had to. God, I was afraid of the things I was learning, because it's like totally new. Your mind blanks it out. I didn't remember it and now I know why ... too painful.”

DIFFERENTIAL DIAGNOSIS

When evaluating a patient presenting for amnesia, clinicians must determine whether the amnesia is a result of a dissociative disorder, another psychiatric disorder, or any number of organic causes.

Amnestic Disorders Amnestic disorders are caused by a variety of organic conditions. Examples of organic causes of amnesia are epileptic seizures, to head trauma, alcoholic blackouts, Korsakoff's syndrome, stroke, postoperative amnesia, postinfectious amnesia, post-ECT, surgery, infection, electroconvulsive therapy (ECT), and transient global amnesia. Less common causes are cerebrovascular disease, metabolic abnormalities, and toxic states.

Amnesia that occurs in the context of an epileptic seizure is called *ictal amnesia* and is characterized by short duration and epileptiform electroencephalograph (EEG) results. In cases of ictal amnesia, there is often anterograde amnesia during the seizure and retrograde amnesia following the seizure. The individual retains a sense of identity and appears otherwise normal. A systematic investigation of amnesia and other dissociative symptoms performed in patients with epilepsy and pseudoseizures found that patients with epilepsy experienced significantly less amnesia, depersonalization, identity confusion, and alteration than patients with pseudoseizures when assessed by SCID-D-R. Patients with a history of nonictal amnesia should be evaluated further to rule out a concomitant dissociative disorder.

Patients who have had a head injury usually experience a brief period of retrograde amnesia and a longer period of anterograde amnesia. Blackouts during alcohol intoxication involve partial to complete amnesia for events occurring during the intoxicated state. In Korsakoff's syndrome, there is significant anterograde amnesia

and variable retrograde amnesia; other cognitive functions are usually left intact. In dementia, the memory loss occurs in combination with multiple cognitive deficits, and many different kinds of memory, including remote memory, are disturbed.

Organic amnesias have several distinguishing features: they do not normally involve recurrent identity alteration, the amnesia is not selectively limited to personal information, the memories do not focus on or result from an emotionally traumatic event, and the amnesia is more often anterograde than retrograde. In cases of amnesia of organic etiology (excluding substance abuse, transient global amnesia, or metabolic abnormalities), the amnesia is usually permanent and does not lend itself to therapeutic techniques. Whereas dissociative amnesia represents a displacement of the memory from awareness, organic amnesias represent the erasure or destruction of that memory through disturbance of the neuropsychological process. If the patient presents with amnesia and symptoms suggestive of an underlying medical disorder, a complete history of the patient's behavior during the amnesia should be obtained as well as a physical and neurological examination, including all necessary laboratory tests and an EEG. Once an organic cause has been ruled out the clinician can evaluate the possible causes of psychogenic amnesia. Use of diagnostic tools such as the SCID-D-R can allow assessment of the severity of the amnesia as well as other core dissociative symptoms, thus enabling the clinician to rule out the presence of dissociative disorder.

Amnesia in Psychiatric Disorders

Amnesia in Depression Amnesia occurs commonly in patients with moderate to severe depression, as well as in patients suffering from the dissociative disorders. Individuals suffering from major depressive disorder frequently experience cognitive impairments that may superficially mimic the organic dementias. Thus, individuals with severe depression have been referred to as having *pseudodementia*. However, amnesia associated with depression is characterized by “I don't knows” rather than near-misses or confabulations, and it is less severe than that in senescent dementia. Individuals suffering from dementia of depressive origin are also more likely to complain about their amnesia than those suffering from dementia caused by medical conditions.

Amnesia in Substance Use Disorders Amnestic experiences are common to patients with histories of alcohol abuse, which is not surprising given the frequency of alcohol-related blackouts. Investigation of amnesia in patients with substance abuse histories using the SCID-D-R found that amnesia by itself is not a diagnostically discriminating symptom in subjects with histories of alcohol abuse; clinicians must evaluate patients for all of the five core dissociative symptoms (amnesia, depersonalization, derealization, identity confusion, identity alteration) as assessed by the SCID-D-R. Substance abuse patients without coexisting dissociative disorders reported amnesia only in the context of substance use (i.e., alcoholic blackouts precipitated by drinking). The diagnosis of dissociative amnesia is excluded when substance abuse patients report that their amnesia occurs only in the context of alcohol consumption. In contrast, amnesia associated with dissociative disorders in substance abusers was characterized by recurrent amnestic episodes as well as other dissociative symptoms such as depersonalization or identity confusion, occuring without the use of drugs or alcohol.”

Amnesia in the Dissociative Disorders as Assessed by SCID-D-R In dissociative amnesia and in the other dissociative disorders amnesia is functional—it results from psychogenic rather than organic factors. In contrast to patients with substance abuse disorders, patients diagnosed with dissociative disorders reported memory gaps in the absence of alcohol intake when assessed with the SCID-D-R. Severe amnesia in patients with underlying dissociative disorders is often characterized by their inability to recall their age, name, address, or other essential personal information. If the memory gap is the predominant disturbance and results in dysfunction or distress, then dissociative amnesia should be ruled out. If the memory gaps occur in conjunction with other dissociative symptoms, the clinician should rule out one of the other dissociative disorders. SCID-D-R-based research indicates that recurrent memory gaps in conjunction with depersonalization, derealization, identity confusion, and identity alteration characterize the symptomatic profile of patients with dissociative identity disorder. Table 18.1-1 presents a summary of the spectrum of amnesia on the SCID-D-R; Figure 18.1-1 is a visual summary of the differential diagnosis of amnesia.

Table 18.1-2 The Spectrum of Amnesias on the SCID-D-R

Proper treatment of amnesia depends on accurate diagnosis, as in the following case study of a patient presenting with global amnesia. Diagnosis based on the administration of SCID-D-R further clarifies the constellation of symptoms associated with the amnesia, and thus allows for accurate diagnostic assessment. This case is presented in the form of a report suitable for inclusion in the patient's records, in order to demonstrate the clinical applications of the SCID-D-R for the documentation of patient's symptoms.

SCID-D-R Psychological Report Mr. Smith

Referral Source: Patient's psychiatrist

Brief summary: Mr. Smith was referred for a diagnostic evaluation due to global amnesia that developed immediately following an episode of syncope at his home in July of 1996. He is a 41-year-old owner of a small business in Chicago and lives with his wife and three children in Lake Forest, Illinois. Immediately following his fainting episode he was taken to a local emergency room where he received a comprehensive medical evaluation. Physical and neurological examinations were unremarkable, and all laboratory tests as well as the computed tomography (CT) scan were within normal limits. He was referred for an EEG with nasopharyngeal leads that was subsequently performed on an outpatient basis; this also was without abnormal findings. The patient had no history of substance abuse, is not a military veteran, and had no known medical problems other than an allergy to ragweed pollen.

Past Psychiatric History: The patient had no history of psychiatric disturbance, and is currently in outpatient treatment for the amnesia with Dr. Jones, a local psychiatrist. The patient is distressed about his inability to recover his memory, particularly because there are apparently no immediate stressors severe enough to account for either the fainting or the amnesia. He also acknowledged recent attacks of agoraphobia, including fear of driving farther than five miles from his house. His wife accompanied him to the interview because of his fear of driving and fear of the dark.

Mr. Smith's only psychiatric hospitalization was following his fainting episode and subsequent global amnesia. He was hospitalized for four weeks and treated with psychotherapy without medication. His discharge diagnosis was dissociative amnesia. Due to his global amnesia Mr. Smith was unable to provide information regarding his childhood or parents, stating that he could not remember the details of his childhood relationships. He was able to report that he is the oldest of six children, and that he felt that he had been punished by physical beatings by his father at unclear intervals of frequency. He completed 3 years of college, and has been married to his present wife since 1973. They have three daughters, aged 18, 15, and 11, respectively. He reports that the marriage has been stable with no separations. The oldest daughter attends college in Michigan, and the younger two reside at home. Mr. Smith indicated that his wife and all three children have been supportive throughout his hospitalization and his present inability to work.

SCID-D-R Evaluation Summary: The findings of Mr. Smith's SCID-D-R interview indicated a modification of his first diagnosis. His endorsement of severe retrograde amnesia is not inconsistent with a tentative diagnosis of dissociative amnesia; Mr. Smith reported a nearly total failure of recall for his life prior to his fainting, with the exception of a few major events such as his wedding. He did not suffer from anterograde amnesia, indicating at a number of points during the interview that he had no difficulty learning new material. However, Mr. Smith also reported the presence of other dissociative symptoms. Had the initial diagnosis of dissociative amnesia been correct, Mr. Smith's amnesia would have been the predominant symptom. However, he mentioned recurrent experiences of depersonalization that included feelings of sitting in two different chairs simultaneously, and out-of-body episodes in which he floated on the ceiling while watching his body on the floor. In terms of derealization, Mr. Smith remarked that his surroundings sometimes seemed “fuzzy” or unreal to him, and that he had frequent “trances” that sometimes lasted for an hour or two. In addition, he was unable to recognize several close relatives at a family funeral. The patient also described experiences suggestive of identity confusion and identity alteration; he reported that he saw “dark beings” resembling humans in his trance states, and that these beings had communicated with his wife and present therapist. On one occasion he walked two of these beings around his bedroom. He mentioned that he experienced an ongoing struggle between two different “sides” of himself, one of which wanted to retrieve his past and one that opposed attempts at recollection. It appeared that one of these sides represented a childlike part of Mr. Smith, in that he would curl up in a fetal position from time to time, act childlike, and state that he was afraid of the dark. The follow-up section of SCID-D-R on “internal dialogues” was administered to explore the extent of Mr. Smith's identity disturbance.

Mr. Smith's responses throughout the administration of the SCID-D-R indicated that his reality testing was excellent, in that he was clearly aware of the distinctions between the “unreal” or “strange” quality of his dissociative episodes and “ordinary” reality. His comment that the “dark beings” in his trance communicated “all kinds of crazy things” to his therapist was typical of his reality testing. During the mental status examination Mr. Smith spoke clearly and intelligently and answered all questions with relevant replies.

Discussion: Based on the SCID-D-R evaluation, Mr. Smith's suffers from severe amnesia, as well as severe depersonalization, derealization, identity confusion and alteration. Although Mr. Smith's different sides did not represent full-fledged alternate personalities, his symptoms of identity confusion and alteration were sufficiently severe to meet the criteria for a subcategory of dissociative disorder not otherwise specified, which includes “clinical presentations similar to Dissociative Identity Disorder that fail to meet full criteria for this disorder. Examples include presentation in which there are not two or more distinct personality states.”

Mr. Smith's case illustrates the importance of a comprehensive evaluation for a range of dissociative symptoms and symptom re-evaluation in patients presenting with dissociative amnesia. Later progress reports indicated that Mr. Smith's symptoms were responding satisfactorily to treatment aimed at reducing the frequency of his trance episodes, and at increasing the cooperation between the different sides of his personality.

COURSE AND PROGNOSIS

Individuals with dissociative amnesia typically experience sudden onset of amnesia, usually following severe psychosocial stressors. When amnesia is localized or selective, recovery is usually complete and termination may be rapid. In cases of generalized amnesia, recovery of memory is usually gradual. Functional impairment varies from mild to severe, depending on the extent of the amnesia. When the dissociative amnesia is recurrent, the clinician should rule out the presence of another more severe dissociative disorder, specifically dissociative identity disorder.

TREATMENT

The more acute and the more recent the instance of dissociative amnesia, the more likely and the more quickly it is to be resolved. However, the clinician should be careful because intrusive attempts to retrieve dissociated memories can result in retraumatization if the patient is not properly prepared. This risk is especially great for longstanding or childhood-onset amnesias. The clinician should control the pace of suggested recollection, usually within the framework of a broader psychotherapy gauged to resolve the complex of events producing the amnesia. In particularly extreme cases, hospitalization may be necessary. Once the patient has been stabilized and a comfortable therapeutic relationship has been established, the clinician may proceed with other measures.

Group Psychotherapy Group psychotherapy has been successful in helping combat veterans and survivors of childhood abuse to regain function. Group interventions may lead to integration of dissociated memories.

Hypnosis Hypnosis can help to contain and modulate the symptoms, to facilitate recall of dissociated memories, and to reintegrate the dissociated material.

Pharmacotherapy To date there have been no double-blind studies of medication for the treatment of dissociative amnesia. Double-blind trials are necessary to evaluate the relative efficacy of pharmacotherapeutic agents in the treatment of dissociative amnesia. The recent development of diagnostic tools such as the *SCID-D-R*, which allows for the assessment of the presence and severity of dissociative amnesia based on operational definitions of symptom severity, can allow for systematic research for the treatment of dissociative amnesia.

Drug-Assisted Interviews Although there have been no reliable studies assessing their efficacy, case reports of drug-facilitated interviews have been reported to have positive results in some patients with especially intransigent dissociations. Agents used include sodium amytal and oral benzodiazepines. Such drug-facilitated interviews should be administered only by mental health professionals experienced in the treatment of individuals with dissociative disorders.

Amnesia occurs in a variety of psychiatric, medical, and substance-related disorders. Comprehensive assessment of the individual's amnesia and its nature, severity, and context can distinguish amnesia in cases of dissociative disorder from amnesia in other nondissociative disorders. Research based on SCID-D-R indicates that amnesia occurs across a spectrum, ranging from the occasional forgetfulness of normal controls to the occasional memory difficulties of patients with a variety of psychiatric disorders, to recurrent or persistent episodes of amnesia (lasting days or longer) in patients suffering from dissociative disorders. Future research is necessary to evaluate the relative efficacy of psychotherapy and pharmacotherapeutic agents in the treatment of dissociative amnesia.

SUGGESTED CROSS-REFERENCES

Dissociative identity disorder is discussed in Section 18.3, and dissociative disorder not otherwise specified and the ICD-10 classification for dissociative disorders are covered in Section 18.5. Alcohol-related disorders are described in Section 11.2. Amnestic disorders, other cognitive disorders, and mental disorders due to a general medical condition are discussed in Chapter 10. Neuropsychiatric aspects of head trauma is presented in Section 2.5.

CHAPTER 18. DISSOCIATIVE DISORDERS

18.2 DISSOCIATIVE FUGUE

PHILIP M. COONS, M.D.

Dissociative fugue (formerly called psychogenic fugue) is an unusual but dramatic type of dissociative disorder. Owing to its rarity, dissociative fugue has been the least studied of the dissociative disorders in recent years.

DEFINITION

In general, a *fugue* is characterized by amnesia for one's identity, which is coupled with sudden, unexpected travel. Both psychological and organic forms of fugue exist.

HISTORY

Although fugues have undoubtedly occurred in individuals for a long time, fugues were not described in detail until the nineteenth century when Freud and his contemporaries, Jean-Martin Charcot and Pierre Janet, began to take an interest in hypnosis and various hysterical phenomena.

Perhaps the most famous case of fugue was the Reverend Ansel Bourne. Bourne was an itinerant preacher, who in January 1887 withdrew over $500 from his bank account in Providence, Rhode Island, paid some bills, and then disappeared. Two months later Rev. Bourne “awoke” in Norristown, Pennsylvania. He apparently had forgotten his original identity and had assumed a new identity, that of A.J. Brown, a shopkeeper. After returning to Providence, Bourne was completely amnesic for his 2-month absence. During his fugue state he was reported to have behaved completely normally by the Norristown residents. When examined under hypnosis 13 years later, it was possible to talk to A.J. Brown and recover the memories of the fugue state, but it was not possible to integrate Brown's memory or identity into that of Reverend Bourne. So far as is known, the identities of Bourne and Brown did not alternate as in dissociative identity disorder.

COMPARATIVE NOSOLOGY

Dissociative fugue was formerly called *psychogenic fugue* in the revised third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III-R). Diagnostic criteria at the time required the assumption of a new identity, either partial or complete. When during the literature search phase for the fourth edition of (DSM-IV) it became obvious that only a minority of historical cases were associated with new identity formation, this criterion was relaxed to allow either confusion about identity or the assumption of a new identity. The 10th revision of *International Statistical Classification of Disease and Related Health Problem* (ICD-10) has not yet adopted this relaxed standard and provides no place to classify psychological fugue states that occur without new identity formation (Table 18.5-3).

EPIDEMIOLOGY

Because of its rarity, very little is known about the epidemiology of dissociative fugue. In a study done on psychiatric inpatient admissions at the Dayton, Ohio Wright Patterson Air Force Medical Center in 1973, dissociative fugues were found in only 0.3 percent of active duty servicemen and female dependents. In a more recent study done in Winnipeg, Canada, no cases of dissociative fugue were found in 502 members of the general population.

Fugues are known to increase in prevalence during times of extremely stressful events, such as wars or natural disasters. The few studies, which have been done previously and which contained relatively large numbers, consisted of collections of cases occurring over a number of years such as during World War II. Unfortunately, these studies were confounded by the different diagnostic conventions of the time and were in many instances gender biased in that they contained mostly men. When dissociative fugues occur, they can be quite dramatic and are frequently the subject of exaggerated accounts in the popular media.

Although most dissociative fugues occur in adults, primarily in the second through fourth decades of life, dissociative fugues have been described in adolescents and in children as young as age 7. The rarity of dissociative fugue in the younger age group is probably related to the inability of most children and adolescents to drive or arrange for independent transportation. It has been speculated that some running-away behavior in children or adolescents may occur during dissociative fugue states but this has never been rigorously studied.

Although clinical lore teaches that dissociative fugue is more frequent in men, this has never been proven. Dissociative fugues may occur in either gender and in one study were approximately equal in gender distribution. Other studies, done in a military setting, have shown a gender bias towards subjects.

ETIOLOGY

Dissociative fugue is thought to be related either to traumatic or overwhelmingly stressful life events and thus may begin after exposure to natural disasters or military combat. Dissociative fugue may also be related to overwhelming stress such as a bankruptcy or an impending divorce. In many cases dissociative fugue is related to an avoidance of responsibility concerning legal or financial matters, sexual indiscretions, or fear of combat. Many individuals who suffer from dissociative fugue have histories of childhood abuse or neglect, although this finding has not been rigorously studied. In some cases the dissociative fugue can be understood as an amnesic state during which forbidden wishes can be symbolically expressed. In other dissociative fugue states, the amnesia may protect against a forbidden wish, such as suicide. Frequently, an underlying dysphoria or depression is present with accompanying shame or guilt. In most cases the dissociative fugue appears to be a symbolic running away from stressful situations. As in all of the other dissociative disorders, the process of dissociation appears to play a central role and results in the symptoms of amnesia and identity change.

DIAGNOSIS AND CLINICAL FEATURES

A baseline evaluation of a fugue state should include a thorough clinical psychiatric history. The clinician should pay particular attention to obtaining history about previous childhood and adult trauma, especially child abuse, financial and marital difficulties, depression, substance abuse, legal difficulties, and sexual indiscretions. A thorough mental status examination should pay particular attention to cognition, memory, and orientation. Because fugues may have either a psychological or organic basis, a thorough physical and neurological examination is indicated in all but the most obvious cases.

Increasingly, the initial evaluation of dissociative disorders involves the use of screening instruments or structured clinical interviews. An excellent instrument for screening for dissociative symptoms is the Dissociative Experiences Scale (DES), a 28-item patient questionnaire that assesses symptoms of amnesia, absorption, depersonalization, derealization, and identity alteration. Patients with dissociative fugue would be expected to elevate only amnesic items and possibly identity alteration items on this easily administered test. The Structured Clinical Interview for DSM-IV Dissociative Disorders (SCID-D) is a clinician-administered semi-structured clinical interview that assesses the dissociative symptoms of amnesia, fugue, depersonalization, derealization, identity confusion, and identity alteration. The SCID-D takes longer to administer, 60 to 90 minutes compared to 10 minutes for the DES. Individuals with dissociative fugue typically endorse only

items on amnesia and some times identity alteration and identity confusion.

The DSM-IV diagnostic criteria for the psychological type of fugue, *dissociative fugue*, are listed in Table 18.2-1.

A. The predominant disturbance is sudden, unexpected travel away from home or one's customary place of work, with inability to recall one's past.
B. Confusion about personal identity or assumption of a new identity (partial or complete).
C. The disturbance does not occur exclusively during the course of dissociative identity disorder and is not due to the direct physiological effects of a substance (e.g., a drug of abuse a medication) or a general medical condition (e.g., temporal lobe epilepsy).
D. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Table 18.2-1 DSM-IV Diagnostic Criteria for Dissociative Fugue

Patients with dissociative fugue suddenly travel away from their home or usual place of work. During such travel they are amnesic for their identities (e.g., autobiographical memory), but their procedural memories are preserved. For example, they know how to operate a motor vehicle or feed themselves. During short dissociative fugues the individual may appear somewhat confused. However, if the dissociative fugue is prolonged, the individual will usually take on a new identity, either partial or complete. Unlike dissociative identity disorder, however, there is no alternation of personality states.

Dissociative fugues may last from less than an hour to a year or more, but generally last in the range of days to weeks. During such time the individual may travel great distances, even across continents or oceans, but generally the distance traveled is anywhere from 10 miles to several hundred miles, which may take the person across state lines.

During most dissociative fugues individuals do not appear to be confused or bizarre and do not attract attention. However, in some cases when the dissociative fugue ceases, they may still be amnesic, are lost, and present themselves to the police or local emergency rooms for help. Such cases often draw dramatic media attention in order to help discover the identities of the individuals involved. Usually, however, when dissociative fugues cease, individuals resume their old identity and are amnesic for events that occurred during the fugue. Even in these situations significant others may be concerned about their loved one's absence and amnesia and will bring the individual for medical attention.

The patient was a 45-year-old man, an attorney, who was in the midst of bankruptcy proceedings and a deteriorating marriage. One day he suddenly disappeared from his office, much to the consternation of his law partners. Fearing foul play, his wife notified the police and an investigation was begun in an attempt to trace his whereabouts. A day later his car was found abandoned and out of gas at an interstate highway rest stop. Nothing was heard from the gentleman for almost a month when he presented himself to a large inner city hospital emergency room several states away from his home. He remained amnesic for his identity and was admitted to the psychiatric unit. His picture and accompanying story was picked up by the wire services and his wife recognized him on television. She was eventually summoned to the hospital where her husband was staying and in a collateral interview provided a full history of her husband to the attending psychiatrist. The patient was confronted with this information but remained amnesic until hypnosis was used to return him to his original personality state. Upon resuming this state, he was transported home and was hospitalized locally by his family physician. He continued to be amnesic for his fugue state. In consultation with a neurologist, a full physical and neurological examination was performed, the results of which were normal. An electroencephalogram and magnetic resonance imaging were performed, neither of which was abnormal. Referral was then made to a psychologist who began psychodynamic psychotherapy. The precipitants, including the patient's failing marriage and poor financial status, were explored, and marital therapy was began as an adjunct. Eventually his memory was restored. However, his financial problems remained unresolved and he left on a shorter 5-day fugue but found his own way home. His treatment continued as the problems in his professional life, including gambling and misappropriation of funds from his legal clients, were explored.

PATHOLOGY AND LABORATORY EXAMINATIONS

Baseline laboratory screening should include an electrocardiogram, blood chemistry screening examination, drug screening, and a blood alcohol level. Further testing may be required and might include an electroencephalogram, toxicology screening test, computed tomography or magnetic resonance imaging of the brain, or neuropsychological testing.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of fugue states is vast. Genuine dissociative fugue must be excluded as a diagnosis if dissociative identity disorder is present or if the fugue is caused by the direct physiological effects of drugs, medications, or alcohol; it cannot be diagnosed if it is due to a general medical condition such as epilepsy.

Probably the most common organic fugue is secondary to epilepsy, especially complex partial seizure disorder. During such seizures or postictally the individual may exhibit wandering behaviors. The clinical differentiation is usually fairly easily accomplished by a good clinical history regarding epileptic symptoms and electroencephalographic studies.

Several medical conditions besides epilepsy can cause organic fugue. These conditions include brain tumor, head trauma, migraine, cerebrovascular accidents, hypertensive neuropathy, limbic system dysfunction, hypoglycemia, uremia, dementia, and malaria.

Organic fugue states may be caused by a wide variety of medications including hallucinogenic drugs, steroids, barbiturates, phenothiazines, triazolam (Halcion), and L-asparaginase. The alcohol blackout can be easily confused with dissociative fugue, but this can be easily differentiated through a good clinical history and alcohol concentrations, if drawn during acute intoxication. The clinician should remember, however, that dissociative fugue and alcohol blackouts may coexist in the same individual.

Dissociative fugue states have been reported to exist cormorbidly with a number of other nondissociative psychiatric diagnoses. These conditions include bipolar I disorder, schizophrenia, various depressive disorders, and alcohol use disorders.

Perhaps the most difficult differential is between dissociative fugue and dissociative identity disorder. At least 50 percent of all patients with dissociative identity disorder experience symptoms of fugue. These fugues are generally but not always brief in duration and involve only short distances of travel. Clinical history and use of the DES and SCID-D should differentiate between the two conditions because patients with dissociative identity disorder experience all types of dissociative symptoms including amnesia, fugue, depersonalization, derealization, identity confusion, and identity alteration.

There are a number of culture-bound psychiatric syndromes in which fugue is a prominent feature. These syndromes include the “running” syndromes, which include *latah* and *amok* that occur in several nations along the western Pacific rim; *grisi siknis* occurring among the Miskito of Nicaragua and Honduras, and *piblokto* (Arctic hysteria) occurring among the Eskimos of northern Greenland. These syndromes are characterized by a high level of agitation, running about, trance-like states, and amnesia for the episode.

Finally, malingering should always be high on the clinician's index of suspicion, especially in a forensic context of presentation. Malingering may be very difficult to differentiate from genuine dissociative fugue, however, because it may be associated with the same stressors as dissociative fugue (e.g., combat, financial problems,

or marital indiscretions).

Hypnosis or amobarbital (Amytal) interviews may be useful in helping the clinician make the differential diagnosis between dissociative fugue and these other conditions. In many cases of genuine dissociative fugue, memories for the events that occurred during the fugue can be elicited; however, the same is true of dissociative identity disorder. The patient with schizophrenia would be expected to exhibit even more trouble thinking and with looser associations while under the effects of amobarbital. It may be impossible to recover memory in fugues caused by physical conditions, but this may be true of dissociative fugue as well. In one study of patients who had an organic etiology of fugue, 41 percent had memory return with sodium amobarbital. Sometimes malingerers vehemently object to either technique. The clinician must keep in mind, however, that the malingerer may consciously deceive the examiner during the use of either hypnosis or sodium amobarbital. The clinician is also cautioned to use a nonsuggestive interviewing style to avoid the possibility of inducing pseudomemories.

COURSE AND PROGNOSIS

Most dissociative fugues are typically short, lasting from a few days to a few weeks. In many of these cases, recovery is spontaneous. In a only a few cases are symptoms refractory to treatment. Dissociative fugues may be recurrent. In one study, 65 percent of those experiencing dissociative fugue had more than one fugue.

TREATMENT

The mainstay of treatment of dissociative fugue is psychodynamic psychotherapy. A gently exploratory and expressive form is preferred in most cases, although a largely supportive form will usually suffice for those of low ego strength. The clinician should begin with a thorough clinical history and pay close attention to possible precipitating events. In many cases, encouraging persons with dissociative fugue to talk about what they already remember will bring the return of other memories; in some cases free association has proven helpful.

In situations where acute traumatic events have precipitated the dissociative fugue, a gentle abreaction of the trauma is indicated. However, the clinician should be very careful to not proceed with abreactive work until a stable therapeutic alliance has been established. In addition, abreactive work should be suspended, at least temporarily, if the patient's condition worsens (e.g., if the patient becomes depressed or suicidal).

If the individual with dissociative fugue continues to be densely amnesic for identity and autobiographical memory, the use of hypnosis or sodium amobarbital interviewing may be tried cautiously, keeping in mind that the dissociative fugue serves a defensive purpose, and that if the amnesia is suddenly lifted the individual may become depressed or even suicidal. Also, after the hypnotic session is completed, the amnesia may recur. Informed consent should be obtained whenever hypnosis or sodium amobarbital is used.

After the amnesia has been lifted, continued psychotherapy is indicated to help the individual cope with the underlying psychological conflicts that initially caused the dissociative fugue. Ideally, the patient should be helped to integrate the memories of the dissociative fugue state into a cohesive self and memory.

SUGGESTED CROSS-REFERENCES

Dissociative mechanisms are also discussed in Chapter 6 on psychoanalytic theory. Dissociative amnesia is discussed in Section 18.1. Psychotherapies are covered in Chapter 30. Dissociative disorders in children and adolescents are discussed in Section 49.8.

18.3 DISSOCIATIVE IDENTITY DISORDER

FRANK W. PUTNAM, M.D., AND RICHARD J. LOEWENSTEIN, M.D.

Interest in dissociative identity disorder (previously called *multiple personality disorder*) has increased in recent years as a result of improved screening and diagnostic tools and a greater awareness of the dissociative sequelae of trauma, especially childhood maltreatment. The cardinal feature of dissociative identity disorder is the existence of two or more distinct personality states that exchange executive control of the individual's behavior. In addition, almost all such patients report dissociative amnesia, a loss of memory for personal history that cannot be explained by ordinary forgetfulness or organic memory impairment.

Debate about the existence of dissociative identity disorder has waxed and waned for more than a century. Critics usually raise the possibility of an iatrogenic cause, although no empirical studies in clinical populations support this notion. On the other hand, sufficient data on pathological dissociation in general and on this disorder in particular have accrued to judge dissociative disorders by the same standards that are applied to the validity of other psychiatric diagnoses.

The most widely accepted standards are based on a set of criteria first articulated by Eli Robins and Samuel Guze and subsequently refined by others. In essence, a psychiatric diagnosis is considered valid if it satisfies three basic requirements: content validity, criterion-related validity, and construct validity. Content validity requires a detailed clinical description of the disorder that is repeatedly independently replicated. More than a dozen clinical phenomenological studies of dissociative identity disorder including those from North America, South America, Europe, Turkey, and Asia, document the presence of a core dissociative psychopathology in these patients that fulfills this requirement. Criterion-related validity requires that laboratory tests or reliable psychological tests are consistent with the defined clinical picture. This stipulation is met by the reliable and valid diagnostic interviews and scales that have increasingly been employed in dissociation research as well as psychological testing protocols that discriminate these patients from normal controls, and subjects with schizophrenia and major depressive disorder, among others.

Construct or discriminant validity requires that the disorder be differentiable from other disorders. This has been empirically demonstrated for dissociative identity disorder with respect to disorders such schizophrenia, borderline and other personality disorders, and mood disorders. Also, patients with dissociative identity disorder can be discriminated from normal individuals and from other psychiatric patient groups, including those with personality disorders, posttraumatic stress disorder, and dissociative disorder not otherwise specified by structured interviews such as the Structured Clinical Interview for DSM-IV Dissociative Disorders. Psychological test batteries and experimental cognitive and psychophysiological studies have discriminated patients with dissociative identity disorder from other subjects including simulators. Thus, this disorder satisfies widely accepted standards for psychiatric validity and should be regarded as a legitimate disorder requiring an informed diagnostic and treatment approach.

HISTORY

Individuals with a multiplicity of selves have been described in Greco-Roman mythology, the Bible, and other writings prior to the modern medical era. Writing in 1646, Paracelsus is credited with the first medical report of an individual with alternating selves. In 1791 Eberhardt Gmelin described a German woman who alternatingly “exchanged” her peasant personality for that of an aristocratic French lady, each amnesic for the other's existence. By the early nineteenth century, such cases, with diagnoses of dual, double, or duplex consciousness, were being regularly reported on both sides of the Atlantic. In 1811 Benjamin Rush, father of American psychiatry, included a classic example in his medical school lectures. Rush proposed that dual personality reflected a functional disconnection between the two cerebral hemispheres. In the same year the case of Mary Reynolds, who became the American archetype of dissociative identity disorder for the remainder of the century, was first published. European cases such as Despine's “Estelle,” a child with this disorder, and Azam's “Felida” drew widespread public as well as professional attention as the nineteenth century advanced, just as these cases continue to do.

By the beginning of the twentieth century, Pierre Janet in France, Morton Prince and William James in the United States, and others were engaged in a lively transatlantic discussion about possible psychological and neurological mechanisms underlying cases of multiple personality disorder. Medical models of the time invoked phenomena such as sleep and dreams, hypnosis and somnambulism, epilepsy, and disconnections between the cerebral hemispheres to explain this condition. Pierre Janet's research and clinical theory, in particular his emphasis on the role of traumatic antecedents of dissociation, is widely regarded as the foundation for modern views of dissociation. Shortly thereafter, however, interest in dissociation waned in the face of the ascendancy of psychoanalytic theory as well as a variety of other historical forces in Western psychiatry and psychology. Clinical interest in dissociative phenomena has recurred in every war since the turn of the century, however, with the observation of amnesia, fugues, and conversion symptoms in traumatized soldiers. Subsequently, these observations tended to be forgotten by the psychiatric community as the wars themselves faded from memory.

A number of cases of dissociative identity disorder, including the famous “Three Faces of Eve,” continued to be published over the next decades. However, the modern era in the study of multiple personality disorder begins with the work of Arnold Ludwig and colleagues at the University of Kentucky during the 1970s. Cornelia Wilbur, widely identified with the case of ‘Sybil,' was influential in describing the clinical features of multiple personality disorder and identifying the role of childhood trauma as a factor in the etiology of the disorder. Wilbur, Richard Kluft, and others began the articulation of a modern treatment approach.

Since the 1980s the study of multiple personality and pathological dissociation has moved beyond single case reports to systematic clinical description of large groups of patients and empirical studies using standardized measures. The increased attention has led to more cases being diagnosed, which in turn has resurrected old controversies about the nature of this disorder. These include the possibility of iatrogenesis in its creation, the actual prevalence of dissociative disorders, the relationship of traumatic experiences and dissociation, and the criminal responsibility of the individual with the disorder.

EPIDEMIOLOGY

Few systematic epidemiological data exist for dissociative identity disorder. One study yielded a prevalence rate of 3.1 percent for a stratified sample ($N = 1055$) of the general population of Winnipeg, Canada, although a more conservative analysis of these data suggests a prevalence of about 1.3 percent. Independent analysis of the Dissociative Experiences Scale (DES) data collected on the same sample found a prevalence rate of 3.3 percent for pathological dissociation. Several studies examine the prevalence rate of dissociative identity disorder in general psychiatric patient samples. Results from the United States, Canada, Turkey, and several western European countries suggest that between 6 to 20 percent of adult inpatients may have the disorder. Available epidemiological data are insufficient and a large-scale, population-based study is necessary to resolve controversies about its prevalence.

Clinicians have long noted gender differences in the frequency of dissociative identity disorder. Clinical studies report between 5:1 to 9:1 female to male ratios for diagnosed cases. Research with dissociation measures such as the DES, however, find no evidence of gender differences in the propensity or capacity to dissociate. Developmental studies indicate that the ratio of female to male dissociative identity disorder cases steadily increases from 1:1 in early childhood to about 8:1 by late adolescence. Reasons proposed for the increased numbers of female patients relative to males include sex-related differences in the types, age of onset, and duration of maltreatment experienced by males and females; differences in clinical presentations such that male cases are more likely to be missed; and the possibility that more male cases end up in the criminal justice system or alcohol and other substance treatment programs rather than the general mental health system.

ETIOLOGY

Pathological levels of dissociation are strongly associated with histories of antecedent trauma. This has proven true across many types of trauma (e.g., rape, combat, natural disasters, and child maltreatment) in clinical and nonclinical samples. In some, but not all, studies indices of the severity of the trauma (e.g., age of onset and number of perpetrators for child abuse or intensity and duration of combat) are significantly related to the degree of dissociation. Studies of *peritraumatic dissociation*, dissociation manifest in the immediate context of trauma, consistently find that it is the best predictor of subsequent posttraumatic stress disorder 6 or more months later. Multiple lines of research strongly associate increased levels of dissociation with antecedent trauma for many different kinds of trauma.

Dissociative identity disorder is strongly linked to severe experiences of early childhood trauma, usually maltreatment, in all studies in both Western and non-Western cultures that have systematically examined this question. The rates of reported severe childhood trauma for both child and adult patients ranges from 85 to 97 percent of cases. Physical and sexual abuse, usually in combination, are the most frequently reported sources of childhood trauma in clinical research studies. Critics have raised questions about the validity of patients' self-reports of childhood trauma. Recent studies that now include rigorous independent corroboration of the patients' reports of maltreatment continue to strongly support a developmental linkage between childhood trauma and dissociative identity disorder.

Early life experiences resulting in disturbances in attachment relationship with the primary caregiver and other abnormal family processes have been implicated in the genesis of pathological levels of dissociation and the development of dissociative identity disorder. Recent research indicates that high levels of dissociation in mothers is associated with disturbed, often dissociative-like, attachment behavior in their children. In another study early presence of these attachment disturbances prospectively predicted higher levels of dissociation in late adolescence. The contribution of genetic factors is only now being systematically assessed, but preliminary studies have not found evidence of a significant genetic contribution.

Memory Disturbances Functional (i.e., nonorganic) amnesias are a hallmark of dissociative psychopathology. Researchers have sought to examine these for the past century. The total number of patients intensively studied is small, but a number of common findings are emerging. Research designs typically investigate differential encoding and retrieval of learned information across the alter personality states of patients with dissociative identity disorder. A variety of memory tests have been used, generally measuring explicit or implicit memory performance. Explicit memory refers to memory for learned information that involves facts or events and is associated with an awareness of the source of that information. Implicit memory refers to memory for information or experience whose source is largely out of the individual's awareness, but nonetheless may influence behavior. In several studies the information to be learned was presented (implicitly or explicitly) to one alter personality state and retrieval performance was measured in the same and different alter personality states.

Memory studies have most consistently found dissociative effects on implicit memory functions. Alter personality state-dependent compartmentalization of explicit information has also been demonstrated in some cases. The degree of ambiguity of the information appears to be a key factor in determining whether learned information is available for recall across different alter personality states. Highly ambiguous information is the most likely to become compartmentalized within the specific alter personality state in which it was acquired and relatively unavailable in other personality states. Patients with this disorder also show alter personality state-dependent disturbances in the retrieval of autobiographical information such that specific memories, typically those containing negative experiences and affects, are most available while in certain personality states. Experimental studies indicate that alter personality state-dependent compartmentalization of learned information is generally relative and rarely absolute, so that some of the information can usually be retrieved across personality states. Finally, comparison of individuals with this disorder with normals in standardized autobiographical memory studies show that the former subjects recall significantly fewer memories for childhood.

Differential Psychophysiology Psychophysiological studies of these patients have largely been directed towards the implicit question of “Are the alter personalities real?” Beginning with Morton Prince's 1908 galvanometer study of electrodermal responses to emotional cue words, investigators have sought to identify differential responses to the same stimulus by alter personality states in patients with dissociative identity disorder. The result is a number of single case or small sample studies reporting differential psychophysiological responses that are not duplicated by simulating control subjects. These include power spectral differences in the electroencephalogram (EEG), differences in the amplitude and latency of visual and auditory evoked potentials, ophthalmological differences, and differences in hemispheric and regional cerebral blood flow as measured by several techniques. Personality state-dependent differences have also been reported for autonomic nervous system variables such as heart rate and blood pressure. None of these studies is definitive. In aggregate, they support long-standing clinical observations of differential alter personality physiological reactivity to medications, allergens, and other stimuli.

Epileptic-and-Limbic System Model Modern scientific models echo the explanations proposed by Pierre Janet, Morton Prince, William James and others at the end of the last century. The epileptic- and-limbic system dysfunction model arises from clinical observations of a higher-than-expected incidence in patients with dissociative identity disorder of apparent seizures and symptoms such as depersonalization, déjà vu, and fugue behaviors that also occur in patients with complex partial seizures. These observations led to a model suggesting that epileptiform discharges were a major factor in the etiology of this disorder. Also, unusually high rates of left temporal lobe EEG abnormalities have been reported in children and adults with histories of childhood maltreatment. However, video EEG studies have not correlated epileptoid activity with dissociative epileptiform symptoms. Also, studies using standardized diagnostic measures have compared epilepsy patients, including those with refractory temporal lobe pathology, to patients with dissociative identity disorder; little clinical similarity was found between seizure patients and dissociative patients in these studies.

Several single case reports document changes in hemispheric lateralization of motor functions across alter personality states, for example, changes in dominant handedness; larger controlled studies have not yet replicated these reports. Overall, when all the available psychophysiological data are considered, patients with dissociative identity disorder generally show significantly greater variability compared to controls when measurements are made comparing different personality states on a specific measure.

Autohypnotic Model The autohypnotic model is widely subscribed to by clinicians working with dissociative patients. It postulates that pathological dissociation is an extreme form of self-hypnosis or autohypnosis. Autohypnosis is postulated to be adaptive in the immediate context of trauma or abuse, but subsequently becomes maladaptively elaborated into dissociative alter personality states. Proponents point to similarities between the phenomenology of deep trance states and some of the clinical phenomenology seen in dissociative identity disorder. Also, adjunctive hypnotherapeutic interventions can be quite helpful in the treatment of many such patients. In addition, studies of hypnotizability using standardized scales have shown that dissociative patients have the highest hypnotizability compared to patients with other diagnoses such as mood disorders, panic disorder, personality disorders, and schizophrenia as well as normal controls.

On the other hand, more than a dozen studies find only low correlations between measures of hypnotizability and dissociation in clinical and nonclinical subjects. A history of trauma is not necessarily associated with increased hypnotizability, although a subgroup of traumatized individuals will show high levels of hypnotizability both clinically and on standardized measures. These findings indicate that hypnotizability and clinical dissociation, as defined by standard measures, are different processes. Although high hypnotizability may be a correlate of traumatization in some patients, the autohypnotic model of the etiology of dissociative identity disorder does not by itself appear to account for the disorder.

Social Role Model The social role model is frequently invoked by skeptics, who regard this disorder as an iatrogenic condition. These critics argue that it is a socially induced behavior that arises through the effects of implicit or explicit suggestion by an authority figure such as a therapist on a susceptible patient. Experiments with undergraduate students demonstrate that with sufficient cueing some individuals will say that they have a second personality that is responsible for alleged misbehaviors. These staged simulations, however, are psychologically transparent and lack any clinical features of dissociative identity disorder. Psychophysiological studies consistently find differences between patients with the disorder and simulating controls, which further indicates that the simulation or malingering social role model is not sufficient to explain the disorder.

Behavioral State Model The behavioral state model conceptualizes the disorder as a developmental failure by a traumatized child to consolidate a core sense of identity. Drawing on research demonstrating the key role of discrete behavioral states in the patterning and organization of normal early childhood behavior and affect regulation, the behavioral state model postulates that trauma disrupts unification of identity in a least two key ways. The first is through the creation of discrete behavioral states associated with the mitigation of and restitution from repetitive traumatic experiences such as incest. These dissociative behavioral states psychologically encapsulate intolerable memories and affects through cognitive mechanisms such as state-dependent learning and memory retrieval. Secondly, repetitive traumatic experiences, together with disturbed caretaker-child attachment and parenting, disrupt the development of normal metacognitive processes involved in the elaboration and consolidation of a unified sense of self. These metacognitive processes, which flower between ages 1 to 6 years, enable the child to integrate the different experiences of self that normally occur across different contexts, for example, with parents, peers, and others. A corollary of this notion is the idea that the failure of integration of self may preserve aspects of parent-child attachment necessary for development because the child may continue to perceive the caretaker as good, despite mistreatment or neglect. Encapsulation of traumatic experiences may also permit more normal maturation in other developmental dimensions such as educational and intellectual tasks, interpersonal relations, and artistic endeavors.

Overall, however, the long-term outcome of these developmental deficits and deformations operating over childhood and adolescence is an individual with multiple,

relatively concretized, quasi-independent senses of self, which are often in psychological conflict with each other. The secondary structuring of these self-states due to a variety of developmental pressures and intrapsychic needs results in the concrete elaboration of the alter identities with names, personal descriptors, and variable ways of presenting themselves to others. These secondary elaborations are not the core aspect of the disorder. However, they may be highly invested in by some patients and thus may be quite resistant to change. At the other extreme, some patients may show significant liability to influence and suggestion in outward presentational features of the alter identities.

Nosology Early clinical conceptualizations considered multiple personality disorder as a manifestation of hysteria. In the first edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-I), published in 1952, multiple personality disorder was included under the category of dissociative reaction. In DSM-II, published in 1968, multiple personality disorder was included as hysterical neurosis, dissociative type. In DSM-III, a new diagnostic category of dissociative disorders was created and has been retained in the revised third edition of DSM (DSM-III-R) and the fourth edition of DSM (DSM-IV). The diagnostic criteria have remained essentially unchanged since DSM-III-R, other than the addition of the requirement of dissociative amnesia in DSM-IV.

DIAGNOSIS AND CLINICAL FEATURES

Table 18.3-1 lists the DSM-IV criteria for dissociative identity disorder. The comparable ICD-10 disorder, multiple personality disorder, falls under the other dissociative (conversion) disorder category (see Table 18.5-3). The DSM and ICD criteria are virtually identical; both require that organic disorders, (e.g., general medical conditions, substance abuse) be ruled out. DSM-IV adds that in children the symptoms cannot be attributable to imaginary playmates or other fantasy play.

A. The presence of two or more distinct identities or personality states (each with its own relatively enduring pattern of perceiving, relating to, and thinking about the environment and self).
B. At least two of these identities or personality states recurrently take control of the person's behavior.
C. Inability to recall important personal information that is too extensive to be explained by ordinary forgetfulness.
D. The disturbance is not due to the direct physiological effects of a substance (e.g., blackouts or chaotic behavior during alcohol intoxication) or a general medical condition (e.g., complex partial seizures). **Note:** In children, the symptoms are not attributable to imaginary playmates or other fantasy play.

Table 18.3-1 DSM-IV Diagnostic Criteria for Dissociative Identity Disorder

Dimensions of Trauma Traditional characterizations of dissociative symptoms largely derive from nineteenth-century formulations and do not incorporate recent understanding of the psychiatric effects of trauma. Comparative study of psychiatric symptoms associated with different types of trauma suggests that a number of common dimensions underlie traumatic sequelae. Affect modulation is frequently disturbed, giving rise to mood swings, depression, suicidality, and generalized irritability. Impulse control is often impaired, leading to risk taking, substance abuse, and inappropriate or self-destructive behaviors; high levels of anxiety and panic are common. A variety of disturbances in sense of self, from the identity diffusion seen in patients with borderline personality disorder to the alter identities of patients with dissociative identity disorder, reflect disruptions in the psychological integration of traumatic and nontraumatic aspects of self. Eating disorders are common in a subgroup of trauma patients and may also relate to disorders of body image and identity. Frequent somatization, conversion, and psychophysiological disorders may represent disruptions in the integration of psychic and somatic representations of overwhelming recollections, intolerable affects, posttraumatic cognitive schema, and intrapsychic conflicts. In addition, studies suggest that childhood sexual abuse survivors with psychophysiological disorders when compared with controls are more likely to have a lower threshold for experiencing physiological phenomena as noxious or painful.

Initial clinical presentations in trauma victims of all kinds may encompass or mimic a variety of psychiatric conditions including mood and anxiety disorders, somatoform disorders, personality disorders, and psychosis. Some of these disorders may also be comorbidly associated with dissociative identity disorder, especially posttraumatic stress disorder, mood disorders, somatoform disorders, substance use disorders, and a mixed personality disorder most commonly with some combination of avoidant, obsessive-compulsive, dependent, and borderline traits. All systematic studies of the clinical phenomenology of dissociative identity disorder emphasize the polysymptomatic presentations of these patients. Therefore, the detection and diagnosis of the disorder involve looking beyond a confusing plethora of symptoms for core dissociative symptoms of functional amnesias, depersonalization and derealization, passive influence experiences, and identity alterations.

Memory Symptoms Dissociative disturbances of memory are manifest in several basic ways and are frequently observable in clinical settings. As part of the general mental status examination, clinicians should routinely inquire about experiences of losing time, blackout spells, and major gaps in the continuity of recall for personal information. Patients rarely report these experiences spontaneously and require active inquiry by the interviewer to uncover amnesia. Positive responses should be documented with specific examples provided by the patient. In some instances, patients report coming to or waking up in the midst of some activity with little or no recall of how they came to be involved in that activity. In other instances patients find evidence of having done or acquired things for which they have no recall. Friends and family members may tell them about significant things that they have said or done that they cannot remember. Patients may find that they have unknowingly traveled some distance (a fugue episode) or that days or even weeks have passed unaccounted for. Dissociative time loss experiences are too extensive to be explained by normal forgetting and typically have sharply demarcated onsets and offsets. It is important to establish that such time-loss experiences occur in the absence of intoxication or substance abuse, although high rates of drug and alcohol abuse in dissociative patients may complicate this determination.

Patients with severe dissociative memory disturbances also report perplexing fluctuations in skills, habits, or well-learned abilities such as fluency in a foreign language or athletic abilities. Patients report drawing a complete blank for skills or knowledge at times, while at other times they easily and reliably access the information in question. This perplexing forgetfulness is believed to be related to the dissociative state-dependent disturbances of implicit memory functions that have been documented in laboratory settings.

Dissociative patients often report significant gaps in autobiographical memory, especially for childhood events. Dissociative gaps in autobiographical recall are usually sharply demarcated and do not fit the normal decline in autobiographical recall for younger ages. For example, a patient may complain of being unable to recall anything between the ages 8 to 12 years, while reporting readily available memories before and afterwards. Another patient may report having no memories available for the first 10 years of life. Available autobiographical memories may have a depersonalized quality such that recalled events seem to be memories of a dream or as if the patient had seen them happen to someone else.

Process Symptoms Dissociative process symptoms include depersonalization and derealization, dissociative hallucinations, passive influence or interference experiences, and dissociative cognition. Some authorities include dissociative alterations in identity in this category. Symptoms of depersonalization and derealization are commonly reported by patients and may include profound out-of-body experiences. Patients frequently report feeling “spaced out” or disconnected from themselves and others. The world is perceived as distant or unreal with a hazy or foggy quality. Patients may report feeling as if they exist in a waking dream state. Out-of-body experiences commonly take the form of watching oneself from a distance (inner as well as outer) as if observing another person, with little or no ability to affect one's actions.

Dissociative auditory hallucinations commonly take the form of voices heard as originating from within the person (pseudohallucinations) as opposed to coming from outside. Individual hallucinated voices typically have distinctive age and gender attributes. They may comment negatively about the patient, argue with each other, command the patient to perform certain acts, discuss neutral topics, and sometimes provide useful information or comfort. Patients generally recognize that the voices are hallucinations and may be reluctant to reveal their existence for fear of being considered psychotic. Many patients report some ability to ignore or disregard hallucinations unless they are stressed. Hallucinated voices often come to be identified with specific alter personality states. Visual hallucinations typically take the form of detailed images with traumatic or frightening content. Other visual hallucinations may be understood as depicting the alter identities or may even have a complex artistic quality. Tactile, gustatory, and olfactory hallucinations may also occur, leading to misdiagnoses of seizure disorder or other organic mental disorders. Intrusive posttraumatic flashbacks and images may also be experienced as complex multimodal hallucinations.

Negative hallucinations, in which external percepts and stimuli are not consciously registered, are not uncommon. Patients also report the volitional ability to block out

various perceptions or sensations, including pain. Most hallucinations, pseudohallucinations, and negative hallucinations in patients with dissociative identity disorder are likely to be homologous to phenomena that can be experienced in deep trance states among highly hypnotizable individuals, and are not a manifestation of a process psychosis.

Passive influence or interference symptoms include many first-rank Schneiderian symptoms such as audible thoughts; voices arguing with each other; influences playing on the body; thought withdrawal and insertion; and ‘made' feelings, impulses, and actions. These symptoms were once considered to be pathognomonic of schizophrenia, but can also be found in patients with mood, organic, and dissociative disorders. Passive influence symptoms now have been demonstrated to be more common in patients who have dissociative identity disorder than in patients with psychotic mental disorders. However, the agents of the passive-influence symptoms are usually experienced by dissociative patients as internal, not external, as in psychotic disorders. In addition, patients may report strong affects or impulses that they experience without a sense of personal ownership, but with a peremptory sense of intrusion and control.

The recognition that dissociative patients frequently manifest subtle but often clinically significant cognitive impairments emerges from clinical research with psychological and cognitive test batteries. Research using projective testing finds distinctive cognitive process markers, including evidence of confusing and contradictory responses to the same stimulus. Distinctive responses to standardized projective testing can often be helpful in distinguishing dissociative patients from other diagnostic groups such as patients with mood disorders, nondissociative forms of posttraumatic stress disorder personality disorders, psychotic disorders, and factitious disorders.

Dissociative Alterations of Identity Clinically, dissociative alterations in identity may first be manifest by odd first person plural or third person singular or plural self-references. In addition, patients may refer to themselves by their own first names or make depersonalized self-references such as “the body” when describing themselves and others, for example, “The father hurt the body so she was upset. We tried to protect her, but it didn't work.” Patients often describe a profound sense of concretized internal division or personified internal conflicts between “parts” of themselves. In some instances these parts may have proper names or be designated by their predominant affect or function (e.g., the angry one or the wife). Patients may suddenly change the way in which they refer to others (e.g., “the son” instead of “my son”).

A set of behaviors, collectively referred to as “switching behaviors,” may be manifest during evaluation or therapy sessions. Switching behaviors include intrainterview amnesias, in which the patient does not seem to recall or is very confused about the process and content of the session. These microdissociative episodes may be manifest by abrupt shifts in the train of thought or sudden inexplicable changes in affect or rapport. A variety of physical signs may occur in conjunction with microdissociative episodes including pronounced upward eye rolls or bursts of rapid blinking and eyelid fluttering. The patient's tone of voice and manner of speaking, posture, and demeanor may show marked alteration. When clinicians encounter evidence of possible microdissociative episodes they should seek to clarify what the patient is experiencing and can recall with nondirective, open-ended questions.

These cognitive, behavioral, and physical shifts are manifestations of alter personality switching or overlap and interference between alter states. The alter personalities of patients with dissociative identity disorder are best conceptualized as discrete behavioral states each organized around a prevailing affect, sense of self (often including a distinct body image), a set of state-dependent autobiographical memories, and a limited behavioral repertoire. Authorities have long cautioned that alter personalities should not be regard as separate people. Rather, the alter personalities are conceptualized as relatively stable and enduring patterns of behavior that are largely unintegrated with each other and often in direct conflict.

The set of alter personality states, usually referred to as the personality system, constitutes the personality of the individual. Most psychotherapeutic work is directed towards this larger personality system and thus towards the individual as a whole. Much has been made of the psychological and physiological differences among the alter personality states of these individuals and popular accounts emphasize the presentation differences among alters. Laboratory studies support clinical accounts of significant differences; however, much general information and many functions and abilities are shared across alter personality states and indicate the fundamental unity of the mental processes of the dissociative individual. This provides the foundation for therapeutic efforts directed at the development of a more consciously integrated sense of self in the patient with dissociative identity disorder.

Apparent differences in the organization and dynamics of alter personality systems have been used to classify dissociative patients into various categories for more than a century. The validity of these classifications remains to be proven, but as a group these patients show considerable variability in the complexity and therapeutic tractability of their alter personality systems. Several alter personality types are commonly reported, including child alter personalities, internalized persecutory alters who inflict pain and may attempt to kill the individual, and depleted and depressed “host” personality states, who function as the primary identity with respect to the world at large. Alter personality states often reflect painful psychological issues for the individual and frequently take the form of polarized pairs representing antithetical positions, although alters representing more neutral and conflict-free processes also commonly occur. In some individuals, virtually every aspect of mental life is structuralized and personified in this form.

Child and Adolescent Presentations A growing clinical research literature documents the diagnosis and treatment of child and adolescent dissociative disorders including dissociative identity disorder. In most respects children and adolescents manifest the same core dissociative symptoms and secondary clinical phenomena as adults. Age-related differences in autonomy and life-style, however, may significantly influence the clinical expression of dissociative symptoms in youth. For example, dissociative amnesias and perplexing forgetfulness are more apparent in school situations rather than work or family life. Younger children in particular have a less linear and less continuous sense of time and are often not able to self-identify dissociative discontinuities in their behavior. Fortunately, there are often additional informants, such teachers and relatives, available to help document dissociative behaviors. A number of normal childhood phenomena, such as imaginary companionship and elaborated daydreams, must be carefully differentiated from pathological dissociation in younger children.

Screening Instruments and Diagnostic Interviews The development and increasing utilization of screening instruments and standardized diagnostic interviews has contributed to the increase in numbers of identified cases of dissociative identity disorder seen since the 1980s. A variety of self-report questionnaires are available for clinical screening. The most widely used, the DES, takes about 10 minutes to complete and has good reliability, sensitivity, and specificity. Two well-validated diagnostic interviews are available. SCID-D is a 277-item, clinician-administered, semi-structured interview that addresses all five of the DSM-IV dissociative disorders. It is currently considered the gold standard. Many clinicians rely on the shorter Dissociative Disorders Interview Schedule (DDIS) for its ease and speed of administration. Child and adolescent dissociation measures are just becoming available and are not as well validated. The Child Dissociative Checklist (CDC) and Adolescent Dissociative Experiences Scale (A-DES) are two commonly used screening measures. Dissociative modules have been drafted for the standard child diagnostic interviews, but these sections are as yet untested. Several stand-alone child or adolescent diagnostic interviews have also recently been introduced.

Ms. A. is a 33-year-old married woman, employed as a librarian in a school for disturbed children. She presented to psychiatric attention after discovering her 5-year-old daughter “playing doctor” with several neighborhood children. Although this event was of little consequence, the patient began to become fearful that her daughter would be molested. Ms. A. became panicked and increasingly obsessed with this idea, much to the bafflement of her husband. The patient was seen by her internist, treated with antianxiety agents and antidepressants, but with little improvement. Ms. A. became increasingly anxious, phobic, depressed, and preoccupied. She sought psychiatric consultation from several clinicians, but repeated good trials of antidepressants, antianxiety agents, and supportive psychotherapy resulted in limited improvement. After the death of her father from complications of alcoholism, the patient became more symptomatic. He had been estranged from the family since the patient was about 12 years old because of his drinking and associated antisocial behavior.

Ms. A. developed a variety of somatic complaints including headaches, abdominal pain, menstrual and gastrointestinal problems, back pain, and sleep difficulties. Repeated medical workup was unrevealing leading to diagnoses such as fibromyalgia, irritable bowel syndrome, and premenstrual tension. Family and marital difficulties increased as the patient withdrew from her husband and was increasingly dysfunctional in taking care of her children; work function also deteriorated. Psychiatric hospitalization was precipitated by the patient's arrest for disorderly conduct in a nearby city. She was found in a hotel, dressed in revealing clothing, engaged in an altercation with a man. She denied knowledge of how she had come to this hotel, although the man insisted she had come there under a different name for a voluntary sexual encounter.

On psychiatric examination the patient described dense amnesia for the first 12 years of her life with the feeling that her “life started at 12 years old.” She reported that for as long as she could remember she had had an imaginary companion, an elderly black woman, who advised her and kept her company. She reported hearing other voices in her head: several women and children, as well as her father's voice repeatedly speaking to her in a derogatory way. She reported that much of her life since age 12 was also punctuated by episodes of amnesia: for work, for her marriage, for the birth of her children, and for her sex life with her husband. She reported perplexing changes in skills; for example, she was often told she played the piano well, but had no conscious awareness that she could do so. Her husband reported that she had always been “forgetful” of conversations and family activities. He also noted that at times she would speak like a child, at times adopt a southern accent, and at other times be angry and provocative. She frequently had little recall of these episodes.

Questioned more closely about her early life, the patient appeared to enter a trance and stated; “I just don't want to be locked in the closet” in a childlike voice. Inquiry about this produced rapid shifts in state between alter identities who differed in manifest age, facial expression, voice tone, and knowledge of the patient's history. One identified itself by a diminutive of the patient's name and appeared childlike. Another spoke angrily, used expletives, and appeared irritable and preoccupied with sex. She discussed the episode with the man in the hotel and stated that it was she who had arranged it. A third alter personality identified itself as a protective entity, experiencing itself as an elderly African-American woman who commented sadly and philosophically about “this whole situation.” Gradually the alter identities described a history of family chaos, brutality, and neglect during the first 12 years of the patient's life, until her mother, also alcoholic, achieved sobriety and left her husband, taking her children with her. In the alter identities, the patient described episodes of physical abuse, sexual abuse, and emotional torment by her father, her siblings, and her mother.

Family sessions with the mother and siblings confirmed many of these reports, with the family recalling episodes of maltreatment that the patient did not recollect. The patient's mother had bid the family never to speak of the earlier difficulties, hoping that everyone would “just forget the whole thing.” After additional assessment of family members, the patient's mother also met diagnostic criteria for dissociative identity disorder, as did her older sister who also had been molested. A brother met diagnostic criteria for posttraumatic stress disorder, major depressive disorder, and alcohol dependence.

The patient improved significantly with psychotherapy directed at stabilization of her dissociative identity disorder and posttraumatic stress disorder. She responded well to clomipramine (Anafranil) with a marked reduction in obsessive-compulsive and depressive symptoms Family therapy was helpful in stabilizing the patient's marriage and helping her husband with the aftermath of the hospitalization and its precipitants. The husband also reported a family history of abuse, although primarily directed at his mother and siblings; he had always seen himself as the family protector. The patient's mother and siblings were already in treatment, but were helped by the opening up of the family history and clarification of their diagnoses. At 3-year follow-up the patient reported fusion of most alter identities, marked diminution of dissociative, somatoform and posttraumatic stress disorder symptoms, but she still required clomipramine (Anafranil) for stabilization of mood and for the symptoms of obsessive-compulsive disorder.

Differential Diagnosis On average, more than 6 years pass between first psychiatric contact and the diagnosis of dissociative identity disorder. Although often portrayed as flamboyant hysterics, only a small minority of patients present in this way. These patients are typically reticent about revealing their dissociative symptoms, especially hallucinations, amnesia, and identity divisions. They most commonly present as relatively inhibited and obsessional, with affective and somatic complaints, and typically acquire three or more psychiatric diagnoses before the disorder is recognized. A subgroup of patients show interpersonal dynamics reminiscent of borderline personality disorder, which some patients with dissociative identity disorder qualify for as a secondary diagnosis once posttraumatic stress disorder and dissociative symptoms are stabilized. The presence of auditory hallucinations, disturbed thinking and behavior, confusion due to amnesic gaps, and Schneiderian first-rank symptoms contributes to the misdiagnosis of schizophrenia in about half of dissociative patients at some point in their psychiatric histories. Rapid changes in mood associated with alter personality switching may suggest a rapid-cycling mood disorder or schizoaffective disorder. Table 18.3-2 lists the most common disorders that must be differentiated from dissociative identity disorder.

Other dissociative disorder (dissociative amnesia, dissociative fugue, dissociative disorder not otherwise specified)
Schizophrenia and other psychotic disorders
Rapid-cycling mood disorder
Borderline personality disorder
Malingering and factitious disorder
Partial complex seizure disorder
Posttraumatic stress disorder

Table 18.3-2 Differential Diagnosis of Dissociative Identity Disorder

COURSE AND PROGNOSIS

Little is known about the natural history of untreated dissociative identity disorder. A few case studies of partially treated patients followed up many years later suggest that the disorder becomes less overt over time, with a decrease in florid dissociative symptoms and less intrapsychic conflict among the alter personality states. These cases, however, are too few and too selected to generalize. Some untreated individuals are thought to continue to be involved involvement in abusive relationships or violent subcultures that may result in the traumatization of their children, with the potential for additional family transmission of the disorder. Many authorities believe that some percentage of undiagnosed or untreated patients die by suicide or as a result of their risk-taking behaviors. Experience with a large number of dissociative identity disorder cases suggests that there are several subgroups of these individuals, ranging from those who function at quite high levels for long periods of time to others who have severely impaired and dysfunctional life trajectories often beginning early in development.

Patient presentations and prognosis vary somewhat across the life span. Children with dissociative identity disorder show many dissociative symptoms and behaviors, but typically have fewer and less crystallized alter personality states that are less invested in their individuality. If diagnosed early, children often have an excellent prognosis and many seem to have relatively spontaneous resolutions when removed from abusive and neglectful environments. In adolescence, alter personality states become more distinct and more invested in their autonomy. Additional alter personalities associated with life stresses such as academic, athletic, social, or sexual challenges may appear and the personality system dynamics become more complicated and polarized. In general, adolescents have a poorer prognosis than children or adults, in part because they are often not invested in their treatment. Better outcome with dissociative adolescents has been reported when the patients' families were successfully engaged in treatment. Young adults typically present in crisis and have a layering of affective, somatic, posttraumatic, and personality

disorder symptoms in addition to their core dissociative pathology.

First presentations in middle-aged or older patients frequently involve a life event such as the loss of a job, death of a parent, or a revictimzation such as a rape that reactivates earlier conflicts and destabilizes the alter personality system. In adult patients, there appear to be both treatment-responsive and treatment-refractory subgroups of patients with dissociative identity disorder. Time course of improvement also may vary, with some patients improving relatively quickly and others requiring intensive treatment over long periods of time.

Prognosis is poorer in patients with comorbid cognitive disorders, psychotic disorders (not dissociative pseudopsychosis), and severe medical illnesses. Refractory substance abuse and eating disorders also suggest a poorer prognosis. Other factors that usually indicate a poorer outcome include significant antisocial personality features, current criminal activity, ongoing perpetration of abuse, and current victimization with refusal to leave abusive relationships. Repeated traumas with recurrent episodes of acute stress disorder may severely complicate the clinical course. Severe personality disorders with overinvestment in multiplicity as a way of life, engagement in psychotherapy primarily to seek gratification, or a refusal to take responsibility for behavior change and symptom management are also generally associated with a poorer prognosis. However, the number of alter personality states has only a moderate effect on treatment course.

TREATMENT

Stages and Goals Current treatment approaches to dissociative identity disorder have evolved considerably with the conceptualization of the disorder as a complex developmental trauma disorder and as the spectrum of patients has been better appreciated. Appropriate treatment of the dissociative patient follows a three-stage model: (1) a phase of symptom stabilization; (2) an optional phase of focused in-depth attention to traumatic material; and (3) a phase of integration or reintegration in which the patient moves more completely away from a life adaptation based on long-term traumatization and victimization. Obviously, these phases are relatively heuristic and aspects of each may be part of the others.

Stabilization of the patient is vital to permit more successful negotiation of all aspects of treatment. Stabilization focuses on safety, stability, and management of core and comorbid symptoms. The vast majority of patients engage in some form of self-destructive behavior, including suicide attempts, self-mutilation, eating disorders, substance abuse, promiscuity, risk-taking activities, and involvement in abusive, violence-based relationships. Many male and some female patients with dissociative identity disorder have difficulty with aggression, violence, and homicidality, including perpetration of child abuse. It is incumbent on the clinician to make these issues the basic focus of treatment. In general, cognitive-behavioral therapy approaches are used, framing these behaviors as part of a set of quasiaddictive trauma-related homeostatic mechanisms. Experienced clinicians find that many dissociative patients can bring self-destructive and high-risk behaviors under control. Cognitive-behavioral therapy methods are used to develop therapeutic agreements (*safety contracts*) so that patients have a repertoire of techniques to manage their difficulties instead of by self-destruction. Eating disorders, severe substance abuse, enmeshment in abusive relationships, and perpetration of violence may be more refractory to these methods and may require concurrent specialty treatment interventions and involvement of police, social service, and community agencies.

Stabilization of severe symptoms generally involves work with posttraumatic stress and dissociative symptoms. Patients with dissociative identity disorder frequently present with highly disturbing symptoms of posttraumatic stress disorder such as intrusive thoughts, imagery, somatic sensations, hyperarousal, and flashbacks. The latter may present as acute behavioral reexperiencing episodes with loss of reality orientation or more subtle and pervasive reliving experiences. Patients may be overwhelmed by dissociative hallucinations, amnesia and fugue episodes, passive influence experiences, or profound identity confusion and disorganization. Sorting out genuinely comorbid disorders from the plethora of posttraumatic, anxiety, mood, and somatic symptoms commonly manifest by dissociative patients in crisis is important because some disorders (e.g., mood disorders) require additional treatment interventions. Assessment of available family and community supports is also important.

Psychotherapy A survey of over 300 clinicians treating patients with dissociative identity disorder found that the vast majority considered psychotherapy to be their primary and most efficacious treatment modality. Successful psychotherapy for the such a patient requires the clinician to be comfortable with a range of psychotherapeutic interventions and willing to actively work to structure the treatment. These modalities include psychoanalytic psychotherapy, cognitive-behavioral therapy, hypnotherapy, and a familiarity with the psychotherapy of the traumatized patient.

Effective stabilization in many patients requires psychotherapeutic work with individual alter personality states. Many patients will not be able to stabilize symptoms in the long term if alter identities who control these symptoms are not therapeutically engaged. Clinicians new to dissociative identity disorder are frequently uncomfortable or perplexed by the need to work with individual alter states and with how to do this without producing a chaotic regression. Certain basic principles are important to understand. No alter is any more or less real than any other or better or worse than another. All are aspects of a single human being and have psychological importance that needs to be heard and respected. All alter states will be held accountable and responsible for the behavior of any part, even if experienced with amnesia or lack of subjective ownership. In the context of psychotherapy, alter personalities can be understood as developmentally concretized, trauma-based metaphors and forms of mental symbolization. These unusual metaphors have many problematic cognitions and affects as well as adaptive attributes such as the alter personality state-dependent memory data. As such, the fullest participation of all mental symbols and sources of knowledge, skills, and adaptations is likely to produce the best outcome in psychotherapy.

Concerns about iatrogenesis are often raised in this context. Understanding the alter personalities as forms of intrapsychic symbolization reduces this concern to a more routine psychotherapeutic task of understanding the meaning of mental contents, rather than a suppression of some mental states as less authentic than others. Most experienced clinicians avoid regression in dealing with dissociative patients' alter identities by insisting that the patient has resources to counter regression. Tendency for regression can be managed by: (1) firm limits and boundaries on the length of sessions; (2) payment of fees; (3) allowing extra-session contacts, and acceptable behavior during sessions; (4) limiting regressive interactions with child alter personalities and insisting that “caretaking” of these entities is the job of the patient, not the clinician; (5) actively structuring sessions to focus on goals of stabilization; (6) using cognitive-behavioral containment and imagery techniques to attenuate the impact of posttraumatic stress disorder intrusions, rather than opening up this material; (7) helping the patient develop new skills to manage symptoms such as dysfunctional switching; (8) using therapeutic contracting to help the patient take active responsibility for symptom management and behavioral control outside of sessions; and (9) actively countering the manifold cognitive distortions presented by the patient.

Typical cognitive distortions include the insistence that alter personalities inhabit separate bodies and are unaffected by the actions of one another (delusional separateness); that patients are unable to control themselves and require the clinician to manage all difficulties; that the clinician is completely untrustworthy and must be not be allowed any access to the patient's mind; that the patient is “bad” and deserved to abused; that anger and violence are the same; that love and sex are the same; that self-injury is safety; and that since trauma and abuse are inevitable it is best to invite them so that at least their timing and intensity can be better controlled.

The continuity, stability, and respectful impartiality of the therapist towards the different alter personalities provides an important therapeutic experience that helps the patient to experience, examine, and integrate these dissociated aspects of the self. The processing of negative life events, often from the multiple perspectives of different alter personality states, is an important part of the narrative reorganization of the patient's fragmented identity into a more coherent whole.

A subgroup of patients with dissociative identity disorder will not progress beyond a long-term supportive treatment entirely directed towards stabilization of their multiple multiaxial difficulties. To the extent that they can be engaged in treatment at all, these patients will require a long-term treatment focused on symptom containment and management of their overall life dysfunction, as would be the case with any other severely and persistently ill psychiatric patient population.

For patients who can stabilize and form a reasonable working alliance in treatment, longer-term treatment goals involve the psychotherapeutic processing of life experiences, especially traumatic experiences, and the transformation of the meaning of these experiences for the individual. Authorities emphasize that in most cases intensive, detailed psychotherapeutic work with traumatic memories should only be initiated after the patient is well stabilized and a solid therapeutic relationship has been established. Experienced clinicians attempt to carefully structure affectively intense sessions focused on traumatic material. In addition, many sessions may be needed to fully explicate the cognitive and emotional meaning of traumatic events so that they may become part of the patient's repertoire of nondissociated, ordinary memories for life experience.

Traumatic Memories Media attention and legal cases have led to concerns over the authenticity of traumatic recollections of patients with dissociative identity disorder. Recent rigorous case series have supported the experience of clinicians who have found corollary information to corroborate patients' recollections or even unearthed data about traumas that the patient does not recall. Based on corollary information, however, some patients can be shown to misinterpret and misrepresent contemporary information or confabulate aspects of their past history. In addition, dissociative patients are hardly immune to ordinary human emotions such as greed, envy, wishes for revenge, wishes to evade consequences for misbehavior, and desires to placate significant others. All these may complicate the patient's veracity,

especially in situations of potential financial gain, media attention, evasion of legal consequences, and possible loss of family contacts. Conversely, collateral informants, such as family members, may be subject to the same sources of unreliability as the index patient and their input should be weighed accordingly. The American Psychiatric Association's statement on recollections of childhood abuse is a helpful guide to these complex matters.

Patients with dissociative identity disorder typically oscillate from regarding their recollections as all true to all false. Specific alter identities may take opposing positions. The clinician is best served by maintaining a stance of neutrality towards the patient's recollections. In this regard it is generally most helpful for the clinician to identify for the patient internal conflicts over the veracity of recollections and invite an open airing of all points of view. Education about the complex factors that may affect autobiographical recall may be helpful, but also may be too abstract for some patients to absorb, especially early in treatment.

The therapist should respond respectfully and thoughtfully to all clinical material brought by the patient. Patients can be helped to not come to premature closure about their views of events. Some patients come to understand life events quite differently as they become less dissociative over the course of treatment. Consequently, clinicians must avoid validating memories for the patient, or dismissing them out of hand, in the absence of reliable collateral information. Therapy is most successful for the patient if the clinician maintains the role of therapist, not personal advocate, detective, or derisive skeptic.
