Withdrawal Syndromes and Negative Reinforcement Although positive reinforcement is a powerful etiological factor in the genesis of cocaine, amphetamine, and (in some cases) opioid dependence, aversive withdrawal phenomena and negative reinforcement may be equally important influences for a number of other drugs and dominant influences for others. One example of this is seen in most persons who become dependent on benzodiazepines taken in the course of treatment for anxiety syndromes. When drug use is interrupted, some seem to experience a reappearance of the original symptoms; others have new distressing symptoms indicating withdrawal. The use of benzodiazepines alleviates both kinds of aversive states. In either case the drug is acting as a negative reinforcer in perpetuating drug use. Benzodiazepines can induce euphoria in alcoholic patients or in persons with histories of sedative abuse, but they are not reliably euphorigenic in normal, nonalcoholic persons. Benzodiazepine anxiolytic agents may induce euphoria in nondependent, nonanxious persons, but such instances are rare relative to the number of those who experience only relief of anxiety.

In most clinical situations, even among users of highly euphoric illicit drugs, the distinction between positive and negative reinforcing effects does not exist. The alcoholic, the heavy smoker, and the heroin user may experience, simultaneously or sequentially, relief of withdrawal, a sense of ease, and perhaps alleviation of dysphoria and depression. With intravenous drugs there may also be a sudden rush of intense pleasure.

Long-Lasting Changes Associated With Chronic Drug Use After long-term use, most drugs of abuse produce adaptive changes in the brain that are manifested as acute and chronic withdrawal syndromes when drug use ceases. How these changes are produced, how long they persist after cessation of drug use, and how they contribute to relapse are still being explored. But much progress has occurred, as is illustrated by several examples of recent developments.

Tolerance and dependence on opioids involves several mechanisms. Opioid agonist binding to the opioid receptors results in an inhibition of adenylyl cyclase and lower intracellular cyclic adenosidine monophosphate (cAMP) concentrations. Long-term exposure elicits compensatory upregulation of the cAMP pathway, internalization of μ- and d-receptors, and a decrease in the number of G proteins, which couple the receptors to the second messengers and ion channels. Upregulation of adenylyl cyclase is mediated by the transcription factor cAMP response element–binding protein (CREB), which also plays a role in the generation of distinct and persistent Fos-like proteins, which are also thought to be involved in tolerance. As a result of upregulation of cAMP, GABAergic neurons innervating the ventral tegmental area become hyperactive when opioids are withdrawn, thus inhibiting dopaminergic neurons. Such a mechanism may account, in part, for the dysphoria and anhedonia of opioid withdrawal. In addition, chronic opioid use reduces the size of dopamine neurons in the ventral tegmental area; increased production of dynorphin may also serve to inhibit dopaminergic activity at the ventral tegmental area and nucleus accumbens. The glutamatergic system is also involved in opioid adaptation, since NMDA receptor sensitivity is altered by opioids and NMDA antagonists can alter the development of opioid tolerance and physical dependence.

With chronic alcohol use, affected neurons develop adaptive changes that include, among a number of others, supersensitivity or increased numbers of NMDA receptors. When the alcohol is withdrawn the actions of excitatory neurotransmitters at supersensitive NMDA receptors are postulated to produce the hyperexcitability of alcohol withdrawal, including hyperactivity in noradrenergic systems and glutamate-induced neuronal excitotoxicity. Alcohol-dependent patients tested 1 week and 1 month after cessation of alcohol use had cerebrospinal fluid with substantially lower concentrations of GABA and substantially higher concentrations of the excitatory transmitters glycine aspartate, glutamate, and *N*-acetylaspartylglutamate (NAAG) than that of healthy controls. Although these changes may be trait markers rather than consequences of long-term alcohol use, they are what might be expected to result from withdrawal of alcohol after adaptive changes have occurred. Most agents currently used to treat alcohol withdrawal act directly or indirectly at GABA receptors, and perhaps those that act at NMDA sites may provide alternative or even superior therapeutic agents.

Nicotine tolerance may involve desensitization of nicotinic receptors. However, chronic nicotine use increases the number of nicotinic cholinergic receptors, and the mechanisms underlying the nicotine withdrawal syndrome remain unclear. From the symptoms, which include craving, inability to concentrate, irritability, increased appetite, dysphoria, and (sometimes) depression, some hypoactivity in dopaminergic systems is likely. Given the many other actions of nicotine on learning, attention, arousal, and appetite, changes in systems in addition to the mesolimbic are probably also involved.

Cocaine and amphetamines can induce tolerance, dependence, and sensitization, depending in part on whether exposure is continuous or intermittent.

One way to determine the contribution of negative reinforcement to the motivation to continue using a substance or to relapse after withdrawal is to introduce agents that can modify withdrawal syndromes or aversive states. Abundant evidence shows that when psychological interventions are held constant, noninhaled nicotine (delivered by transdermal patches [Nicoderm] or nicotine gum [Nicorette]) significantly increases the probability that smokers trying to quit will be successful. Neither nicotine gum nor transdermal patches produce positive reinforcing effects, but they do alleviate aspects of the nicotine withdrawal syndrome. Thus, it is reasonable to infer that although the symptoms may not be life threatening, the avoidance of nicotine withdrawal plays a significant role in continued smoking and relapse. However, evidence suggests that for some, nicotine (or some other component of tobacco) controls negative effects other than those usually associated with withdrawal. Persons with histories of major mood disorder are more likely to become regular smokers if they try cigarettes and may experience symptoms of depression when they try to stop smoking; those symptoms are suppressed by returning to smoking. Heroin addicts treated with oral methadone or sublingual buprenorphine (Subutex) experience a reduction in opioid withdrawal symptoms but little or no euphoric effects from those agents. Yet, such treatment dramatically reduces elf-administration of heroin. Such findings support the view that acute and protracted opioid withdrawal (or opioid suppression of aversive affects) is an important factor in the perpetuation of heroin use and relapse after withdrawal. Similarly, acamprosate, a structural analogue of glutamate is postulated to reduce relapse in alcoholics following alcohol withdrawal by dampening the hyperexcitability in the glutamatergic system.

Conditioned Withdrawal and Stress Sensitivity In addition to the direct contribution of withdrawal phenomena to the perpetuation of drug use are the indirect effects exerted through learning mechanisms. The regular recurrence of withdrawal-induced aversive states provides ample opportunity for those states to become linked through learning to environmental cues and other mood states, and the rapid relief of withdrawal by drug use results in repeated reinforcement of drug-taking behavior. Long after there are measurable manifestations of acute withdrawal, certain moods or environmental cues can evoke components of the original withdrawal state along with urges to use the drug again. Considerable evidence shows that in former opioid addicts, stress can trigger both craving and relapse, and dysregulation of the hypothalamic-pituitary-adrenal axis persists for long periods after drug cessation.

How long withdrawal phenomena, stress sensitivity, or both continue to contribute to risk of relapse is not clear. Substantial evidence supports a withdrawal syndrome period for alcohol, opioids, and certain sedatives with subtle disturbances of mood, sleep, and cognition that persists for many weeks or months after the acute syndrome subsides. Whether the dysregulation of the hypothalamic-pituitary-adrenal axis is causally related to protracted withdrawal or has a similar time course is still uncertain.

Biological Factors—Vulnerability The children of alcoholic parents are at higher risk for developing alcoholism and drug dependence than are children of nonalcoholic parents. Dependence on other drugs also shows a familial pattern. The increased risk is partly due to environmental factors (parental modeling, neglect, early child abuse), but genetic factors are also important. Numerous studies of laboratory animals have revealed genetically transmitted differences in the reinforcing effects of alcohol and various drugs such as cocaine and opioids and show that genetic factors powerfully influence sensitivity to toxic effects. The evidence for genetic factors in human vulnerability to alcoholism and other drug dependence is derived most convincingly from twin and adoption studies, but family studies are also revealing. Several studies of twins have found a higher concordance rate for alcoholism among identical twins than among fraternal twins. Although identical twins are generally believed to have more social contact than fraternal twins, when the effects of environmental factors are adjusted statistically, genetic factors are still found to have a major influence on the likelihood of becoming dependent. Indeed, in one population-based twin study 48 to 58 percent of the variation in liability to dependence was attributable to genetic factors; the remainder was due to general environmental influences not shared by family members.

In studies of 3372 Vietnam-era veteran twin pairs, the concordance rates for dependence on at least one illicit drug were higher for monozygotic twins (26.3 percent) than for dizygotic (16.5 percent) twins. Generally, overall rates of dependence did not differ among these veterans and contemporary civilians. Biometric modeling identified both common (shared) and drug-specific genetic vulnerability factors as well as general and drug-specific effects of family and nonfamily environment. In the common vulnerability models, 31 percent of the variance for common (shared) vulnerability was due to additive genetic factors, 25 percent to family environmental effects, and 44 percent to nonfamily environmental effects. The importance of common (shared) genetic factors versus drug-specific genetic factors varies considerably for different categories of drugs. For marijuana, stimulant, and sedative abuse, common genetic vulnerability factors accounted for most of the genetic variance, with unique specific genetic factors accounting little. For psychedelics, no specific genetic influence was found. For heroin, 54 percent of the total variance was due to genetic factors, with 38 percent (70 percent of total genetic variance) contributed by unique genetic factors and only 16 percent by common (shared) ones. Another analysis of data from this group of veterans showed that both genetic and environmental factors influenced the initiation of cigarette smoking, but genetic effects accounted for 70 percent of the variance in the persistence of smoking for those who became regular smokers. This study, which is consistent with other genetic studies of smoking, found the genetic contribution to the persistence of smoking to be as great as or greater than the genetic contribution in the genesis of other psychiatric disorders, including alcoholism.

Twin studies in women have revealed strong genetic contributions to the use of caffeine and development of caffeine tolerance, dependence, and withdrawal.

Family studies also point towards general and drug-specific vulnerability factors. In a study of alcoholic probands and their siblings, about 50 percent of the brothers and 25 percent of the sisters met lifetime criteria for alcohol dependence. Compared with controls, these siblings also showed higher rates of tobacco, cocaine, and marijuana use, but the siblings of subjects who were dependent on alcohol and another drug, (presumably a more severe form of dependence), were not more likely to develop alcoholism than siblings of subjects who were dependent only on alcohol. However, siblings of probands who were dependent on both alcohol and marijuana had an elevated risk for marijuana dependence; siblings of probands dependent on alcohol and cocaine were more likely to become cocaine dependent. Statistical analysis that controlled for access to the drugs still showed specific family clustering.

Studies of boys adopted soon after birth have shown higher rates of alcoholism among those whose biological fathers were alcoholics than among those whose biological fathers were not. Some adoption studies pointed toward subtypes of alcoholism among men: one is a later-onset disorder that is less severe and far more sensitive to environmental factors (type I) and the other is associated with early onset, antisocial behavior and criminality in the biological fathers, and a stronger genetic basis for the increased vulnerability (type II). The hypothesis that two genetically distinct types of alcoholism (type I and type II) exist has been criticized on the grounds that it is essentially a relabeling of the older primary-secondary categorization. In the latter, alcohol-dependent persons who do not have antisocial personality disorder are designated as having primary alcoholism; those who first exhibit antisocial personality disorder and later develop alcoholism are designated antisocial personality disorder with secondary alcoholism. Also, several groups have been unable to use the type I and type II criteria to categorize patients with alcohol dependence accurately in clinical studies. However, arguments about the validity of the type I–type II categorization do not diminish the importance of genetic factors in vulnerability to developing alcohol dependence. The results of a large-scale efforts to identify the genes that contribute to vulnerability to alcoholism are now emerging.

As many as one third of alcohol-dependent persons have no family history of the disorder. Men are more likely to develop alcoholism than are women (fourfold to fivefold in the United States). This is true across every culture studied, probably reflecting, in part, social sanctions on drug use and deviant behavior by women. But it is also postulated that women are less likely to drink heavily because they are less tolerant to alcohol. Women who do drink heavily run the same risk of developing alcoholism as men who drink heavily, and women who use illicit drugs are about as likely to develop dependence as men who use such drugs.

In some, but not all studies alcohol-dependent persons are at far higher risk for developing other varieties of drug dependence. A more consistent finding is that drug-dependent persons also are at high risk for alcoholism and often have a family history of alcoholism. Such findings are consistent with data from the twin studies that have found general as well as drug-specific vulnerability factors.

Most researchers believe that no single gene will be found to account for the complexities of inherited risk for drug and alcohol dependence. Some genetic factors may not increase vulnerability to alcoholism but decrease it. A genetically determined variation in the activity of enzymes that metabolize alcohol (alcohol dehydrogenase and aldehyde dehydrogenase [ALDH]), common among some Asian groups, results in high levels of acetaldehyde in response to alcohol ingestion. The effect is to cause alcohol flush reaction and to exert some deterrent effect on alcohol ingestion. Alcoholism is lower among many Asian groups than among whites. Further, Asians with alcoholism are much less likely to have the inactive form of the ALDH enzyme.

Biological and Behavioral Differences Studies exploring how persons with and without family histories of alcoholism might differ have involved measures of personality, drug-use and alcohol-use patterns, psychomotor and cognitive performance, electrical activity of the brain, endocrine responses to challenges with alcohol and other substances, as well as measures of receptor numbers and affinities and enzyme activities (e.g., MAO) in peripheral tissues (e.g., blood platelets and lymphocytes). One finding that has been replicated is that under some conditions, the electrical response of the brain that occurs about 300 ms after a sensory stimulus (the P300 wave) has a smaller amplitude in nondrinking sons and daughters of alcoholic fathers than in control subjects without family histories of alcoholism. The decreased amplitude is believed to reflect a decreased capacity to recognize and interpret complex environmental stimuli. Most studies have found

no differences in intelligence among subjects with and without family histories of alcoholism. However, the results of personality studies are conflicting; some find no differences and others find greater impulsivity, adventurousness, and sensation seeking among those with a positive family history. Studies of the drinking patterns of adolescent and young adult sons of alcoholic persons also have not yielded consistent results; some (but not all) studies show that sons of alcoholic parents are heavier drinkers. Other studies have compared the subjective, motoric, and endocrine responses of young men with and without family histories of alcoholism following challenge exposures to alcohol and other potentially euphoriant drugs (such as benzodiazepines). Sons of alcoholic fathers seem to be more tolerant to the intoxicating effects of modest doses of alcohol, and in some (but not all) studies, higher doses of alcohol produced smaller changes in their prolactin and cortisol concentrations. Furthermore, one study found that sons who had smaller responses to test doses of alcohol at age 20 (i.e., were more tolerant) were fourfold more likely to have developed alcoholism 8 years later. Another study of sons of alcoholic parents found that those who had exhibited smaller electroencephalographic (EEG) alpha frequency responses to alcohol were more likely to be alcohol dependent at 10-year follow-up.

The results of studies using benzodiazepine challenges are also not consistent; one showed a greater euphoric response to alprazolam (Xanax) in sons of alcoholic parents, and another showed no difference between positive and negative family-history groups after a dose of diazepam.

A number of studies have shown that conduct disorder and early childhood aggression are associated with a substantial increase in the likelihood of early involvement with illicit drug use and development of dependence on alcohol and illicit drugs. Considerable evidence supports a role for both genetics and environmental factors in the development of conduct disorder. Antisocial personality disorder represents an independent additional risk factor for addictive disorders. The effects of antisocial personality disorder and family history of an substance-related disorder appear to be additive rather than synergistic. It seems possible that in some of the studies of children and young people at high risk for later drug dependence, the electrophysiological differences, cognitive deficits, and personality differences reflected the presence of conduct disorder or antisocial personality disorder rather than a family history of alcoholism per se.

Psychodynamic Factors and Psychopathology Early psychoanalytic formulations postulated that drug users, in general, suffered from either a special form of affective dysregulation (tense depression) that was alleviated by drug use or from a disorder of impulse control in which the search for pleasure was dominant. More-recent formulations postulate ego defects, which are evinced by the addict's inability to manage painful affects (guilt, anger, anxiety) and to avoid preventable medical, legal, and financial problems. The newer formulations postulating ego defects are to some degree the older formulations with a modest change in terminology that gives greater weight to the inability to cope with painful affects than to the intensity or abnormality of the affects per se. It is postulated that some substances pharmacologically and symbolically aid the ego in controlling those affects and that their use can be viewed as a form of self-medication. For example, it has been suggested that opioids help users control painful anger, that alcohol helps alcoholics control panic, and that nicotine may help some cigarette smokers control symptoms of depression. Although it is conceded that some of those observations may reflect problems produced by long-term use, the psychodynamic perspective is that the psychopathology is the underlying motivation for initial use, dependent use, and relapse after a period of abstinence. However, traditions of passivity and uncovering techniques derived from the psychoanalysis of neurosis are poorly suited to the treatment of most drug addicts. Further, some addicts have great difficulty differentiating and describing what they feel, a difficulty that has been called alexithymia (i.e., no words for feelings).

Family Dynamics One family member's substance abuse is often influenced by substance-using behaviors of others in the family, and these complex interrelationships can profoundly affect their lives. An understanding of the relationships among substance-using patients and their families is relevant for understanding the etiology of substance dependence and its treatment and for helping other family members to cope with problems associated with the substance-using behavior.

More has been written about the families of alcohol-dependent persons and heroin users than about families affected by users of other drugs. Similarities between the family dynamics in these two prototypical dependencies have led researchers and clinicians to assume that certain general principles apply to all varieties of substance dependence. The observation that alcoholism is commonly found in the families of those seeking treatment for other types of dependence, that alcohol-dependent persons are often dependent on other substances as well, and that those addicted to illicit drugs are often alcoholic suggests that there are common features among families with an addicted member. However, there are few data to suggest that the families of those dependent on tobacco or benzodiazepines are as dysfunctional as those affected by alcohol, opioids, or cocaine.

It is not always clear to what degree one family member's behavior causes the substance-using behavior of another or is primarily a response to that behavior. Some writers emphasize that the addiction is a symptom that provides a displaced focus for conflict among other family members and that the user (the designated patient) may be playing a role in maintaining the homeostasis of a dysfunctional family. At the same time, addiction often arises in families in which one or both parents (and sometimes grandparents) have drug or alcohol problems and other psychopathology. Some characteristics commonly observed both in families of persons who are alcohol dependent and of those addicted to illicit drugs are multigenerational drug dependence; a high incidence of parental loss through divorce, death, abandonment, or incarceration; overprotection or overcontrol by one parent (usually the mother), whose life is inordinately dependent on the behavior of the addicted offspring (symbiotic relationships); distant, cold, disengaged, or absent father (when the father is alive); defiant drug-using child, who appears to be engaged with peers but remains unusually dependent on the family well into adult life (pseudo-independence). The actual family dynamics are difficult to characterize because the family members' self-reports about their relationships do not reliably correspond to what outsiders observe. Such families typically do not describe themselves in the way that family therapists see them. Some workers have proposed that unresolved family grief plays a role in the genesis of drug addiction in a family member and that such families cannot deal effectively with separation because of previous losses. Despite the pathological interdependence between the addict and other family members, the addict is often described as passive, dependent, withdrawn, and unable to form close relationships.

Despite all the apparent pathology found in families, in many instances the family brings the substance user into treatment, and the patient often believes that it is the family that is most likely to be helpful in recovery. Furthermore, clinicians now generally believe that involving families in treatment is important, if not essential, to effective intervention. One aspect of treating families is dealing with the tendency of some members to shield the patients from the consequences of their substance use, a behavior usually labeled by clinicians as “enabling” but usually experienced by the family member as loving, supporting, accepting, and protecting. A variation on family therapy, sometimes called network therapy, involves enlisting family members and close friends as allies of the therapist to provide social support and reinforcement of drug-abstaining behaviors. The persons selected to fulfill this role function as part of a treatment team rather than as patients.

CODEPENDENCE The terms “coaddiction,” “coalcoholism,” or more commonly “codependency” or “codependence” have recently come into vogue to designate the behavioral patterns of family members who have been significantly affected by another family member's substance use or addiction. The terms have been used in various ways, and there are no established criteria for codependence, a concept that some writers have expanded far beyond its origins to encompass any personality disorder that involves difficulty in expressing emotions. However, many have criticized the expanded concept of codependence as a largely invalid notion based solely on anecdote. The following summary of some characteristics frequently described as aspects of codependence is not meant to imply the validity of a unitary syndrome.

Enabling Enabling was one of the first and more agreed upon characteristics of codependence or coaddiction. Sometimes family members feel that they have little or no control over the enabling acts. Either because of the social pressures for protecting and supporting family members or because of pathological interdependencies, or both, enabling behavior often resists modification. Other characteristics of codependence include an unwillingness to accept the notion of addiction as a disease. The family members continue to behave as if the substance-using behavior were voluntary and willful (if not actually spiteful) and the user cares more for alcohol and drugs than for the members of the family. This results in feelings of anger, rejection, and failure. In addition to those feelings, the family members may feel guilty and depressed because the addict, in an effort to deny loss of control over drugs and to shift the focus of concern away from their use, often tries to place the responsibility for such use on the other family members, who often seem willing to accept some or all of it.

Denial Family members, like the substance users themselves, often behave as if the substance use that is causing obvious problems were not really a problem; that is, they engage in denial. The reasons for the unwillingness to accept the obvious vary. Sometimes denial is self-protecting, in that the family members believe that if there is a drug or alcohol problem, then they are responsible.

Like the addicts themselves, codependent family members seem unwilling to accept the notion that outside intervention is needed and, despite repeated failures, continue to believe that greater will power and greater efforts at control can restore tranquility. When additional efforts at control fail, they often attribute the failure to themselves rather than to the addict or the disease process, and along with failure come feelings of anger, lowered self-esteem, and depression.

Other Problems Some clinicians have reported high levels of somatic disorders, such as ulcers, colitis, and migraine, among family members of alcoholic persons and addicts and have attributed those illnesses to stress or a somatic expression of the feelings engendered by trying to cope with the family member's addiction. However, in light of the findings that there may be a genetic basis for somatization disorders among the daughters of certain subtypes of alcoholic persons, it is not clear that all of the illnesses seen among the family members of substance users are responses to the stresses of living with an addict.

Other Factors There are other factors that influence the pattern of use and cessation of any given substance. For example, the decision not to use a substance also has consequences that can be aversive or reinforcing, and evidence indicates that when the rewards of not using the substance are high, the likelihood of use is reduced. In addition, many of the substances associated with dependence act directly on systems that subserve both motivation and decision making, raising questions about whether use is always influenced solely by its consequences (learning processes). The cognitive processes and skills that would ordinarily subserve decision-making appear to be impaired by alcohol, barbiturates, cannabis, and several other categories of self-administered agents. Thus, whereas substance use is influenced by learning, the substances also alter the brain itself. This suggests additional problems and possibilities for intervention. Evidence is accumulating that limited cognitive skills reduce the likelihood of successful recovery from substance use and that coping skills can help a person avoid or deal with aversive affective states, environmental stresses, and situations that are associated with a high risk for substance use.

Other factors that influence the course of substance use and dependence are difficult to operationalize or teach or prescribe, but they deserve mention. Studies of the natural history of substance use indicate that recovery is powerfully influenced by the support of family and friends. Many persons report that hope, faith, formal religious affiliation, or the sustaining love of some significant person was more important to their recovery than any specific treatment.

Multiple Factors The biopsychosocial general model of substance dependence presented here does not attempt to assign a weight or special significance to any one factor or interaction. The implication is that for different categories of drugs, different factors may play more or less powerful causal roles in perpetuating substance use or facilitating relapse. For example, positive reinforcing effects may be more important for the development of cocaine dependence, whereas acute and protracted withdrawal phenomena may be more important in the return to opioid use following withdrawal. Even with the same substance, different factors may be more or less important for different persons. Thus, the emergence of depressive symptoms may make it difficult for some cigarette smokers to quit, particularly those with a history of major depressive disorder, and those persons may be helped by antidepressants. Such a multifactorial model implies that certain treatments or interventions may be more effective for one substance category than another and that even among persons using the same substances, different treatments may be indicated.

Figure 11.1-1 also implies that the notion of dependence is not a property of any one element but an abstraction inferred from the relations among the elements of the system. While it is convenient (and required by DSM-IV) to see dependence as a disorder located within a person, any interpretation that overemphasizes one part of the system, whether the biology of the person, social influences, or behavior, is missing part of the nature of dependence.

Comorbidity *Comorbidity* is the co-occurrence of two or more psychiatric disorders in a single patient. A high prevalence of additional psychiatric disorders is found among persons seeking treatment for alcohol, cocaine, or opioid dependence. Although opioid, cocaine, and alcohol abusers with current psychiatric problems are more likely to seek treatment, it should not be assumed that those who do not seek treatment are free of comorbid psychiatric problems; such persons may have social supports that enable them to deny the impact that drug use is having on their lives. Two large epidemiological studies have shown that even among representative samples of the population, those who meet the criteria for alcohol or drug abuse and dependence (excluding tobacco dependence) are far more likely to meet the criteria for other psychiatric disorders also. In the NCS, 51 percent of those who met the criteria for a lifetime addictive disorder received at least one additional mental disorder diagnosis; in the earlier ECA study, the comparable figure was 38 percent. In the ECA study, among those diagnosed with drug dependence the most common additional diagnosis was alcohol abuse-dependence, followed in frequency by antisocial personality disorder, phobic disorders, and major depression for men and phobic disorders, major depression, and dysthymia for women. Almost every psychiatric diagnosis was more common among those who met the criteria for drug dependence, with notable increases in odds ratios for alcoholism, antisocial personality disorder, and mania among women, and for mania, antisocial personality disorder, and dysthymia among men. Both men and women with drug abuse-dependence are at a substantially higher risk for schizophrenia. The extent of comorbidity among individuals in the ECA study is illustrated in Figure 11.1-2.

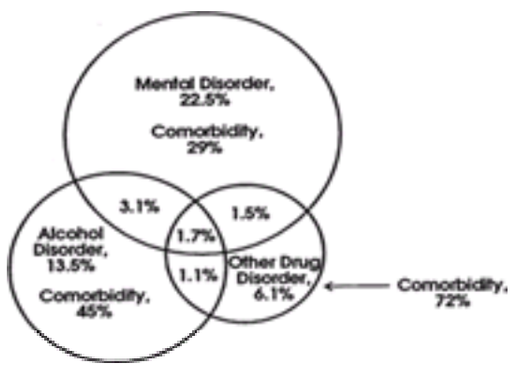

FIGURE 11.1-2 Lifetime prevalence of comobid mental and addictive disorders in the United States, combined community and institutional five-site Epidemiologic Catchment Area data, standardized to the U.S. population. (Reprinted with permission from Regier DA, Farmer ME, Rae DS, Locke BZ, Keith SJ, Judd LL, Goodwin FK: Comorbidity of mental disorders with alcohol and other drug abuse. JAMA *264:*2511, 1990.)

In general, the probability of comorbidity is higher for those with a lifetime diagnosis of an opioid or cocaine disorder than for those with a diagnosis of cannabis abuse. Among people in prison the comorbidity rates were even higher than in the general population; addictive disorders were found in 92 percent of prisoners with schizophrenia, 90 percent of those with antisocial personality disorder, and 89 percent of those with bipolar disorders. Among persons with mental disorders seeking treatment in psychiatric specialty settings, 20 percent have a current substance abuse disorder diagnosis.

The findings from the NCS largely confirm the observations of the ECA study that those with substance use disorders are substantially more likely to experience other mental disorders and that those with other mental disorders are far more likely to develop substance use disorders. The NCS also underscored the finding that although 52 percent of respondents had never experienced any DSM-III-R disorder and 21 percent had one such disorder, 13 percent had two disorders and 14 percent had three or more disorders. Furthermore, the 12-month prevalence of a disorder was more likely among those with more than one disorder: 59 percent of all of 12-month disorders occurred in the 14 percent with a lifetime history of three or more disorders, and 89 percent of severe 12-month disorders occurred in the same group.

These findings describe rather than explain comorbidity. They do not shed much light on the question of whether, or in which cases, drug use is at least initially an adaptive effort at self-medication, or whether those with a variety of psychiatric disorders are less able to cope with the effects of substance use and so are more likely to become dependent. It is also not clear whether psychiatric disorders increase the vulnerability to drug abuse and drug dependence or whether some common factor contributes to both. In some cases, however, there does appear to be a causal link between drug use and some psychiatric disorders. For example, evidence indicates that substance abuse (especially alcohol) can cause or increase the risk for depressive disorder; cocaine can increase the frequency of panic disorder; and cannabis, cocaine, and amphetamine use can aggravate or precipitate schizophrenic symptomatology. Some of these are drug-induced disorders (particularly some of the depressive symptoms seen in alcoholics) and clear with cessation of alcohol use. However, some psychiatric disorders (e.g., mood disorder and antisocial personality disorder) often antedate substance use and can be viewed as risk factors or predictors for substance abuse and dependence. This is particularly true of conduct disorder adult antisocial behavior, in which the symptoms often begin before the onset of problematic drug use. The NCS found that the odds of developing alcohol or drug dependence increased fivefold in the presence of conduct disorder without adult antisocial behavior and 10- to 14-fold if only adult antisocial behavior or both conduct disorder and antisocial behavior were present. Of the Axis I disorders, bipolar I disorder is more strongly related to dependence on alcohol or drugs than any other mood or anxiety disorder. In general, about 24.5 percent of those with a 12-month addictive disorder had a mood disorder as well, and 35.6 percent had an anxiety disorder. Overall, 42.7 percent of those with a 12-month addictive disorder had at least one 12-month Axis I mental disorder. In terms of lifetime disorders, 41 to 65.5 percent of those with a lifetime addictive disorder have a lifetime history of at least one Axis I mental disorder, while 51 percent of those with one or more lifetime mental disorders (Axis I or II) have a history of one or more addictive disorders. For lifetime conduct disorder or adult antisocial behavior, the rate of lifetime substance use disorder rises to 82 percent.

Although the possibility of recall bias exists, those with both an affective and an addictive disorder usually report that depression began earlier than substance use. However, temporal relationship between two disorders does not prove causality, even when the development of the first disorder is a predictor of both the likelihood and course of the subsequent disorder. There is the possibility, as has been suggested for smoking and depression, that both disorders are linked to some third common factor. In the NCS, a more chronic course of an addictive disorder was found for those who reported earlier development of primary anxiety disorder, conduct

disorder, or adult antisocial behavior but was not found with earlier onset of other mental disorders.

In the NCS, co-occurring mental disorders also influenced the likelihood of seeking treatment and the treatment sector from which service would be sought. As mentioned, those who had a substance dependence problem were far more likely to seek and receive treatment if they also had a co-occurring mental disorder. About one-third of people with a 12-month history of affective disorder received some treatment; but those who also had an addictive disorder were more likely to have received it in a specialty addiction treatment program.

A collaborative study of the genetics of alcoholism used extensive structured interviews to separate independent mood and anxiety disorders from those that occurred only within the context of active drinking or withdrawal. This study found that over a lifetime, independent mood disorder was less common in alcoholics (14 percent) than in controls (17.1 percent), although more than twice as many alcoholics (2.3 percent) as controls (1.0 percent) met criteria for bipolar disorder. Panic disorder and social phobia were also substantially more common as independent disorders among alcoholics. In general, in this study the large majority of alcohol-dependent men and women did not have independent mood or anxiety disorders. This suggests that the higher rates of co-occurrence of most anxiety and affective disorders found in epidemiological studies or clinical populations probably reflect substance (alcohol)-induced anxiety and mood disorders that will resolve without special intervention once drug use ceases.

TREATMENT

Many people who develop substance-related problems recover without formal treatment. For those who do seek help or advice, particularly those patients with less severe disorders, relatively brief interventions are often as effective as more intensive treatments. Since these brief interventions do not change the environment, alter drug-induced brain changes, or provide new skills, a change in the patient's motivation (cognitive change) probably best explains their impact on the drug-using behavior. For those individuals who do not respond or whose dependence is more severe, a variety of interventions appear to be effective. Although each section in this chapter discusses treatment relevant to the particular substance use disorder, the clinician sees few drug-dependent people who use only one drug. (Nicotine dependence may be an exception.) For example, among patients using an illicit drug, the most common additional diagnosis is alcohol dependence.

It is useful to distinguish among specific procedures or techniques (e.g., individual therapy, family therapy, group therapy, relapse prevention, and pharmacotherapy) and treatment programs. Most programs use a number of specific procedures and involve several professional disciplines as well as nonprofessionals who have special skills or personal experience with the substance problem being treated. The best treatment programs combine specific procedures and disciplines to meet the needs of the individual patient after a careful assessment. However, there is no generally accepted classification either for the specific procedures used in treatment or for programs making use of various combinations of procedures. This lack of standardized terminology for categorizing procedures and programs presents a problem, even when the field of interest is narrowed from substance problems in general to treatment for a single substance, such as alcohol, tobacco, or cocaine. Except in carefully monitored research projects, even the definitions of specific procedures (e.g., individual counseling, group therapy, and methadone maintenance) tend to be so imprecise that one usually cannot infer just what transactions are supposed to occur. Nevertheless, for descriptive purposes, programs are often broadly grouped on the basis of one or more of their salient characteristics: whether the program is aimed at merely controlling acute withdrawal and consequences of recent drug use (detoxification) or is focused on longer-term behavioral change; whether the program makes extensive use of pharmacological interventions; and the degree to which the program is based on individual psychotherapy, AA or other 12-step principles, or therapeutic community principles. For example, government agencies recently categorized publicly funded treatment programs for drug dependence as either methadone maintenance (mostly outpatient), outpatient drug-free programs, therapeutic communities, or short-term inpatient programs. However, these broad descriptions mask as much as they reveal, tend to confuse the setting with the procedures, and obscure differences in the etiological models underlying the treatments used in different programs.

Selecting a Treatment Not all interventions are applicable to all varieties of substance use or dependence, and some of the more coercive interventions used for illicit drugs are not applicable to substances that are legally available, such as tobacco. Changes in addictive behaviors do not occur abruptly, but rather through a series of stages. Five stages in this gradual process has been proposed: precontemplation, contemplation, preparation, action, and maintenance. For some types of addiction the therapeutic alliance is enhanced when the treatment approach is tailored to the patient's stage or readiness to change. For some drug use disorders, a specific pharmacological agent may be an important component of an intervention; for example, disulfiram, naltrexone (ReVia) or acamprosate for alcoholism; methadone, levomethadyl acetate (ORLAAM) (also called L-a-acetylmethadol [LAAM]) or buprenorphine (Buprenex) for heroin addiction; nicotine delivery devices or bupropion (Zyban) for tobacco dependence. Not all interventions are likely to be useful to health care professionals. For example, many youthful offenders with histories of drug use or dependence are now remanded to special facilities (boot camps), other programs for offenders (and sometimes for employees) rely almost exclusively on the deterrent effect of frequent urine testing, and a third group are built around religious conversion or rededication in a specific religious sect or denomination. In contrast to the numerous studies suggesting some value for brief interventions for smoking and for problem drinking, there are few controlled studies of brief interventions for those seeking treatment for dependence on illicit drugs.

In general, for those persons who are severely dependent on illicit opioids, brief interventions (such as a few weeks of detoxification, whether in or out of a hospital) have limited effect on outcome measured a few months later. Among patients dependent on cocaine or heroin, substantial reductions in illicit drug use, antisocial behaviors, and psychiatric distress are much more likely following treatment lasting at least 3 months. Such a time-in-treatment effect is seen across very different modalities, from residential therapeutic communities to ambulatory methadone maintenance programs. Although some patients appear to benefit from a few days or weeks of treatment, a substantial percentage of users of illicit drugs drop out (or are dropped) from treatment before they have achieved significant benefits. Some of the variance in outcome of treatment can be attributed to differences in the characteristics of patients entering treatment and by events and conditions following treatment. However, programs based on similar philosophical principles and using what seem to be similar therapeutic procedures vary greatly in effectiveness. Some of the differences among programs that seem to be similar reflect the range and intensity of services offered. Programs with professionally trained staffs that provide more-comprehensive services to patients with more severe psychiatric difficulties are more likely to be able to retain those patients in treatment and to help them to make positive changes. Differences in the skills of individual counselors and professionals can powerfully affect outcomes. Such generalizations concerning programs serving illicit drug users may not hold for programs dealing with those seeking treatment for alcohol or tobacco or even cannabis problems uncomplicated by heavy use of illicit drugs. In such cases, relatively brief periods of individual or group counseling can produce long-lasting reductions in drug use. The outcomes usually considered in programs dealing with illicit drugs have typically included measures of social functioning, employment, and criminal activity, as well as decreases in drug-using behavior. Treatment for alcoholism and other mental health problems generally has more limited expectations (e.g., reduction in alcohol use and symptoms of psychiatric disorders), although changes in the use of health care resources subsequent to treatment is sometimes an additional measure of treatment efficacy.

Measuring Treatment Outcome The latest published large multisite study of treatment, the Drug Abuse Treatment Outcome Study (DATOS, carried out from 1991 to 1993), interviewed patients at intake and 1, 3, and 12 months after treatment. As in previous multisite studies, sites selected were stable representatives of four major program types: drug-free outpatient, methadone maintenance, short-term residential (chemical dependency), and long-term residential (therapeutic community). Except at the methadone programs, which used group and individual counseling about equally, group counseling was the common element of the other treatments. Some antidepressants and antipsychotic agents were used in the nonmethadone programs, but they were incidental.

This study found a lower level of services available to patients seeking treatment then were available decade earlier. Also, the patients were older and more likely to have a variety of special medical problems (e.g., HIV positive, concurrent psychiatric disorders) and social needs (homelessness). Treatment outcomes were generally consistent with those of previous studies of drug treatment in the public sector. One year after treatment there were substantial decreases in drug use. Levels of weekly or daily cocaine use at 1 year were about 50 percent of pretreatment levels, with greater reduction for those who participated in treatment for 3 months or more. Daily heroin use was lower among patients who remained in methadone maintenance treatment than among those who left. Although cocaine use among patients treated with methadone was somewhat lower, the reduction could not be attributed to treatment. Alcohol and marijuana use did not decline significantly. There was also no apparent decrease in suicidal thoughts or increase in employment, and in contrast to a number of previous multisite studies, multivariate analysis in this study did not confirm the widely reported reduction in predatory and or high-risk sexual behaviors for those in methadone programs. Those who stayed in long-term residential treatment for 6 months or longer showed a major decrease in drug use from preadmission levels for all categories of drugs—66.4 to 22 percent for cocaine; 17.2 to 5.8 percent for heroin; alcohol and marijuana use reduced by more than half. These individuals also reported a 50 percent decrease in illegal activities and about a 10 percent increase in full-time employment.

In DATOS, outpatient drug-free and short-term inpatient programs had very few admissions in which the major drug problem was heroin; the most common presenting drug problem for both was cocaine, followed by alcohol and marijuana. Participation in the outpatient drug-free programs for 3 months or more was associated with a greater decrease in cocaine use at 1 year, (about 50 percent compared with those who stayed 3 months or less). But even 58 percent of those who stayed less than 3 months reported some decrease in cocaine use over preadmission levels. Patients who entered short-term inpatient programs also reported major decreases in drug use at 1 year, but there was no difference between those who stayed more than 2 weeks and those who stayed less than 2 weeks. Since the decision to enter any of the programs studied in DATOS was made by the patient, the study does not give much guidance to a clinician weighing a recommendation for a specific patient.

More guidance comes from a large-scale, random-assignment study of the treatment of alcoholics, which found that three distinct methods of delivering individual therapy over a 12-week period—12-step facilitation, cognitive-behavioral coping skills, and motivational enhancement (four sessions only)—produced comparable and generally quite favorable outcomes. Patient characteristics interacted significantly with the treatment in only one area, alcoholics with low-level psychiatric problems had better outcomes in terms of days of abstinence if assigned to 12-step facilitation rather than cognitive behavioral therapy. Patients who received individual therapy after a brief period of inpatient and intensive day-care treatment (aftercare) had better 1-year outcomes than those who began individual treatment as outpatients.

Currently, entry into treatment rarely reflects a truly informed choice aimed at matching the characteristics and needs of the patient with the capacities and skills of a provider. Findings from studies of public-sector programs serving drug users with relatively few social supports show that more-intensive services, such as vocational, health, and mental health services, increase retention and produce better outcomes at follow-up.

Influence of Philosophical Orientation The kinds of therapeutic procedures deemed valuable or essential by treatment professionals are profoundly affected by their philosophical orientation. For example, one study found that many professionals who adhere to a disease model of substance dependence view reduction of denial, acceptance of disease, need for lifelong abstinence, commitment to recovery, and affiliation with AA as the most important elements of intervention. In contrast, dealing with responsibility, instilling motivation and confidence, teaching relapse prevention, and avoiding high-risk situations were rated highest by psychologists espousing a behavioral model of dependence. Until quite recently, even physicians were unlikely to view pharmacological interventions as having significant value in treating alcoholism or most other forms of drug dependence, although some physicians did prescribe various forms of nicotine for tobacco dependence.

Many controlled studies over many years have shown that the use of illicit opioids (heroin) can be markedly reduced by supervised administration of oral methadone or LAAM. Because of government regulations, the use of these agents is currently limited to practitioners and programs who have obtained special licenses; such programs and practices are rigidly regulated. Buprenorphine, a partial opioid agonist, is also effective. Data also show that naltrexone can reduce relapse rates for alcoholics following withdrawal. Controlled studies conducted in Europe show that acamprosate, a drug believed to act via actions on the glutamatergic system, can also reduce alcoholism relapse rates. However, to date, the pharmacological agents available to treat substance-related disorders have not been widely used, even when there are few regulatory barriers. The relatively indifferent or negative attitudes of physicians toward the use of pharmacological agents in the treatment of alcoholism and drug dependence may change if new and more effective medications become available at reasonable cost and unencumbered by burdensome government regulations. However, at present there seems to be only a modest correlation between the evidence showing that a given intervention or procedure is effective and the likelihood that it will be widely used.

Treatment of Comorbidity—Integrated Versus Concurrent The treatment of the severely mentally ill (primarily those with schizophrenia and schizoaffective disorders) who are also drug dependent continues to pose problems for clinicians. Although some special facilities have been developed that use both antipsychotic drugs and therapeutic community principles, for the most part specialized addiction agencies have difficulty treating these patients. Generally, integrated treatment in which the same staff can treat both the psychiatric disorder and the addiction is more effective than either parallel treatment (a mental health and a specialty addiction program providing care concurrently) or sequential treatment (treating either the addiction or the psychiatric disorder first and then dealing with the comorbid condition.)

Services and Outcome The extension of managed care into the public sector has produced a major reduction in the use of hospital-based detoxification and virtual disappearance of residential rehabilitation programs for alcoholics. Unfortunately, managed-care organizations tend to assume that the relatively brief courses of outpatient counseling that are effective with private-sector alcoholic patients are also effective with patients who are dependent on illicit drugs and who have minimal social supports. For the present, the trend is to provide the care that costs least over the short term and to ignore studies showing that more services can produce better long-term outcomes.

Treatment is often a worthwhile social expenditure. For example, treatment of antisocial illicit drug users in outpatient settings can produce decreases in antisocial behavior and reductions in rates of HIV seroconversion that more than offset the treatment cost. Treatment in a prison setting can produce favorable decreases in postrelease costs associated with drug use and rearrests. Despite such evidence there are problems maintaining public support for treatment of substance dependence, both in the public and private sectors. This lack of support suggests that these problems continue to be viewed, at least in part, as moral failings rather than as medical disorders.

SUGGESTED CROSS-REFERENCES

Individual sections discuss in detail the relevant substances and treatment for their related disorders: alcohol-related disorders in Section 11.2; amphetamine-related disorders, Section 11.3; caffeine-related disorders, Section 11.4; cannabis-related disorders, Section 11.5; cocaine-related disorders, Section 11.6; hallucinogen-related disorders, Section 11.7; inhalant-related disorders, Section 11.8; nicotine-related disorders, Section 11.9; opioid-related disorders, Section 11.10; PCP-related disorders, Section 11.11; sedative-hypnotic–related disorders, Section 11.12, and anabolic-androgenic steroid abuse, Section 11.13. Brief psychotherapy is covered in Section 30.8; alternative therapies, in Section 30.10; and methadone (and other maintenance therapies) in Section 31.23. Drug and alcohol abuse among elderly persons is discussed in Section 51.3h.

11.2 ALCOHOL-RELATED DISORDERS

MARC A. SCHUCKIT, M.D.

An understanding of the effects of alcohol and the clinical importance of alcohol-related disorders is essential for the practice of psychiatry. Alcohol intoxication is capable of causing irritability, violent behavior, feelings of depression, and in rare instances, hallucinations and delusions. Longer-term, escalating levels of consumption of alcohol can produce tolerance as well as such intense adaptation of the body that cessation of use can precipitate a withdrawal syndrome usually marked by insomnia, evidence of hyperactivity of the autonomic nervous system, and feelings of anxiety. Therefore, the adequate evaluation of life problems and psychiatric symptoms in a patient requires that the clinician consider the possibility that the clinical situation reflects the effects of alcohol.

The clinical importance of the relation between alcohol use patterns and psychiatric symptoms is amplified by the high prevalence of alcohol intake and related problems in the general population. Ninety percent of people in most Western societies consume alcohol at some time during their lives, and perhaps 30 percent or more of drinkers develop temporary alcohol-related life problems. Severe, repetitive alcohol-related life impairment (i.e., alcohol dependence) is observed at some time during the lives of approximately 10 percent of men and 3 to 5 percent of women, with an additional 5 to 10 percent of each sex developing persistent but less intense alcohol-related life problems that are diagnosed as abuse. Because high levels of alcohol intake can cause diverse medical and psychiatric problems, it has been estimated that 20 to 35 percent of people seeking help from a health care provider have alcohol abuse or dependence. Thus, alcohol-related problems are very common in society.

Despite the diverse nature of the symptomatology and the high prevalence of alcohol-related disorders, the alcoholic is rarely easy to identify. Alcohol abuse and dependence are seen in both genders, all races and ethnic groups, and in all socioeconomic strata. The alcoholic individual usually has a job, functions moderately well in a family setting, and often appears in the psychiatrist's office with general complaints that rarely point directly toward the alcoholism. The clinician establishes the contribution of alcohol to the clinical complaints by avoiding the false stereotype of the alcoholic as a nonfunctional street person, recognizing the high prevalence of this disorder, and considering the diagnosis in all psychiatric patients.

DEFINITION AND COMPARATIVE NOSOLOGY

Alcohol Use Disorder In all diagnostic systems, the definition of alcoholism indicates evidence of repeated impairments from alcohol in multiple areas of life functioning, despite which the person returns to drinking. These basic elements were present in the third edition (1980) and the revised third edition (1987) of the American Psychiatric Association's *Diagnostic and Statistical Manual* (DSM-III, DSM-III-R) and have continued into the fourth edition (DSM-IV) published in 1994. In the most recent manual, dependence is diagnosed as the presence of at least three of seven major areas of life impairment related to alcohol occurring repeatedly and clustering together in the same 12-month period. These difficulties include tolerance, evidence of a withdrawal syndrome when the drug is discontinued or intake is decreased, potential interference with life functioning associated with spending a great deal of time using the substance, and returning to use despite evidence of physical or psychological problems. It is the syndrome of dependence for which the best data are available regarding the usual clinical course of problems, appropriateness of treatment, and potential importance of genetic factors.

DSM-III-R and DSM-IV do not require evidence of tolerance or withdrawal for the definition of dependence. Recognizing the large change in the concept of “alcoholism” associated with the absence of the centrality of these physiological components of the disorder, DSM-IV allows clinicians to subtype dependence into those syndromes with evidence of a physiological component (i.e., tolerance or withdrawal) and those without these phenomena. Some recent data support the clinical importance of withdrawal, and it is hoped that the request for subtyping will facilitate the accrual of data to determine if it is appropriate to continue to emphasize these physiological conditions in DSM-V.

Thus, all patients with a possible alcohol use disorder should first be evaluated for the presence of alcohol dependence. For those who do not meet the criteria for this disorder, however, there is a second potential syndrome to consider, *abuse*. Here an individual who is not dependent on alcohol demonstrates repeated problems within any 12-month period in any one or more of four potential areas of difficulties. These include repeated legal, interpersonal, social, or occupational impairments related to alcohol, as well as use of alcohol in physically hazardous situations. DSM-IV reformulated the concept of abuse in order to identify criteria that were independent of those noted for dependence. However, it is likely that if they continue to drink, the majority of individuals with abuse will go on to develop dependence in the future.

A similar definition of dependence occurs in the tenth revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10). Here, however, the threshold for diagnosis is any three of six (rather than seven) items. The items in ICD-10 dependence include all the concepts in DSM-IV, although they are expressed and numbered differently and some concepts are combined into one criterion. ICD-10 also lists a second and less intense alcohol use disorder, known as *harmful use*. The definition of this second syndrome is quite different from DSM-IV because the ICD-10 approach is based on evidence of repeated interference with psychological and physical health functioning, and does not include social impairment, legal problems, or use in physically hazardous situations. Thus, although the definitions of dependence are quite similar in the United States and ICD-10 systems, there is less obvious overlap between *abuse* and *harmful use*.

Attempts have been made to further divide alcohol-dependence into clinically meaningful subgroups. One such approach is demonstrated in DSM-IV where persons with dependence syndromes are to receive an additional notation of whether a physiological component (i.e., tolerance, withdrawal, or both) is present. Other authors have called for the recognition of a more severe early-onset alcohol dependence syndrome, often accompanied by criminality and dependence on other drugs, which has been labeled as *type II* or *type B alcoholism*. These latter approaches are consistent with the recognition that an earlier-onset alcohol dependence syndrome, like most medical and psychiatric disorders, is likely to have a more severe course, but it appears as if some of the prognostic significance of type II or B alcoholism rests with an elevated risk for a concomitant antisocial personality disorder in the early-onset group.

Severity and Remission The DSM-IV definition of dependence also attempted to better clarify the concepts of severity and remission. Regarding the former, no reliable criteria could be developed, and the manual offers the clinician the possibility of incorporating the relatively imprecise divisions of *mild* (with few symptoms), *moderate* (with functional impairment intermediate between mild and severe), and *severe* (with many symptoms); ICD-10 has no formal notation of severity.

Remission is a more complex phenomenon, and the definition was created from data gathered in a field trial that was incorporated into the DSM-IV process. The diagnostic criteria distinguish between the high-risk period in the first 12 months of recovery and at later time points and ask the clinician to specify whether the patient is totally free of substance-related problems. The criteria also consider whether or not the individual is living in a controlled environment such as prison or a hospital; ICD-10 makes similar but not identical distinctions.

EPIDEMIOLOGY

Psychiatrists need to be concerned about alcoholism because this condition is common, and the usual alcoholic person resembles most other patients (i.e., does not fit a stereotype). Thus, it is always important to evaluate the drinking patterns of all patients because alcohol can interact with medications and intensify pre-existing major psychiatric disorders. Clinicians also need to recognize that a high proportion of their patients have temporary but potentially important alcohol-induced

psychiatric syndromes.

Prevalence of Drinking At some time during their lives, 90 percent of the population in the United States drinks, with most persons beginning their alcohol intake in the early to mid-teens years (Table 11.2-1). At any time two out of three men are current drinkers, with a ratio of persisting alcohol intake of approximately 1.3 men to 1 woman. A *current drinker* is defined most commonly as anyone who has used alcohol during the preceding 1 to 3 months, and is differentiated from persons with alcohol problems. The age of highest prevalence of drinking and of greatest alcohol intake is from the middle or late teens years to the mid 20s.

Condition	Population (%)
Ever had a drink	90
Current drinker	60–70
Temporary problems	40+
Abuse*	Male: 10+ Female: 5+
Dependence*	Male: 10 Female: 3–5

* 20–30 percent of psychiatric patients.

Table 11.2-1 Alcohol Epidemiology

Different groups in the United States have different proportions of drinkers. Generally, those who have high education and high socioeconomic status have the highest proportion who are current drinkers. Among religious groups, Jews have the highest proportion who consume alcohol, but the lowest number of persons with alcohol problems. Conservative Protestants and Catholics use alcohol less frequently than liberal Protestants and Catholics. Other groups, such as the Irish, have higher rates of severe alcohol problems, but they also have significantly higher rates of abstention. High rates of alcohol problems are also found among Native Americans and Eskimos.

In the United States in the early 1990s the average person over the age of 14 years consumed 2.31 gallons of absolute alcohol a year. This amount sounds substantial, but it is considerably less than the over 5 gallons of absolute ethanol consumed each year at the time of the American Revolution. The current figure also represents a significant decrease from the amounts consumed during the mid 1970s, and the 2.7 gallons per capita in 1981.

Alcohol Problems Because a high proportion of persons are drinkers, especially in their middle teens to mid-20s, and because the per-capita consumption of alcohol is high, it is not surprising that a large proportion of persons have alcohol-related problems sometime in their lives. A recent 10-year follow-up study of almost 500 men evaluated at age 33 found that during the preceding decade between one quarter and one third had alcohol-related blackouts, approximately one third admitted to driving after consuming enough alcohol to be impaired, and 20 percent reported missing school or work because of either a hangover or a desire to party with alcohol rather than work.

As common as these problems are and as much as they contribute to lost work time and to physical morbidity and mortality, most people appear to mature out of alcohol problems with the passage of time. Thus, people probably experience fewer alcohol-related difficulties during their 30s than during their 20s, and even fewer difficulties in their 40s and 50s. Both per-capita consumption and the proportion of persons with problems related to alcohol appear to decrease with increasing age beyond middle adulthood.

Alcohol Abuse or Dependence The lifetime risk for alcohol dependence is approximately 10 percent for men and 3 to 5 percent for women. The rate of alcohol abuse and dependence combined may be as high as 20 percent for men and 10 percent for women. Those figures translate to perhaps a total of 200,000 deaths a year in the United States from accidents (perhaps 25,000 persons a year alone), suicide, cancer, and heart disease—the leading causes of death among alcoholic men and women. Cirrhosis is also found at increased rates; 15 percent of alcoholic persons meet the criteria for cirrhosis. Because alcoholism is associated with numerous medical and psychiatric problems, alcoholic persons are overrepresented in psychiatric settings, where they make up one quarter to one third of the usual patient load, even in facilities that serve the affluent.

The age of peak onset of alcohol problems severe enough to lead to a diagnosis of alcohol dependence is probably in the middle 20s to approximately age 40. Despite multiple difficulties in social relationships, families, and jobs, high functioning in some areas is likely to remain. Thus, the stereotypical alcoholic person who is a homeless bum is very much the exception rather than the rule, representing only 5 percent of all persons with severe, recurring alcohol-related difficulties.

Age-related differences are found in the pattern of alcohol-related problems. As is true with almost all psychiatric and many medical disorders, the earlier the onset of alcoholism, the greater the chance that the disorder is severe and that another psychiatric disorder pre-existed. Therefore, when alcohol dependence is noted in a teenager, the person probably has another problem, usually conduct disorder (i.e., early antisocial personality disorder). In that instance, the alcohol-related problems are likely to be associated with severe drug difficulties and antisocial problems in school and with family or peers that occurred before the onset of alcohol dependence. At the other extreme, although most alcoholic persons have their problems early in life, perhaps 10 percent or so have an onset of recurring difficulties after the age of 55. The late onset of the disorder tends to be associated with less severe social difficulties and more subtle signs and symptoms, but a greater likelihood of associated medical problems than among younger alcoholic persons.

Comorbid Conditions The alcohol-related disorders are highly prevalent conditions, and psychiatric symptoms are common during intoxication and withdrawal. Therefore, if diagnoses were to be used to indicate prognosis and optimal treatment, an algorithm had to be developed to help the clinician disentangle temporary substance-related psychopathology from independent psychiatric syndromes.

Alcohol is an organic agent, and most diagnostic algorithms formulated from the time of Emil Kraepelin through DSM-IV have recognized the potential dangers of labeling psychiatric disorders when the symptoms develop during a condition strongly influenced by an organic cause. This hierarchical approach has many parallels in medicine. For example, pneumonias that develop *de novo* are recognized as having a cause and a long-term prognosis different from similar clinical conditions superimposed on congestive heart failure, a bronchus blocked by a carcinoma, or during the course of a severe immune deficiency. The symptoms of pneumonia must be recognized, but the treatment and the prognostic implications of the condition are quite different in the diverse situations. Similarly, in psychiatry depressive episodes that are observed during hypothyroid states; tremor and symptoms of anxiety seen in hyperthyroidism; and psychotic symptoms observed in connection with a brain tumor must be recognized and are likely to require intervention. However, in each instance the prognostic and treatment implications of the syndrome are quite different from major depressive episodes, panic disorder, or schizophrenia that developed in the absence of those major preexisting disorders.

This is also true of the alcohol-related disorders. All the diagnostic manuals since DSM-III have warned the clinician that psychiatric syndromes developing only during intoxication or withdrawal from substances do not necessarily indicate an independent psychiatric disorder. Recognizing that those caveats are easy to overlook in clinical pratice, DSM-IV has added an overall statement about the inadvisability of labeling independent psychiatric disorders based on symptoms observed only during alcohol intoxication or within 4 weeks of abstinence from alcohol. Depressions, panic attacks, and psychotic thought processes occurring in the context of alcohol problems usually improve rapidly and then disappear. Thus, they do not usually carry the same prognostic implications as actual major depressive episodes, panic disorders, and schizophrenia. Similarly, DSM-IV reminds clinicians that such symptoms of mood, anxiety, or psychotic disorders that are documented before severe life problems from alcohol or that remain beyond 4 weeks of total abstinence should be carefully evaluated as possible indicators of true comorbidity with the occurrence of two or more independent psychiatric syndromes. These issues are discussed in greater detail in sections on alcohol-induced mood, anxiety, and psychotic disorders.

Finally, three psychiatric syndromes—bipolar I disorder, schizophrenia, and antisocial personality disorder—carry well established heightened risks for subsequent alcohol-related disorders. Individuals with panic disorder or generalized social phobia might also carry a small but statistically significant risks for alcohol abuse or dependence.

PHARMACOLOGY

Including a discussion of pharmacology in a section on alcohol-related disorders is not meant to imply that a disorder can be defined solely through the use of a substance. Most drinkers do not have serious problems related to alcohol and only a minority of drinkers have difficulties severe and pervasive enough to be labeled abuse or dependence. However, all alcoholic persons have a problem with that potent substance. As a result, clinicians cannot understand the disease or its syndromes without knowing something about alcohol itself.

Ethanol (beverage alcohol) is a simple molecule that is well absorbed through the mucosal lining of the digestive tract in the mouth, the esophagus, and the stomach. The most prominent area of absorption, however, is in the proximal small intestine, which is also the site of absorption of many of the B vitamins. Ethanol rapidly enters the bloodstream and, as a result of its high solubility in water, is distributed to almost every body system. As a consequence of its modest fat solubility, alcohol is likely to have effects on body membranes rich in fat, including neurons.

Wine, beer, and such distilled spirits as whiskey, gin, and vodka differ in their content of congeners. *Congeners* are responsible for much of the characteristic taste of the beverage, and consist of combinations of methanol, butanol, aldehydes, phenols, tannins, lead, cobalt, iron, and other substances. Under certain circumstances congeners can have physiological effects, but their potency pales in comparison with the potency of alcohol.

A drink of an alcoholic beverage is usually defined as containing 10 to 12 grams of ethanol. In round figures this is the amount of alcohol contained in approximately 12 ounces of beer (which in the United States has approximately 3.6 percent ethanol), 4 ounces of table wine (containing about 12 percent ethanol), and between 1 and 1.5 ounces of 80-proof spirits (containing 40 percent ethanol). For the average 70-kg (155-pound) person who has an average amount of body fat, one drink is likely to raise the blood alcohol level by approximately 15 to 20 mg/dL. The body subsequently metabolizes and excretes approximately one drink an hour. The rate of absorption of alcohol from the digestive tract is likely to be faster on an empty stomach than after a full meal, especially one rich in fats and carbohydrates.

After absorption into the bloodstream from the small intestine, between 2 and 10 percent of the alcohol is then excreted unchanged from the lungs or the kidneys or through sweat; the majority is metabolized in the liver. Liver metabolism occurs mostly through four pathways, with each resulting in the production of acetaldehyde. Most of the process occurs through the actions of alcohol dehydrogenase (ADH) in the cytosol of hepatic cells. Especially at high blood alcohol levels, some of the alcohol is also broken down in the microsomes of the smooth endoplasmic reticulum (the microsomal ethanol oxidizing system [MEOS] system). The ADH process is the usual rate-limiting metabolic step, occurring relatively slowly because of the liver's need to handle the produced hydrogen ions through use of a cofactor that is in relatively short supply, nicotinamide adenine dinucleotide (NAD).

The acetaldehyde produced by ADH and MEOS is then destroyed by the enzyme aldehyde dehydrogenase (ALDH) in both the liver cell cytosol and mitochondria. This step occurs rapidly, with the result that the average person does not have substantial levels of this substance; this is fortunate because at high levels acetaldehyde can produce histamine release, which through a variety of mechanisms contributes to falling blood pressure, nausea, and vomiting.

The ALDH isoenzyme pattern of an individual is related to the risk for developing alcoholism. Approximately 10 percent of Asian (e.g., Japanese, Chinese, Korean) men and women fully lack the low k_m ALDH form responsible for metabolizing low blood concentrations of acetaldehyde—that is they are homozygotes for the inactive form of this specific isoenzyme. An additional approximately 40 percent of Asian men and women are heterozygotes, being able to produce low concentrations of this most efficient ALDH form. In homozygote individuals, even one half of a standard drink is likely to cause a severe reaction, resulting in intense facial flushing, rapid heartbeat, nausea, and vomiting. Consequently, most such people rarely drink, and have an associated alcoholism risk that is close to zero. Individuals who are heterozygotes regarding this low k_m ALDH form are more likely to drink but demonstrate relatively high levels of sensitivity to alcohol, and are likely to consume relatively low amounts of alcohol compared to other individuals. Thus, the genetically controlled ALDH isoenzyme pattern is an important factor in the alcoholism risk, although one that applies only to Asians because the absence of the low k_m ALDH is not found in other racial groups.

ALDH activity is also important in another context. A variety of medications, such as disulfiram (Antabuse), inhibit the functioning of this low k_m ALDH form. Thus, when alcoholic individuals regularly take disulfiram, even relatively small amounts of alcohol are likely to produce facial flushing, a rapid heartbeat, and nausea within 20 minutes or so of having consumed the alcoholic beverage. Such drugs, known as alcohol-sensitizing agents, have been considered for the treatment of alcohol dependence.

Neuropharmacology All substances of abuse share the ability to produce changes in feeling states and subsequently increase the likelihood that a person will have a psychological drive to continue to take the substance despite potentially severe adverse consequences (psychological dependence). That effect is distinct from the physical dependence that produces the withdrawal or abstinence syndrome that characterizes drugs like alcohol. However, the 300 or so diverse psychoactive drugs differ in many important ways. For example, only a few produce physiological tolerance and clinically relevant levels of withdrawal symptoms when the substance is discontinued. Some drugs markedly increase the chances that a person will have temporary psychoses or depressions; other drugs do not. Some are likely to be lethal in overdose; others appear to be relatively safe at high levels. Clinicians therefore are presented with a daunting challenge if they attempt to memorize all the attributes for each of the hundreds of psychoactive substances.

A useful shortcut is to place drugs of abuse into categories on the basis of their most prominent effects at the usual doses at which they are taken. In this scheme, substances that have as their most prominent usual effects the production of somnolence and decreased neuronal activity but that are not powerful in attenuating pain are labeled as depressants or sometimes as sedative-anxiolytics. They include alcohol, all the benzodiazepines, all the barbiturates, and the carbamate antianxiety drugs, such as meprobamate (Miltown). These substances produce a similar profile of symptoms during intoxication, are potentially lethal in overdose (especially when multiple depressant drugs are taken at the same time), are cross-tolerant, are physically addicting, and produce similar withdrawal syndromes.

The behavioral and physiological changes observed with any substance differ with the dose, the patient's prior history of exposure to the drug, and clinical conditions, including physiological disorders and the patient's state of fatigue. With a drug like alcohol, the effects also change over time after intake, with more pronounced symptoms observed while the blood alcohol levels are rising then when the blood alcohol levels are falling, a phenomenon called *acute tolerance* or the *Mallenby effect*.

Debate continues about the most important mechanisms of action of alcohol on the brain. One of the problems occurs because the drug has a major effect on most neurochemical systems, demonstrating different effects at different doses and sometimes opposite effects during intoxication and withdrawal. One series of theories on the mechanisms underlying intoxication relates to the effects that alcohol has on the cell membrane: alcohol tends to fluidize or decrease the levels of rigidity of the membrane, with subsequent impairments in the cell's ability to control the influx and the efflux of electrolytes. Other research focuses on changes in dopamine, attempting to tie in the effects of alcohol to the pleasure centers of the limbic system, or on serotonin, a neurotransmitter related to appetitive behaviors. Still other investigators point to the potential importance of the neurochemical compounds that may, at least theoretically, be formed between acetaldehyde and the neurotransmitters serotonin and dopamine, producing alkaloids that have properties resembling opioids. Another set of investigations point out the indirect effects that alcohol can have on the benzodiazepine-receptor complexes in the brain. Finally, alcohol has potent effects on glutamate-gated ionophoric receptors, especially those that bind *N*-methyl-D-aspartate (NMDA). With such a diverse range of effects and the absence of an obvious receptor system reacting specifically to alcohol, many leads are promising but few answers are definitive regarding the most clinically relevant effects of alcohol on the nervous system or the way in which the alterations may relate to abuse or dependence on alcohol.

Tolerance With repeated administration of alcohol, larger and larger doses of the drug are required to produce the desired effect. That phenomenon, called *tolerance*, is the ability to tolerate higher and higher doses of the substance and is the result of at least three processes.

Behavioral tolerance reflects the ability of a person to learn how to perform tasks effectively despite the effects of alcohol. It is a learned behavior and the result of repeated practice. *Pharmacokinetic tolerance* is an adaptation of the metabolizing system to rid the body of alcohol rapidly. After several weeks of daily drinking, the liver produces more ADH than usual and expands the MEOS system, with a resulting increase of up to 30 percent in the rate of breakdown of ethanol. Finally, *pharmacodynamic* or *cellular tolerance* is an adaptation of the nervous system so that it can function, despite high blood alcohol concentrations, by resisting the actions of alcohol on the cell. Thus, persons have been observed to be awake, relatively alert, and relatively coordinated despite blood alcohol concentrations of 250 mg/dL, and some people have been awake at blood alcohol concentrations above 600 mg/dL.

Once tolerance has developed for one of the brain depressants, a person often shows a similar reaction to a second drug of that class (*cross-tolerance*). Therefore, a person who has been drinking heavily, has tolerance for alcohol, and then stops drinking can be expected to require a higher dose of benzodiazepines for sleep

induction. If the person took two depressant drugs at the same time, tolerance is not likely to be observed and the mixing of the two substances can have lethal effects. Just as tolerance requires a period of days or weeks to develop, the phenomenon is likely to disappear within a similar period of time after the intake of any depressant drug has ceased.

Some clinicians and researchers have described a phenomenon of *reverse tolerance* or *sensitization*. This is a complex situation that might involve multiple physiological components. For example, whether alcoholic or not, as persons grow older they have increasing levels of sensitivity to most brain depressants, including alcohol. This is because of several age-related changes in the body, including a decrease in the rate at which alcohol is metabolized in the liver and a relative decrease in body water as a consequence of an increasing percentage of body fat. The result of these changes is that higher blood alcohol levels develop in older people, whose neurons also have an enhanced sensitivity to the effects of alcohol. Even more dramatic examples of increased sensitivity to alcohol are seen after severe brain damage (e.g., the consequence of an auto accident or alcohol-related brain deterioration) and after impairment in any of the major alcohol-metabolizing systems, as occurs in cirrhosis.

Effects on the Body Some data indicate that alcohol use is not always harmful and may under certain circumstances even have some beneficial effects. However, any amount of alcohol is considered harmful to the developing fetus, to recovering alcoholics, to people taking medications that may adversely interact with alcohol, and to individuals with certain medical disorders or psychiatric syndromes (such as major depressive disorder or schizophrenia) that might be intensified by alcohol. For other people a maximum of one or two drinks a day appears to be associated with a decreased risk of cardiovascular disease. This association may be caused by an alcohol-induced decrease in platelet adherence or to an increase in at least one portion of high-density lipoprotein (HDL) cholesterol, although the fraction affected does not appear to be the one most potent in protecting against heart disease. Unfortunately, the intake of more than two drinks a day is likely to increase low-density lipoprotein (LDL) cholesterol and triglycerides and to raise blood pressure, with the overall result of increasing the risk of cardiac disorders. Also, even low levels of alcohol intake may increase the risk for breast cancer.

Central and Peripheral Nervous Systems

BLACKOUT *Blackout* indicates a memory impairment (*anterograde amnesia*) for the period of time when the person was drinking heavily but remained awake. This common difficulty is related to the ability of any brain depressant to interfere with the acquisition of memory at high enough doses. Perhaps 40 percent of teenaged and young adult males have blackouts, and memory loss does not by itself indicate a high likelihood of alcohol abuse or dependence. The blackout, which is temporary and limited to memory problems involving a short period of time, is not a DSM-IV diagnosis, and is distinct from *alcohol-induced persisting amnestic disorder*, formerly known as *Wernicke-Korsakoff syndrome*.

SLEEP IMPAIRMENT Alcohol intoxication can help a person fall asleep more quickly, but it tends to depress rapid eye movement sleep and inhibit stage 4 sleep. It is likely to be associated with frequent alternations between sleep stages, a process sometimes referred to as *sleep fragmentation*.

PERIPHERAL NEUROPATHY A more serious and potentially permanent problem is seen in perhaps 10 percent of alcoholic persons after years of heavy drinking. The deterioration of nerve functioning to the hands and feet, called *peripheral neuropathy*, arises through an apparent combination of vitamin deficiencies and the direct effects of alcohol or its metabolites. The symptoms include numbness of the hands and feet, often bilateral, frequently accompanied by tingling and paresthesias. Although the condition is usually relatively mild and often improves with abstinence, the pain and the numbness can result in a permanent impairment.

CEREBELLAR DEGENERATION Characterized by unsteadiness of gait, problems with standing, and mild nystagmus, cerebellar degeneration is probably caused by a combination of the effects of ethanol and acetaldehyde, along with vitamin deficiencies. Treatment usually consists of total abstinence and vitamin supplementation, although complete recovery is not common.

OTHER EFFECTS ON THE CENTRAL NERVOUS SYSTEM A series of temporary but intense psychiatric symptoms are likely to be observed during alcohol intoxication and withdrawal, including depressed mood, severe anxiety, and psychoses. These symptoms often mimic psychiatric disorders but are likely to disappear within weeks of abstinence. Severe amnestic disorders and dementias may also occur.

Gastrointestinal Problems Second only to the nervous system, the gastrointestinal system is most severely affected by heavy drinking. Probably the most common gastrointestinal problem associated with alcohol intake is an acute and at times severe inflammation of the esophagus or the stomach, with stomach inflammation often accompanied by vomiting and bleeding. If gastritis occurs in the presence of dilated esophageal veins seen with cirrhosis, it can induce potentially lethal bleeding.

The liver and the pancreas are especially vulnerable to alcohol. In the liver, increasing alcohol doses result in the accumulation of fats and proteins in the cells, producing a reversible swelling often described as a *fatty liver*. Inflammation of the liver cells accompanied by a subsequent intense rise in some liver function tests and other signs of alcoholic hepatitis can lead to the deposition of excessive amounts of hyalin and collagen near blood vessels, an early stage of cirrhosis. As damage progresses, the normal flow of blood through the liver is impaired, dilated veins or varices develop from the increased abdominal venous pressure, and fluid seeps from the liver capsule, accumulating in the abdomen as ascites. As liver failure progresses, secondary cognitive impairment can develop as various levels of hepatic encephalopathy.

Perhaps 15 percent of alcoholic persons respond to large doses of alcohol with an inflammation of the pancreas that can present as the abdominal emergency of acute pancreatitis. This can lead to a chronic irreversible condition of pancreatic destruction, with associated signs of insufficiency in sugar metabolism (a form of diabetes) and digestive enzymes.

Cerebrovascular and Cardiovascular Problems Heavy intake of alcohol increases the blood pressure and elevates both LDL cholesterol and triglycerides, thus enhancing the risk for myocardial infarction and thrombosis. At high doses, alcohol is also a striated-muscle toxin with a resulting production of what is usually but not always a reversible deterioration in the heart muscle that manifests itself as beating irregularities and signs of heart failure *(alcoholic cardiomyopathy)*. Similar levels of swelling of muscle cells and subsequent muscle pain can be observed in the skeletal muscles.

Blood-Producing Systems High levels of alcohol intake, often in the range of four to eight drinks a day, decrease the production of white blood cells and impairs the ability of those cells to migrate to sites of infection. Such drinking can also affect the stem cells that produce the red blood components, significantly increasing the average size of the red cell (the mean corpuscular volume [MCV]), and can impair the production and the efficiency of blood platelets.

Cancer High rates of many types of cancer are seen in alcoholic persons, especially cancers of the head, neck, esophagus, and stomach; additional areas of enhanced risk include the liver, the colon, and the lungs. The risks probably reflect alcohol-related immune system suppression, but might also be a result of the direct effects of ethanol on mucosal membranes. The heightened rates of malignant tumors in alcoholic persons remain significant even when the possible effects of smoking and poor nutrition are considered.

Fetal Alcohol Effect Alcohol and acetaldehyde can have deleterious effects on the developing fetus. Both substances cross the placenta with ease, and in high enough doses can produce fetal death and spontaneous abortion. Surviving infants of heavy-drinking mothers can evidence any mixture of the components of a syndrome that in its full-blown form can include severe mental retardation, a small head, a diminished physical size, facial abnormalities (including a flat bridge of the nose, an absent philtrum, and an epicanthal eye fold), an atrial septal heart defect, and syndactyly. None of these problems is reversible; once present, the cognitive defects, physical irregularities, and behavioral problems remain throughout life. Because the exact amount of alcohol required and the most vulnerable periods of pregnancy have not been definitively established all pregnant women are advised to abstain from any use of alcohol.

ETIOLOGY

Many factors affect the decision to drink, the development of temporary alcohol-related difficulties in the teenage years and the 20s, and the development of alcohol dependence. The initiation of alcohol intake probably depends on social, religious, and psychological factors, although the high rate of persons who have tried alcohol at some time during their lives indicates that drinking is an almost ubiquitous phenomenon in most Western societies. However, it is important to remember that the factors that influence the decision to drink or those that contribute to temporary problems might be different from those that contribute to the severe, recurring problems of alcohol dependence.

Psychological Theories A variety of theories relate to the use of alcohol to reduce tension, increase feelings of power, and decrease the effects of psychological

pain. Perhaps the greatest interest has been paid to the observation that persons with alcohol-related problems often report that alcohol decreases their feelings of nervousness and helps them cope with the day-to-day stresses of life. The psychological theories are built in part on the observation among nonalcoholic persons that the intake of alcohol in a tense social setting or after a difficult day can, especially in low doses, be associated with an enhanced feeling of well-being and an improved ease of interactions. However, data indicate that in high doses, especially at falling blood alcohol levels, most measures of muscle tension and psychological feelings indicate that heavy drinking is likely to be associated with increased nervousness and tension. The theories that focus on alcohol's potential to enhance feelings of being powerful and sexually attractive and to decrease the effects of psychological pain are difficult to evaluate definitively.

Psychodynamic Theories Perhaps related to the disinhibiting or anxiety-lowering effects of alcohol, at least at rising blood alcohol concentrations, is the hypothesis that some persons may use alcohol to help them deal with self-punitive harsh superegos as a way of decreasing unconscious stress levels. Also, classical psychoanalytical theory hypothesizes that at least some alcoholic persons have become fixated at the oral stage of development and use alcohol to relieve their frustrations by taking the substance by mouth. Alcoholic persons may also use the drug as part of a need for enhanced feelings of power. However, hypotheses regarding arrested phases of psychosexual development, although heuristically useful, have had little effect on the usual treatment approaches and are not the focus of extensive ongoing research. Similarly, several hypotheses have questioned the potential importance of addictive personality attributes because they may reflect levels of impulsiveness and sensation-seeking behavior. However, careful studies have failed to identify a unique personality profile that is prone to addictions, with the exception of antisocial personality disorder.

Behavioral Theories Expectations about the rewarding effects of drinking and subsequent actual reinforcement after alcohol intake contribute to the decision to drink again after the first experience with alcohol. These issues are important in efforts to modify drinking behaviors in the general population, and they contribute to some important aspects of alcoholic rehabilitation.

Sociocultural Theories Sociocultural theories are often based on observations of social groups that have high and low rates of alcoholism. Theorists hypothesize that ethnic groups such as Jews that introduce children to modest levels of drinking in a family atmosphere and that eschew drunkenness have low rates of alcoholism. Some other groups such as Irish men, with high rates of abstention but a tradition of drinking to the point of drunkenness among drinkers, are thought to have high rates of alcoholism. However, these theories often depend on stereotypes that are frequently erroneous and there are several exceptions to these rules. For example, some theories based on observations of the Irish and the French would have predicted high rates of alcoholism among the Italians, although alcohol problems are not generally observed at a high level in this group.

In the final analysis, social and psychological theories probably have more than heuristic value. They outline factors that contribute to the onset of drinking, the development of temporary alcohol-related life difficulties, and even alcoholism. The problem is how to find a way to gather relatively definitive data to support or refute the theories.

BIOLOGICAL THEORIES

Genetic Theories The best supported of the biological theories of alcoholism centers on genetics (Table 11.2-2). One finding supporting the genetic conclusion is the threefold to fourfold increased risk for severe alcohol problems in *close relatives of alcoholic persons*. The rate of alcohol problems increases with the number of alcoholic relatives, the severity of their illness, and the closeness of their genetic relationship to the person under study. The family investigations do little to separate the importance of genetics and environment, but twin studies take the data a step further. The rate of similarity or concordance for severe alcohol-related problems is significantly higher in identical twins of alcoholic individuals than in fraternal twins in most studies. The adoption-type studies have all revealed a significantly enhanced risk for alcoholism in the offspring of alcoholic parents, even when the children had been separated from their biological parents close to birth and raised without any knowledge of the problems within the biological family. The risk for severe alcohol-related difficulties is not further enhanced by being raised by an alcoholic adoptive family.

Close family members have a fourfold increased risk.
The identical twin of an alcoholic person is at higher risk than is a fraternal twin.
Adopted-away children of alcoholic persons have a fourfold increased risk.

Table 11.2-2 Data Supporting Genetic Influences in Alcoholism

These data not only support the importance of genetic factors in alcoholism, but also highlight the complexity of the phenomenon. The absence of evidence of a single major locus indicates the possibility that a limited number of genes operate with incomplete penetrance, or that a combination of genes is required before the disorder expresses itself (a polygenic mode of inheritance). Making matters even more complex is the likelihood that the disorder is solely an expression of environmental events in some families, and the probability that different genetic factors operate in different families to produce a picture of genetic heterogeneity.

Despite these problems, studies have identified men and women at high future risk of alcoholism, usually defined as having an alcoholic parent. Persons at high and low future risk are then compared on psychological and biological parameters. Some protocols then expose young adults to an alcohol challenge, and several investigations have subsequently followed them over time.

Related Biological Theories Different approaches have highlighted several potential leads to biological factors that may affect the risk of developing alcoholism. Investigations of early-teenage children of alcoholic parents, usually including inner-city families or children of persons with antisocial personality disorder, have shown the potential importance of several neurocognitive test results as possible predictors of a risk for alcoholism. Additional leads have come from electrophysiological evaluations of children of alcoholic persons, including the finding that perhaps one third of the sons of severely alcoholic men may have a decreased amplitude of the positive wave observed 300 milliseconds after a rare but unexpected sensory stimulus, the P3 wave of *event-related potential* (ERP). Other studies have shown a potential decrease in the amount of power in the slow alpha range on the background cortical electroencephalogram (EEG), or relative deficiencies in beta waves.

An additional potential phenotypic marker involves the intensity of a person's reaction to an alcohol challenge. An ongoing study involves 453 sons of alcoholics and controls who were originally evaluated at approximately age 20, at which time they were all drinkers but none was alcohol dependent. At the time of initial evaluation, despite matching the two family history groups on drinking and drug use histories, and despite identical blood alcohol concentrations during the drinking experiment, 40 percent of the sons of alcoholics but less than 10 percent of the controls showed remarkably low levels of response to alcohol. The intensity of the reaction was measured by a combination of subjective feelings of intoxication, changes in motor performance while under the influence of alcohol, as well as alcohol-induced changes in blood hormones and electrophysiological functioning of the brain. An average of 8.2 years later, all 453 subjects were located, and information about functioning during the follow-up period was obtained from the subject and an additional informant for 450 individuals (99.3 percent). The low level of response to alcohol at approximately age 20 was a potent predictor of future alcoholism, with 60 percent of the sons of alcoholics who had a low response developing alcoholism by approximately age 30, whereas the same was true for only 15 percent of the sons of alcoholics who showed high levels of response to the alcohol challenge. Sons of nonalcoholics showed a similar pattern of relationship between the low response to alcohol and the future risk of alcoholism. The data revealed that for this relatively highly functional, often white-collar population the low response to alcohol was responsible for a large proportion of the ability of the family history to predict the risk of alcoholism.

These follow-up data underscore some of the important issues related to genetic influences in this disorder. First, it is unlikely that anyone inherits a predestination for alcoholism. Rather, there are likely to be a variety of different genetically influenced characteristics that interact with the environment to increase the risk for severe

and repetitive alcohol-related life problems. Second, identification of traits that enhance the alcoholism risk, and possibly the genes related to these characteristics, might help to pinpoint the social and cultural factors that interact with a biological predisposition to produce the final level of risk for this disorder. It is possible that more knowledge about environmental and potentially changeable influences might help to develop more precise prevention approaches that can be applied to individuals who carry the highest risk.

DIAGNOSIS AND CLINICAL FEATURES

Alcohol use disorders are probably the most common of the serious diagnosable behavioral or psychiatric disorders, and the diagnosis of alcohol dependence or abuse requires a high index of suspicion for the disorder in any patient. The average man or woman presenting with severe and repetitive alcohol problems is likely to be neatly dressed, to show no signs of severe alcohol withdrawal, to have a job and a family, and to complain of a variety of physical conditions or temporary but potentially severe psychiatric complaints. Thus, the clinician must gather a history of alcohol-related life problems from the patient and, whenever possible, a resource person, and must try to determine whether alcohol has caused or contributed to the psychiatric or physiological syndrome. Table 11.2-3 lists the alcohol-related disorders in DSM-IV, and also presents a comparable listing from ICD-10.

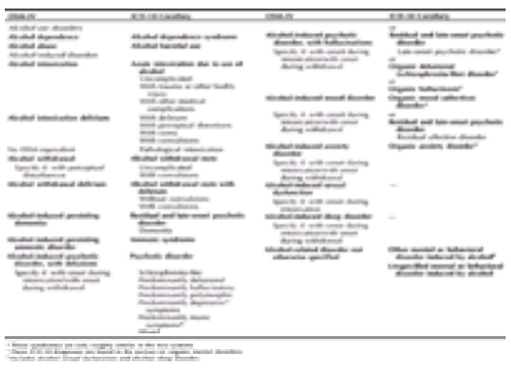

Table 11.2-3 DSM-IV Alcohol-Related Disorders and Corresponding ICD-10 Disorders

For patients presenting with psychiatric symptoms (e.g., anxiety, depression, or psychoses) as well as evidence of alcohol-related problems, the first step is to obtain a careful history from both the patient and a resource person who knows the patient well. Second, in taking the information the clinician must emphasize syndromes that meet diagnostic criteria for major depressive disorder or full anxiety syndromes or other disorders, not just symptoms such as sadness or nervousness. Third, the clinician must establish a time line from birth to the present, noting (1) the approximate age of onset of alcohol problems severe and repetitive enough to justify a diagnosis of alcohol dependence; (2) periods of abstinence of several months or more; and (3) the ages at which the patient met the criteria for any major psychiatric disorders, taking care to emphasize full-blown psychiatric clinical conditions, not isolated symptoms. If a review of the time line reveals no evidence that the additional psychiatric syndromes either antedated the severe alcohol problems or persisted for 4 or more weeks during a period of abstinence, alcoholism is the major disorder. Under these conditions the other psychiatric syndromes are important but temporary conditions that occurred during alcohol intoxication or withdrawal.

Depressive, anxiety, and psychotic syndromes are often seen in people with alcohol-related disorders. However, even if the psychiatric symptoms are intense, they do not indicate a separate psychiatric syndrome when seen only during intoxication or withdrawal (i.e., they can be temporary alcohol-induced conditions). In an effort to encourage clinicians and researchers to consider the entire span of clinical conditions that might be relevant to any syndrome being observed, in DSM-IV all important diagnostic entities related to a specific phenomenon (e.g., depressive disorders, anxiety disorders, psychotic disorders) are now listed within the clinically relevant sections (e.g., the mood disorder section). For the sake of clarity, disorders associated with substances are now labeled as *substance-induced disorders*.

To be termed a substance-induced condition, the syndrome must be clinically meaningful and must resemble the type of disorder described within that DSM-IV section (e.g., a mood disorder). There must be evidence indicating a likelihood that the clinical condition developed during, or within a month of, substance intoxication or withdrawal from a specific substance (such as alcohol) that would be capable of producing a relevant temporary clinical condition (such as a severe mood disturbance). The clinician and researcher are warned that the substance-induced condition should only be diagnosed when the psychiatric symptoms (e.g., depression) are in excess of those usually associated with intoxication or withdrawal. The diagnostic criteria further list the specific substances involved and ask that, if possible, the clinician specify whether the condition had an onset during intoxication or withdrawal. These latter modifiers are important to indicate to the clinician when additional medical and psychiatric treatment might be required. For alcohol-induced mood disorders, diagnoses can also be subtyped regarding the presence or absence of depressive, manic, or mixed features.

DSM-IV offers similar information regarding a substance-induced anxiety disorder, which is listed in the section on anxiety disorders. Again, the condition must be clinically relevant; there must be evidence that a substance, such as alcohol, capable of producing a severe temporary anxiety condition was involved; and a distinction regarding an onset during intoxication or withdrawal is encouraged. The anxiety conditions can be further subdivided regarding the relevance of generalized anxiety symptoms, repetitive panic attacks, obsessive-compulsive symptoms, or phobic symptoms.

The documentation of hallucinations and delusions associated with intoxication or withdrawal from relevant substances is covered in DSM-IV section on psychotic disorders. When the condition is clinically relevant and when evidence exists that a substance (such as alcohol) capable of causing the psychotic symptoms was involved, a diagnosis of a substance-induced psychotic disorder (in this instance alcohol-induced psychotic disorder) can be made. Additional criteria have been developed for alcohol-induced sexual dysfunction (see Table 19.1a-20) and alcohol-induced sleep disorders (see Table 21-18).

Alcohol Dependence DSM-IV provides general criteria for all substance use disorders (see Table 11.1-3). Dependence concerns a history of a broad array of problems, including compulsive intake of alcohol, an increasingly important place in life occupied by the substance, and possibly evidence of physical withdrawal symptoms. Dependence criteria also concern life impairment related to the substance.

Physical dependence or is a phenomenon that appears to be related to tolerance. As the body changes to resist the effects of alcohol, it is likely to reach a condition in which it cannot function optimally unless the brain depressant is present. That condition takes days or weeks to develop.

DSM-IV substance dependence criteria include seven items that are subsets of the nine originally listed in DSM-III-R. These seven items are similar to the ICD-10 dependence syndrome criteria, although ICD-10 deals more directly with evidence of a compulsion to use (see Table 11.1-4). In addition, while maintaining the broad concept of dependence that appeared in DSM-III-R, DSM-IV asks the clinician to use the two items that deal with tolerance or withdrawal to further classify dependent persons into those with and those without evidence of physiological symptoms. This division allows clinicians and researchers to determine the treatment and the prognostic implications of tolerance and withdrawal. The framers of the fifth edition of DSM (DSM-IV) in the twenty-first century will then have data to help them decide whether to return to the emphasis on physiological symptoms that characterized earlier manuals (e.g., DSM-III).

> A 23-year-old graduate student in physics was referred for evaluation by her adviser who was concerned about tardiness at work and recent problems with a lack of clarity of thinking. As he discussed these difficulties with her, the student admitted to being concerned about her drinking, which had been dramatically emphasized to her in a recent intervention carried out by her father and mother. She related that for the last 5 years or so she has regularly consumed 1.5 to two or three bottles of wine each evening (approximately 9 to 18 drinks). In the last 2 years she has noted a marked increase in the need for more alcohol to get the same effects, reported giving up activities with her family in order to drink, spending a great deal of her time drinking, and driving long distances to obtain alcohol. She has repeatedly tried to cut down, often setting a limit of two drinks in an evening, but regularly going on to nine or more standard drinks before stopping. Despite her high general level of functioning, her active participation in a graduate education program, and close interpersonal relationships, this history of alcohol dependence is fairly typical among alcohol-dependent individuals.

Alcohol Abuse The DSM-IV diagnostic criteria for abuse focus on the impairment of social, legal, interpersonal, and occupational functioning in a person who is not alcohol dependent (see Table 11.1-8). ICD-10 presents a diagnosis of *harmful use* that is only roughly similar to DSM-IV. The major difference is the restriction of the international system to issues of physical or psychological problems. The DSM-IV criteria were developed through careful comparisons of DSM-III and DSM-III-R

concepts, and were refined through a series of reanalysis of existing data sets and a large field trial of the criteria for abuse and dependence. The field trial involved comparisons of clinical coverage and demographic correlates of DSM-III-R and possible DSM-IV criteria, as applied to more than 1000 men and women from diverse groups and representing persons from the general population as well as those with diverse substance problems in six centers in the United States and four locations in other countries.

Alcohol Intoxication The DSM-IV diagnostic criteria for alcohol intoxication are based on evidence of recent ingestion of ethanol, maladaptive behavior, and at least one of six possible physiological correlates of intoxication (Table 11.2-4). The ICD criteria for acute alcohol intoxication are generally similar to the DSM-IV criteria. There are seven physiological signs of intoxication listed in the international system, some of which, such as conjunctival injection, are not listed in the DSM-IV criteria.

A. Recent ingestion of alcohol.
B. Clinically significant maladaptive behavior or psychological changes (e.g., inappropriate sexual or aggressive behavior, mood lability, impaired judgment, impaired social or occupational functioning) that developed during, or shortly after, alcohol ingestion.
C. One (or more) of the following signs, developing during, or shortly after, alcohol use:
(1) slurred speech
(2) incoordination
(3) unsteady gait
(4) nystagmus
(5) impairment in attention or memory
(6) stupor or coma
D. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

Table 11.2-4 DSM-IV Diagnostic Criteria for Alcohol Intoxication

As a conservative approach to identifying blood levels that are likely to have major effects on driving abilities in the majority of people, the legal definition of intoxication in most states in the United States requires a blood concentration of 80 or 100 mg ethanol per dL of blood (mg/dL), which is the same as 0.08 to 0.10 grams per deciliter (g/dL). For most people, a rough estimate of the levels of impairment likely to be seen at various blood alcohol concentrations can be outlined. Evidence of behavioral changes, a slowing in motor performance, and a decrease in the ability to think clearly occurs at doses as low as 20 to 30 mg/dL, as shown in Table 11.2-5. Blood concentrations between 100 and 200 mg/dL are likely to produce a progression of the impairment in coordination and judgment to severe problems with coordination (ataxia), increasing lability of mood, and progressively greater levels of cognitive deterioration. Anyone who does not show significant levels of impairment in motor and mental performance at about 150 mg/dL probably has significant pharmacodynamic tolerance. In that range most persons without significant tolerance also experience relatively severe nausea and vomiting. With blood alcohol concentrations in the 200 to 300 mg/dL range, the slurring of speech is likely to become more intense, and memory impairment *(anterograde amnesia* or *alcoholic blackouts)* becomes pronounced. Further increases in blood alcohol concentration result in the first level of anesthesia, and the nontolerant person who reaches 400 mg/dL or higher risks respiratory failure, coma, and death.

Level	Likely Impairment
20–30 mg/dL	Slowed motor performance and decreased thinking ability
30–80 mg/dL	Increases in motor and cognitive problems
80–200 mg/dL	Increases in incoordination and judgment errors Mood lability Deterioration in cognition
200–300 mg/dL	Nystagmus, marked slurring of speech, and alcoholic blackouts
>300 mg/dL	Impaired vital signs and possible death

Table 11.2-5 Impairment Likely to Be Seen at Different Blood Alcohol Concentrations

Prior editions of DSM also described *alcohol idiosyncratic intoxication*. Currently termed *pathological alcohol intoxication* in ICD-10, it was characterized by extreme aggressive behavior occurring within minutes of ingesting relatively small amounts of alcohol, such as two drinks. According to DSM-III-R the person was usually amnestic for the episode, and the aggressive behavior was atypical of the person's usual sober comportment. However, a literature review before the publication of DSM-IV revealed little convincing evidence that such a disorder really exists, and it was deleted from the manual. The status of the condition in ICD-10 is being examined and must be regarded as tentative.

Alcohol Withdrawal In persons who have been drinking heavily over a prolonged period of time, a rapid decrease in the amount of alcohol in the body might produce a variety of physical symptoms. This *withdrawal* or *abstinence syndrome* is characterized by a group of symptoms that are the opposite of what was initially experienced with intoxication. Therefore, after a person is physically dependent on alcohol, abstinence is likely to be accompanied by a coarse tremor of the hands, insomnia, anxiety, and increased blood pressure, heart rate, body temperature, and respiratory rate—a condition labeled in DSM-IV as *alcohol withdrawal* and described in Table 11.2-6. In ICD-10 the criteria for alcohol withdrawal are similar to those listed in DSM-IV, although there are differences in the items listed as physiological correlates of withdrawal as well as in the number of signs required (i.e., three) to make a diagnosis. The DSM-IV criteria for alcohol withdrawal also require that the symptoms must cause clinically significant distress or impairment in an important area of functioning.

A. Cessation of (or reduction in) alcohol use that has been heavy and prolonged.
B. Two (or more) of the following, developing within several hours to a few days after criterion A:
(1) autonomic hyperactivity (e.g., sweating or pulse rate greater than 100)
(2) increased hand tremor
(3) insomnia
(4) nausea or vomiting
(5) transient visual, tactile, or auditory hallucinations or illusions
(6) psychomotor agitation
(7) anxiety
(8) grand mal seizures
C. The symptoms in criterion B cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The symptoms are not due to a general medical condition and not better accounted for by another mental disorder.

Specify if:
With perceptual disturbances

Table 11.2-6 DSM-IV Diagnostic Criteria for Alcohol Withdrawal

Although 95 percent or more of withdrawals are limited to these mild or moderate symptoms, for 3 to 5 percent the symptoms include convulsions or delirium. Withdrawal phenomena are likely to begin within 8 hours of abstinence, reach a peak intensity on the second or third day, and markedly diminish by the fourth or fifth day. The symptoms can persist in a mild form for 3 to 6 months or more as part of a protracted withdrawal syndrome.

This 23-year-old graduate student in physics with alcohol dependence was unable to establish even 24 hours of sobriety as an outpatient. Therefore, reflecting her continued drinking, she was referred for inpatient care. Following approximately 10 hours of abstinence, and with a documented blood alcohol concentration of 0 mg/dL, she was noted to be mildly diaphoretic, with a respiratory rate of 25 breaths per minute, blood pressure of 130/90, a mild bilateral tremor of the hands, and a pulse rate of 85 beats per minute. She had a history of jogging 2 to 5 miles a day and these figures represented moderate elevations in her usual vital signs. Treated with multiple vitamins, good nutrition, oral fluids, and benzodiazepines, the symptoms rapidly improved, and her vital signs were close to normal by day four of abstinence.

Alcohol Intoxication and Alcohol Withdrawal Delirium For the small proportion of intoxications and withdrawals that are accompanied by severe cognitive symptoms, both DSM-IV and ICD-10 contain the diagnoses of *alcohol intoxication delirium* and *alcohol withdrawal delirium* (see Table 10-22 and Table 10-23).

When the symptoms of withdrawal are accompanied by a state of severe agitated confusion or delirium, sometimes associated with tactile or visual hallucinations, the diagnosis of *alcohol withdrawal delirium* (also called *delirium tremens* [*DTs*]) can be made. During withdrawal, some alcoholic persons show one or several grand mal convulsions, sometimes called *rum fits*.

A 73-year-old professor emeritus at a university was thought to be in good health when he entered the hospital for an elective hernia repair. Perhaps reflecting his status in the community, the relatively brief history contained no detailed notes of his drinking pattern, and made no mention that his g-glutamyltransferase (GGT) values of 55 units per liter, along with the mean corpuscular volume (MCV) of 93.5 cubic microns. Eight hours postsurgery the nursing staff noted a sharp rise in the pulse rate to 110, an increase in blood pressure to 150/100, prominent diaphoresis, and a tremor to both hands, following which the patient demonstrated a brief but intense grandmal convulsion. He awoke after approximately 15 minutes extremely agitated and disoriented to time, place, and person. A reevaluation of the history and a separate interview with the wife documented alcohol dependence with a consumption of at least six to nine standard drinks per night. Over the following 4 days, the patient's autonomic nervous system dysfunction decreased as his cognitive impairment disappeared. His condition is classified as *alcohol withdrawal delirium* in DSM-IV.

Alcohol-Induced Persisting Amnestic Disorder One of the most intensely studied alcohol-related central nervous system (CNS) syndromes is the relatively rare DSM-IV diagnosis of *alcohol-induced persisting amnestic disorder* (see Table 10-39), which is the result of a relatively severe deficiency in the B vitamin thiamine. Similar criteria are offered in ICD-10 as an amnesic syndrome. Some persons are at higher risk for this syndrome than are others because of a genetically influenced transketolase deficiency. The condition has been historically subdivided into (1) *Wernicke's encephalopathy*, with prominent ataxia and palsy of the sixth cranial nerve, a condition that tends to reverse fairly rapidly with vitamin supplementation, and (2) *Korsakoff's syndrome*, which is permanent in at least a partial form in perhaps 50 to 70 percent of the persons affected. Korsakoff's syndrome is characterized by a pronounced anterograde and retrograde amnesia and potential impairment in visuospatial, abstract, and other types of learning. In most cases the level of recent memory is out of proportion to the global level of cognitive impairment. The 25 percent or so of patients with Korsakoff's syndrome who are likely to recover fully and the 50 percent or so who recover partially appear to respond to 50 to 100 mg of oral thiamine a day, usually administered for many months.

Alcohol-Induced Persisting Dementia An alcohol-related CNS diagnosis relevant to psychiatry is the relatively heterogeneous and poorly studied long-term cognitive problem that can develop in the course of alcoholism, namely *alcohol-induced persisting dementia* (see Table 10-31). Similar syndromes are described in ICD-10 as *residual and late-onset psychotic disorder* or as *other persisting cognitive impairment*. Global decreases in intellectual functioning, cognitive abilities, and memory are observed. Recent memory difficulties are consistent with global cognitive impairment, an observation that helps to distinguish the syndrome from alcohol-induced persisting amnestic disorder. The decreased brain functioning, including problems with psychomotor performance, tends to improve with abstinence, but perhaps half of all affected patients have long-term and even permanent memory and thinking disabilities. Perhaps 50 to 70 percent of these patients evidence increased size of the brain ventricles and shrinkage of the cerebral sulci, although these changes appear to be partially or completely reversible during the first year of complete abstinence. In the final analysis, it is unlikely that there is a single alcoholic dementia syndrome; rather, the problem seems to represent the combined effects of trauma, vitamin deficiencies, and the direct actions of alcohol and acetaldehyde.

Alcohol-Induced Mood Disorder In the context of heavy and repetitive intake of any brain depressant, such as alcohol, symptoms of severe depression are common and may be labeled as an *alcohol-induced mood disorder* (Table 14.6-18). Like DSM-III-R, ICD-10 retains this and most related substance-induced syndromes in the section on organic mental disorders labeled as an *organic mood [affective] disorder*. For long-lasting mood disturbances, ICD-10 also has the labels of *other persistent mood [affective] disorders* and *persistent mood [affective] disorder*. The diagnosis in DSM-IV or ICD-10 focuses on either sadness or mania-like symptoms severe enough to impair functioning that occur only in the context of repeated heavy drinking and continue for several days to 4 weeks after abstinence. Heavy intake of alcohol over several days results in many of the symptoms observed in major depressive disorder, but the intense sadness improves within days to weeks of abstinence. Consistent with the theory that intoxication with brain depressants can cause severe symptoms of depression is the documentation that 80 percent of alcoholic persons report histories of intense depression; 30 to 40 percent were depressed for 2 or more weeks, during which they had symptoms that resembled a major depressive episode. However, when information from patients and resource persons was carefully evaluated, only 5 percent of alcoholic men and 10 percent of alcoholic women ever had depressions that met the criteria for major depressive disorder when they had not been drinking heavily.

Clinical data reveal that when even severe depression develops in alcoholic persons, they are likely to improve fairly rapidly without medications or intensive psychotherapy aimed at the depressive symptoms. A recent study of almost 200 alcoholic men found that 40 percent had severe levels of depression after 1 week of abstinence. However, the percentage with pervasive depressive symptoms decreased to about 5 percent after 3 additional weeks of abstention from alcohol, even though no treatment was given for the mood symptoms.

At the end of several weeks, most alcoholic patients are left with mood swings or intermittent symptoms of sadness that can resemble cyclothymic disorder or dysthymic disorder. Even those mild and intermittent depressive symptoms are likely to diminish and disappear with time. The presence of the dysthymic symptoms usually indicates the normal course of a withdrawal syndrome and not an independent mood disorder.

A consultation was requested on a 42-year-old woman with alcohol dependence who complained of persisting severe depressive symptoms despite 5 days of abstinence. In the initial stage of the interview she noted that she had “always been depressed” and felt that she “drank to cope with the depressive symptoms.” Her current complaint included a prominent sadness that had persisted for several weeks, difficulties concentrating, initial and terminal insomnia, and a feeling of hopelessness and guilt. In an effort to distinguish between an alcohol-induced mood disorder and an independent major depressive episode, a time-line based history was obtained. This focused on the age of onset of DSM-IV alcohol dependence, periods of abstinence that extended for several months or more since the onset of dependence, and the ages of occurrence of clear major depressive episodes lasting several weeks or more at a time. Despite this patient's original complaints, it became clear that there had been no major depressive episodes prior to her mid-20s when alcohol dependence began, and that during a 1-year period of abstinence related to the gestation and neonatal period of the birth of her son, her mood had significantly improved. A provisional diagnosis of an alcohol-induced mood disorder was made. The patient was offered education, reassurance, and cognitive therapy to help her to deal with the depressive symptoms, but no antidepressant medications were prescribed. The depressive symptoms remained at their original intensity for several additional days, and then began to improve. By approximately 3 weeks abstinent the patient no longer met criteria for a major depressive episode, although she demonstrated mood swings similar to dysphemia for several additional weeks. This case is a fairly typical example of an alcohol-induced mood disorder in an individual with alcohol dependence.

Alcohol-Induced Anxiety Disorder Anxiety symptoms fulfilling the diagnostic criteria for *alcohol-induced anxiety disorder* are also common in the context of acute and protracted alcohol withdrawal (see Table 15.6-18). In ICD-10 these are listed as organic anxiety disorders resembling generalized anxiety or panic disorders. Almost 80 percent of alcoholic persons report panic attacks during acute withdrawal; their complaints can be intense enough for the clinician to consider diagnosing a panic disorder. Similarly, during the first 4 to 6 weeks of abstinence, persons with severe alcohol problems are likely to avoid some social situations for fear of being overwhelmed by anxiety (i.e., they have symptoms resembling social phobia); their problems can at times be severe enough to resemble agoraphobia. The symptoms of nervousness during acute and protracted withdrawal can also include many of the problems seen in generalized anxiety disorder. However, when psychological or physiological symptoms of anxiety are observed in alcoholic persons only in the context of heavy drinking or within the first several weeks or months of abstinence, the symptoms are likely to diminish and subsequently disappear with time alone. If one correctly identifies temporary substance-induced syndromes, alcoholic persons are no more likely than people in the general population to have most independent major anxiety disorders. They are, however, much more likely to have temporary but intense symptoms of anxiety. Two anxiety disorders that might be more closely tied to alcoholism are panic disorder and social phobia.

A 52-year-old African-American male lawyer entered treatment for alcohol dependence with the chief complaint of “panic attacks” as well as alcohol problems. In light of evidence of concomitant panic disorder and alcohol dependence, a time-line history was established. This individual first met criteria for panic disorder by approximately age 18, and an intensification of occasional panic attacks occurred as he went off to college. After several visits to an emergency room during his freshman year, the diagnosis of panic disorder was made, and the current retrospective history revealed no evidence of dependence on alcohol or any other substance at that time. His panic disorder was treated with behavioral therapy and antidepressant medication, and was under good control when, at approximately age 33, he experienced an intensification of his alcohol intake and developed associated problems. He appears to have fulfilled criteria for alcohol dependence. During the course of his alcoholism, his panic disorder symptoms increased and decreased in intensity over time, with obvious exacerbations whenever he attempted to cut back on his alcohol intake. The diagnosis was alcohol dependence along with an independent panic disorder. Treatment focused on a continuation of the cognitive-behavioral therapy, antidepressant medications (when needed) for the panic disorder, as well as alcohol rehabilitation.

Alcohol-Induced Psychotic Disorder About 3 percent of alcoholic persons have psychotic symptoms in the context of heavy drinking and withdrawal. In DSM-III-R those problems were labeled *organic hallucinosis* or *delusional disorders*. In ICD-10 they are presented as organic delusional disorders in the organic section and as a psychotic disorder in the substance use disorders section. Many of the symptoms resemble those seen in schizophrenia, but when the psychotic features develop only in the context of alcohol problems they are likely to clear spontaneously. The syndromes are likely to recur only if heavy alcohol intake resumes.

A 39-year-old male letter carrier was brought to an emergency room by the police after he behaved in an unusual fashion at home and complained that his neighbors were trying to kill him. The history obtained from the patient and his wife revealed that his psychotic thinking developed slowly over the preceding 3 weeks; he began with feelings that people were looking at him at work, progressed to vague feelings that people were against him, and went on to frank auditory hallucinations that people at work and in the neighboring houses were talking about their plans to kill him. He had no insight into those paranoid delusions and auditory hallucinations. The relatively abrupt onset of the syndrome—he was in his late 30s—pointed to a potential organic cause, and further probing documented his daily drinking of between 6 and 18 beers for at least the preceding 10 weeks. A diagnosis of alcohol-induced psychotic disorder with onset during intoxication was made, and both hallucinations and delusions disappeared after 3 weeks of abstinence. After alcohol treatment, the man stayed sober for the next 8 months. Unfortunately, he later resumed heavy drinking and had a recurrence of both hallucinations and delusions.

Alcohol-Related Disorder Not Otherwise Specified DSM-IV allows for the diagnosis of *alcohol-related disorder not otherwise specified* for alcohol-related disorders that do not meet the diagnostic criteria for any of the other diagnoses (Table 11.2-7). ICD-10 offers the listings of *other or unspecified mental and behavioral disorders induced by alcohol*.

The alcohol-related disorder not otherwise specified category is for disorders associated with the use of alcohol that are not classifiable as alcohol dependence, alcohol abuse, alcohol intoxication, alcohol withdrawal, alcohol intoxication delirium, alcohol withdrawal delirium, alcohol-induced persisting dementia, alcohol-induced persisting amnestic disorder, alcohol-induced psychotic disorder, alcohol-induced mood disorder, alcohol-induced anxiety disorder, alcohol-induced sexual dysfunction, or alcohol-induced sleep disorder.

Table 11.2-7 DSM-IV Diagnostic Criteria for Alcohol-Related Disorder Not Otherwise Specified

Laboratory and Physical Examination Establishing the diagnosis for alcohol abuse or dependence centers on obtaining from the patient and a resource person a history of the patient's life problems and the possible role played by alcohol. Up to one third of all psychiatric patients are likely to have an alcohol problem that either caused or exacerbated the presenting clinical condition.

The process of identification can also be facilitated by a series of blood tests, outlined in Table 11.2-8. Those state markers of heavy drinking reflect physiological alterations likely to be observed if the patient regularly ingests four or more drinks a day over many days or weeks. One of the most sensitive and specific of the markers (perhaps 60 to 80 percent sensitivity and specificity) is a level of 30 or more units per liter of g-glutamyltransferase (GGT), an enzyme that aids in the transport of amino acids and that is found in most areas of the body. Because this enzyme is likely to return to normal levels after 2 to weeks of abstinence, even 20 percent increases in enzyme levels above those observed after 4 weeks of abstinence can be useful in identifying patients who have returned to drinking after treatment. Equally impressive results have been reported for the measure of a deglycosylated form of the protein transferrin, known as *carbohydrate-deficient transferrin* (*CDT*). Using a commercially available assay, CDTect, and employing a cutoff of 20 mg/L, this test has both a sensitivity and a specificity of 65 to 80 percent for the identification of the heavy consumption of alcohol (e.g., 5 to 8 drinks per day for a week); these figures might be slightly lower for women. With a biological half-life of about 16 days, this test can also be useful in monitoring abstinence in alcoholics. It appears that patients not identified by higher GGT values might still have elevations in CDT so that both tests should be used for identification and abstinence-monitoring functions in alcoholics.

Test	Relevant Range of Results
Gamma glutamyl transferase (GGT)	>30 U/L
Carbohydrate-deficient transferrin (CDT)	>20mg/L
Mean corpuscular volume (MCV)	>91 μm,
Uric acid	>6.4 mg/dL for men >5.0 mg/dcL for women
Serum glutamic-oxaloacetic transaminase (aspartate aminotransferase) [SGOT (AST)]	>45 IU/L
Serum glutamic-pyruvic transaminase (alanine aminotransferase) [SGPT (ALT)]	>45 IU/L
Triglycerides	>160 mg/dL

Table 11.2-8 State Markers of Heavy Drinking Useful in Screening for Alcoholism

The MCV blood test, with perhaps 70 percent sensitivity and specificity, is a state marker when the size of the red blood cell is 91 or more cubic micrometers. The 120-day life span of the red cell does not allow the test to be used as an indicator of a return to drinking after about 1 month of abstinence. Other tests that can be helpful in identifying patients who are regularly consuming heavy doses of alcohol include those for high normal concentrations of uric acid (greater than 6.4 mg/dL, with a range that depends on the sex of the person); mild elevations in the usual liver function tests, including aspartate aminotransferase and alanine aminotransferase; and elevated levels of triglycerides or LDL cholesterol.

A number of physical findings can also be useful in identifying the alcoholic patient. These findings include modest elevations in blood pressure, frequent bruising, cancer of the head and neck and upper digestive tract, an enlarged liver, evidence of cirrhosis, and symptoms consistent with pancreatitis.

A 41-year-old mechanic consulted a physician for a physical examination related to his application for an insurance policy. The history revealed a prior divorce along with some problems in the current marriage, difficulties getting along with his foreman at work who complained about the patient's occasional absences, and some difficulties with insomnia and restless sleep. The patient denied symptoms of intense depression, but did admit to moodiness. The physical examination revealed a mild elevation in blood pressure (140/90), but was otherwise within normal limits. The panel of laboratory results included a MCV of 94.8 cubic microns, a CDT value of 25 mg/L, and a GGT of 55 units per liter. Although the patient had initially reported himself to be a “moderate social drinker,” a more detailed history revealed that he drank 6 to 8 beers on weeknights, and 12 to 20 beers a day on weekends. The physician shared her impressions regarding the pattern of life problems, noted the elevation in the state markers of heavy drinking, and told the patient that she felt that he had reached a point where alcohol was causing repeated problems, while noting in the chart the diagnosis of alcohol dependence. The objective data available to the physician regarding laboratory values helped her efforts to optimize this patient's motivation for abstinence.

DIFFERENTIAL DIAGNOSIS

Once the pattern of alcohol-related life problems has been established, the diagnosis of alcohol abuse or dependence is fairly obvious. A substantial proportion of the information presented in this chapter also helps the clinician to take the next logical step: determining whether an independent major psychiatric disorder exists. Briefly, individuals who present with clinically significant levels of depression, anxiety, or psychotic symptoms in addition to their alcoholism should be evaluated using the time-line approach in order to determine whether the psychiatric symptoms are likely to have been substance-induced (and are thus temporary) or represent independent and longer-term psychiatric disorders. In addition, the clinical course of the psychiatric symptoms should be closely observed during the subsequent several weeks to a month or so of abstinence, in order to determine whether the depression, anxiety, and other symptoms decrease in intensity over time. Although some symptoms might remain as part of a protracted withdrawal syndrome, if the disorder is substance-induced the individual should no longer fulfil criteria for the full diagnostic syndrome after a month or so of abstaining from alcohol.

Antisocial Personality Disorder When the emphasis on the chronological development of symptoms is used, at least three diagnoses— *antisocial personality disorder, schizophrenia*, and *bipolar I disorder*—are likely to predate alcohol abuse or dependence and to be true comorbid conditions. Antisocial personality disorder, listed on Axis II, begins early in life and has major effects on many aspects of life functioning. The diagnosis is based on evidence of severe antisocial behaviors in many areas beginning before the age of 15 years and continuing into adulthood. Persons with antisocial personality disorder are described as impulsive, frequently violent, highly likely to take risks, and unable to learn from their mistakes or to benefit from punishment. A person who carries these characteristics into adolescence, the typically time for experimentation with alcohol and drugs, can be expected to have difficulty controlling substance use. Thus, perhaps 80 percent or more of persons with antisocial personality disorder are likely to have severe secondary alcohol problems in the course of their lives. A diagnosis of pre-existing antisocial personality disorder with subsequent alcohol abuse or dependence indicates someone who is more likely than the average alcoholic person to have severe coexisting drug problems, to be violent, to discontinue treatment prematurely, and to have a much less than optimistic prognosis.

Debate continues on the optimal manner of viewing the co-occurrence of antisocial personality disorder and alcoholism, but most researchers agree that the personality disorder is a separate entity worthy of diagnosis. The genetic factors that increase the risk for antisocial personality disorder may be separate from those that affect the development of alcoholism. In most treatment programs, perhaps 5 percent of alcoholic women and between 10 and 20 percent of alcoholic men have preexisting antisocial personality disorder. Other Axis II-type symptoms are often observed during intoxication and as part of the acute and protracted abstinence syndromes, but they have not been documented to predate the alcohol-related disorders.

Schizophrenia A second disorder in which secondary alcohol problems are more common than in the general population is schizophrenia. Characterized by what is usually a slow onset of paranoid delusions and auditory hallucinations in a clear sensorium and typically beginning in the mid-teens to the 20s, schizophrenia is likely to be severe and debilitating. Possibly because of a lack of long-term treatment facilities, persons with schizophrenia are likely to live in inner-city areas and to spend a great deal of time on the streets. Perhaps because they use alcohol to decrease feelings of isolation or to self-medicate their symptoms, persons with schizophrenia are more likely than those in the general population to go on to have severe alcohol-related life problems. Their alcohol intake is likely to undercut the effectiveness of appropriate antipsychotic medications, to increase mood swings and signs of psychoses, and to contribute to a downward course of schizophrenia that entails repeatedly revolving into and out of inpatient care. Because most alcohol treatment programs exclude actively psychotic patients, schizophrenia persons rarely appear in inpatient alcohol treatment programs. However, severe alcohol-related disorders are observed in 30 percent or so of schizophrenic persons being treated in public mental health facilities.

A 34-year-old unemployed, divorced white male entered treatment for alcohol dependence. His history revealed seven prior hospitalizations since the age of 23, with most discharge diagnoses including schizophrenia, and some noting alcohol dependence. The patient was a poor historian, and no additional informants were available. However, the information from prior hospitalizations revealed that at the time of the initial inpatient stay the patient had experienced approximately 1 year of auditory hallucinations and paranoid delusions. During that time he had not yet demonstrated severe enough problems related to alcohol or other drugs to fulfill criteria for dependence. Subsequently, a hospitalization at age 28 was followed by a 6-month stay in a recovery home during which the records indicated that there had been no alcohol or illicit drug use, despite which the patient continued to demonstrate auditory hallucinations and paranoid delusions without insight. The current hospitalization involved a thorough physical examination and initiation of treatment of alcohol withdrawal while re-evaluating and stabilizing the antipsychotic medication level for this individual who demonstrated both alcohol dependence and an independent schizophrenia disorder.

Bipolar I Disorder The third disorder in which severe alcohol problems are overrepresented is bipolar I disorder. In a manic episode, the patient is hyperexcited and impulsive, carries out most activities to excess, has poor judgment, and is likely to develop temporary alcohol problems. The severity of the manic symptoms usually precludes inpatient alcohol rehabilitation while the patient is actively manic. However, alcohol-related difficulties must be evaluated in histories taken from persons with manic features entering mental health facilities.

Major Anxiety Disorders Finally, there are data from recent studies that support a small but statistically significant association between independent (i.e., not alcohol-induced) panic disorder and perhaps independent social phobia and alcohol dependence. One large investigation involved over 3000 personal interviews carried out across six centers in different parts of the United States. While about 90 percent of alcohol-dependent men and women did not have a major anxiety disorder there was no evidence for a significant increased risk for most major anxiety disorders, the rates of independent panic disorder and independent social phobia were significantly higher than in controls.

Other Disorders Debate in the literature continues about whether major depressive disorder, agoraphobia, obsessive-compulsive disorder, and other major psychiatric diagnoses are overrepresented in the histories of alcoholic persons. Several studies indicate that, when the time-line method is used and a history is obtained from many informants, little evidence is found for very high rates of most independent psychiatric disorders among alcoholic persons, other than the three disorders noted above. Therefore, although the majority of alcoholic persons have temporary psychiatric symptoms, they are not more likely than are persons in the general population to carry an independent psychiatric syndrome other than the three exceptions discussed above.

There are interesting and complex relations between alcohol dependence and dependence on other drugs. Men and women with the antisocial personality disorder demonstrate a marked increased risk for dependence on multiple substances, including alcohol. It is also probable that individuals with dependence on opiates and stimulants (such as cocaine and amphetamines) exhibit an increased risk for alcohol dependence even in the absence of antisocial personality disorder. However, most alcohol-dependent people do not meet the criteria for dependence on other drugs. Several recent investigations of children of alcohol-dependent men and women, as well as the large Collaborative Study on the Genetics of Alcoholism (COGA) indicated that once the effects of the antisocial personality disorder were controlled, alcohol dependence appeared to run relatively true within families, without evidence of a marked crossover between alcoholism and other dependencies. An exception to this general rule is nicotine dependence, which has long been noted to be elevated among alcohol-dependent individuals, a finding that has been hypothesized to relate to either attempts to use nicotine to try to moderate some of the effects of high doses of alcohol or withdrawal, or a possible genetic relationship between nicotine and alcohol-dependence syndromes.

COURSE AND PROGNOSIS

Details of a clinical course that fit the great majority of persons with any disorder are difficult to describe. However, sufficient data regarding alcohol-related disorders are available to offer a general outline of the typical pattern of problems.

Several recent evaluations of large numbers of alcohol-dependent individuals suggest that most subgroups of alcoholics are more similar than different on the time course and prevalence of alcohol-related life difficulties. The differences that do exist reflect characteristics of individuals in society in general and do not appear to

indicate any unique aspects of their alcoholism as such. Thus, for example, similar to women in the general population, compared to male alcoholics, female alcoholics have higher rates of independent depressive episodes, and slightly lower proportions of women who have ever engaged in alcohol-related violence or have had severe alcohol-related driving problems. However, in general, the clinical courses of alcohol-dependent men and women are relatively similar. Older as compared to younger alcohol-dependent individuals are more likely to have medical problems, to take multiple medications, to experience more severe withdrawal syndromes, probably to have a less extensive social support system. Again, these characteristics reflect differences between older versus younger individuals in general more than they indicate potential unique aspects of alcoholism in the geriatric population. Thus, while the reader is advised to take the following information as general guidelines that must be applied with common sense to subgroups of individuals, it is possible to present generalities regarding the usual clinical course of alcoholism and its treatment.

Early Course Patients with antisocial personality disorder who later go on to develop alcoholism have an early onset of drinking, intoxication, and alcohol-related problems, but that scenario is not applicable to the other 80 to 90 percent of alcoholic men and 95 percent of alcoholic women. Usually, alcoholic persons have their first drink (other than taking a sip from a parent's glass) between the ages of 13 and 15 years, the first intoxication is likely to occur at 15 or 16 years, and the first evidence of a minor alcohol-related problem is usually observed in the late teenage years. These milestones do not differ significantly from what is expected for people in the general population who do not later go on to develop alcohol abuse or dependence.

For the average person the pattern of severe difficulties becomes apparent in the middle 20s to the middle 30s when a constellation of symptoms of relatively great severity is likely to be observed: an alcohol-related breakup of a significant relationship, a second alcohol-related driving or public intoxication arrest, evidence of alcohol withdrawal, being told by a physician that alcohol has harmed the person's health, or significant interference with functioning at school or work. This pattern probably does not vary much with the type of beverage used—beer, wine, or spirits.

The landmarks in Table 11.2-9 are only rough estimates and can differ greatly between people and among various groups. Women, for example, are likely to begin drinking later than men, but their subsequent escalation of symptoms is likely to be slightly more rapid than that seen in men.

Age at first drink*	13–15 years
Age at first intoxication*	15–17 years
Age at first problem*	16–22 years
Age at onset of dependence	25–40 years
Age at death	60 years
Fluctuating course of abstention, temporary control, alcohol problems	
Spontaneous remission in 20 percent	

* Same as general population.

Table 11.2-9 Clinical Course of Alcohol Dependence

Later Course Once alcohol's interference with life functioning has become apparent, the future is likely to include periods of drinking problems that repeatedly alternate with periods of abstinence and periods of alcohol intake unassociated with problems *(temporary controlled drinking)*. Abstinence often develops in response to some interpersonal, social, or legal crisis and is likely to produce only mild withdrawal symptoms. Average alcoholic persons are then likely to use the temporary cessation of drinking problems to convince themselves that alcohol is not really a cause for concern after all. Those periods of abstinence, lasting days to months, are common in the course of most persons with alcoholism and are usually followed by periods during which drinking rules are established and are temporarily followed. The person is likely to consume only beer or wine (forgetting that a glass of beer, a glass of wine, and a shot of whiskey have similar amounts of alcohol) and tries to drink only at certain times of the day and under certain conditions. This period of temporary control soon leads to an escalation of alcohol intake, the accumulation of a new set of problems, and a subsequent crisis. These events, in turn, are likely to precipitate a new period of abstinence, and the cycle begins again. Thus, controlled drinking is a common but temporary condition for most alcoholic persons. Those who have less severe alcohol problems, such as those who may fulfill the diagnostic criteria for alcohol abuse in DSM-IV, are probably more likely to have long-term and even permanent periods of control. However, several research projects have indicated that long-term continued control is not likely to be seen once a person meets the diagnostic criteria for alcohol dependence.

An additional attribute important in the course of alcohol dependence is the phenomenon of spontaneous remission. Perhaps in response to nonspecific events or to a crisis, the alcoholic person promises to abstain and keeps the promise forever. Whatever the cause of the abstinence, about 20 percent or more of alcoholic persons, if followed over a long enough period of time, probably do achieve permanent abstinence, even without formal treatment or participation in such self-help groups as Alcoholics Anonymous (AA).

Even in the average blue- or white-collar alcohol-dependent person, the life span is likely to be decreased. This foreshortening of 10 to 15 years is associated with many causes, including the marked increased risks for heart disease, cancer, accidents, and suicide among alcoholic individuals.

Prognosis Between 10 and 40 percent of alcoholic persons enter some kind of formal treatment program during the course of their alcohol problems. A number of prognostic signs are favorable. First is the absence of preexisting antisocial personality disorder or a diagnosis of other substance abuse or dependence. Second, evidence of general life stability with a job, continuing close family contacts, and the absence of severe legal problems also bodes well for the patient. Third, if the patient stays for the full course of the initial rehabilitation (perhaps 2 to 4 weeks), the chances of maintaining abstinence are good. The combination of these three attributes predicts at least a 60 percent chance for 1 or more years of abstinence. Few studies have documented the long-term course, but researchers agree that 1 year of abstinence is associated with a good chance for continued abstinence over an extended period of time. However, alcoholic persons with severe drug problems (especially intravenous drug use or cocaine or amphetamine dependence) and those who are homeless may have only a 10 to 15 percent or so chance of achieving 1 year of abstinence.

Accurately predicting whether any specific person will achieve or maintain abstinence is impossible, but the prognostic factors listed above are associated with an increased likelihood of abstinence. However, the factors reflecting life stability probably explain only 20 percent or less of the course of alcohol use disorders. Many forces that are difficult to measure have significant effects on the clinical course; they are likely to include such intangibles as levels of motivation and the quality of the patient's social support system.

In general, alcoholic persons with preexisting independent major psychiatric disorders—such as antisocial personality disorder, schizophrenia, and bipolar I disorder—are likely to run the course of their independent psychiatric illness. Therefore, for example, clinicians must treat the patient with bipolar I disorder who has secondary alcoholism with appropriate psychotherapy and lithium (Eskalith), use relevant psychological and behavioral techniques for the patient with antisocial personality disorder, and offer appropriate antipsychotic medications on a long-term basis to the patient with schizophrenia. The goal is to keep the symptoms of the independent psychiatric disorder as minimal as possible in the hope that a greater level of life stability will be associated with a better prognosis for the patient's alcohol problems.

TREATMENT

The elements of treatment appropriate for patients with severe alcohol problems are fairly straightforward. Much of the clinical challenge comes in recognizing how prevalent the alcohol-related disorders are, how often those conditions present with symptoms of other psychiatric syndromes, and how to use clinical clues, physical findings, and laboratory tests to identify alcoholism.

Three general steps are involved in treating the alcoholic person once the disorder has been diagnosed—intervention, detoxification, and rehabilitation. Those approaches assume that all possible efforts have been made to optimize medical functioning and to address psychiatric emergencies. Thus, for example, the alcoholic person with symptoms of depression severe enough to be suicidal requires inpatient hospitalization for at least several days until the suicidal ideation disappears.

Similarly, the person presenting with cardiomyopathy, liver difficulties, or gastrointestinal bleeding first needs adequate attention paid to the medical emergency.

The patient with alcohol abuse or dependence must then be brought face-to-face with the reality of the disorder *(intervention)*, be detoxified if needed, and begin rehabilitation. The essentials of these three steps for an alcoholic person with independent psychiatric syndromes are quite similar to the approaches used for the primary alcoholic person without independent psychiatric syndromes. However, in the former case the treatments are applied after the psychiatric disorder has been stabilized to the maximum degree possible.

Intervention The goal in this step, which has also been called *confrontation*, is to break through feelings of denial and to help the patient recognize the adverse consequences likely to occur if the disorder is not treated. Intervention is as a process aimed at increasing to as high a level as possible the levels of motivation for treatment and for continued abstinence.

This step often involves convincing patients that they are responsible for their own actions while reminding them how alcohol has created significant life impairments. The psychiatrist often finds it useful to take advantage of the person's chief presenting complaint, whether it is insomnia, difficulties with sexual performance, an inability to cope with life stresses, depression, anxiety, or psychotic symptoms. The psychiatrist can then teach the patient how alcohol has either created or contributed to these problems, and can reassure the patient that abstinence can be achieved with a minimum of discomfort.

> A physician was consulted by a 43-year-old businessman who was concerned about his wife. He had recently been confronted by their 21-year-old daughter who felt that her mother was an alcoholic. The daughter noted her mother's slurred speech on several recent occasions when the daughter called home, times during the day when the mother was apparently home but did not answer the telephone, and observed high levels of alcohol consumption. A more detailed history revealed that the husband had been concerned about the wife's drinking pattern for at least 5 years, relating her practice of staying up after he went to bed, retiring later with alcohol on her breath. He also noted her consumption of 10 to 12 drinks at parties, with the resulting tendency to isolate herself from the remaining guests, her panic-like behavior regarding the need to pack liquor when they go on trips where alcohol might not be readily available, and what he observed to be a tremor of her hands some mornings during breakfast. The husband was given several potential courses of action, including the possibility of referring the spouse for treatment with the physician. The husband was advised to share his concern with his wife at a time when she was not actively intoxicated, emphasizing specific times and events where her impairment with alcohol was noted. He was also asked to consider whether a close friend of many years and the adult daughter might be included in this intervention, and it was suggested that a tentative appointment might be made with the clinician (or with an alcohol and drug treatment program) so that a next step could be established if the intervention was successful.

A physician intervening with a patient can use the same nonjudgmental but persistent approach each time an alcohol-related impairment is identified. It is the level of persistence rather than exceptional interpersonal skills that usually gets results. A single intervention is rarely enough. Most alcoholic persons need a series of reminders of how alcohol contributed to each developing crisis before they seriously consider abstinence as a long-term option.

Family The family can be of great help in the intervention. Family members must learn not to protect the patient from the problems caused by alcohol otherwise the patient may not be able to gather the energy and the motivation necessary to stop drinking.

During the intervention stage, the family can also suggest that the patient meet with persons who are themselves recovering from alcoholism, perhaps through AA, and they can meet with groups, such as Alanon, that reach out to family members. Those support groups for families meet many times a week and help family members and friends see that they are not alone in their fears, worry, and feelings of guilt. Members share coping strategies and help each other find community resources. The groups can be most useful in helping family members rebuild their lives, even if the alcoholic person refuses to seek help.

Detoxification Most persons with alcohol dependence have relatively mild symptoms when they stop drinking. If the patient is in relatively good health, adequately nourished, and has a good social support system the depressant withdrawal syndrome usually resembles a mild case of the flu. Even intense withdrawal syndromes rarely approach the severity of symptoms described by some early textbooks in the field.

The essential first step in detoxification is a thorough physical examination. In the absence of a serious medical disorder or combined drug abuse, severe alcohol withdrawal is unlikely. The second step is to offer rest, adequate nutrition, and multiple vitamins, especially those containing thiamine.

Mild or Moderate Withdrawal Withdrawal develops because the brain has physically adapted to the presence of a brain depressant and cannot function adequately in the absence of the drug. Giving enough of a brain depressant on the first day to diminish symptoms and then weaning the patient off the drug over the next 5 days offers most patients optimal relief and minimizes the possibility that a severe withdrawal will develop. Any depressant—including alcohol, barbiturates, or any of the benzodiazepines—can work, but most clinicians chose a benzodiazepine for its relative safety. Adequate treatment can be given with either short-acting drugs, such as lorazepam (Ativan), or long-acting substances, such as chlordiazepoxide (Librium) and diazepam (Valium).

An example of treatment is the administration of 25 mg of chlordiazepoxide by mouth three or four times a day on the first day, with a notation to skip a dose if the patient is asleep or feeling sleepy. An additional one or two 25-mg doses during the first 24 hours can be used if the patient is jittery or shows signs of increasing tremor or autonomic dysfunction. Whatever the dosage required on the first day, the benzodiazepine can be decreased by 20 percent of it each subsequent day, with a resulting need for no further medication after 4 or 5 days. When using a long-acting agent, such as chlordiazepoxide, the clinician must avoid producing excessive sleepiness through overmedication; if the patient is sleepy, the next scheduled dose should be omitted. When taking a short-acting drug, such as lorazepam, the patient must not miss any dose because rapid changes in blood benzodiazepine concentrations may precipitate a severe withdrawal.

A social model program of detoxification saves money by avoiding medications while using social supports. This less expensive regimen can be helpful for mild or moderate withdrawal syndromes. Some clinicians have also recommended b-adrenergic receptor antagonists, such as propranolol (Inderal), or a-adrenergic receptor such as agonists, clonidine (Catapres), although these medications do not appear to be superior to the benzodiazepines. Unlike the brain depressants, these other agents do little to decrease the risk of seizures or delirium.

Severe Withdrawal For the approximately 1 to 3 percent of alcoholic patients with extreme autonomic dysfunction, agitation, and confusion—that is, those with alcoholic withdrawal delirium, also called delirium tremens—no optimal treatment has yet been developed. The first key step is to ask why such a severe and relatively uncommon withdrawal syndrome has occurred; the answer often relates to a severe concomitant medical problem that needs immediate treatment. The withdrawal symptoms can then be minimized either through the use of benzodiazepines (in which case high doses are sometimes required), or through antipsychotic agents, such as haloperidol (Haldol) and thioridazine (Mellaril). Once again, doses are used on the first or second day to control behavior, and the patient can be weaned off the medication by about the fifth day.

Another 1 to 3 percent of patients may have a single grand mal convulsion; the rare person has multiple fits and the peak incidence is on the second day of withdrawal. Such patients require a neurological evaluation, but in the absence of evidence of a seizure disorder they do not benefit from anticonvulsant drugs.

Rehabilitation For most patients, rehabilitation includes three major components: (1) continued efforts to increase and maintain high levels of motivation for abstinence, (2) work to help the patient readjust to a life-style free of alcohol, and (3) relapse prevention. Because these steps are carried out in the context of acute and protracted withdrawal syndromes and life crises, treatment requires repeated presentations of similar materials that remind the patient how important abstinence is and that help the patient develop new day-to-day support systems and coping styles.

No single major life event, traumatic life period, or identifiable psychiatric disorder is known to be a unique cause of alcoholism. In addition, the effects of any causes of alcoholism are likely to have been diluted by the effects of alcohol on the brain and the years of an altered life-style, so that the alcoholism has developed a life of its own. This is true even though many alcoholic persons believe that the cause was depression, anxiety, life stress, or pain syndromes. Research, data from records, and resource persons usually reveal that the alcohol contributed to the mood disorder, accident, or life stress, not vice versa.

The same general treatment approach is used in inpatient as well as outpatient settings. The selection of the more expensive and intensive inpatient mode often depends on evidence of additional severe medical or psychiatric syndromes, the absence of appropriate nearby outpatient groups and facilities, and the patient's history of having tried but failed in outpatient care. The treatment process in either setting involves intervention, optimizing physical and psychological functioning, enhancing motivation, reaching out to family, and using the first 2 to 4 weeks of care as an intensive period of help. Those efforts must be followed by at least 3 to 6 months of less frequent outpatient care. Outpatient care uses a combination of individual and group counseling, the judicious avoidance of psychotropic medications

unless needed for independent disorders, and involvement in such self-help groups as AA.

Counseling Counseling efforts in the first several months should focus on day-to-day life issues to help patients maintain a high level of motivation for abstinence and to enhance their levels of functioning. Psychotherapy techniques that provoke anxiety or that require deep insights have not been shown to be of benefit during the early months of recovery and, at least theoretically, may actually impair efforts at maintaining abstinence. Therefore, this discussion focuses on the efforts likely to characterize the first 3 to 6 months of care.

Counseling or therapy can be carried out in an individual or group setting; few data indicate that either approach is superior to the other. The technique used is not likely to matter greatly, and usually boils down to simple day-to-day counseling or almost any behavioral or psychotherapeutic approach focusing on the here and now. To optimize motivation, treatment sessions should explore the consequences of drinking, the likely future course of alcohol-related life problems, and the marked improvement that can be expected with abstinence. Whether in an inpatient or an outpatient setting, individual or group counseling is usually offered for a minimum of three times a week for the first 2 to 4 weeks, followed by less intense efforts, perhaps once a week, for the subsequent 3 to 6 months.

Much time in counseling deals with how to build a life-style free of alcohol. Discussions cover the need for a sober peer group, a plan for social and recreational events without drinking, and approaches for reestablishing communication with family members and friends.

The third major component, relapse prevention, begins with identifying situations in which the risk for relapse is high. The counselor must help the patient to develop modes of coping to be used when the craving for alcohol increases or when any event or emotional state makes a return to drinking likely. An important part of relapse prevention is reminding the patient about the appropriate attitude toward slips. Those short-term experiences with alcohol can never be used as an excuse for returning to regular drinking. The efforts to achieve and maintain a sober life-style are not a game in which all benefits are lost with that first sip. Rather, recovery is a process of trial and error; patients use slips when they occur to identify high-risk situations and to develop more appropriate coping techniques.

Most treatment efforts recognize the effects that alcoholism has on the significant people in the patient's life and an important aspect of recovery involves helping family members and close friends to understand alcoholism and how rehabilitation is an ongoing process that lasts for 6 to 12 or more months. Couples and family counseling and support groups for relatives and friends help the persons involved to rebuild relationships, to learn how to avoid protecting the patient from the consequences of any drinking in the future, and to be as supportive as possible of the alcoholic patient's recovery program.

Medications If detoxification has been completed and the patient is not one of the 10 to 15 percent of alcoholic persons who have an independent mood disorder, schizophrenia, or anxiety disorder, there is little evidence in favor of prescribing psychotropic medications for the treatment of alcoholism. Lingering levels of anxiety and insomnia as part of a reaction to life stresses and protracted abstinence should be treated with behavior modification approaches and reassurance. Medications, including benzodiazepines, for these symptoms are likely to lose their effectiveness much faster than the insomnia disappears; as a result the patient may increase the dose and have subsequent problems. Similarly, sadness and mood swings can linger at low levels for several months. However, controlled clinical trials indicate no benefit in prescribing antidepressant medications or lithium to treat the average alcoholic person who has no independent or long-lasting psychiatric disorder. The mood disorder will clear before the medications can take effect, and patients who resume drinking while on the medications face significant potential dangers. With little or no evidence that the medications are effective, the dangers significantly outweigh any potential benefits from their routine use.

One possible exception to the proscription against the use of medications is the alcohol-sensitizing agent disulfiram. Disulfiram is given in dosages of 250 mg a day before the patient is discharged either from the intensive first phase of outpatient rehabilitation or from inpatient care. The goal is to place the patient in a condition in which drinking alcohol precipitates an uncomfortable physical reaction, including nausea, vomiting, and a burning sensation in the face and stomach. Unfortunately, few data convincingly prove that disulfiram is more effective than a placebo, probably because most people stop taking the disulfiram when they resume drinking. Many clinicians have stopped routinely prescribing the agent, partly in recognition of the dangers associated with the drug itself: mood swings, rare instances of psychosis, the possibility of an increase in peripheral neuropathies, the relatively rare occurrence of other significant neuropathies, and a potentially fatal hepatitis. Moreover, patients with pre-existing heart disease, cerebral thrombosis, diabetes, and a number of other conditions cannot be given disulfiram because an alcohol reaction to the disulfiram could be fatal.

Two additional promising pharmacological interventions have recently been studied. The first involves the opiate antagonist naltrexone (ReVia), which is at least theoretically believed to possibly decrease the craving for alcohol or blunt the rewarding effects of drinking. In any event, two relatively small (i.e., approximately 90 patients on the active drug across the studies) and short-term (i.e., 3 months of active treatment) investigations using 50 mg per day of this drug had potentially promising results. However, it is difficult to evaluate the full impact of this medication unless longer-term studies of relatively large groups of more diverse patients are evaluated.

The second medication of interest, acamprosate (Campral), has been tested in over 5000 alcohol-dependent patients in Europe, this drug is not yet available in the United States. Used in dosages of approximately 2000 mg per day, this medication was associated with an approximately 10 to 20 percent higher rate of positive outcome than placebo when used in the context of the usual psychological and behavioral treatment regimen for alcoholism. Once again, the mechanisms of actions of acamprosate are not known but might relate to an impact on g-aminobutyric acid (GABA) or on the NMDA system craving or the rewarding effects of alcohol.

Another medication with potential promise in the treatment of alcoholism is the nonbenzodiazepine antianxiety drug, buspirone (BuSpar), although the effect of this drug on alcohol rehabilitation is inconsistent between studies. However, at the same time, there is no evidence that antidepressant medications such as the SSRIs, lithium, or antipsychotic medications, are significantly effective in the treatment of alcoholism.

Self-Help Groups Clinicians must recognize the potential importance of self-help groups like AA. Members of AA have help available 24 hours a day, associate with a sober peer group, learn that it is possible to participate in social functions without drinking, and are given a model of recovery by observing the accomplishments of sober members of the group.

Learning about AA usually begins during inpatient or outpatient rehabilitation. The clinician can play a major role in helping patients understand the differences between specific groups. Some groups are composed only of men or women, and others are mixed; some meetings are composed mostly of blue-collar men and women whereas others are mostly for professionals; some groups place great emphasis on religion, and others are eclectic. Patients with coexisting psychiatric disorders may need some additional education about AA. The clinician should remind them that some members of AA may not understand their special need for medications and should arm the patients with ways of coping when group members inappropriately suggest that the required medications be stopped.

SUGGESTED CROSS-REFERENCES

Classification of mental disorders is discussed in Chapter 9, epidemiology in Section 5.1, and the sociocultural sciences in Chapter 4. Delirium and amnestic disorders are discussed in Chapter 10. Other substance-related disorders are discussed in Chapter 11; mood disorders are discussed in Chapter 14, anxiety disorders are discussed in Chapter 15, personality disorders are discussed in Chapter 24, and schizophrenia is presented in Chapter 12. Psychotherapies are discussed in Chapter 30.

11.3 AMPHETAMINE (OR AMPHETAMINE-LIKE)-RELATED DISORDERS

JEROME H. JAFFE, M.D.

Amphetamines are the most widely used illicit drugs, second only to cannabis, in Great Britain, Australia, and several countries of western Europe. In the United States, lifetime and current cocaine use still exceeds the nonmedical use of amphetamines; but in some parts of the country methamphetamine use increased significantly in the 1990s and became a matter for serious concern.

Despite the important pharmacological differences between amphetamine and amphetamine-like drugs and cocaine, the patterns of use, dependence, and toxicity associated with them are similar, as are the treatment approaches currently used. Among the drugs that produce subjective effects quite similar to those of amphetamine and methamphetamine and also have abuse potential, are methylphenidate (Ritalin) and phendimetrazine (Preludin), which are included in Schedule (Control Level) II of the Controlled Substance Act (CSA), and diethylpropion (Tenuate), benzphetamine (Didrex), and phentermine (Ionamin), which are included in Schedules III or IV of the CSA.

DEFINITIONS

Amphetamine use may be associated with a number of distinct disorders, of which dependence and abuse are but two. In the case of amphetamine and amphetamine-like agents, at least 10 other substance-related disorders have been described.

Amphetamine dependence is defined in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) as a cluster of physiological, behavioral, and cognitive symptoms that, taken together, indicate that the person continues to use amphetaminelike drugs despite significant problems related to such use (see Table 11.1-3). This brief definition emphasizes the drug-using behavior itself, its maladaptive nature, and how the choice to engage in that behavior shifts and becomes constrained as a result of interaction with the drug over time. *Amphetamine abuse* is a term used to categorize a pattern of maladaptive use of amphetamine or an amphetaminelike drug leading to clinically significant impairment or distress and occurring within a 12-month period in which the symptoms have never met the criteria for amphetamine dependence (see Table 11.1-8).

The amphetamine-induced disorders include amphetamine intoxication, amphetamine withdrawal, amphetamine-induced psychotic disorder with delusions and amphetamine-induced psychotic disorder with hallucinations, amphetamine intoxication delirium, amphetamine-induced mood disorder, (amphetamine-induced anxiety disorder, amphetamine-induced sleep disorder, amphetamine-induced sexual dysfunction, and amphetamine-related disorder not otherwise specified. The coding scheme of DSM-IV provides distinct numbers for amphetamine dependence and amphetamine abuse, but the codes for the other amphetamine-induced disorders are common to several other substance-related disorders.

HISTORY

Amphetamines were introduced into clinical use in the early 1930s. By late in the decade, there was some concern about amphetamine dependence, and in 1938 the first reports of amphetamine psychosis appeared. Nevertheless, between 1932 and 1946 almost three dozen clinical uses of amphetamine were proposed and tried by the medical profession, and some amphetamines were available in over-the-counter nasal inhalers until as late as 1971.

Immediately following World War II, Japan experienced an epidemic of intravenous methamphetamine abuse and dependence, but until the end of the 1960s there was reluctance in the United States to believe that amphetamine and related drugs could cause addiction. However, because of growing concern over their misuse and overuse, the Food and Drug Administration (FDA) placed them under regulatory control in the mid-1960s. Despite these controls the quantity of drugs smuggled into the country or produced illegally in clandestine laboratories increased. There were enough drugs on the street, (which up to that time had come primarily from diversion of legitimately produced drugs), to fuel a major epidemic of amphetamine and methamphetamine abuse in the late 1960s. This epidemic made clear the potential toxicity of the amphetamines, especially when used intravenously, and such terms as “speed freaks” and “speed kills” left an enduring legacy in the popular vocabulary. Over the next decade regulatory controls on legitimately produced amphetamines were progressively tightened. Some misuse of amphetamines and amphetamine-like drugs persisted in the United States, with much of the supply coming from illicit laboratories. When it became illegal to obtain the commonly used precursor phenyl-2-propanone, (P2P), illicit manufacturers found ways to produce methamphetamine from ephedrine and/or pseudoephedrine widely available in over-the-counter medications for colds and asthma. The new method of synthesis actually yields a higher percentage of the active d-isomer of methamphetamine and was adopted both by criminal organizations using large-scale laboratories and by independent producers whose small laboratories, usually located in remote rural areas, are more difficult to detect and eliminate.

In the late 1980s there were reports that smoking of crystalline methamphetamine (“ice”) was on the rise, especially in Hawaii, but through the mid-1990s the use of amphetamine-like stimulants continued to be overshadowed by cocaine abuse in most parts of the United States. Over this same period in the United Kingdom, Australia, and Western Europe amphetamine use always exceeded cocaine use. In the mid-1990s, methamphetamine use rose sharply in several areas of the United States, especially in California and several states in the southwest and northwest. This increased use was evident from surveys, drug testing of arrestees, and emergency room visits for methamphetamine toxicity.

Amphetamines are used legitimately almost exclusively for the treatment of narcolepsy and attention-deficit/hyperactivity disorder, although methylphenidate is more widely prescribed for the latter indication. Some amphetaminelike agents are still prescribed as appetite suppressants, but the use of amphetamine itself for that purpose has been discouraged and is illegal in some states. Amphetamines may be useful in the treatment of atypical depression, but concern about abuse potential has discouraged the controlled clinical studies that would be necessary to define just which patients (if any) might benefit more from amphetamine-like agents than from tricyclic antidepressants or selective serotonin reuptake inhibitors (SSRIs).

COMPARATIVE NOSOLOGY

The DSM-IV diagnostic criteria for amphetamine dependence are the same generic criteria applied to other substances ranging from opioids and cocaine to alcohol. The notion of a generic concept of dependence is shared with the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10). In making a diagnosis of dependence there is generally a high level of agreement between DSM-IV and ICD-10: they use similar concepts (the dependence syndrome varying in severity), although the wording of the criteria for determining the presence and severity of the syndrome differ. Both require that three elements of the syndrome occur within a 12-month period. Although DSM-IV appears to lay greater stress on tolerance and physiological dependence by asking clinicians to specify if these elements are present, it is not certain whether patients who exhibit these phenomena have a distinct form of the disorder. Patients diagnosed with alcohol dependence who exhibit tolerance or withdrawal have a more severe syndrome. One study of cocaine users found that even if tolerance and physical dependence had been required to make the diagnosis there would have been about the same number of patients meeting the criteria for dependence.

There is a major difference between ICD-10 and DSM-IV in the classification of what is called substance abuse in DSM-IV. ICD-10 does not use the term “abuse.” Instead, it includes a category of harmful use, which is substantially different from the concept of “abuse” used in DSM-IV. The concept of “harm” is limited to physical

and mental health (e.g., hepatitis, cardiac damage, episodes of depression, or toxic psychosis). It specifically excludes social impairments as follows:

Harmful patterns of use are often criticized by others and frequently associated with adverse social consequences of various kinds. The fact that a pattern of use of a particular substance is disapproved of by another person or by the culture, or may have led to socially negative consequences such as arrest or marital arguments, is not in itself evidence of harmful use.

Another difference between ICD-10 and DSM-IV is in the coding systems, which limit the number of distinct drug categories that can be recorded. ICD-10 separates cocaine-related disorders from those caused by other stimulants. Because of the limits of the system the code for stimulants includes caffeine with the amphetamines and amphetamine-like stimulants. It is not clear whether 3,4-methylenedioxymethamphetamine (MDMA)-related disorders would be included under stimulants or other drugs.

EPIDEMIOLOGY

The National Household Survey on Drug Abuse (NHSDA) conducted in 1997 found that 4.5 percent of adults (ages 12 and older) reported lifetime nonmedical use of stimulants, a slight decline from the previous year. Past-30-day use was 0.3 percent in 1997. The highest rates of use in the past year (1.5 percent) were among 18- to 25-year-olds, followed by 12- to 17-year-olds. The sample was not large enough to detect increases in methamphetamine use in the western and southwestern states that are reflected in emergency room visits for amphetamine-related toxicity or drug testing programs for arrestees

The Monitoring the Future Study (High School Survey) considers amphetamines and similar drugs together as stimulants. Among high school seniors self-reported use of stimulants has been consistently higher than use of cocaine and crack cocaine. Despite the recent increases in methamphetamine use in some parts of the United States, stimulant use for the country as a whole has fallen from the high past-30-days rate of 15.8 percent seen in 1981 to a past-30-days rate of 4.8 percent in 1997.

Two population surveys that used accepted diagnostic criteria to measure the extent of drug abuse and dependence were the Epidemiologic Catchment Area (ECA) study, carried out in the early 1980s using criteria from the third edition of DSM (DSM-III) Survey (NCS), carried out from 1990 to 1992 using criteria from the revised third edition of DSM (DSM-III-R). The ECA report combined categories of dependence and abuse for amphetamine and amphetamine-like drugs. The 1-month, 6-month, and lifetime prevalences of amphetamine abuse or dependence were 0.1, 0.2, and 1.7 percent, respectively. The NCS lifetime dependence rate for 15- to 54-year-olds was 1.7 percent; about 15 percent of respondents gave a history of some nonmedical use of stimulants. Among those who reported nonmedical use about 11 percent met criteria for dependence.

ETIOLOGY

Drug dependence, including amphetamine and amphetamine-like substance dependence, is viewed as resulting from a process in which multiple interacting factors (social, psychological, cultural, and biological) influence drug-using behavior. This process, in some cases, leads to the loss of flexibility with respect to drug use that is the hallmark of drug dependence. According to this biopsychosocial perspective, the actions of the drug are seen as critical. However, not everyone who becomes dependent experiences the effects of a given drug in the same way or is influenced by the same set of factors. Even with the same class of pharmacological agents, different factors, (social, biological, cultural) may be more or less important at different stages of the process.

As with most substances, largely social and cultural factors influence availability and initial use of amphetamines and amphetamine-like drugs; however, pharmacological factors are believed to be very important in perpetuating use and progressing to dependence on these drugs. Amphetamines have potent mood-elevating and euphorigenic actions in humans and are powerful reinforcers in animal models, particularly when the drug effects have rapid onset, as when they are injected or inhaled. Although some physical dependence develops, in contrast to the opioids and sedatives, an aversive withdrawal syndrome probably plays a less prominent role in perpetuating the use of amphetamines and amphetamine-like drugs.

Comorbidity Additional psychiatric diagnoses are quite common among those dependent on amphetamines and amphetamine-like drugs. How this comorbidity is linked etiologically to amphetamine dependence is not always clear, but epidemiological evidence shows that the presence of psychiatric disorders not related to substance abuse (e.g., mood disorders, schizophrenia, and antisocial personality disorder) substantially increases the odds of developing substance abuse or dependence. Those with conduct disorder or antisocial personality disorder are more likely to take risks and to disregard social prohibitions against using illicit drugs. Amphetamines and amphetamine-like drugs may alleviate various psychiatric disorders or dysfunctional states in some persons. For example, some users (a relative few) may find relief from adult attention-deficit disorders. The drugs may alleviate a persistent dysthymic disorder in others, and for such users the anhedonic state following amphetamine cessation may be experienced as more intense. Still others may have found that the drug facilitated sexual activity. Although such factors may explain drug use on more than one occasion, they do not account for progression to dependence or abuse.

In the United States more is known about the characteristics of young people who experiment with, and become dependent on, cocaine and “crack” than about those who use amphetamines. High school juniors and seniors who use illicit drugs in general perform less well in school, have poorer family relationships, report more psychological symptoms and health problems, and exhibit more delinquent behavior. Those who use cocaine and crack are the most delinquent, but reported anxiety and depression is no greater among this group than among those whose illicit drug use does not include cocaine or crack.

Research on the temporal appearance of the syndromes indicates that in some instances and for some syndromes drug use antedates the psychiatric disorders. In one component of the ECA study subjects were reinterviewed 1 year later. Those who reported using amphetamines, amphetamine-like drugs, or cocaine in the time between interviews were almost 8 times more likely than nonusers to have developed a depressive disorder and 14 times more likely to have experienced a panic attack. Amphetamine users report a wide range of psychiatric symptoms, most of which are correlated with high levels of drug use. These are discussed more fully below.

Genetic Factors A study of Vietnam era twins found higher concordance rates for stimulant dependence among monozygotic twins than dizygotic twins. The analyses indicated that genetic factors and unique (unshared) environmental factors contributed about equally to the development of dependence. In this study, cocaine, amphetamines, and amphetamine-like drugs were all considered stimulants.

Other Factors Social, cultural, and economic factors are powerful determinants of initial use, continued use, and relapse. Excessive use is far more likely to occur where amphetamines are readily available; this is amply demonstrated by the epidemics of amphetamine use in Japan and the United States and by more recent sharp increases in use that have followed the emergence of illicit large-scale and “kitchen” laboratories synthesizing cheap, relatively pure methamphetamine.

Since in both human and animal studies alternative positive reinforcers compete with drugs as reinforcers, the absence of such nondrug alternatives can be seen as a factor contributing to their use, especially in communities where drugs are available and the social pressures against using them are not strong. Alternative positive reinforcers are not limited to material rewards but include the kinds of psychological rewards associated with satisfactory interpersonal relationships and the self-esteem that derives from achievements in socially acceptable roles.

Learning and Conditioning Learning and conditioning are also believed to be important in perpetuating amphetamine use. Each ingestion, inhalation, or injection of the drug reinforces prior drug-taking behavior. In addition, the environmental cues associated with amphetamine use become associated with the euphoric state so that long after cessation, such cues (e.g., paraphernalia, friends who use drugs) can elicit memories that reawaken a craving for the drug. Also, other drug effects may become cues, so that the effects of alcohol, often consumed with amphetamines, can become a cue eliciting an urge to use amphetamines.

Pharmacological Factors The reinforcing and toxic effects of amphetamines and amphetamine-like drugs play an important role in the genesis of amphetamine dependence and other amphetamine-related disorders. Amphetamines produce subjective effects very similar, if not identical, to those produced by cocaine. Both categories of drugs can produce a sense of alertness, euphoria, and well-being. Performance impaired by fatigue is usually improved. There may be decreased hunger and decreased need for sleep. Patterns of toxicity are also similar, although not identical. Both the amphetamines and cocaine can induce paranoia, suspiciousness, and overt psychosis that can be difficult to distinguish from paranoid-type schizophrenia; both can produce major cardiovascular toxicities. However, the amphetamines and cocaine differ distinctly in their mechanisms of action at the cellular level, their duration of action, and their metabolic pathways.

Amphetamines enhance talkativeness, self-confidence, and sociability. Some people's beliefs about the capacity of these drugs to increase sexual drive and performance also play an important, if indirect, role in their reinforcing effects. Evidence for the enhancement of sexual performance by amphetamines is still largely

anecdotal but seems convincing to some well-trained observers. Amphetamine users, both heterosexual and homosexual, report more frequent sexual activity with more partners than heroin users.

Mechanisms of Action Although amphetamines inhibit reuptake of monoamines to a small degree, their major action is the release of monoamines from storage sites in axon terminals, which in turn increases monoamine concentrations in the synaptic cleft. The release of dopamine in the nucleus accumbens and related structures is thought to account for their reinforcing and mood-elevating effects; the release of norepinephrine is probably responsible for the cardiovascular effects. In contrast to cocaine, which binds to neurotransporters and inhibits reuptake of the neurotransmitters released into the synapse, amphetamine-like drugs are taken into the neurons where they are transported into the neurotransmitter storage vesicles. By changing the internal environment of the vesicles, the drugs cause the neurotransmitters to leak out into the cytoplasm and into the synaptic cleft. The dopamine released into the cytoplasm may undergo oxidation, which results in the production of several highly toxic and reactive chemicals (oxygen radicals, peroxides, and hydroxylquinones). Some of the neuronal toxicity of methamphetamine is due, therefore, not to the drug per se, but to the intracellular accumulation of dopamine.

Methylphenidate, widely used for the treatment of attention-deficit/hyperactivity disorder, has a mechanism of action quite distinct from that of the other amphetamine-like drugs, but is generally grouped with them. Like cocaine, methylphenidate produces actions in the central nervous system (CNS) largely by blocking the dopamine transporters responsible for the reuptake of dopamine from synapses following its release. Recent studies suggest that the relatively low abuse potential of orally administered methylphenidate is due to slow occupation of dopamine transporters in the brain: it takes about 60 minutes for an oral dose to produce peak concentrations in the brain. In clinical studies only one of seven normal adults reported a “high” after doses that produced blockade of 50 percent of the dopamine transporters—a degree of blockade comparable to that achieved with intravenous doses of cocaine. These studies and studies on other drugs show that reinforcing effects depend critically on the rate of change in dopamine concentrations in relevant brain circuits. Furthermore, unlike cocaine, which leaves the brain relatively rapidly, methylphenidate occupies the transporter sites for a much longer time.

Common Routes of Administration Amphetamines and amphetamine-like drugs can be taken orally, by injection, by absorption through nasal and buccal membranes, or by heating, inhalation of the vapors, and absorption through the pulmonary alveoli. As with nicotine, opioids, freebase cocaine, and phencyclidine (PCP), inhaled amphetamine or methamphetamine is almost immediately absorbed with a rapid onset of effects. Unlike cocaine, amphetamine and methamphetamine salts can be vaporized without much destruction of the molecule, thus obviating the need for preparing a freebase form for smoking.

As with the opioids the rapid onset of amphetamine effects from intravenous injection or inhalation produces an intensely pleasurable sensation referred to as a “rush.” The duration of the amphetamine rush has not been studied in the laboratory, but it is presumed to be shorter than the duration of elevated mood. Despite the rapid onset of action following smoked amphetamines, some users, particularly young users in Australia and Great Britain, make a transition from oral to intravenous use. Amphetamine injectors seem to be more likely than injectors of other drugs, such as heroin, to share injection equipment.

Metabolism Amphetamine and methamphetamine are extensively metabolized in the liver, but much of what is ingested is excreted unchanged in the urine. The half-lives of amphetamine and methamphetamine (weak bases) are considerably shortened when the urine is acidic. The half-life of amphetamine after therapeutic doses ranges from 7 to 19 hours and that of methamphetamine appears slightly longer. Thus, after toxic dosage, resolution of symptoms may take far longer (up to several days) with amphetamines than with cocaine, depending on the pH of the urine.

Tolerance and Sensitization Most amphetamine users who seek treatment report needing progressively more amphetamine to get the same euphoric effect; they have developed *tolerance*. Some tolerance also develops to the cardiovascular effects of amphetamine.

In animal models, chronic administration of amphetamine or amphetamine-like drugs (as well as cocaine) also produces a form of *sensitization* in which the response to a given dose is actually enhanced. One theory holds that sensitization to drug effects is attributable to a variety of kindling in the CNS. In the classic studies of kindling, electrical stimulation of the limbic system, which initially has little effect, is applied repeatedly; after a matter of days the threshold for effects decreases and major, long-lasting seizures appear. Animals show similar effects with CNS stimulants, so that repeated doses of amphetamine eventually elicit seizures or stereotyped behaviors not seen with initial doses. The sensitization can be long lasting.

The paranoid states and toxic psychoses that chronic amphetamine users commonly develop are believed to be phenomena to which sensitization develops. Those who have experienced amphetamine psychosis may do so more rapidly with subsequent exposures.

Withdrawal States Although the amphetamine withdrawal syndrome has aversive qualities (e.g., dysphoria and anhedonia), it is generally not deemed as aversive as opioid withdrawal. In most cases it is probably not as critical in perpetuating amphetamine use, although withdrawal anhedonia and fatigue may contribute to an urge to use after brief withdrawal. Postdrug-use anhedonia and dysphoria may be more important for users who have come to depend on the drugs for high energy or helping to project a confident persona, who may be temporarily unable to function without them. For others, withdrawal dysphoria may exaggerate the intensity of an antecedent mood disorder. There does not appear to be a protracted amphetamine withdrawal syndrome.

Mechanisms of CNS Changes Chronic administration of amphetamines results in several adaptive changes in the brain. For example, stimulation of dopamine receptors activates cyclic adenosine monophosphate (cAMP) within neurons in the nucleus accumbens and striatum. This activation initiates a chain of intracellular events that results in altered expression of a number of genes, some of which is mediated by phosphorylation of the transcription factor cAMP response element binding protein (CREB). One of the actions of CREB is to increase transcription of dynorphin in ribonucleic acid (RNA). This action is significant because dynorphin is a selective k-opioid agonist. k-receptor agonists inhibit release of dopamine. Recurrent collateral axons from neurons in the nucleus accumbens are thought to release dynorphin on k-receptors at dopaminergic terminals, thus dampening excessive dopaminergic activity. However, when amphetamine use is stopped and the excessive dopamine release ceases, the compensatory high levels of dynorphin persist and further diminish dopaminergic activity, thus exaggerating the anhedonia and dysphoria of amphetamine withdrawal.

Additionally, neurons of the nucleus accumbens exhibit decreases in the concentration of G_i protein (which inhibits adenylyl cyclase) and increases in levels of cAMP-dependent protein kinase. Both of these changes may persist for weeks and would be expected to upregulate the cAMP pathway. In animal models, manipulations that upregulate the cAMP pathway produce increased self-administration of cocaine (and probably of amphetamine). The persistent changes in the cAMP pathway appear to represent one mechanism of tolerance to the reinforcing effects of stimulants.

Repeated administration of amphetamine results in induction and accumulation of Fos-like proteins, chronic *fos*-related antigens (FRAs) (mediated by phosphorylation of CREB). These chronic FRAs are long-lived and are distinct from Fos-like proteins seen after a single drug exposure. In addition to persistent changes in gene transcription, repeated amphetamine administration produces persistent morphological changes in neurons of the nucleus accumbens. Glutamate transmission, which appears to play an important role in modulating the rewarding and behavior-sensitizing effects of cocaine, does not appear to be involved in these actions of amphetamine. This difference may be important, distinguishing the adaptive changes induced by these two classes of stimulants.

Other Actions Neither the actions of amphetamine nor those of amphetamine-like drugs are selective for dopamine. Amphetamine-like drugs release norepinephrine and serotonin. Some of those actions are relevant to the toxic actions of amphetamine, especially its cardiovascular toxicity.

DIAGNOSIS AND CLINICAL FEATURES

DSM-IV lists a number of amphetamine (or amphetamine-like)-related disorders (Table 11.3-1) but specifies diagnostic criteria only for amphetamine intoxication (Table 11.3-2), amphetamine withdrawal (Table 11.3-3), and amphetamine-related disorder not otherwise specified (Table 11.3-4) in the section on amphetamine (or amphetaminelike)-related disorders. The diagnostic criteria for the other amphetamine (or amphetaminelike)-related disorders are contained in the DSM-IV sections dealing with the primary phenomenological symptom (e.g., psychosis).

Amphetamine use disorders
Amphetamine dependence
Amphetamine abuse
Amphetamine-induced disorders
Amphetamine intoxication
Specify if: with perceptual disturbances
Amphetamine withdrawal
Amphetamine intoxication delirium
Amphetamine-induced psychotic disorder, with delusions
Specify if: with onset during intoxication
Amphetamine-induced psychotic disorder, with hallucinations
Specify if: with onset during intoxication
Amphetamine-induced mood disorder
Specify if: with onset during intoxication/with onset during withdrawal
Amphetamine-induced anxiety disorder
Specify if: with onset during intoxication
Amphetamine-induced sexual dysfunction
Specify if: with onset during intoxication
Amphetamine-induced sleep disorder
Specify if: with onset during intoxication/with onset during withdrawal
Amphetamine-related disorder not otherwise specified

Table 11.3-1 DSM-IV Amphetamine (or Amphetamine-like)-Related Disorders

A. Recent use of amphetamine or a related substance (e.g., methylphenidate).
B. Clinically significant maladaptive behavioral or psychological changes (e.g., euphoria or affective blunting; changes in sociability; hypervigilance; interpersonal sensitivity; anxiety, tension, or anger; stereotyped behaviors; impaired judgment; or impaired social or occupational functioning) that developed during, or shortly after, use of amphetamine or a related substance.
C. Two (or more) of the following, developing during, or shortly after, use of amphetamine or a related substance: (1) tachycardia or bradycardia (2) pupillary dilation (3) elevated or lowered blood pressure (4) perspiration or chills (5) nausea or vomiting (6) evidence of weight loss (7) psychomotor agitation or retardation (8) muscular weakness, respiratory depression, chest pain, or cardiac arrhythmias (9) confusion, seizures, dyskinesias, dystonias, or coma
D. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.
Specify if: With Perceptual Disturbances

Reprinted with permission from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, ed 4. © American Psychiatric Association, Washington, DC, 1994.

Table 11.3-2 DSM-IV Diagnostic Criteria for Amphetamine Intoxication

A. Cessation of (or reduction in) amphetamine (or a related substance) use that has been heavy and prolonged.
B. Dysphoric mood and two (or more) of the following physiological changes, developing within a few hours to several days after criterion A: (1) fatigue (2) vivid, unpleasant dreams (3) insomnia or hypersomnia (4) increased appetite (5) psychomotor retardation or agitation
C. The symptoms in criterion B cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The symptoms are not due to a general medical condition and are not better accounting for by another mental disorder.

Table 11.3-4 DSM-IV Diagnostic Criteria for Amphetamine-Related Disorder Not Otherwise Specified

Amphetamine Use Disorders The DSM-IV generic criteria for dependence and abuse are applied to amphetamine and related substances (see Table 11.1-3 and Table 11.1-8). Depending on the dose, the route of administration, and the pattern of use, amphetamine dependence has quite variable effects on behavior, the capacity to work, and toxic consequences. With relatively low doses taken orally, behavior may be within normal limits and dependence is manifested only by the fatigue and depressive symptoms that ensue when drug use is interrupted and by the effort devoted to ensuring a supply. With higher doses, in addition to preoccupation with getting the drug, there is often hyperactivity, restlessness, bruxism, hypertalkativeness, irritability and short-tempered behavior, decreased sleep, and decreased appetite often accompanied by weight loss. Generally, mood is elevated; the amphetamine user is gregarious and may express confidence, even some grandiosity. With very high doses and intravenous or pulmonary routes behavior and judgment can be severely disrupted, dependence can develop quickly, and the likelihood of developing toxic paranoid states is high. There may also be repetitive behaviors that appear to have no rational basis, such as taking objects apart or rearranging objects. Such behaviors are probably analogous to the stereotypy seen when animals are repeatedly dosed with amphetamine. Severe aggressive behavior is uncommon, but it may occur during episodes of intoxication or during amphetamine-induced psychosis.

Likelihood of Progression Patients with narcolepsy and children with attention-deficit/hyperactivity disorder can take amphetamine-like drugs or methylphenidate daily for many years without developing significant tolerance to their therapeutic effects and with little escalation of dose or toxicity. When amphetamine and amphetamine-like drugs were more widely used in the treatment of obesity, relatively few patients who took them daily developed dependence. Even when amphetamine-like drugs are taken for nonmedical reasons (e.g., to reduce fatigue or for euphorigenic effects), not all users progress to abuse or dependence. Although the absolute risk of such progression is not precisely known, all estimates suggest that it is high enough to justify a policy that discourages experimentation. One estimate of risk comes from a classic study, carried out in 1974 and published in 1976, of drug use among a representative sample of young men. Seventy-three percent reported having had no experience with amphetamines, but of the 27 percent who had some experience, almost 10 percent (3 percent of the total) reported daily use. Findings from the NCS conducted in the early 1990s were remarkably similar. About 15 percent of interviewees had used a stimulant other than cocaine for extramedical reasons. Of these users, 11.2 percent had become dependent on them (DSM-III-R criteria) by the time of the interview.

Varied Patterns of Use There are several patterns of abuse of amphetamines and similar agents. Some persons may use the drugs intermittently in relatively low doses; for example, truck drivers or students may use them to overcome fatigue or the need for sleep or to derive some positive mood effects. Some intermittent users become dependent and find it difficult to stop; some may eventually escalate the dosage. Since the drugs are no longer available legitimately for these purposes, persons with that pattern of use are likely to obtain them from illicit sources.

Some persons use amphetamines primarily to induce euphoria. Such users often progress to high dosages, especially if they use the drugs intravenously or by

inhalation. These are obviously the most dangerous patterns of use, and they commonly lead to compulsive use or toxic effects. Although intravenous use initially may be intermittent, with days or weeks elapsing between episodes, such high-dose use often progresses to sprees or speed runs, during which several grams of amphetamine might be smoked or injected. The runs can last for days or weeks and are commonly punctuated by episodes of toxicity (amphetamine-induced psychotic disorder with delusions or amphetamine intoxication delirium) or by brief periods of abstinence (crashing), generally precipitated by an interruption in the supply of the drug or exhaustion. Some clinicians have observed that in contrast to cocaine users who prefer to smoke cocaine and use in binges interrupted by periods of cocaine abstinence, methamphetamine users are more likely to use on a daily basis and tend to change routes of administration because the drug is irritating to the nasal mucosa and lungs.

High-dose amphetamine users often combine amphetamine with sedatives, benzodiazepines, or opioids to modulate the stimulant effects. Alcohol use and alcohol abuse are common concomitants of high-dose amphetamine abuse and dependence. Methamphetamine is sometimes used to reduce the sedating effects of alcohol and facilitate and prolong socializing and sexual activity. Some observers believe that methamphetamine use increases the likelihood of multiple sex partners and the transmission of human immunodeficiency virus (HIV). In a study of gay and bisexual men who were methamphetamine injectors (and were not seeking treatment), 54 percent reported sharing needles within the preceding 30 days, and 74 percent reported exchanging sex for money or drugs. The recent increase in the use of methamphetamine in California and several western states has been predominantly among white men 25 to 34 years old.

Comorbidity The frequent co-occurrence of other psychiatric disorders and amphetamine dependence was first noted in the 1950s. The presence of other psychiatric disorders sharply increases the odds of drug dependence in general, and drug-dependent persons are more likely than the general population to meet the criteria for additional psychiatric disorders.

Patients with schizophrenia commonly use amphetamine or cocaine and develop both dependence and toxic syndromes. It has been suggested that schizophrenia patients use stimulants to alleviate negative symptoms or adverse effects of antipsychotic agents. Special programs involving peer-based support groups seem to be effective in linking drug-using schizophrenia patients with outpatient treatment programs.

Amphetamine-Induced Disorders All of the disorders listed in DSM-IV for cocaine (intoxication, psychotic disorder, intoxication delirium, mood disorder, anxiety disorder, sleep disorder, and sexual dysfunction) may occur in association with the use of amphetamine or amphetamine-like drugs. The clinical pictures are similar, if not identical; the DSM-IV diagnostic criteria and codes are identical except for substitution of the word “amphetamine” for the word “cocaine.”

Amphetamine Intoxication The intoxication syndromes of cocaine and amphetamines are similar. Amphetamine intoxication can occur as a result of single doses in non-tolerant individuals, but it is most commonly seen in those who are amphetamine-abusers or are dependent. Some of the manifestations are exaggerated effects of the drug, including euphoria, grandiosity, restlessness, hypervigilance, talkativeness, and stereotyped repetitive behaviors. The patient is generally oriented to time, place, and situation. However, intoxication may be accompanied by visual and tactile hallucinations or illusions. Generally, patients recognize that the symptoms are drug induced. When they do not, a diagnosis of amphetamine-induced psychotic disorder should be considered. Symptoms of amphetamine intoxication usually resolve as the drug is excreted over a period of 24 to 48 hours.

In DSM-IV, the diagnostic criteria for amphetamine intoxication (Table 11.3-2) and cocaine intoxication (see Table 11.6-2) are separated but are virtually the same. DSM-IV allows for noting the presence of perceptual disturbances as a symptom of amphetamine intoxication.

Amphetamine Withdrawal The severity of the amphetamine withdrawal syndrome is presumably related to the intensity and duration of the antecedent drug use. Some elements of the syndrome (dysphoria and fatigue) can be seen after relatively brief binges or “runs” of only a few days, with some less severe aspects of “crashing” reported to occur even after 24 hours of use. During phases of the amphetamine withdrawal syndrome users may experience severe depression that tends to resolve without special treatment when sleep normalizes.

Amphetamine users stabilized on amphetamine prior to withdrawal have been studied. Among the findings noted as early as 1963 were a marked shortening of time to first rapid eye movement (REM) sleep and a marked rebound in total REM sleep. A return to normal levels in some cases required several weeks.

The DSM-IV criteria for amphetamine withdrawal and those for cocaine withdrawal are identical; the ICD-10 criteria are virtually identical. Less is known about the later stages of amphetamine withdrawal, but it is likely that there are periods of increased vulnerability when stimuli previously associated with use elicit memories of drug effects and craving.

Amphetamine-Induced Psychotic Disorder and Intoxication Delirium Although amphetamine-induced psychotic disorder or intoxication delirium are usually seen only when high doses are used for a long time, such syndromes have been reported in apparently vulnerable persons even after therapeutic doses given for a short time. Haloperidol (Haldol) and phenothiazines have been used to treat the psychotic syndrome. Although with cocaine the delusional syndrome is typically of short duration, with the amphetaminelike drugs it may not resolve for many days after drug cessation. Following recovery from either a psychotic or delirium syndrome there may be amnesia for the entire episode or some part of it.

Psychiatrists in Japan have presented data showing that amphetamine-induced psychosis may persist for several years and that in the acute stage there may be disturbance of consciousness (confusion, disorientation) in addition to the more typical mood and delusional symptoms. Following recovery persons who have experienced an amphetamine-induced psychosis seem to be sensitized and will experience acute paranoid psychosis on reexposure to small doses of amphetamines, and some have exacerbations in response to stress.

Rhesus monkeys show hallucinatory-like behaviors and stereotypies in response to low-dose amphetamine challenge as long as 28 months after a 12-week course of low-dose amphetamine exposure.

Amphetamine-Induced Mood Disorder According to DSM-IV, the onset of amphetamine-induced mood disorder can occur during intoxication or withdrawal (see Table 14.6-18). In general, intoxication is associated with manic or mixed mood features, whereas withdrawal is associated with depressive mood features. The manic and hypomanic symptoms often seen during amphetamine use rarely (if ever) persist beyond the period of drug use, but hypophoria, depressive, and anhedonic symptoms that persist well beyond the period of withdrawal are not uncommon. Patients may seek treatment for such persisting symptoms. In such situations the clinician should consider a diagnosis of amphetamine-induced mood disorder. However, it is often difficult to distinguish a substance-induced mood disorder from a primary mood disorder, especially in patients who have a history of depressive symptoms antedating the onset of amphetamine use. Given the pharmacology of amphetamine it is possible that drug-induced changes could aggravate and intensify a primary depressive disorder.

Amphetamine-Induced Anxiety Disorder In DSM-IV, the onset of amphetamine-induced anxiety disorder can also occur during intoxication or withdrawal (see Table 15.6-18). Amphetamine, like cocaine, can induce symptoms similar to those seen in obsessive-compulsive disorder, with repetitive, stereotyped behaviors. However, these ordinarily do not persist beyond the period of drug intoxication and rarely merit a distinct diagnosis. Amphetamine-like drugs can also induce panic attacks in individuals with no previous history of panic attacks. When such episodes persist well beyond the period of drug use and require clinical attention a distinct diagnosis should be entertained.

Amphetamine-Induced Sexual Dysfunction Although amphetamine is often used to enhance sexual experiences, high doses and long-term use are associated with impotence and other sexual dysfunctions. These dysfunctions are classified in DSM-IV as amphetamine-induced sexual dysfunction with onset during intoxication (see Table 19.1a-20).

Amphetamine-Induced Sleep Disorder The diagnostic criteria for amphetamine-induced sleep disorder with onset during intoxication or withdrawal are found in the DSM-IV section on sleep disorders (see Table 21-18). Amphetamine use can produce insomnia and sleep deprivation; persons undergoing amphetamine withdrawal can experience hypersomnolence and nightmares. However, unless these disturbances persist beyond the period of drug use or well beyond withdrawal and are severe enough to merit clinical attention they do not require a separate diagnosis.

Disorder Not Otherwise Specified If an amphetamine (or amphetamine-like)-related disorder does not meet the criteria of one or more of the previous discussed categories, it can be diagnosed as an amphetamine-related disorder not otherwise specified (Table 11.3-4). With the increasing illicit use of designer amphetamines, syndromes may arise that do not meet the criteria outlined in DSM-IV and that necessitate the frequent use of the not otherwise specified category.

Toxicity and Complications Subjects in a survey of amphetamine users in Australia reported various physical and psychological problems that they attributed to

amphetamine use. Commonly reported physical symptoms were tiredness (89 percent), loss of appetite (85 percent), dehydration (73 percent), and jaw clenching (73 percent). Also reported were headaches, muscle pains, shortness of breath, and tremors. The most frequently reported psychological symptoms were mood swings (80 percent), sleep problems (78 percent), anxiety, difficulty concentrating, depression, and paranoia (each about 70 percent), hallucinations, and episodes of aggression and violence (each about 45 percent). Daily use, heavier use, and being male and unemployed were correlated with reporting more symptoms.

Amphetamines produce their most dramatic toxic effects on the CNS and the cardiovascular system. In animal models (rodents and primates), chronically administered high doses of amphetamines produce long-lasting depletion of brain norepinephrine, and more selective but even longer-lasting depletion of dopamine, alterations in dopamine uptake sites, and reduction in serotonergic activity. Because these effects involve damage to both axons and axon terminals, largely sparing the cell bodies, it is not known to what degree these long-lasting effects are permanent. Methamphetamine in particular seems capable of inducing damage to serotonergic fibers, but the noradrenergic system is largely unaffected. These effects may be due to toxic biotransformation products of excessive dopamine within the neuron. The long-lasting dopaminergic changes probably account for the altered, elevated threshold for self-stimulation in animals and the anhedonia reported by chronic amphetamine users for prolonged periods following cessation. It is not known to what degree methamphetamine use causes neuronal damage in humans, but data from patients with Parkinson's disease suggest that there must be considerable damage to the dopaminergic pathways before it becomes evident in function and behavior. In monkeys the toxic effects of chronic amphetamine use include damage to cerebral blood vessels, neuronal loss, and microhemorrhages. In humans high doses of amphetamine have also been associated with lethal hyperpyrexia and with destructive deterioration of arterioles. High doses can also produce convulsions and ultimately coma and death.

Amphetamine-like drugs can cause catastrophes of the cardiovascular system (e.g., intracranial hemorrhage, arrhythmias, and acute cardiac failure) because of their capacity to release norepinephrine, dopamine, and serotonin, and to raise blood pressure. With amphetamines, considerable tolerance develops to the effect on blood pressure. The likelihood of such cardiovascular effects is related to dose and the rapidity with which the drug is absorbed. The use of methamphetamine by smoking or intravenous injection is likely to result in greater cardiovascular toxicity. Amphetamine-induced hyperthermia and free radical formation are believed to be involved in causing rhabdomyolosis and the consequent renal tubular obstruction that is occasionally reported. Because amphetamine use can be associated with increased sexual activity, often accompanied by poor judgment, amphetamine users are at increased risk for venereal diseases, including infection with HIV.

PATHOLOGY AND LABORATORY EXAMINATIONS

Amphetamine and amphetaminelike drugs can be detected for varying lengths of time in urine (several days, depending on dose and sensitivity of the method). Metabolites can also be detected in blood, saliva, and hair. Blood and saliva furnish a better index of current levels, whereas urine provides a longer window of opportunity for detecting use over the previous few days. Hair analysis can reveal drug use over a period of weeks to months but has little applicability in clinical situations.

Such procedures as positron emission tomography (PET) and single photon emission computed tomography (SPECT) have not yet been used during the immediate postamphetamine cessation period, but given the findings seen at autopsy and the pharmacology of amphetaminelike agents, it would not be surprising if there were arteriolar pathology and alterations in dopamine systems.

DIFFERENTIAL DIAGNOSIS

The disorders associated with the use of amphetamine and amphetamine-like drugs need to be distinguished from both primary mental disorders and disorders induced by other classes of drugs. A history of the drug ingestion is important for making these distinctions. However, given the unreliability of self-reports about drug use and the likelihood that many users will deny any drug use at all, laboratory testing for drugs in body fluids and histories from collaterals are very important. Disorders associated with amphetamine use cannot be easily distinguished from those associated with cocaine except by a reliable history or laboratory tests. Users of amphetamine or cocaine and related drugs may exhibit inappropriate optimism, euphoria, and expansiveness; excessive talkativeness; and a decreased need for sleep sometimes associated with irritability in the context of a clear sensorium, a pattern that is also observed in manic and hypomanic episodes of bipolar I disorder and bipolar II disorder, respectively. Those symptoms, however, may not be obvious enough to suggest their relation to drug use, and the first indication of drug dependence may be financial difficulties, an arrest for selling drugs or possessing them, or some drug-induced toxicity.

Intoxication Amphetamine intoxication is diagnosed when the effects of the drug exceed the mood-elevating effects that users typically seek when they use amphetamines. The diagnosis of intoxication would be appropriate when the drug effects are problematic enough to require differentiation from hypomanic or manic behavior.

Amphetamine and amphetamine-like drug intoxication can also be confused with PCP intoxication, although the latter is usually associated with nystagmus, motor incoordination, and some cognitive impairment. Endocrine disorders (such as Cushing's disease) and the excessive use of steroids should also be considered.

Psychotic Disorders Amphetamine-induced toxic psychosis can be exceedingly difficult to differentiate from schizophrenia and other psychotic disorders characterized by hallucinations or delusions. Paranoid delusions occur in about 80 percent of patients, and hallucinations in 60 to 70 percent. Consciousness is clear and disorientation is uncommon. The presence of vivid visual or tactile hallucinations should raise suspicion of a drug-induced disorder. In areas and populations where amphetamine use is common it may be necessary to provide only a provisional diagnosis until the patient can be observed and drug test results are obtained. Even then, there may be difficulties because in some urban areas a high percentage of persons with established diagnoses of schizophrenia also use amphetamines or cocaine. Typically symptoms of amphetamine psychosis remit within a week, but in a small proportion of patients, psychosis may last for more than a month.

Anxiety Disorders Amphetamine-induced anxiety disorder must also be distinguished from panic disorder and generalized anxiety disorder.

Other Symptoms The symptoms that may emerge during withdrawal—depression, dysphoria, anhedonia, disturbed sleep—need to be distinguished from those of primary mood disorders and primary sleep disorders. Unless the symptoms are more intense or more prolonged than is typical of amphetamine withdrawal and require independent treatment, the diagnosis should be limited to withdrawal rather than amphetamine-induced mood disorder. When a diagnosis of amphetamine-induced mood disorder is made, one must specify whether its onset was during intoxication or in withdrawal. It is also possible to specify the subtype of mood disorder (with depressive, manic, or mixed features). In differentiating amphetamine-induced mood disorder from the primary mood disorder the critical factor is the clinician's judgment that the mood disorder was caused by the drug. An amphetamine-induced mood disorder or mood disorder with onset during intoxication or withdrawal usually remits within a week or two. It is appropriate, therefore, to withhold judgment about the diagnosis during the early phase of withdrawal. If depressed mood and related symptoms persist beyond a few weeks, the possibility of alternative causes should be entertained. In considering diagnostic possibilities the clinician should consider the age of the patient at the onset of symptoms and a history of episodes of mood disorder that developed before the onset of drug use or during any long intervals when there was no significant drug abuse.

COURSE AND PROGNOSIS

The natural history of amphetamine dependence in the United States is less well documented than that of opioids or cocaine. Some researchers believe that some intravenous amphetamine users in the 1960s moved on to heroin use in the 1970s. However, it seems likely that many whose use was less severe simply stopped or recovered, whereas others intensified their use of alcohol. Japanese clinicians believe that some amphetamine users may develop persistent psychosis and that those who recover remain at high risk of reexperiencing psychosis if they use amphetamines again (sensitization).

A 3- to 8-year follow-up study of 110 methamphetamine users hospitalized for drug-related problems in Japan in the 1980s found that 12 former patients had died, a mortality rate 11 times that of age- and sex-matched general population controls. However, 56 percent of those still alive had not used amphetaminelike drugs in the year before interview, and most of them also showed improvements in work and family relationships. Twenty-five percent were thought to have highly or moderately unfavorable outcomes in terms of drug use, work, and family relationships. Findings from treatment programs in California suggest that the course and prognosis for amphetamine dependence are probably similar to those for cocaine dependence. The prognosis for Japanese convicted and imprisoned for crimes related to stimulant drug use seems as bleak as that in the United States; 58 percent committed crimes within 1 year after release and 98 percent committed crimes within 5 years.

TREATMENT

There are no specific, well-established treatments for dependence on amphetamine or amphetamine-like drugs and few controlled studies on the treatment of amphetamine dependence. Most casual users do not need or seek treatment. Those with moderately severe dependence obtain treatment in a variety of settings (mostly outpatient drug free) that were not designed specifically to treat amphetamine dependence. The most severe cases, those within the criminal justice system, and the homeless generally drop out of outpatient treatment because of their complex needs or are unable to access treatment at all. Some data on treatment seeking and outcome are available for the state of California where amphetamine abuse began to increase in the early 1990s. In general, methamphetamine users in the state gave reasons for entering treatment similar to those of other substance users—personal motivation (69 percent) and pressure from the criminal justice system (31 percent) and from family or other significant persons (22 percent). Treatment received ranged from residential and ambulatory detoxification to day treatment, 12-step activities, and case management. Although those leaving 12-step programs were more likely to have been considered treatment completers, at follow-up, patients reported similar reductions in drug use (unverified by urine tests) regardless of the treatment received and were neither more nor less successful in this respect than those receiving treatment for heroin, cocaine, or marijuana use. One program that provided a highly structured and manualized cognitive-behavioral treatment making use of a combination of group and individual counseling initially developed for crack cocaine users found that this type of treatment produced equal levels of participation in treatment and equally good outcomes for those dependent on methamphetamine.

A wide variety of pharmacological agents have been explored as adjuncts to, or major elements in, the treatment of amphetamine dependence. Some have been studied in controlled trials. Virtually all of these agents had been previously tried in the treatment of cocaine dependence and produced comparably disappointing results. For example, although imipramine (Tofranil) (150 mg a day) improved treatment retention, it had no significant effect on methamphetamine use. Although an open-label trial of fluoxetine (Prozac) (20 mg a day) was reported to be useful in amphetamine dependence, success in dozens of open-label trials with cocaine-dependent patients has rarely been confirmed when the same agents were studied in double-blind controlled trials.

In Europe and Australia the ethics and efficacy of prescribing oral amphetamines for amphetamine users are hotly debated. This practice is allowed in Great Britain, although it varies from region to region, and virtually no safeguards exist against diversion of prescribed amphetamines to the illicit market. No outcome studies exist that evaluate the values and risks of this practice.

Selection of Treatment Setting The general principles of treatment for amphetamine dependence are not very different from those for cocaine and opioid dependence, but there are fewer replicated studies on the efficacy of any particular treatment approach. As with cocaine and opioid dependence, amphetamine dependence severe enough to require formal treatment is often associated with other psychiatric diagnoses.

Patient heterogeneity requires thoughtful selection among available alternatives. Not all amphetamine users require extensive treatment; some users who are not dependent respond to external pressures, as when employers insist on careful monitoring of drug use. The executive with little history of psychopathology, a supportive social network, economic assets, and personal skills has a different prognosis and a wider range of options than does a patient who is unemployed, alienated from the family, and perhaps also using opioids. Severe depression, psychotic manifestations beyond the initial withdrawal period, and drug use that is completely out of control (i.e., repeated failure to respond to outpatient efforts) seem to be the major accepted criteria for hospitalization.

OTHER AGENTS

Substituted Amphetamines MDMA (“Ecstasy,” “Adam”) is one of a series of substituted amphetamines that also includes 3,4-methylenedioxyethylamphetamine (MDEA, “Eve”), 3,4-methylenedioxyamphetamine (MDA), 2,5-dimethoxy-4-bromoamphetamine (DOB), paramethoxyamphetamine (PMA), and others. These drugs produce subjective effects resembling those of amphetamine and lysergic acid diethylamide (LSD), and in that sense, MDMA and similar analogues may represent a distinct category of drugs (“entactogens”).

A methamphetamine derivative that came into use in the 1980s, MDMA was not technically subject to legal regulation at the time. Although it has been labeled a designer drug in the belief that it was deliberately synthesized to evade legal regulation, it was actually synthesized and patented in 1914. Several psychiatrists used it as an adjunct to psychotherapy and concluded that it was of value. At one time it was advertised as legal and was used in psychotherapy for its subjective effects. However, it was never approved by the FDA. Its use raised questions of both safety and legality, since the related amphetamine derivatives MDA, DOB, and PMA had caused a number of overdose deaths, and MDA was known to cause extensive destruction of serotonergic nerve terminals in the CNS. Using emergency scheduling authority, the Drug Enforcement Agency made MDMA a Schedule I drug under the CSA, along with LSD, heroin, and marijuana. Despite its illegal status MDMA continues to be manufactured, distributed, and used in the United States, Europe, and Australia. Its use is common in Australia and Great Britain at extended dances (“raves”) popular with adolescents and young adults.

Mechanisms of Action The unusual properties of the drugs may be a consequence of the different actions of the optical isomers: the *R*(–) isomers produce LSD-like effects and the amphetamine-like properties are linked to *S*(+) isomers. The LSD-like actions, in turn, may be linked to the capacity to release serotonin. The various derivatives may exhibit significant differences in subjective effects and toxicity. Animals in laboratory experiments will self-administer the drugs, suggesting prominent amphetamine-like effects.

Subjective Effects After taking usual doses (100 to 150 mg), MDMA users experience elevated mood and, according to various reports, increased self-confidence and sensory sensitivity; peaceful feelings coupled with insight, empathy, and closeness to people; and decreased appetite. Difficulty in concentrating and an increased capacity to focus have both been reported. Dysphoric reactions, psychotomimetic effects, and psychosis have also been reported. Higher doses seem more likely to produce psychotomimetic effects. Sympathomimetic effects of tachycardia, palpitation, increased blood pressure, sweating, and bruxism are common. The subjective effects are reported to be prominent for about 4 to 8 hours, but they may not last as long or may last longer, depending on the dose and route of administration. The drug is usually taken orally, but it has been snorted and injected. Both tachyphylaxis and some tolerance are reported by users.

The acute adverse effects reported include precipitation of episodes of panic and anxiety. More-severe brief psychiatric disturbances can also occur, and preexisting pathology does not appear to be a requisite for severe reactions. A healthy drug-free subject, known to be without personal and family psychiatric illness was given a 140-mg dose of the drug and developed a psychosis lasting 2½ hours that included vivid auditory and visual hallucinations and a belief that people were making noise to annoy him intentionally.

Following the acute effects of MDMA there may be a combination of some diminishing residual effects gradually superseded by feelings of drowsiness, fatigue, depression, and difficulty concentrating, somewhat comparable to the crash after cessation of amphetamine use. When young adults who were Saturday night MDMA users were compared with alcohol-only users who frequented the same club, the MDMA users reported elevated mood on the following day but feelings of depression (Beck Depression Inventory scores of about 12) by the fifth day. In contrast, alcohol-only users showed relatively little mood change over the 5-day period; their highest Beck depression scores (about 8) occurred on the second day. In a double-blind placebo-controlled study of normal volunteers given 1.7 mg per kg of body weight of MDMA, some subjects continued to report symptoms typical of MDMA actions (suppressed appetite, jaw clenching, restlessness, heaviness in the legs, difficulty concentrating) 24 hours later. More-persistent neuropsychiatric adverse effects associated with MDMA use include anxiety, depression, flashbacks, irritability, panic disorder, psychosis, and memory disturbance.

Toxicity Although it is not as toxic as MDA, various somatic toxicities attributable to MDMA use have been reported, as well as fatal overdoses. It does not appear to be neurotoxic when injected into the brain of animals, but it is metabolized to MDA in both animals and humans. In animals MDMA produces selective, long-lasting damage to serotonergic nerve terminals. It is not certain if the levels of the MDA metabolite reached in humans after the usual doses of MDMA suffice to produce lasting damage. Nonhuman primates are more sensitive than are rodents to MDMA's toxic effects and show more prolonged or permanent neurotoxicity at doses not much higher than those used by humans (Fig. 11.3-1). Users of MDMA show differences in neuroendocrine responses to serotonergic probes, and studies of former MDMA users show global and regional decreases in serotonin transporter binding, as measured by positron emission tomography. Although psychological assessment of a small sample of users did not reveal evidence of current anxiety or a mood disorder, eight of nine subjects had at least some impairment on at least one test of neuropsychological function.

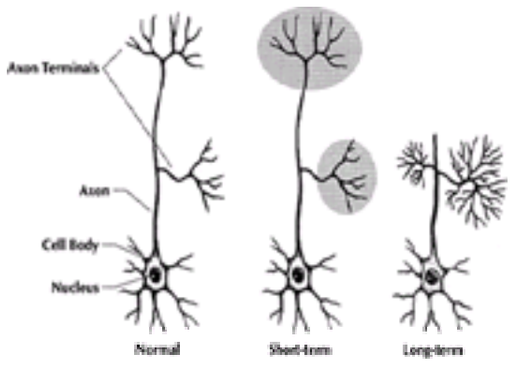

FIGURE 11.3-1 Neurotoxic effects of MDMA. MDMA damages serotonin-producing neurons in the brains of nonhuman primates. The *left illustration* shows a normal neuron. The shaded area in the *middle illustration* shows the axon terminals of the neurons that are damaged by MDMA. The *right illustration* shows how, 12 to 18 months after being damaged by MDMA, serotonin-producing nerve fibers have regrown excessively in some areas and not at all in others. (Reprinted with permission from Mathias R: Like methamphetamine, "ecstasy" may cause long-term brain damage. NIDA Notes *11:*7, 1996.)

Other reported toxicities include arrhythmias, cardiovascular collapse, hyperthermia, rhabdomyolysis, disseminated intravascular coagulation, acute renal failure, and hepatotoxicity. The role that contaminants in illicit MDMA played in the toxic reactions is uncertain, but significant elevations of blood pressure and temperature have been observed after administration of pure MDMA.

MDMA dependence does not appear to be a significant problem in the United States, but cases of dependence have been reported in England. Among a sample of MDMA users in Australia, 28 percent reported that problems related to the use of the drug were mostly acute reactions, such as panic, paranoia, loss of reality, and hallucinations. Only 2 percent reported feeling dependent (needing to use it every day to cope), but 22 percent claimed that they knew someone who had been dependent, and 47 percent believed it was possible to become addicted. MDA, MDMA, PMA, and MDEA have all been linked to psychosis and overdose deaths. The toxic manifestations of overdose include restlessness, agitation, sweating, rigidity, high blood pressure, tachycardia, hyperpyrexia, and convulsions. Chlorpromazine (Thorazine) prevented lethality in dogs, but there are no clinical reports of its use for this purpose in humans.

There are currently no established clinical uses for MDMA, although before its regulation, there were several reports of its beneficial effects as an adjunct to psychotherapy.

Khat The fresh leaves of *Catha edulis*, a bush native to East Africa, have been used as a stimulant in the Middle East, Africa, and the Arabian peninsula for at least 1000 years. Khat is still widely used in Ethiopia, Kenya, Somalia, and Yemen. The amphetamine-like effects of khat have long been recognized, and although efforts to isolate the active ingredient were first undertaken in the nineteenth century, only since the 1970s a has cathinone (*S*(–)a-aminopropriophenone or *S*-2-amino-1-phenyl-1-propanone) been identified as the substance responsible. Cathinone is a precursor moiety that is normally enzymatically converted in the plant to the less active entities norephedrine and cathine (norpseudoephedrine), which explains why only the fresh leaves of the plant are valued for their stimulant effects. Cathinone has most of the CNS and peripheral actions of amphetamine and appears to have the same mechanism of action. In humans it elevates mood, decreases hunger, and alleviates fatigue. Like amphetamine, it is self-administered by laboratory animals and produces increased locomotor activity and stereotypy. At high doses it can induce an amphetamine-like psychosis in humans. Because it is typically absorbed buccally after chewing the leaf and because the alkaloid is metabolized relatively rapidly, high toxic blood levels are not frequently reached. Concern about khat use is linked to its dependence-producing properties rather than to its acute toxicity. It is estimated that five million doses are consumed each day, despite prohibition of its use in a number of African and Arab countries.

In the 1990s several clandestine laboratories began synthesizing methcathinone, a drug with actions quite similar to those of cathinone. Known by a number of street names (e.g., CAT, goob, and crank), its popularity is due primarily to its ease of synthesis from ephedrine or pseudoephedrine, which were readily available until placed under special controls. Methcathinone has been moved to Schedule (Control Level) I of the CSA. The patterns of use, adverse effects, and complications are quite similar to those reported for amphetamine.

SUGGESTED CROSS-REFERENCES

The neural sciences are presented in Chapter 1 and neuropsychiatry and behavioral neurology in Chapter 2. A classification of mental disorders appears in Chapter 9. An introduction to and overview of substance-related disorders is presented in Section 11.1, cocaine-related disorders in Section 11.6, and various drugs in Chapter 31 on biological therapies, particularly sympathomimetics in Section 31.27. Schizophrenia is discussed in Chapter 12, other psychotic disorders in Chapter 13, and attention-deficit disorders in Section 39.1

11.4 CAFFEINE-RELATED DISORDERS

ERIC C. STRAIN, M.D. AND ROLAND R. GRIFFITHS, PH.D.

The most widely consumed psychoactive substance in the world is caffeine. It is estimated that over 80 percent of adults in the United States consume caffeine regularly, and throughout the world caffeine consumption is well integrated into daily cultural practices (e.g., the coffee break in the United States, tea time in the United Kingdom, and kola nut chewing in Nigeria). Because caffeine use is so pervasive and widely accepted, disorders associated with caffeine use may be overlooked. However, it is important to recognize that caffeine is a psychoactive compound that can produce a wide variety of syndromes, and the fourth edition of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)* recognizes several caffeine-related disorders (such as caffeine intoxication, caffeine-induced anxiety disorder, and caffeine-induced sleep disorder). In addition, other caffeine-related disorders, such as caffeine withdrawal and caffeine dependence, are not official diagnoses in *DSM-IV*, but can be of clinical interest.

HISTORY

Caffeine-containing foods and beverages have been consumed for hundreds if not thousands of years. Tea has been cultivated and consumed in China since at least 350 AD, and coffee cultivation spread from Ethiopia to Arabia in the fifteenth century and subsequently became a popular beverage in Arabic cultures during the sixteenth century. However, most caffeine consumption occurred in restricted geographical regions, and it was not until the seventeenth century that caffeine use began to spread, eventually becoming nearly universally available, as it is today. The Dutch imported caffeine in the form of coffee from Arabic countries to Europe, where it first became popular around the middle to end of the seventeenth century (along with tea, tobacco, and chocolate). Medical literature during this time period described coffee as a useful beverage for a wide variety of conditions, although it is notable that coffee's use to induce sobriety was a particularly attractive feature. However, considerable controversy about whether the use of coffee was beneficial or detrimental to health was associated with its expansion into Western cultures—a controversy that is mirrored in the contemporary concerns over the use of caffeine.

The expansion of coffee consumption during the seventeenth and eighteenth centuries can be demonstrated by the estimate that there were between 2000 and 3000 coffeehouses in London by the early part of the seventeenth century (about 1 coffeehouse for 200 to 300 people). The spread and popularity of coffeehouses in Europe highlights how coffee was initially a beverage consumed in public; it was only later that coffee became a beverage consumed in the home. Perhaps the most famous of the coffeehouses in London was operated by Edward Lloyd. Like most coffeehouses, Lloyd's was a center of business, especially for insurance agents, and by the end of the eighteenth century Lloyd's actually became the well-known Lloyd's of London insurance company. However, in England, coffee use was eventually supplanted by tea consumption, with the shift in beverage preference occurring in the first half of the eighteenth century.

In the United States a shift from tea to coffee use occurred in 1773 when colonists protesting British taxes threw cargoes of tea overboard in the Boston harbor—the Boston tea party. The repercussions of this event continue to the present day; the United States is the major consumer of coffee in the world.

In the late nineteenth century caffeine began appearing in various soft drink beverages. While some caffeine contained in soft drink beverages is derived from the cola nut, most caffeine in sodas is added. In the United States caffeine is also added to noncola sodas and to some bottled waters, and consumption of soda has been increasing markedly in the past 25 years.

In the contemporary world caffeine is integral to the economic activity of several countries. For example, only crude oil produces more foreign exchange earnings than coffee for developing countries. In the United States coffee is the major agricultural import and is second only to oil among all imports. This economic and trade activity underscores the extent to which caffeine use has spread over the past four centuries, so that caffeine is now available and accepted virtually everywhere in the world.

COMPARATIVE NOSOLOGY

There is no mention made of caffeine-related disorders in the first edition of DSM (DSM-I), which was published in 1952. In the second edition of DSM (DSM-II), published in 1968, caffeine (and interestingly, tobacco) are explicitly excluded from consideration for a diagnosis of drug dependence, and no other mention of caffeine use disorders is included in this edition. The American Psychiatric Association first included caffeine (and tobacco) use disorders in the third edition of DSM (DSM-III) in 1980. At that time *caffeine intoxication*—the only caffeine-related disorder in DSM-III—was included as a discrete syndrome with specific criteria for its diagnosis. Over successive editions of the DSM, caffeine intoxication has remained and DSM-IV has included criteria for caffeine withdrawal in the appendix. The text suggests that further research is needed to establish caffeine withdrawal as a discrete syndrome. The *DSM-IV* has also included diagnoses of caffeine-induced anxiety and caffeine-induced sleep disorders—that is, conditions in which specific caffeine-induced symptoms (anxiety, sleep disturbance) require clinical attention. Caffeine abuse and caffeine dependence are not included in DSM-IV, although there is evidence that some patients can exhibit a caffeine dependence syndrome.

The 10th revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) contains criteria for caffeine intoxication ("Acute intoxication due to the use of other stimulants, including caffeine"), and also includes several other diagnostic categories that can be applied to caffeine such as "harmful use," "dependence syndrome," and "withdrawal states from other stimulants, including caffeine." Thus, while DSM has tended to restrict the clinical syndromes associated with caffeine use, it is important to note ICD-10, another prominent diagnostic system for psychiatric disorders, has a more inclusive set of conditions associated with caffeine use.

EPIDEMIOLOGY

It is difficult to determine the average amount of caffeine used on a daily basis, partly because of the multiple sources of caffeine available to consumers. Caffeine is found in beverages (coffees, teas, sodas), foods (chocolate), and medications (both prescription and over-the-counter drugs), although most caffeine consumed is derived from coffee and tea. Some sources of caffeine such as coffees and colas, are readily identifiable, others are less easily recognized. Thus, for example, noncola sodas can contain caffeine, and certain over-the-counter analgesics also contain caffeine.

Estimates of caffeine consumption require knowledge of the caffeine content of these different sources of caffeine. Also, there can be variability within categories, so that different colas, for example, may have different caffeine contents, and the procedure used to prepare a beverage (i.e., brewed versus instant coffee) can also influence the caffeine content. Table 11.4-1 provides a list of the typical caffeine content of selected caffeine-containing products, although these values represent estimates and amounts may vary.

Substance	Caffeine content
Brewed coffee	100mg/6 oz
Instant coffee	70mg/6 oz
Decaffeinated coffee	4mg/6 oz
Leaf or bag tea	40mg/6 oz
Instant tea	25mg/6 oz
Caffeinated soda	45mg/12 oz
Cocoa beverage	5mg/6 oz
Chocolate milk	4mg/6 oz
Dark chocolate	20mg/1 oz
Milk chocolate	6mg/1 oz
Caffeine-containing cold remedies	25–50 mg/tablet
Caffeine-containing analgesics	25–65 mg/tablet
Stimulants	100–350 mg/tablet
Weight-loss aids	75–200 mg/tablet

Adapted from DSM-IV and Barone JJ, Roberts HR: Caffeine consumption. Food Chem Toxicol *34*:119, 1996.

Table 11.4-1 Typical Caffeine Content of Foods and Medications

Caffeine consumption also varies by age. Figure 11.4-1 shows estimates of per capita caffeine consumption, by those who consume caffeine, for different age groups in the United States. These estimates demonstrate the wide variability in caffeine consumption for different ages. As shown in Fig. 11.4-1, the average daily caffeine consumption for all ages of caffeine consumers is 2.79 mg/kg in the United States. It is worth noting that there is substantial caffeine consumption even by young children (i.e., over 1 mg/kg for children between the ages of 1 to 5 years). Worldwide it is estimated the average daily per capita caffeine consumption is about 70 mg.

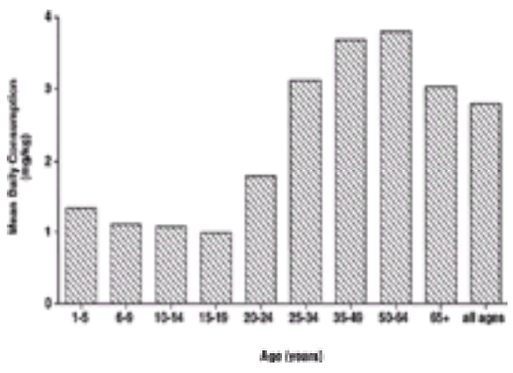

FIGURE 11.4-1 Mean daily caffeine consumption (mg/kg) for different age groups and all ages, in the United States of America. (Adapted from Barone JJ, Roberts HR: Caffeine consumption. Food Chem Toxicol *34:*119, 1996.)

In the United States, the major source of caffeine is coffee, although coffee use peaked in 1962 with a gradual decline throughout the 1980s and 1990s (Fig. 11.4-2). Fifty-two percent of the United States population 10 years of age or older drank coffee in 1993. While coffee is the most popular form in which caffeine is consumed, caffeine use in children was equally divided between tea and coffee until the late 1980s, when there was a decrease in tea use and a compensatory increase in coffee use. Estimates of soda-related caffeine use are more difficult to determine, although it is notable that soda use (predominantly caffeinated) has been steadily increasing in the United States (Fig. 11.4-2). It is estimated that approximately 70 percent of the soda consumed in the United States is caffeinated.

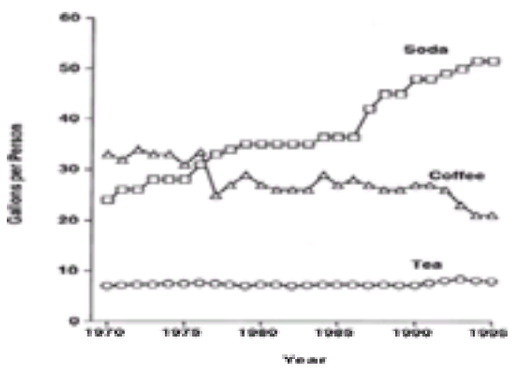

FIGURE 11.4-2 Consumption by year for soda, coffee, and tea in the United States of America (gallons per person). Values represent both caffeinated and noncaffeinated products. (Adapted from Liebman B: The changing American diet. Nutr Action Healthlett *24*(3):8, 1997.)

The average daily caffeine consumption for all adults in the United States is generally estimated to be 3 mg/kg, and for adult consumers of caffeine it is estimated to be 4 mg/kg (the equivalent of about 3 or more cups of brewed coffee in a man of average weight). Among the heaviest adult consumers of caffeine, caffeine intake is at least 5 to 7 mg/kg per day (the equivalent of about 6 cups of brewed coffee in a man of average weight).

ETIOLOGY

It is not uncommon for the first exposure to caffeine to occur during childhood. Following exposure to caffeine, continued caffeine consumption may be influenced by several different factors, such as the pharmacological effects of caffeine, caffeine's reinforcing effects, genetic predispositions to caffeine use, and personal attributes of the consumer (e.g., age).

PHARMACOLOGY AND EFFECTS IN THE CENTRAL NERVOUS SYSTEM

Caffeine is a methylxanthine, as are theobromine (found in chocolate) and theophylline (Theo-Dur), typically used in the treatment of asthma. It is well absorbed from the gastrointestinal tract, with peak plasma concentrations typically occurring within 1 hour after ingestion. Caffeine crosses the blood-brain barrier and is metabolized by the liver. Caffeine metabolism is increased by smoking, and it is not uncommon to find higher rates of caffeine consumption in people who smoke tobacco.

Caffeine (and the methylxanthines in general) exert several different effects, including the relaxation of smooth muscle (hence their therapeutic application in the treatment of asthma, where they relax the smooth muscle of bronchi), complex but probably only modest actions on heart rate and blood pressure (which depend in part upon whether or not the person is tolerant to the effects of caffeine), and increased production of urine (although the mechanism of these diuretic effects is not clear).

Numerous investigations have examined the effects of caffeine in the central nervous system in order to understand the molecular basis for caffeine's effects. Mechanisms proposed as mediating caffeine's effects have included the inhibition of phosphodiesterases and effects on intracellular calcium (although these effects may only occur with higher doses of caffeine), and antagonism at the adenosine receptor. This latter action—adenosine receptor antagonism—appears to be the primary site of action for caffeine's effects at doses typically ingested by humans. Recent studies also suggest an important role of dopamine in mediating some of the behavioral effects of caffeine.

Subjective Effects and Reinforcement Single low to moderate doses of caffeine (i.e., 20 to 200 mg) can produce a profile of subjective effects in humans that is generally identified as pleasurable. Thus, studies have shown that such doses of caffeine result in increased ratings on measures such as well-being, energy and concentration, and motivation to work. In addition, these doses of caffeine produce decreases in ratings of feeling sleepy or tired. Doses of caffeine in the range of 300 to 800 mg (the equivalent of several cups of brewed coffee ingested at once) produce effects that are rated as being unpleasant, such as anxiety and nervousness. Although animal studies have generally found it difficult to demonstrate that caffeine functions as a reinforcer, well-controlled studies in humans have shown that people choose caffeine over placebo when given the choice under controlled experimental conditions. Thus, the profile of caffeine's subjective effects and its ability to function as a reinforcer can contribute to the regular use of caffeine.

Genetics and Caffeine Use Studies examining the possibility of genetic influences on caffeine use have generally focused only on coffee use (rather than on all sources of caffeine), and thus conclusions from these studies need to be viewed with caution. However, several investigations comparing coffee use in monozygotic versus dizygotic twins have shown higher concordance rates for monozygotic twins, suggesting that there may be some genetic predisposition to continued coffee use following exposure to coffee.

Age, Sex, and Race The relation between long-term chronic caffeine use and demographic features such as age, sex, and race has not been widely studied. There is some evidence that suggests that older people may use more caffeine, although caffeine use in adolescents is not uncommon. There is no known evidence that caffeine use differs for men versus women, and there is no data that specifically addresses caffeine use for different races. There is some evidence suggesting that in the United States whites consume more coffee and tea than African-Americans although the survey that found this difference did not distinguish between caffeinated and noncaffeinated products. This survey found no difference in the rates of soda consumption by race.

Special Populations Caffeine's metabolism is increased in people who smoke tobacco, and several studies have shown higher amounts of daily caffeine consumption in people who smoke. Caffeine metabolism is decreased in women who take oral contraceptives, so that lower daily caffeine consumption in this population may simply reflect compensation because of decreased metabolism.

There have also been several studies showing high daily amounts of caffeine use in psychiatric patients. For example, several studies have found such patients consume the equivalent of an average of five or more cups of brewed coffee each day. Finally, high daily caffeine consumption has also been noted in prisoners.

Personality Although attempts have been made to link preferential use of caffeine to particular personality types, results from these studies do not suggest that any particular personality type is especially linked to caffeine use.

DSM-IV DISORDERS

Caffeine use can be associated with five discrete syndromes. Three of these conditions—caffeine intoxication, caffeine-induced anxiety disorder, and caffeine-induced sleep disorder—are described in DSM-IV (Table 11.4-2). A fourth syndrome—caffeine withdrawal—is included in the appendix of DSM-IV, and a final condition—caffeine dependence—is not included in DSM-IV but will be discussed here. These latter two conditions can be diagnosed using the category caffeine-related disorders not otherwise specified, which is included in DSM-IV as a substance-related disorder.

Table 11.4-2 DSM-IV Caffeine-Related Disorders

Caffeine Intoxication Caffeine intoxication has long been recognized as a discrete syndrome associated with the use of a significant amount of caffeine (Table 11.4-3). Intoxication can be the result of an ingestion of a large amount of caffeine in a person who has not regularly consumed caffeine (a nontolerant individual), and thus may represent an overdose of caffeine. Alternatively, caffeine intoxication can occur in the context of a person who chronically consumes large amounts of caffeine, which produces a more complicated clinical picture. Interestingly, while intoxication by some psychoactive substances, such as alcohol, is sought out by some people, it appears that most individuals do not actively seek repeated episodes of caffeine intoxication.

A. Recent consumption of caffeine, usually in excess of 250 mg (e.g., more than 2–3 cups of brewed coffee).
B. Five (or more) of the following signs, developing during, or shortly after, caffeine use:
(1) restlessness
(2) nervousness
(3) excitement
(4) insomnia
(5) flushed face
(6) diuresis
(7) gastrointestinal disturbance
(8) muscle twitching
(9) rambling flow of thought and speech
(10) tachycardia or cardiac arrhythmia
(11) periods of inexhaustibility
(12) psychomotor agitation
C. The symptoms in criterion B cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder (e.g., anxiety disorder).

Table 11.4-3 DSM-IV Diagnostic Criteria for Caffeine Intoxication

Epidemiology There have been few studies examining the prevalence of caffeine intoxication, and most of these studies have looked at selected populations (e.g., psychiatric inpatients, college students) and used ambiguous criteria. Notably, one random-digit telephone survey of caffeine use in the general community found that 12 percent of respondents had met the revised third edition of DSM (DSM-III-R) criteria for caffeine intoxication in the past year.

Comorbidity Given the limited number of studies of caffeine intoxication, it is not surprising that there is even less known about comorbid disorders associated with this condition. However, it is notable that there appear to be some associations between the amount of caffeine typically consumed by individuals and certain psychiatric conditions (although it should be stressed that these are associations between the amount of caffeine consumed, not a specific diagnosis of caffeine intoxication). Thus, for example, high caffeine consumption has been noted in patients with psychiatric disorders such as bipolar I disorder, schizophrenia, and personality disorders. Excessive caffeine consumption has also been noted in people who smoke tobacco and may be due to increased metabolism of caffeine in smokers. Finally, although rare, it may be possible for a patient to develop delirium from ingesting an acute, extremely high dose of caffeine, and rare cases of suicide have been noted with excessive caffeine consumption.

There are some patient populations that tend to not consume caffeine—patients with anxiety disorders. It has been shown that patients with generalized anxiety disorder and patients with panic disorder can be more sensitive to the effects of caffeine, and that patients with panic disorder tend to have lower caffeine

consumption. Thus, these may be patient populations in whom there is less likelihood that caffeine intoxication will be observed.

Diagnosis and Clinical Features Caffeine intoxication can present with a variety of clinical features, as shown in the criteria from DSM-IV (Table 11.4-3). In addition to these signs and symptoms, reports have found patients with caffeine intoxication can have fever, irritability, tremors, sensory disturbances, tachypnea, and headaches. It appears that the most common features of caffeine intoxication are anxiety, nervousness, insomnia, gastrointestinal disturbances, tremors, tachycardia, and psychomotor agitation.

Differential Diagnosis Caffeine intoxication severe enough to come to clinical attention is probably a relatively rare condition, and several other disorders should be considered for patients who present with features suggesting caffeine intoxication. These include other substance-related disorders, such as intoxication with other stimulants (e.g., cocaine or amphetamines), and withdrawal from drugs such as sedative-hypnotics (e.g., benzodiazepines), alcohol, or nicotine. In addition, medication adverse effects such as akathisia can present with features suggestive of caffeine intoxication. The final diagnosis of caffeine intoxication depends upon demonstrating the ingestion of a significant quantity of caffeine prior to the onset of symptoms.

Course and Prognosis Caffeine has a relatively short halflife (3-6 hours), so caffeine intoxication will typically resolve quickly and with no significant sequelae. Patients with caffeine intoxication generally have a good prognosis, although there have been isolated reports of people who have completed suicide by ingesting a massive amount of caffeine.

Treatment The first step in treating a patient presenting with evidence suggesting caffeine intoxication is to confirm the diagnosis. It is important to consider all possible sources of caffeine when considering a diagnosis of caffeine intoxication, including medications and beverages that may not be initially recognized as containing caffeine (e.g., some noncola sodas). Because caffeine has a relatively short half-life, short-term management of the patient can be supportive while the syndrome resolves spontaneously. For the patient who habitually consumes large amounts of caffeine and repeatedly experiences episodes of caffeine intoxication, it may be helpful to aid the patient to recognize their total daily caffeine consumption through the use of daily diaries, and then to teach the patient about the adverse effects associated with caffeine use.

Caffeine-Induced Anxiety Disorder A caffeine-induced anxiety disorder can be panic disorder, generalized anxiety disorder, social phobia, or obsessive-compulsive disorder, although the patient does not need to fulfill all the criteria for one of these disorders to quality for a diagnosis of caffeine-induced anxiety disorder (see Table 15.6-18).

There has been no work examining this caffeine-related disorder, although there have been investigations examining the relationship between caffeine use and anxiety. Patients with anxiety disorders generally consume less caffeine than control patients, and experience greater self-reports of anxiety after consuming caffeine. In addition, caffeine has been used as a pharmacological probe in subjects without an anxiety disorder, and a sufficiently high dose can produce panic attacks in subjects.

The diagnosis of caffeine-induced anxiety disorder depends upon linking the use of caffeine to the anxiety symptoms of concern. For a patient with a suspected caffeine-induced anxiety disorder, a trial of caffeine abstinence may aid in clarifying the diagnosis.

Mr. B. was a 28-year-old single African-American male graduate student who was in good health and had no history of previous psychiatric evaluation or treatment. He took no medications, did not smoke or consume alcohol, and had no current or past history of illicit drug use.

His chief complaint was that he had begun feeling mounting “anxiety” when working in the laboratory where he was pursuing his graduate studies. His work had been progressing well, he felt his relationship with his advisor was good and supportive, and he could not identify any problems with staff or peers that might explain his anxiety. He had been working long hours, but found the work interesting and had recently had his first paper accepted for publication.

Despite these successes, he reported feeling a “crescendoing anxiety” as his day would progress. He noted that by the afternoon he would be experiencing palpitations, bursts of his heart racing, tremors in his hands, and an overall feeling of “being on the edge.” He also noted a nervous energy in the afternoons. These experiences were occurring daily, and seemed confined to the laboratory (although he admitted he was in the laboratory every day of the week).

When reviewing Mr. B.'s caffeine intake, it was found he was consuming excessive amounts of coffee. Staff made a large urn of caffeinated coffee each morning, and Mr. B. routinely started with a large mug of coffee. Over the course of the morning he would consume 3 to 4 mugs of coffee (the equivalent of about 6 to 8 5-ounce cups of coffee), and continued this level of use throughout the afternoon. He occasionally had a single can of caffeinated soda, and used no other forms of caffeine on a regular basis. Mr. B. estimated he drank a total of 6 to 8 or more mugs of coffee per day (which was estimated to be at least 1200 mg of caffeine per day). Once pointed out to him, he realized this level of caffeine consumption was considerably higher than at any other time in his life. He admitted he liked the taste of coffee, and felt a burst of energy in the morning when he drank coffee that helped him start his day.

Mr. B. and his physician developed a plan to decrease his caffeine use by tapering off caffeine. Details of such a tapering schedule can be found in the section on treatment of caffeine dependence. Mr. B. was successful in decreasing his caffeine use, and had good resolution of his anxiety symptoms once his daily caffeine use had been markedly decreased.

Caffeine-Induced Sleep Disorder Forms of a caffeine-induced sleep disorder can be insomnia, hypersomnia, parasomnia, or mixed. However, caffeine use is most frequently associated with insomnia (although there are case reports of patients who have hypersomnia in response to caffeine). Caffeine-induced sleep disorder should be diagnosed in patients with caffeine intoxication only if the sleep disturbance is in excess to that which would be expected from intoxication (see Table 21-18).

Although there are essentially no studies directly examining caffeine-induced sleep disorder, there has been work on the relationship between caffeine use and sleep. In general, ingestion of caffeine prior to bedtime results in a delay in sleep onset and poorer sleep quality. For some people, it has been shown that consuming 200 mg of caffeine before bedtime (the equivalent of about 2 cups of brewed coffee) can delay the onset of sleep for up to 4 hours.

Sleep disturbances secondary to caffeine use are more likely in people who are not regular consumers of caffeine. For people who consume caffeine on a daily basis, there is evidence to suggest that some tolerance occurs to the sleep-inhibiting effects of caffeine.

Caffeine-Related Disorder Not Otherwise Specified This category is included in DSM-IV as a substance-related disorder, and is to be used when the patient has a condition that is caffeine-related but not diagnosable as caffeine intoxication, caffeine-induced anxiety disorder, or caffeine-induced sleep disorder (Table 11.4-4). Thus, for example, caffeine withdrawal or caffeine dependence could be coded as a caffeine-related disorder not otherwise specified.

The caffeine-related disorder not otherwise specified category is for disorders associated with the use of caffeine that are not classifiable as caffeine intoxication, caffeine-induced anxiety disorder, or caffeine-induced sleep disorder. An example is caffeine withdrawal.

Table 11.4-4 DSM-IV Diagnostic Criteria for Caffeine-Related Disorder Not Otherwise Specified

Caffeine Withdrawal Caffeine withdrawal was not included in DSM-III-R, apparently because the symptoms of caffeine withdrawal were believed to be mild. Caffeine withdrawal has been included in the appendix of DSM-IV with a set of diagnostic criteria to be used for further evaluation of the disorder (Table 11.4-5). It is not included in the body of DSM-IV, despite evidence for a discrete caffeine withdrawal syndrome, because of concerns that there were only a limited number of symptoms (three), some symptoms were similar, and the symptoms have a high prevalence in the general population and can be frequently associated with other circumstances besides caffeine withdrawal.

A. Prolonged daily use of caffeine.
B. Abrupt cessation of caffeine use, or reduction in the amount of caffeine used, closely followed by headache and one (or more) of the following symptoms:
   (1) marked fatigue or drowsiness
   (2) marked anxiety or depression
   (3) nausea or vomiting
C. The symptoms in Criterion B cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The symptoms are not due to the direct physiological effects of a general medical condition (e.g., migraine, viral illness) and are not better accounted for by another mental disorder.

Table 11.4-5 DSM-IV Research Criteria for Caffeine Withdrawal

Epidemiology Several studies have examined caffeine withdrawal under conditions where it is experimentally induced in a population of subjects. In a study of normal community volunteers whose average daily caffeine consumption was similar to that of the general population, one half of the subjects had moderate or severe headache when they had experimentally induced caffeine withdrawal; 8 to 11 percent of subjects in that study also experienced anxiety, fatigue, and depression while in withdrawal. Other similar studies have found that one third to one half of subjects will experience symptoms of caffeine withdrawal when it is experimentally induced (i.e., subjects undergo a double-blind discontinuation of their daily caffeine use).

There have been relatively few attempts to conduct population-based studies on caffeine withdrawal. Such studies have usually been surveys, and found a wide range of reports of caffeine withdrawal (i.e., from 8–42 percent). In the United States it is estimated that over 80 percent of the adult population are regular consumers of caffeine, and even if the incidence of caffeine withdrawal is low, this still would suggest there are large numbers of people who could experience caffeine withdrawal.

Comorbidity There have been no studies that have specifically sought to determine conditions that are comorbid with caffeine withdrawal. However, patients with higher daily consumption of caffeine may be at increased risk for developing caffeine withdrawal if they miss consuming their typical dose of caffeine.

Diagnosis and Clinical Features A withdrawal condition associated with the cessation of caffeine use has been long recognized, and the most common feature noted with caffeine withdrawal has been headache. DSM-IV also includes marked fatigue or drowsiness, marked anxiety or depression, and nausea or vomiting in the diagnostic criteria. However, several other signs and symptoms of caffeine withdrawal have been noted, such as impaired concentration, yawning, decreased sociability, lassitude, work difficulty, irritability, muscle aches, stiffness, and other flu-like symptoms (Table 11.4-6). In addition, performance on psychomotor tasks has shown to be impaired when subjects are experiencing caffeine withdrawal.

Headache
Sleepiness or drowsiness
Impaired concentration, lassitude, work difficulty
Anxiety
Depression
Irritability
Nausea or vomiting
Muscle aches or stiffness
Yawning
Flu-like symptoms

Table 11.4-6 Clinical Features of Caffeine Withdrawal

CAFFEINE WITHDRAWAL HEADACHE Headache is the most common feature associated with caffeine withdrawal. It is usually described as a generalized, throbbing headache that is worsened by exercise and Valsalva's maneuver, and responds best to caffeine consumption. It typically begins 12 to 24 hours after the last ingestion of caffeine, although the onset can occur as long as 40 hours after the last dose. It usually resolves in 2 to 4 days, although sporadic headaches can continue for up to 11 days.

CAFFEINE WITHDRAWAL HEADACHE AND OTHER SIGNS AND SYMPTOMS OF CAFFEINE WITHDRAWAl There are several other signs and symptoms associated with caffeine withdrawal. Patients can experience these signs and symptoms even without the concurrent presence of headache, suggesting that the other features of caffeine withdrawal are not simply secondary to the headache.

CAFFEINE WITHDRAWAL AND POSTOPERATIVE HEADACHE Headache is a frequent postoperative symptom. Patients undergoing operative procedures are required to abstain from all oral intake prior to the procedure, including daily dietary caffeine they would typically consume, and several studies have examined whether postoperative headache could reflect caffeine withdrawal. Interestingly, patients with higher daily caffeine consumption are at increased risk for developing postoperative headache, and the consumption of a caffeinated beverage on the day of an operative procedure has been shown to lower the rate of postoperative headache.

CAFFEINE WITHDRAWAL AND DOSAGE OF CAFFEINE The risk of developing caffeine withdrawal, and the severity of the withdrawal syndrome are both related to the daily dosage of caffeine consumed (with risk and severity increasing as the dose of caffeine increases). However, it should be noted that caffeine withdrawal can occur with relatively low dosages of caffeine, such as 100 mg per day (the equivalent of about one cup of brewed coffee).

CAFFEINE WITHDRAWAL AND AGE Most studies of caffeine withdrawal have determined the presence and features of caffeine withdrawal in adults. However, caffeine withdrawal has also been shown to occur in children. Like caffeine withdrawal in adults, headache and other caffeine withdrawal symptoms can occur in children.

Differential Diagnosis There are a wide variety of medical conditions and psychiatric disorders that can overlap with the symptoms of caffeine withdrawal. In part, it was this relative nonspecificity of the criteria for caffeine withdrawal that contributed to the decision to not include it in the body of DSM-IV. When considering a patient who may have caffeine withdrawal, disorders as diverse as viral illnesses, sinus conditions, drug withdrawal states (e.g., from amphetamines, cocaine), other types of headaches such as tension or migraine, and medication reactions should be considered in the differential diagnosis. The final determination of caffeine withdrawal should rest upon a determination of the pattern and amount of caffeine consumption, the time interval between the last ingestion of caffeine and the onset of symptoms, and the particular clinical features presented by the patient. Resolution of symptoms by a dose of caffeine may also be useful in clarifying the diagnosis.

Course and Prognosis Caffeine withdrawal typically begins 12 to 24 hours after the last dose of caffeine, and usually resolves in 2 to 7 days. Most symptoms reach their maximal intensity within the first 48 hours after cessation of caffeine use, with subsequent decreasing intensity over the following days. However, it should be noted that there can be considerable variability between people in the manifestations, severity, and time course of caffeine withdrawal. Furthermore, it has been shown that the same person can experience different symptoms and different degrees of severity of symptoms across different episodes of caffeine withdrawal.

Treatment There has been little work systematically investigating the optimal treatment for caffeine withdrawal. The symptoms of caffeine withdrawal typically resolve with the ingestion of a dose of caffeine, and a person with a provisional diagnosis of caffeine withdrawal who continues to be symptomatic after caffeine consumption has been terminated for more than 2 weeks should be carefully re-evaluated and considered for other possible diagnoses. Caffeine withdrawal headaches may also respond to aspirin.

If caffeine withdrawal occurs because a person is attempting to abruptly stop all caffeine use, it may be better to attempt a tapering caffeine dosage schedule.

> Ms. E. was a 32-year-old single white woman employed full-time at a local factory. She occasionally used nonsteroidal anti-inflammatory drugs, but was taking no regular prescription medications. She had a history of alcohol dependence, in remission for 9 years, and was otherwise in good health.
>
> She first began consuming caffeine when she started college, and her current beverage of choice was coffee. She typically drank 4 to 5 mugs of coffee each day, and preferred to drink it without cream, milk, or sugar. She estimated that 5 minutes elapsed between the time she got up in the morning and the time she had her first cup of coffee; her roommate made a pot before Ms. E. got up, and Ms. E. immediately poured a mug when she got out of bed. She spaced her mugs over the course of the day, with her last mug either after lunch or with dinner.
>
> Physicians had recommended she cut down or stop her coffee use because of complaints of mild indigestion, but she had been unable to do so. Her roommate had also complained about her coffee use at times. Ms. E. routinely drank hot coffee in her car, and had spilled it and burned herself on one occasion.
>
> When she had stopped caffeine abruptly, Ms. E. experienced marked irritability; poor concentration; and a severe, generalized headache. When asked to rate the severity of the headache, she replied that “on a scale of 1 to 10 it's a 12.” She also had muscle aches, low energy, lethargy, and a craving to drink a mug of coffee. On the day that she had stopped coffee use abruptly, she left work 2 hours early because of problems with concentrating on the job, and went to bed several hours earlier than usual. She then returned to her usual pattern of coffee use.

Caffeine Dependence Caffeine dependence is not included in DSM-IV, and it is explicitly stated that “A diagnosis of Substance Dependence can be applied to every class of substance except caffeine.” Despite the absence of caffeine dependence in DSM-IV, there is evidence supporting a diagnosis of caffeine dependence in some people with problematic caffeine consumption.

Before reviewing the features of caffeine dependence, it is important to clarify the use of the word “dependence.” Dependence is sometimes used to indicate the presence of physical dependence—a condition characterized by physiological adaptation to the effects of a drug, and usually indicated by the presence of a withdrawal syndrome when drug ingestion is discontinued. There is considerable evidence that caffeine can produce physical dependence, as indicated by the presence of caffeine withdrawal.

The term *dependence* is also used in a second way—to indicate a clinical diagnosis of dependence. Clinical diagnoses of dependence typically have included a constellation of diagnostic criteria that are loosely linked by the theme of problematic use of the drug. Included in these criteria can be evidence of physical dependence, although physical dependence is usually neither necessary nor sufficient to make a diagnosis of a clinical syndrome of dependence. The DSM criteria are used to make a clinical diagnosis of dependence.

Although there are numerous studies and reports on caffeine's ability to produce physical dependence, as evidenced by caffeine withdrawal, there is little research on whether or not some people who consume caffeine can develop a clinical syndrome of dependence. This is a question that only a few studies have addressed.

Epidemiology Caffeine use is common throughout the world. Over 80 percent of adults in the United States consume caffeine regularly, and their average daily caffeine consumption has been estimated to be 280 mg (the equivalent of about 3 cups of brewed coffee). Given the substantial number of people who consume caffeine regularly, and their use of daily dosages that produce psychoactive effects, even a low prevalence rate of caffeine dependence could represent substantial numbers of people.

However, there has only been one study that has examined the prevalence of caffeine dependence in the general population—a random-digit telephone survey that used the generic criteria from DSM-III-R. That study found that 3 percent of respondents fulfilled criteria for severe dependence (7–9 criteria), 14 percent fulfilled criteria for moderate dependence (5–6 criteria), and 27 percent fulfilled criteria for mild dependence (3–4 criteria).

Comorbidity The only study that has reported on comorbid conditions in patients with caffeine dependence was a selected series of case reports and thus it is difficult to generalize to the general population using those results. The study found that about two thirds of patients had a psychiatric disorder in remission, most commonly another substance abuse disorder. However, nearly one half had a mood disorder in remission, one quarter had an anxiety disorder in remission, and one fifth had an eating disorder in remission. Notably, there was a clustering of nicotine dependence, caffeine dependence, and a history of an alcohol use disorder in several subjects, and this clustering of these three disorders has been noted in other studies.

CAFFEINE USE AND NONPSYCHIATRIC ILLNESSES There has been considerable interest in determining whether caffeine use is associated with other physical illnesses (analogous to findings of the relationship between nicotine use and conditions such as heart disease and cancer). Numerous studies have sought to determine whether caffeine use might be associated with heart disease, cancer, breast disease, osteoporosis, and other physical illnesses. In general, no such associations have been found, although large epidemiological studies continue to seek such relationships. When patients question a clinician about the possible association of caffeine with various such physical conditions, they can generally be reassured that there is no evidence of a strong relationship between caffeine use and physical illnesses. Interestingly, despite this lack of association between caffeine use and physical illnesses, a survey of medical specialists found that over three quarters recommended that patients decrease or eliminate their caffeine use for certain conditions (such as anxiety, arrhythmias tachycardia, esophagitis or hiatal hernia, and fibrocystic disease).

It may be that there is a mild association between higher daily caffeine use in women and delayed conception and slightly lower birth weight. However, there are studies that have not found such associations, and effects when found are usually with relatively high daily dosages of caffeine (e.g., the equivalent of 5 cups of brewed coffee per day). For a woman who is considering pregnancy, especially if there is some difficulty in conceiving, it may be useful to counsel eliminating caffeine use. Similarly, for a woman who becomes pregnant and has a high daily caffeine consumption, a discussion about decreasing her daily caffeine use may be warranted.

Diagnosis and Clinical Features DSM-IV provides a generic set of diagnostic criteria that are to be used for determining the presence of a substance dependence syndrome (see Table XX-X). There is little work examining the particular clinical features of caffeine dependence, although there is one report of a series of 16 cases of subjects who fulfilled the DSM-IV criteria for caffeine dependence. Only 4 of the 7 criteria were used in that study, and most of the cases had evidence of the 4 criteria (withdrawal, use continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance use, persistent desire or unsuccessful efforts to cut down or control substance use, and tolerance). In a telephone survey of caffeine users, the most common DSM-III-R dependence criterion reported by respondents was a persistent desire or unsuccessful efforts to cut down or control substance use.

Differential Diagnosis When considering a possible diagnosis of caffeine dependence, it is useful to include other substance dependence syndromes in the differential diagnosis. A clinical syndrome of dependence upon caffeine probably goes overlooked by most clinicians because it is not included in DSM-IV and it is not widely recognized and acknowledged as a substance-related abuse disorder. Most people have no problems associated with being dependent upon caffeine so long as their supply is available on a daily basis. Even if they are unable to obtain caffeine for some reason, the withdrawal syndrome is relatively short-lived and is not life

threatening.

Course and Prognosis No studies have examined the course and prognosis for patients with a diagnosis of caffeine dependence. Subjects with caffeine dependence have reported continued use of caffeine despite repeated efforts to discontinue their caffeine use.

Treatment There have been case reports describing the treatment of patients with problematic caffeine use, although there have been no systematic studies of treating patients with a confirmed diagnosis of caffeine dependence. In general these approaches have used a combination of three techniques to aid patients to decrease or eliminate their caffeine use: gradual tapering of the daily dose, self-monitoring of daily use, and reinforcement for decreased use.

The first step in reducing or eliminating caffeine use is to have patients determine their daily consumption of caffeine. This can best be accomplished by having the patient keep a daily food diary. It is important for the patient to recognize all sources of caffeine in the diet, including different forms of caffeine (e.g., beverages, medications) and to accurately record the amount consumed. After several days of keeping such a diary, the clinician can meet with the patient, review the diary, and determine the average daily caffeine dose in milligrams.

The patient and clinician should then decide upon a fading schedule for caffeine consumption. Such a schedule could involve decreases in increments of 10 percent every few days. Since caffeine is typically consumed in beverage form, the patient can use a substitution procedure in which decaffeinated beverage is gradually used in place of caffeinated beverage. A diary should continue to be maintained during this time, so that the patient's progress can be monitored. The fading schedule should be individualized for the patient so that the rate of decrease in caffeine consumption minimizes withdrawal symptoms. Abruptly stopping all caffeine use should probably be avoided because withdrawal symptoms are likely to develop with sudden discontinuation of all caffeine use.

Ms. G. was a 35-year-old married white homemaker with three children ages 8,6, and 2 years old. She took no prescription medications, took a multivitamin and vitamins C and E on a daily basis, did not smoke, and had no past history of psychiatric problems. She drank moderate amounts of alcohol on the weekends, had smoked marijuana in college but had not used it since, and had no other history of illicit drug use.

She had started consuming caffeinated beverages while in college, and her current beverage of choice was caffeinated diet cola. Ms. G. had her first soda early in the morning, shortly after getting out of bed, and she jokingly called it her “morning hit.” She spaced out her bottles of soda over the course of the day, with her last bottle at dinner time. She typically drank 4 to 5 20-ounce bottles of caffeinated diet cola each day.

She and her husband had argued about her caffeinated soda use in the past, and her husband had felt she should not drink caffeinated soda while pregnant. However, she had continued to do so during each of her pregnancies. Despite a desire to stop drinking caffeinated soda, she was unable to do. She described having a strong desire to drink caffeinated soda, and if she resisted this desire she found that she could not think of anything else. She drank caffeinated soda in her car, which had a manual transmission, and noted that she would fumble while shifting and holding the soda, and spill soda in the car. She also noted that her teeth had become yellowed, and she suspected this was related to her tendency to swish soda in her mouth before swallowing it. When asked to describe a time when she stopped using soda, she reported that she had run out of it on the day one of her children was to have a birthday party, and she did not have time to leave her home to buy more. In the early afternoon of that day, a few hours before the scheduled start of the party, she felt extreme lethargy, a severe headache, irritability, and craving for a soda. She called her husband and told him she planned to cancel the party. She then went to the grocery store to buy soda, and after drinking two bottles she felt well enough to host the party.

While initially expressing interest in decreasing or stopping her caffeinated soda use, Ms. G. failed to attend scheduled follow-up appointments after her first evaluation. When finally contacted at home, she reported she had only sought help initially at her husband's request, and she had decided to try to cut down on her caffeine use on her own.

11.5 CANNABIS-RELATED DISORDERS

WAYNE MACFADDEN, M.D. AND GEORGE E. WOODY, M.D.

Known in central Asia and China for at least 4000 years, the Indian hemp plant *Cannabis sativa* is a hardy, aromatic annual herb (Fig. 11.5-1). The bioactive substances derived from it are collectively referred to as cannabis. By most estimates, cannabis remains the world's most commonly used illicit drug, with approximately 200 to 300 million regular users. It occupies fourth place in worldwide popularity among psychoactive drugs, after caffeine, nicotine, and alcohol.

FIGURE 11.5-1 Marijuana *(Cannabis sativa)*.

Cannabis sativa is widely cultivated for its fiber, which is used to make rope and cloth; for its seeds, which are used to make oil; and for its psychoactive resin. This resin contains over 60 structurally similar compounds called cannabinoids, of which D_9-tetrahydrocannabinol (THC) is responsible for most of its psychoactive effects. The term *marijuana* most commonly refers to the upper leaves, flowering tops, and stems of the plant, which are cut, dried, and chopped and usually formed into cigarettes. Hashish is the dried black-brown resinous exudate from the tops and undersides of the leaves of the female plant. Other names for cannabis or its products include *bhang, charas, dagga*, and *ganja*; common slang terms are “grass,” “pot,” and “weed.”

The THC content and concentration of different parts of the plant and between species varies greatly. The effects of THC depend on dosage, frequency, and route of administration; setting; and the experience and expectations of subjects. Most marijuana purchased illicitly varies from about 1 to 5 percent THC content; sinsemilla, a more potent variety made from just the buds and flowering tops of female plants may contain 7 to 14 percent THC. Hashish, a sticky resin obtained from the female plant flowers, contains up to 10 percent THC, and hashish oil, a concentrated distillate of hashish, has been assayed at up to 15 to 70 percent THC. In addition to genetic variability, the amount of THC produced by the plant is related to environmental conditions such as the amount of sunlight received, humidity, and soil condition. Other factors that affect the amount of THC actually consumed are smoking technique, the amount destroyed by pyrolysis (about 75 percent), and how quickly the drug is used, because THC deteriorates by about 5 percent per month at room temperature. Assertions that the marijuana available today is much more potent than it was 15 to 20 years ago are difficult to validate. THC content in some specimens confiscated in the mid-1970s was reported to be 5 percent or higher, which most investigators consider relatively potent.

Cannabis is most commonly smoked in marijuana cigarettes, or joints, and experienced users inhale deeply and hold their breath for as long as possible to extract the THC. Amounts ranging from 2 to 50 percent of the THC in the smoke may be absorbed in this manner. Its intoxicating effects may be increased by mixing other drugs or chemicals into the cigarette, such as opium, cocaine paste, or phencyclidine (PCP). It may also be eaten and is often baked in lipid-rich foods, such as brownies.

HISTORY

Archeological evidence suggests that cannabis was introduced to western Europe in approximately 500 BC. There are reports of its widespread use for pleasure-seeking purposes in the early 19th century by Napoleon's soldiers in Egypt. Although previous knowledge of its use existed in the United States, it may have been more widely introduced by Mexican immigrants in the 1920s. Soon afterward Western states pressured the federal government to control cannabis use because it was linked to violence from foreign (often unwelcome) laborers, who were allegedly growing the plant. The Marijuana Tax Act of 1937 established government control over sale and transfer of the drug, and no stamps or licenses were available for its public use. During that time its use was associated with jazz musicians or minority groups who were not well assimilated into the overall culture.

Marijuana's image shifted during the 1960s when the youthful counterculture rediscovered cannabis. It became associated with social protest, and its use spread rapidly throughout the general society. Occasional use, even by adolescents, became common. The use of cannabis became “normalized” in many parts of the United States culture, a fact contributing to the initial difficulty many investigators encountered in associating cannabis with health problems. The favorable attitude toward cannabis reached a peak in about 1978. Since that time its use declined yearly in the overall population until 1993 when it began rising again. In attempts to suppress its use, penalties have risen against users and dealers, but enforcement varies widely among states and municipalities. As possible medicinal uses of cannabis are being explored, with strong advocates for its use in acquired immune deficiency syndrome (AIDS) patients and patients receiving chemotherapy, attempts to provide compassionate use have been undertaken by various constituencies. In 1996, referendums in California and Arizona approved ballot measures allowing the use of marijuana as a medical treatment. In California, this measure allowed possession and use of marijuana by patients or caregivers if recommended by two medical doctors. Controversy continues, as some lawmakers and law enforcement agencies have attempted to curb this practice by enacting preventive legislation to prosecute physicians who recommend use of substances such as cannabis that lack approval of the federal Food and Drug Administration (FDA).

The World Health Organization (WHO) and other governmental advisory and regulatory agencies have consistently maintained that cannabis is a drug requiring close monitoring and stringent control. In 1965 WHO declared that “the harm to society derived from abuse of cannabis rests in the economic consequences of the impairment of the individual's social functions and his enhanced proneness to asocial and antisocial behavior.” In 1969 WHO considered cannabis not physically habit forming but a drug of dependence and recommended keeping it under legal control. The classification of cannabis as a highly controlled (class I) substance by the United States Drug Enforcement Administration is consistent with that view.

Comparative Nosology The diagnostic criteria for cannabis intoxication in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) and the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) are similar. Both require at least one of the following four signs of intoxication: conjunctival injection, increased appetite, dry mouth and tachycardia, though DSM-IV requires them to develop within 2 hours of cannabis use. (1) Maladaptive or dysfunctional behavior or (2) psychological or perceptual changes are also required for both manuals. However, ICD-10 identifies 12 specific symptoms for the examiner to choose (one) from, where DSM-IV does not specify but notes it should be “clinically significant.”

DSM-IV does not recognize a clinically significant cannabis withdrawal state. Withdrawal from cannabis is identified in ICD-10, but definite diagnostic criteria are

omitted. It is noted as lasting several hours to up to 7 days, and describes several nonspecific signs and symptoms.

EPIDEMIOLOGY

Prevalence and Recent Trends The Monitoring the Future survey of adolescents in school indicates recent increases in lifetime, annual, current (use within the past 30 days) and daily use of marijuana by eighth and tenth graders, continuing a trend that began in the early 1990s. In 1996, 23.1 percent of eighth graders and 39.8 percent of tenth graders reported lifetime marijuana use. By 1996, past-month marijuana use had increased over 250 percent since 1991 for eighth graders and over 150 percent since 1992 for 10th graders. Lifetime use for high school seniors peaked at 60 percent in 1979, then began decreasing yearly until 1993, when rates began to rise again. Some investigators believe that softening attitudes about the hazards associated with cannabis may be responsible for these recent increases. In evaluating these trends, one should note that occasional use does not imply abuse or dependence. The percentage of users who fulfill criteria for either of these diagnoses is unclear at this time, though it is likely to be relatively low, somewhat analogous to the case with alcohol.

Another measure of the prevalence of marijuana use comes from the National Household Survey on Drug Abuse, a population-based random sample of households throughout the United States. Marijuana was the most commonly used illicit drug in the 1995 study, which found that approximately 77 percent of current illicit drug users were marijuana or hashish users. About one third (31 percent) of the population reported that they had used marijuana one or more times in their lifetime, 8 percent had used it in the past year, and 5 percent had used it in the past month. Those percentages translate to approximately 66 million persons who had used marijuana in their lifetime, 18 million in the past year, and 10 million in the past month. Lifetime prevalence of marijuana use increased with each age group until 34 years, then decreased gradually. Those aged 18 to 21 were the most likely to have used marijuana in the past year (25 percent) or the past month (14 percent), and use was lowest among those age 50 or older, where it was at or below 1 percent.

Demographic Correlates The rate of past year and current marijuana use by males was almost twice the rate for females overall among those age 26 and older. This gap between the sexes narrows with younger users; at ages 12 to 17, there are no significant differences.

Race and ethnicity were also related to marijuana use, but the relationships varied by age group. Among those ages 12 to 17, whites had higher rates of lifetime and past-year marijuana use than blacks. Among 17- to 34-year-old adults, whites reported higher levels of lifetime use than blacks and Hispanics. But among those 35 and older, whites and blacks reported the same levels of use. The lifetime rates for black adults were significantly higher than those for Hispanics. There were no differences in past-month use between whites and blacks among those 12 to 34 years old. Among females, whites reported the highest levels of lifetime use (30 percent), followed by blacks (20 percent) and Hispanics (15 percent). Variations in patterns of marijuana use by geographic region were small as were variations in use between metropolitan and nonmetropolitan areas.

For younger adults (18 to 25), marijuana use was similar across all educational levels, except for lower rates of current use among college graduates. For those ages 26 to 34, current use decreased significantly at higher educational levels. Individuals with less than a high school diploma had higher rates of past-year and current marijuana use than those all in other education categories. Among adults 35 and older, however, this trend was reversed for lifetime use; 33 percent of college graduates reported having ever used marijuana versus 12 percent of those with less than a high school diploma.

Among the total adult surveyed population, past-year and past-month marijuana use were substantially higher among the unemployed than in those in any other employment category.

Current users of marijuana were more likely than nonusers to drink alcohol, smoke cigarettes, and use other illicit drugs. This finding was most marked in younger adults and adolescents; in every age group up to age 35, current marijuana users were 10 to 12 times more likely to use other illicit drugs than those who were not current users.

PHARMACOLOGY

The THC dose needed to produce pharmacological effects in humans from smoking range from 2 to 22 mg. THC is lipid soluble and rapidly absorbed after inhalation. It is highly protein bound and quickly redistributed from blood into other tissues. The percentage of ingested THC that reaches the brain is small; about 1 percent penetrates the blood-brain barrier. The THC that reaches the liver is almost completely metabolized, primarily into active 11-hydroxy-THC and inactive 9-carboxy-THC. More-extensive metabolism in the liver converts 11-hydroxy-THC to many inactive metabolites, including 11-norcarboxy-D-THC, which is detected minutes after smoking. It is the most abundant metabolite in plasma and urine, and also the primary cannabinoid metabolite excreted in the urine; typically it can be detected 2 to 3 days after smoking a single cannabis cigarette. Blood levels of THC peak in about 30 minutes and then decline precipitously as it redistributes through the body to lipid-rich tissues, reaching nearly undetectable levels within 3 to 4 hours.

After some equilibrium between concentrations in the blood and other tissues is established, THC slowly and unevenly reenters the bloodstream from its tissue stores. Its concentration declines slowly in this second phase, with a half-life of 3 days. This low concentration of THC or its active 11-hydroxy-THC metabolite is believed to be below the threshold to produce an effect and is thus clinically insignificant. However, the half-life of these metabolites is at least 50 hours. About two thirds of the drug is excreted via the enterohepatic circulation into the feces, and the remaining one third is removed through the kidney. Most of the metabolites of THC are produced by the liver. Among these compounds, 11-norcarboxy-THC has the highest concentration in the urine and is the metabolite usually screened for in routine toxicological analyses. This and other cannabinoid metabolites can be detected in the urine for 2 to 3 days after casual use; for daily heavy users, detectable levels can persist for up to 4 weeks.

Cardiovascular and central nervous system (CNS) effects, such as mood-altering properties, begin less than 1 minute after inhalation. Peak clinical effects may be delayed for 20 to 30 minutes and persist for at least 2 to 3 hours. Immediately after smoking marijuana, plasma concentrations of cannabinoids are high while effects are low; this reverses at later times. Peak blood concentrations of THC are reached rapidly, within 10 minutes of smoking and decline to 5 to 10 percent of their initial level within 1 hour. Because of this delay between peak blood concentrations and peak drug effects, establishing a relationship between blood levels of THC or its metabolites and the degree of impairment has been difficult. The precise method and time of cannabis use must be known before any useful prediction of impairment from THC can be made. The apparent half-life of THC in both plasma and body fat is about 4 days. However, concentrations of THC in blood correlate only modestly with cannabis intoxication, and there is no consistently demonstrated correlation between concentration of THC in blood and effects on performance.

The pharmacological effects of orally ingested cannabis begin after 30 minutes, peak in 2 to 3 hours, and last 3 to 6 hours. Residual effects, such as subtle changes in mood and fine motor control, can be measured for a longer period if very sensitive testing procedures are used.

An oral dose of approximately 20 mg of marijuana or smoking a cigarette containing about 0.5 to 2 percent THC usually produces intoxication. Orally ingested marijuana requires about three times as much THC as smoked marijuana to produce equivalent effects because only 3 to 6 percent of ingested THC is absorbed.

THC demonstrates weak barbiturate-like actions such as anticonvulsant activity and opioid-like effects, including analgesia, increased catecholamine synthesis, hypothermia, and antidiarrheal activity. Increased limbic system activity has been noted with cannabis use, suggesting that THC may stimulate pleasure-reward mechanisms in the brain.

Cannabis is often used in combination with other drugs. It may alter the effects of amphetamines, atropine, barbiturates, clomipramine (Anafranil), cocaine, ethanol, nicotine, opiates, and phencyclidine. Because of shared hepatic metabolic systems, ethanol and phenobarbital (Donnatal, Quadrival) can inhibit metabolism of THC. Similarly, THC can slow the metabolism of a variety of drugs, including theophylline (Theo-Dur), ethanol, and pentobarbital (Nembutal). Some limited cross-tolerance exists between THC and CNS-depressant drugs. However, there is no evidence that THC is useful for detoxification from sedatives, although they both can enhance or prolong the other's behavioral and psychological effects.

Mechanism of Action The creation and radiolabeling of certain cannabinoids led to identification of a receptor in rat brain membranes. A single binding site was identified that displayed saturable and reversible binding and selectivity for cannabinoids. The pharmacological potency of cannabinoids correlates with their affinity for the cannabinoid binding site. Receptor binding was also found in the peripheral B lymphocyte–enriched areas including the marginal zone of the spleen, the nodular corona of Peyer's patches, and the cortex of the lymph nodes.

Another advance has been the recent isolation of an endogenous cannabinoid-like ligand within the brain, named anandamide, from a Sanskrit word meaning “bliss.” Soon after, a cannabinoid antagonist was discovered that antagonizes cannabinoid-induced inhibition of adenyl cyclase and smooth muscle contraction. This recent

progress suggests the presence of a cannabinoid neurochemical pathway. The function of such a system is unclear, but cannabinoids exert many of their actions by influencing several neurotransmitter systems and their neuromodulators. These include acetylcholine, dopamine, g-aminobutyric acid (GABA), histamine, serotonin, norepinephrine, opioid peptides, and prostaglandins. Cannabinoids enhance the formation of norepinephrine, dopamine, and serotonin. Notably, they stimulate the release of dopamine from rat brains by activating opiate receptors; after THC infusions, dopamine levels in the nucleus accumbens increase as much as twofold, analogous to the surge seen with other addictive drugs. GABA turnover is enhanced by cannabinoids. Catalepsy can result from the interaction of THC with neurotransmitter systems in the basal ganglia. Studies of catalepsy and depression of spontaneous locomotor activity caused by cannabinoids suggest that these effects are mediated by acetylcholine, GABA, and prostaglandins.

Despite these advances, interpretation of the actions of cannabinoids on neurotransmitter systems is often unclear, as evidence suggests that cannabinoids both inhibit and stimulate uptake of transmitters. Recent evidence suggests that few, if any, irreversible effects on brain chemistry are caused by THC administration.

Cannabinoid receptor location and density in animal models has corresponded with its clinical effects in humans. The highest density of receptors occurs in the basal ganglia and molecular layer of the cerebellum, which correlate with its interference in motor coordination. Intermediate levels of binding were found in the hippocampus, the dentate gyrus, and layers I and IV of the cortex, consistent with cannabinoid effects on short-term memory and cognition. Low receptor density is noted in the brainstem areas controlling cardiovascular and respiratory functions, which is consistent with the cannabinoids' lack of lethality.

After binding to receptors, cannabinoids also produce effects through second-messenger systems including inhibition of adenyl cyclase and calcium channels, and by possibly enhancing potassium channels activity. In summary, the biological bases for the multiple effects of cannabis are beginning to be understood, but as expected, they are complex and not yet fully elucidated.

DIAGNOSIS AND CLINICAL FEATURES

Patterns of use vary widely; the most common is intermittent use of marijuana cigarettes, such as smoking one or two joints on a weekly or monthly basis, often on social occasions. As with alcohol, a small proportion of cannabis users develop the pattern of intermittent or daily use of high doses that is typically associated with abuse or dependence. The proportion of users who progress to dependence is unknown but is probably similar to alcohol.

Marijuana has mild-to-moderate reinforcing effects, and benign experiences with it may lead users to try more reinforcing drugs in the belief that drug effects are pleasurable and not to be feared. In fact, initial marijuana usage is a common behavioral pattern in patients who eventually progress to so-called harder drugs such as opiates, stimulants, and stronger psychedelics. It is unlikely that the relationship is causal, however. The purchase or use of marijuana may imply a willingness to use other illicit substances and may also put the user in contact with people who distribute them. From self-report data, marijuana use has been associated with problematic alcohol use and a pattern of general deviance that leads to poor workplace performance.

New studies have postulated a neurobiological basis for the “gateway hypothesis,” in which smoking marijuana is thought to cause some people to abuse harder drugs. Marijuana and heroin both produce dopamine surges in rat brains by activating opiate receptors; marijuana, however, presumably does so indirectly by causing the release of an endogenous opiate. Some speculate that marijuana may thus prime the brain to seek substances like heroin that act in a similar way. Additionally, long-term cannabis use increases release of corticotropin-releasing factor during antagonist-precipitated withdrawal in rats. As corticotropin-releasing factor is believed to be a key element of withdrawal syndromes from alcohol, opiates, and cocaine, causing stress reactions and anxiety, some also speculate that marijuana users may seek these harder drugs to provide relief from the similar neurochemically induced stress and anxiety noted in cannabis withdrawal syndromes.

DSM-IV lists the cannabis-related disorders (Table 11.5-1) but has specific criteria only for cannabis intoxication (Table 11.5-2). The diagnostic criteria for the other cannabis-related disorders are general and are contained in the DSM-IV sections that focus on the major phenomenological symptom—for example, cannabis-induced psychotic disorder in the schizophrenia and other psychotic disorders.

Cannabis use disorders
Cannabis dependence
Cannabis abuse
Cannabis-induced disorders
Cannabis intoxication
Specify if:
With perceptual disturbances
Cannabis intoxication delirium
Cannabis-induced psychotic disorder, with delusions
Specify if:
With onset during intoxication
Cannabis-induced psychotic disorder, with hallucinations
Specify if:
With onset during intoxication
Cannabis-induced anxiety disorder
Specify if:
With onset during intoxication
Cannabis-related disorder not otherwise specified

Table 11.5-1 DSM-IV Cannabis-Related Disorders

A. Recent use of cannabis.
B. Clinically significant maladaptive behavioral or psychological changes (e.g., impaired motor coordination, euphoria, anxiety, sensation of slowed time, impaired judgment, social withdrawal) that develop during, or shortly after, cannabis use.
C. Two (or more) of the following signs, developing within 2 hours of cannabis use:
(1) conjunctival injection
(2) increased appetite
(3) dry mouth
(4) tachycardia
D. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.
Specify if:
With perceptual disturbances

Table 11.5-2 DSM-IV Diagnostic Criteria for Cannabis Intoxication

Cannabis Dependence and Cannabis Abuse DSM-IV includes the diagnoses of cannabis dependence and cannabis abuse (see Table 11.1-3 and Table 11.1-8). The experimental data clearly show tolerance to many of the effects of cannabis with sustained use of high doses. Tolerance develops to most of the physical effects of cannabis, including tachycardia, decreased skin temperature, increased body temperature, decreased intraocular pressure, sleep disturbance (decreased rapid eye movement [REM] sleep), electroencephalogram (EEG) changes (increased alpha waves), and impairment of performance on psychomotor tests. There is less agreement about tolerance to the common mood and behavioral changes, but progressive loss of the so-called high has been reported.

Cannabis Intoxication DSM-IV formalizes the diagnostic criteria for cannabis intoxication (Table 11.5-2). These criteria specify that the diagnosis can carry the phrase “with perceptual disturbances.” If perceptual disturbances are present but reality testing is impaired, the diagnosis becomes cannabis-induced psychotic disorder.

Acute intoxication due to use of cannabinoids as outlined in ICD-10 closely mirrors the descriptive themes in DSM-IV. Cannabis intoxication commonly heightens the user's sensitivity to external stimuli, reveals new details, makes colors seem brighter and richer than before, and makes time seem to pass more slowly. With high doses, the user may also experience depersonalization, derealization, illusions, hallucinations, suspiciousness or paranoid ideation.

Cannabis Intoxication Delirium Cannabis intoxication delirium is a DSM-IV diagnosis (Table 10-22). The delirium associated with cannabis intoxication is

characterized by marked impairment on cognition and performance tasks. Even modest doses of cannabis impair memory, reaction time, perception, motor coordination, and attention. High doses that also impair the user's level of consciousness have even more marked effects on these cognitive measures. However, a cannabis-induced, longer-lasting toxic-organic delirium characterized by confusion with disorganization of thought processes, affective lability, delusions, and hallucinations has been reported. This reaction, similar to the delirium produced by other psychomimetics, hallucinogens, or toxins, may last up to 10 days. Whether cannabis is the primary etiological agent in these cases has been questioned by some investigators, however.

Cannabis-Induced Psychotic Disorder High doses of cannabis are more likely than low doses to induce brief psychotic symptoms such as persecutory delusions or auditory and visual hallucinations, especially in persons with underlying psychiatric disorders. Such cases may fulfill the DSM-IV criteria for cannabis-induced psychotic disorder (see Table 13.3-4). It is uncertain whether persons with unstable character structures are more susceptible to these brief psychotic episodes.

Cannabis-induced psychotic disorder is rare; transient paranoid ideation is more common. Florid psychosis is somewhat common in countries where persons have long-term access to cannabis of particularly high potency. The psychotic episodes are sometimes referred to as “hemp insanity.” Cannabis use is rarely associated with a bad-trip experience, such as that associated with hallucinogen intoxication. No persistent cannabis psychosis has been identified, even in chronic heavy users. However, it appears likely that cannabis can exacerbate schizophrenia, as is the case with other drugs that have hallucinogenic properties, though there is no conclusive evidence that cannabis is a causative factor in the development of schizophrenia. Thus, despite worldwide reports associating cannabis with mental illness, chronic psychosis has not yet been reliably and consistently demonstrated to result from cannabis use. Chronic psychotic disorders that may be precipitated by cannabis appear to be related to premorbid vulnerability or psychopathology.

Cannabis-Induced Anxiety Disorder Cannabis-induced anxiety disorder is a common diagnosis (see Table 15.6-18) for acute cannabis intoxication, which in many persons induces short-lived anxiety states that are often provoked by paranoid thoughts. In such circumstances, panic attacks may be induced, based on ill-defined and disorganized fears. The appearance of anxiety symptoms is correlated with the dose and is the most frequent adverse reaction to the moderate use of smoked cannabis. Some cannabis users report occasional unpleasant adverse experiences, most often described as anxiety reactions of mild-to-moderate intensity. Inexperienced users are much more likely to experience anxiety symptoms than are experienced users.

Cannabinoid Withdrawal State ICD-10 notes cannabinoid withdrawal state; DSM-IV does not. It is described as an “ill-defined syndrome for which definitive diagnostic criteria cannot be established at present,” substantiating the lack of systematic nosological research in this area. Symptoms and signs noted in ICD-10 include anxiety, irritability, tremor of outstretched hands, sweating, and muscle aches.

Cannabis-Related Disorder Not Otherwise Specified DSM-IV does not formally recognize cannabis-induced mood disorders; therefore, such disorders are classified as cannabis-related disorders not otherwise specified (Table 11.5-3). Cannabis intoxication can be associated with depressive symptoms, although such symptoms may suggest long-term cannabis use. Hypomania, however, is a common symptom in cannabis intoxication.

The cannabis-related disorder not otherwise specified category is for disorders associated with the use of cannabis that are not classifiable as cannabis dependence, cannabis abuse, cannabis intoxication, cannabis intoxication delirium, cannabis-induced psychotic disorder, or cannabis-induced anxiety disorder.

Table 11.5-3 DSM-IV Diagnostic Criteria for Cannabis-Related Disorder Not Otherwise Specified

DSM-IV also does not formally recognize cannabis-induced sleep disorders or cannabis-induced sexual dysfunction; therefore, both are classified as cannabis-related disorders not otherwise specified. When either sleep disorder symptoms or sexual dysfunction symptoms are present and related to cannabis use, they almost always resolve within days or a week after the cessation of cannabis use.

Flashbacks Flashbacks, in which feelings and perceptions experienced in the intoxicated state are suddenly thrust into consciousness in the nondrugged condition, have also been reported with cannabis use, although not as often as with lysergic acid diethylamide (LSD). It has been suggested that flashbacks result from intermittent release of psychoactive components from the CNS, where they are stored during periods of active use, but that explanation remains highly speculative. A few clinical reports suggest that marijuana use may precipitate flashbacks in persons who have previously used LSD.

Amotivational Syndrome An amotivational syndrome associated with chronic cannabis use was described in the older clinical literature from the Middle East, the Orient, and the United States. The syndrome is marked by apathy, poor concentration, social withdrawal, and loss of interest in achievement. Those features may correlate with the reversible decrement in cerebral blood flow that has been documented as an effect of marijuana. However, most of the reports are not rigorously scientific and lack controls that distinguish between the effects of cannabis and preexisting psychological and social conditions. Subsequent reports using different populations and better scientific methods have failed to demonstrate the syndrome. Several authors have noted that it is difficult to determine which came first, the drug or the amotivation. Most plausible perhaps is the suggestion that in certain persons the pharmacological effects of the drug interact with psychological and social factors to retard motivation and productivity.

Thus, the direct causal role of marijuana in the amotivational syndrome has been seriously questioned. Symptoms may indicate ongoing intoxication or represent normal psychosocial variants that predispose to the use of cannabis and other substances. However, because persistent functional and structural changes in hippocampal neurons in animals subjected to long-term THC administration have been observed, the concept that a developing personality can be altered by chronic intoxication should not be entirely dismissed. In any event, cessation may lead to gradual improvement. Despite those potential adverse effects, many regard cannabis as a relatively safe drug because lethal doses are unknown in humans.

Physical Dependence Although DSM-IV provides no criteria for a cannabis withdrawal syndrome, withdrawal signs elucidated in rats after administration of the newly developed cannabinoid antagonist provide strong evidence that cannabinoids produce physical dependence. In humans, the withdrawal signs and symptoms that result from abrupt cessation of chronic high-dose cannabis abuse are not severe. They may reach their peak about 8 hours after last use and persist for 2 to 3 days. The most prominent symptoms reported are increased irritability and restlessness. Other less reliable signs and symptoms include anxiety, sleep disturbances, anorexia, perspiration, nausea, and muscle pain. Objective signs include increased body temperature, diarrhea, vomiting, weight loss, and hand tremors. No specific treatment is generally required.

Recent animal research has linked corticotropin-releasing factor to these stress-like negative affective states typical of cannabis withdrawal. Corticotropin-releasing factor concentrations are markedly elevated in the brains of chemically treated rats after antagonist-induced withdrawal. This stress hormone may mediate a similar final common pathway of anxiety and emotional stress in withdrawal states produced by various drugs of abuse (opiates, cocaine, and alcohol).

Tolerance Animal species develop tolerance to a variety of pharmacological effects, including antinociception, anticonvulsant activity, catalepsy, depression of locomotor activity, hypothermia, hypotension, corticosteroid release, and ataxia. Tolerance may reach 100-fold. Other psychoactive cannabinoids including nabilone also produce tolerance. Neuronal changes such as downregulation, conformational change, and internalization of receptors have been postulated to produce this tolerance.

Because of tolerance and learned behavior, detecting cannabis intoxication in an experienced user by motor performance may be difficult. In an inexperienced user, intoxication can be detected by many performance tests.

Several factors contribute to tolerance, including potency, expectations, environmental influences, individual differences, and frequency of use. There is evidence for the development of tolerance in humans to THC-induced decreases in intraocular pressure, sleep disturbances, and mood changes. High doses over long periods of time are necessary to produce behavioral tolerance.

ADVERSE EFFECTS

CNS THC exerts prominent effects on the CNS that are highly variable and depend on the user, the dose, and the environment. An initial stimulant effect commonly produces an increased sense of well-being and euphoria and is associated with spontaneous laughter, disinhibition, or quiet reverie. Some experience heightened imagination and creative thinking. Mood changes vary, and anxiety and depression may be induced. These initial effects are often followed by relaxation or lethargy and drowsiness, especially at higher doses. Many users report perceptual and sensory changes, such as a sense that time is passing slowly, accentuation of auditory and visual perceptions, or actual sensory distortions, occasionally involving hallucinations. Because of these perceptual changes (usually only at very high doses), some consider marijuana a hallucinogen with very low potency. Dry mouth and throat and increased hunger are also common.

Most psychoactive adverse marijuana-induced effects disappear when the acute intoxication has ended, depending on individual vulnerability, environmental factors (whether the user is in a nonthreatening area), and dose. Less common adverse effects are changed sensations of bodily perceptions, depersonalization, derealization, acute panic, and frank paranoia.

THC has well-known deleterious effects on higher cognitive functions, related to the duration of cannabis use. It reliably impairs short-term memory but not retrieval of previously learned facts. Attention span, recall, the ability to store knowledge, and the ability to perform tasks requiring multiple mental steps are also adversely affected. In addition, the ability to verbalize is often diminished. The term “temporal disintegration” has been coined to characterize THC's effects on the CNS. Intoxicated persons may have difficulty integrating earlier experiences, expectations, and current perceptions into goal-directed action (e.g., learning new material is usually impaired). College students who used marijuana regularly had impaired skills related to attention, memory, and learning 24 hours after they had last used the drug. Acute neurophysiological changes include suppression of REM sleep and diffuse slowing of background activity on the EEG. Those acute effects last for minutes up to a few hours, depending on dose and individual sensitivity to the drug. However, they can measurably impair performance if higher levels of cognitive or psychomotor skills are required.

THC increases cerebral blood flow in experienced users, correlating with intoxication. Acute THC also increases cerebral metabolic rate, primarily in the cerebellum and prefrontal cortex. Chronic effects have been more elusive, but long-term use has been hypothesized to impair the frontal lobe, which functions in the temporal organization of behavior. Frontal lobe impairment is consistent with the altered perception of time and also with cerebral blood flow studies that demonstrate greatest effects in the frontal lobe region. Some studies suggest that impairment assessed by sensitive measures of brain function can be detected after 5 years of use, but research has yet to demonstrate conclusively that chronic heavy marijuana use results in cognitive deficits that persist after prolonged abstinence. Studies of cerebral morphological changes in humans have not been compelling, though animal studies have shown structural damage to the hippocampus, a structure critical in learning and memory.

Quantitative EEG studies have reported increased alpha power, decreased alpha frequency, and decreased beta activity following acute exposure, which is consistent with a state of drowsiness. Quantitative EEG changes such as increased frontal-central theta wave activity in association with increased alpha wave activity may occur following long-term (5 years or more) exposure.

Psychomotor A variety of motor skills are affected by acute use, including decreased muscle strength, hand steadiness, and performance of simple motor tasks and reflex responses. At higher doses coordination and balance are impaired in a dose-related way. These effects may last several hours after subjective effects have subsided, and they are additive to those produced by alcohol or other sedatives.

Simple reaction time has not been shown to be adversely affected, but response to complex and unforeseen situations is impaired. As these skills are functional components important to driving, they may be related to marijuana-induced impairment of automobile driving. Some data suggest that marijuana produces a significant decrease in speeding and other risk-taking behavior, effects opposite those that often result from alcohol consumption.

Few studies are available on marijuana's effect in causing auto or airplane accidents. In one report of roadside sobriety tests, trained observers found that 94 percent of subjects were intoxicated 90 minutes after smoking moderate amounts of marijuana, and 60 percent after 2 hours. Despite numbers like these, several studies indicate that marijuana use by itself is a relatively minor risk factor in fatal traffic accidents. Although some observations suggest an increased accident risk for THC-positive drivers, interpretation of the data is confounded by concurrent alcohol use, which may synergistically worsen impairment. Some authors speculate that because persons with substance use disorders commonly use cannabis, marijuana testing may be of value as a monitor for more serious types of drug use—particularly, heavy drinking.

Several controlled studies indicate that cannabis intoxication impairs the ability to fly airplanes more than driving ability. That finding can be explained by the increased complexity of the tasks involved in flying. For both flying and driving, no correlation has been established between the degree of impairment and blood or urine levels of THC, rendering it difficult to establish reliable legal levels of intoxication as has been done for alcohol.

Cardiovascular Effects One of the first effects of the drug is a predictable dose-dependent increase in heart rate, probably due to an inhibition of vagal tone. Along with conjunctival reddening from dilation of blood vessels, the heart rate increase correlates with the appearance and duration of psychic effects as well as plasma concentrations of the drug. Myocardial oxygen demand is increased, and exercise tolerance decreased. These effects can lead to myocardial ischemia if a person with coronary artery disease exercises when intoxicated. Cannabinoids may exacerbate preexisting cardiovascular conditions such as angina and congestive heart failure. Orthostatic hypotension can also occur, especially at high doses. Tolerance appears to develop to all these cardiovascular effects.

Pulmonary Effects Smoking is by far the most popular route of cannabis administration. Although not yet subject to the same large-scale, long-term epidemiological analyses that identified tobacco as a carcinogen, cannabis is known to induce pulmonary pathology. Chronic smokers often experience bronchitis, pharyngolaryngitis, and asthma, most likely from marijuana smoke's highly irritating effect on the bronchial epithelium. Marijuana cigarettes contain far more tar (particulates) and respiratory irritants than tobacco. Tar produced by burning marijuana is more carcinogenic to animals than that derived from tobacco, and some workers predict that marijuana smoking will result in malignancies. Adding to the long-term toxic potential is the fact that marijuana smoke is usually inhaled longer and more deeply than cigarette smoke, delivering up to four times more tar to the lungs.

Heavy marijuana smoking causes mild, but significant, large airway obstruction, probably through chronic irritation or inflammation of the bronchial lining. THC itself causes bronchodilation to which little tolerance develops.

Immunological and Carcinogenic Effects Marijuana smoke inhibits pulmonary antibacterial defense systems, primarily alveolar macrophages, neutrophils, and lymphocytes. Cannabinoids may also suppress cellular and humoral immune responses in animals. The clinical significance of these effects has not been demonstrated.

In vitro and in vivo animal studies using relatively high doses of cannabinoids have shown them to have mutagenic and carcinogenic effects and to impair the synthesis of nucleic acids and proteins. While it is impossible to dismiss the potential clinical significance of those reports, no cytogenic abnormalities have yet been consistently documented in human marijuana smokers.

Hormonal and Reproductive Effects In animals, cannabis disrupts all phases of reproductive functioning by direct action on both the hypothalamic-pituitary axis and the gonads. In humans, all aspects of these effects have been suspected but are difficult to confirm. Cannabis has been reported to reversibly inhibit spermatogenesis, with a reduction in the number of sperm cells and an increased prevalence of abnormal cells. Decreased levels of testosterone and decreased size of the testes and prostate after heavy use are also seen but are believed to be reversible. A single marijuana cigarette can suppress plasma leutinizing hormone during the luteal phase of the menstrual cycle. This may account for the higher frequency of anovulatory cycles often associated with marijuana smoking. These phenonema may be due to THC's central effect of interfering with the release of gonadotropin-releasing hormone at a suprapituitary site, thereby disrupting the release of circulating luteinizing and follicle-stimulating hormones.

Cannabinoids cross the placental barrier and appear in maternal milk. Experimentally, cannabis is teratogenic at high doses in some species of animals. However,

cannabis's deleterious effects on the human fetus have been difficult to assess because of the frequent concurrent use of other drugs, cigarettes, and alcohol. Studies that have attempted to control for these variables have frequently associated marijuana with low birth weight. Its effects on other types of human fetal abnormalities have been reported, but the correlation is not well documented.

LABORATORY EXAMINATION

Urine testing for marijuana and other drugs has become common in many settings, including drug treatment programs and places of employment. Most laboratories use the enzyme-multiplied immunoassay (EMIT), although a radioimmunoassay is also commonly used. Both tests, while relatively sensitive and inexpensive, provide an unacceptable level of false-positive results. Thus confirmation by gas chromatography–mass spectrometry is routinely used. Cannabis and its metabolites may be detected in urine at the usual cutoff level of 100 ng/mL for 42 to 72 hours after the psychological effects subside. Passive inhalation that occurs under unusually crowded conditions may also reveal cannabis metabolites in the urine but only if the cutoff level used in the urine test is decreased to 20 to 25 ng/mL, a procedure that increases the frequency of false-positive results.

No clear linear relation between psychoactive effects and urine levels has been demonstrated. Urine that contains cannabis metabolites only implies that cannabis exposure occurred at an indeterminate time prior to testing. To avoid problems that may be associated with identifying very low levels of metabolites in the urine, such as can occur with passive inhalation, most laboratories use a cutoff point of 100 ng/mL or above.

TREATMENT

Persons who use marijuana are often referred for treatment. Referrals are made for persons with widely varying use patterns and treatment needs. At one extreme is the person who uses cannabis intermittently at low doses who was identified by a random drug screening test. At the other extreme is the person who uses high doses daily and meets criteria for dependence. The first person may need only periodic urine testing and infrequent supportive counseling. The second probably requires referral to a specialized, intensive drug rehabilitation program. Thus, as in other clinical situations involving substance use, treatment should begin only after a complete history is taken and a diagnosis is established. A psychiatric examination helps reveal any underlying psychopathology and determine the relation of drug use to mood states and psychiatric symptoms.

Cannabis dependence and abuse are usually treated by the psychosocial methods typically used in drug-free rehabilitation programs. These include attempts to promote realistic and rewarding alternatives to the drug and the associated lifestyles along with a commitment to abstinence from self-administered or unprescribed psychotropic drugs. Treatment usually involves a combination of interventions, including urine testing, participation in 12-step programs, education about drug effects, drug counseling, psychotherapy, and family therapy. Drug-focused group therapy is perhaps the most common treatment for all substance-related disorders, including cannabis-related disorders. Common strategies used by the group are social pressure to reinforce abstinence, teaching socialization and problem-solving skills, reducing stress and the sense of isolation often associated with drug use, relapse-prevention exercises, and varying degrees of confrontation. A trial comparing group-based relapse prevention and social support yielded results comparable to those obtained for treatment of alcohol or nicotine dependence.

Relative to those seeking treatment for alcohol or other substance use disorders, few adults seek treatment for cannabis abuse and dependence alone. Other drug abuse usually precipitates treatment and cannabis dependence is treated along with the other drug problems. However, cannabis use is one of the more common presenting problems among youth seeking treatment for substance abuse. Denial of a drug problem appears commonly in many persons with cannabis abuse or dependence, as it does in persons with other substance use disorders.

Treatment of unpleasant adverse reactions, usually anxiety, consists of calm and gentle reassurance in a warm and supportive atmosphere. Short-term use of anxiolytic agents, such as benzodiazepines, is necessary in some instances when anxiety symptoms are prominent or severe. Short-term use of low doses of antipsychotic medication may be justified if the patient has more-persistent and more-troubling symptoms, such as delusional ideas or frightening flashbacks. Treatment of toxic-delirious states is similarly supportive, symptomatic, and short-term because of their self-limited nature.

Therapeutic Uses Cannabis has been tried as a therapeutic agent for a variety of ailments. Data in this field are exceedingly difficult to collect for a variety of reasons including obtaining regulatory approval and support for research and difficulty in matching placebo against smoked marijuana. Synthetic THC (e.g., drobinol) which can be orally administered, contains the principal psychoactive component of the cannabis leaf. But cannabis contains over 400 chemicals, and it is difficult to ascertain with certainty which have therapeutic properties.

THC has antiemetic effects on the nausea and vomiting caused by chemotherapy. A synthetic oral cannabinoid (dronabinol [Marinol]) has been shown to be generally equal or superior to prochlorperazine (Compazine) but inferior to metoclopramide (Reglan). The relative efficacy of cannabinoids versus newer antiemetics such as ondansetron (Zofran) combined with dexamethasone (Decadron) has not been evaluated. The data on smoked marijuana versus these older and newer agents are limited, but reports suggest that it may be effective in a certain percentage of patients who had no benefit from older agents.

Dronabinol can also reduce the nausea and diarrhea associated with AIDS or with chemotherapy used to treat human immunodeficiency virus (HIV) infection. It also increases appetite and produces weight gain in AIDS and cancer patients, although the weight gain is not in lean body mass. As a result, THC has gained orphan drug status from the FDA to treat nausea and vomiting from chemotherapy and to stimulate appetite in AIDS patients. However, there are no controlled studies of smoked marijuana for this condition, nor any systematic studies of the effects of smoked marijuana on immunological status in HIV-infected patients. With repeated smoking, patients may be expected to experience the typical symptoms of intoxication, such as mood changes and decreases in concentration, coordination, and the ability to estimate time. Separating the undesired side effects of cannabis from its therapeutic effects has been difficult. More controlled studies are needed.

Smoked marijuana lowers intraocular pressure. This has stimulated interest in its use as a treatment for glaucoma. The mechanism of action for this feature is unknown, which limits development of similar agents. This effect is mostly short-lived (3 to 4 hours) and there is no evidence that cannabis is more effective than several other agents in treating patients suffering from glaucoma.

Preclinical and clinical studies of the use of cannabinoids in neurological and movement disorders have been reported. Currently, there is no evidence that cannabinoids are superior to available therapies for multiple sclerosis and partial spinal cord injury. Case studies have reported some benefit of smoked marijuana in treatment of dystonic states, and some evidence suggests a possible role for cannabinoids in the treatment of the epilepsies, but studies are lacking.

Oral THC has analgesic efficacy for cancer pain, but there is a narrow therapeutic margin between the doses that produce useful analgesia and those producing unacceptable adverse CNS effects. Mild hypothermia, prolongation of barbiturate anesthesia, and hyperglycemia are other disorders for which cannabis has not yet demonstrated clinical utility.

SUGGESTED CROSS-REFERENCES

An overview of the substance-related disorders, including substance abuse and substance dependence, appears in Section 11.1. Substance intoxication delirium is discussed in Chapter 10 on cognitive disorders and mental disorders due to a general medical condition. Substance-induced psychotic disorder is discussed in Section 13.3 on acute and transient psychotic disorders and culture-bound syndromes. Substance-induced anxiety disorder appears in Section 15.6.

11.6 COCAINE-RELATED DISORDERS

JEROME H. JAFFE, M.D.

More than 25 million people in the United States used cocaine at least once in the 1980s and 1990s. For many of those people, use progressed to abuse and dependence. In the early 1990s it was more common to have a lifetime history of cocaine dependence than of bipolar disorder (2.7 percent versus 1.6 percent). While the epidemic appears to have passed its peak, cocaine use is still prevalent, and people with cocaine abuse and dependence disorders continue to come for treatment. A wealth of information now exists on the effects of cocaine on the brain and behavior, and on cocaine toxicity, cocaine dependence, and the efficacy of treatment.

DEFINITIONS

Substance use may be associated with a number of distinct disorders of which dependence and abuse are but two. In the case of cocaine, the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) describes 10 other substance-related disorders. Cocaine dependence is defined in DSM-IV as a cluster of physiological, behavioral, and cognitive symptoms that, taken together, indicate that the person continues to use cocaine despite significant problems related to such use. It is defined in the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) as a cluster of physiological, behavioral, and cognitive phenomena in which the use of cocaine takes on a much higher priority for a given individual than do other behaviors that once had a greater value. Central to these definitions is the emphasis placed on the drug-using behavior, its maladaptive nature, and how over time the voluntary choice to engage in that behavior shifts and becomes constrained as a result of interactions with the drug.

Cocaine abuse is a term used in DSM-IV to categorize a pattern of maladaptive cocaine use leading to clinically significant impairment or distress within a 12-month period, but one in which the symptoms have not met criteria for cocaine dependence. ICD-10 does not use the term.

Other cocaine-related disorders include cocaine intoxication, cocaine withdrawal, cocaine-induced psychotic disorder with delusions or with hallucinations, cocaine intoxication delirium, cocaine-induced mood disorder, cocaine-induced anxiety disorder, cocaine-induced sleep disorder, cocaine-induced sexual dysfunction, and cocaine-related disorder not otherwise specified (Table 11.6-1). The DSM-IV coding scheme provides distinct code numbers for cocaine dependence and cocaine abuse, but the codes for the other substance-related disorders do not differentiate cocaine-induced disorders from the other substance-induced disorders, with the exception of those related to alcohol use.

Cocaine use disorders
Cocaine dependence
Cocaine abuse
Cocaine-induced disorders
Cocaine intoxication
Specify if: with perceptual disturbances
Cocaine withdrawal
Cocaine intoxication delirium
Cocaine-induced psychotic disorder, with delusions
Specify if: with onset during intoxication
Cocaine-induced psychotic disorder, with hallucinations
Specify if: with onset during intoxication
Cocaine-induced mood disorder
Specify if: with onset during intoxication with onset during withdrawal
Cocaine-induced anxiety disorder
Specify if: with onset during intoxication/with onset during withdrawal
Cocaine-induced sexual dysfunction
Specify if: with onset during intoxication
Cocaine-induced sleep disorder
Specify if: with onset during intoxication/with onset during withdrawal
Cocaine-related disorder not otherwise specified

Table 11.6-1 DSM-IV Cocaine-Related Disorders

HISTORY

Purified cocaine first became commercially available in 1884. Reports of compulsive cocaine use and cocaine psychosis appeared in the European medical literature within the decade. By the beginning of the twentieth century, cocaine use and dependence were not uncommon in the United States. Cocaine was an ingredient of Coca-Cola until 1900; nonprescription proprietary nostrums containing cocaine were widely promoted until the Harrison Act was passed in 1914; and 100 mg of illicit cocaine could still be bought for a quarter in the 1920s. With growing public awareness in the United States of the physical and legal risks of drug use, cocaine use and dependence declined gradually. It remained fairly common in Europe, however. Hans Maier's classic *Der Kokainismus*, published in 1926, included descriptions of relatively contemporaneous clinical cases.

There appears to have been little cocaine use and dependence from the late 1930s to the early 1970s. Although some heroin users also used cocaine, virtually no cocaine-dependent patients entered the U.S. Public Health Service Hospital at Lexington, Kentucky, in the 1960s. Starting in the 1970s and continuing throughout the 1980s, the availability of cocaine increased noticeably. For the first few years of its renewed popularity among affluent young adults, there were few reports of cocaine toxicity or of persons seeking treatment. Some observers who were apparently unaware of previous epidemics, in which the compulsive nature of cocaine use and its serious toxicity had been repeatedly documented, declared cocaine to be a relatively benign drug. Its use spread from those affluent young adults (who tended to use it intranasally) throughout all economic and age levels of society. More-hazardous routes of administration, including injection and inhalation of freebase forms such as “crack,” became common.

By 1985, owing to its increasing availability and declining price, 20 million people had tried cocaine. Its toxicity became quite apparent as the number of emergency room visits for cardiovascular, neurological, and psychiatric complications rose sharply; and its capacity to induce dependence was apparent from the escalating number of requests for treatment. Increasing numbers of drug users, overdose deaths, crime, and the images of “crack babies” damaged in utero by cocaine-using pregnant women gave national visibility to the drug problem, particularly to cocaine use. Federal expenditures for law enforcement escalated. Penalties for drug selling and possession were increased, and national prevention campaigns were initiated. Drug (urine) testing in the workplace became more common. Toward the end of the 1980s casual use declined, as did the number of cocaine-related medical emergency cases seen in hospital emergency rooms. The number of heavy users did not decline as sharply, however, and urine tests of people who were arrested showed that a substantial number of criminals were still using cocaine. The drug continued to be relatively available, less costly than in the 1970s, and by the early 1990s emergency room visits began to increase slightly. However, by the mid-1990s arrestee drug testing indicated that in some large cities people who got in trouble with the law, particularly the younger ones, were using cocaine less.

COMPARATIVE NOSOLOGY

The DSM-IV criteria for cocaine dependence are the same generic criteria as are applied to other psychoactive drugs. The notion of a generic concept of dependence is shared with the revised third edition of DSM (DSM-III-R) and ICD-10. Despite some changes in wording, the syndromes and criteria for making the diagnosis of

dependence are similar in DSM-III-R and DSM-IV. A generally high level of agreement also exists between DSM-IV and ICD-10: they use similar concepts (the dependence syndrome varying in severity), although the wording of the criteria for determining the presence and severity of the syndrome differs. Both require that three elements of the syndrome be noted within a 12-month period. Although DSM-IV appears to place greater stress than ICD-10 on tolerance and physiological dependence (because it asks clinicians to specify if these criteria are present), in practice this has little impact on the proportion of patients seeking treatment who meet diagnostic criteria for dependence. Most patients who meet current DSM-IV criteria for dependence report some tolerance, withdrawal, or both.

ICD-10 and DSM-IV differ in the classification of what is called substance abuse in DSM-IV. ICD-10 does not use the term “abuse” but includes instead the category of harmful use, which differs substantially from the concept of “abuse” used in DSM-IV. However, the concept of harm is limited to physical and mental health (e.g., hepatitis, cardiac damage, episodes of depression, or toxic psychosis). It specifically excludes social impairments, as follows:

> Harmful patterns of use are often criticized by others and frequently associated with adverse social consequences of various kinds. The fact that a pattern of use or a particular substance is disapproved of by another person or by the culture, or may have led to socially negative consequences such as arrest or marital arguments is not in itself evidence of harmful use.

EPIDEMIOLOGY

Cocaine use has fluctuated dramatically over the past three decades, not just in the United States, but also in South America and in western Europe. In the United States the various activities aimed at estimating the extent and consequences of psychoactive drug use are the annual Monitoring the Future Study (MTF) (formerly known as the High School Senior Survey); the National Household Survey on Drug Abuse (NHSDA); the Drug Abuse Warning Network (DAWN), which obtains reports from a selected group of hospital emergency rooms and medical examiners' offices on drug-related adverse effects and deaths; and the Arrestee Drug Abuse Monitoring (ADAM) program (formerly DUF), which obtains its data from urine tests of arrestees at selected jails. All of those estimating techniques have sampling limitations, and none apply standardized diagnostic criteria to substance-use patterns or adverse effects. Consequently, although they provide a picture of use over time, these methods do not reveal changes in the incidence and prevalence of specific substance-related disorders, such as dependence and abuse

In the annual MTF study all indicators of self-reported cocaine use among high school seniors (lifetime, past-year, and past-month use) declined substantially from the high annual prevalence level of 13.1 percent in 1985 to 3.1 percent in 1992, the lowest since the survey began in 1975. Cocaine use then gradually rose again, reaching an annual prevalence rate of 5.5 percent in 1997. The NHSDA found steady declines in the annual use of cocaine, from peak levels of more than 5 percent, from 1982 to 1985, to 2.1 percent in 1992, and then a slower decline to 1.9 percent by 1997. There was relatively little decline in the number of heavy (weekly) cocaine users between 1985 and 1993, but by 1997 past-30-day use was down from an estimated 3.0 percent in 1985 (5.7 million users) to 0.7 percent (1.5 million users). The use of crack cocaine and the incidence of new crack users also declined.

Two population surveys used accepted diagnostic criteria to measure the extent of substance abuse and dependence: the Epidemiologic Catchment Area (ECA) Study, carried out in the early 1980s, used third edition of DSM (DSM-III) criteria; the National Comorbidity Survey (NCS), carried out from 1990 to 1992, used DSM-III-R criteria. The ECA report combined categories of dependence and abuse for cocaine. The 1-month and 6-month prevalence rates for cocaine abuse-dependence were too low to be measurable; the lifetime rate was 0.2 percent. The NCS carried out just after the peak of the cocaine epidemic reported a lifetime prevalence rate for cocaine dependence of 2.7 percent among 15- to 54-year-olds; 16 percent of respondents reported a history of some use of cocaine.

ETIOLOGY

Substance dependence is currently viewed as the result of a process in which social, psychological, cultural, and biological factors influence substance-using behavior. The actions of the drug are seen as critical, but it is recognized that not everyone who becomes dependent experiences the effects of a given drug in the same way. Further, depending on the individual, different factors may be more or less important at different stages of the process, even with the same class of pharmacological agents.

Social and cultural factors largely influence the availability and initial use of cocaine and other substances. In the case of cocaine, pharmacological factors are believed important in perpetuating use and progression to dependence. Cocaine has potent mood-elevating and euphorigenic actions, especially when its effects have rapid onset, as when cocaine is injected or inhaled. Although some physical dependence develops, an aversive withdrawal syndrome probably is less prominent in perpetuating cocaine use than that of opioids and sedatives.

Comorbidity Additional psychiatric diagnoses are quite common among those dependent on cocaine. It is not always evident how this comorbidity is linked etiologically to cocaine, but the epidemiological evidence clearly shows that the presence of a psychiatric disorder not related to substance abuse (e.g., mood disorders, schizophrenia, and antisocial personality disorder) substantially increases the odds of developing substance abuse and dependence. For some persons cocaine may serve to alleviate various psychiatric disorders or dysfunctional states. Some users, for example, may find relief from dysthymic disorder. Others may find that cocaine facilitates sexual activity, permits extended socializing, or counteracts the sedative effects of alcohol. However, while such factors may explain substance use on more than one occasion, they do not account for progression to dependence or abuse.

Cocaine use may induce psychiatric syndromes (e.g., panic disorders) that may persist even after drug use is stopped. Persons with certain types of psychiatric disorders may be prone to experiment with cocaine or other substances, and factors that predispose to psychiatric disorders may also predispose cocaine users to become cocaine dependent.

Research on the temporal appearance of the syndromes indicates that in some instances and for some syndromes, substance use antedates the psychiatric disorder. In one component of the ECA study subjects were reinterviewed 1 year later. Those who reported cocaine or stimulant use in the interval were almost eight times more likely than nonusers to experience depression and 14 times more likely to have had a panic attack. Cocaine users were almost 12 times more likely to experience a manic episode.

The ECA data also show a relation between the extent of cocaine use and other psychiatric disorders. Among men 18 to 44 years of age, those who had never used cocaine or had used it fewer than five times had a lifetime prevalence of major depression of 7.6 percent; it was 11 percent for users who were never daily users and almost 26 percent for those who met the DSM-III criteria for cocaine abuse. Similarly, the lifetime prevalence of panic disorder was related to the extent of cocaine use.

Genetic Factors Laboratory animal strains differ greatly in their willingness to self-administer psychoactive drugs, including cocaine, and strains can be developed that differ even more markedly. The most convincing evidence to date of a genetic influence on cocaine dependence comes from studies of twins. A study of male twins who served in the U.S. military between 1965 and 1975 found higher concordance rates for stimulant dependence (cocaine, amphetamines, and amphetamine-like drugs) among monozygotic than dizygotic twins. The analyses indicated that genetic factors and unique (unshared) environmental factors contributed about equally to the development of stimulant dependence. Other studies have shown genetic contributions to attention-deficit/hyperactivity syndrome, conduct disorder, and antisocial personality disorder. Since these disorders are important risk factors for drug use and dependence, these findings also support genetic involvement in the etiology of drug dependence in general.

Other Factors Social, cultural, and economic factors are powerful determinants of initial use, continuing use, and relapse. Excessive use is far more likely in countries where cocaine is readily available. Different economic opportunities may influence certain groups more than others to engage in selling illicit drugs, and selling is more likely to be carried out in familiar communities than in those where the seller runs a high risk of arrest.

Since in both human and animal studies alternative positive reinforcers compete with drugs as reinforcers, the absence of such nondrug alternatives can be seen as a causal factor for use, especially where drugs are available and the social pressures against using them are not strong. Alternative positive reinforcers are not limited to material rewards but include psychological rewards associated with satisfying interpersonal relationships and the self-esteem that derives from achievements in socially acceptable roles. In animal models, chronic stress mediated by high levels of cortisol increases sensitivity to the reinforcing effects of cocaine and induces relapse to drug self-administration in withdrawn animals.

Learning and Conditioning Learning and conditioning are also considered important in perpetuating cocaine use. Each inhalation or injection of cocaine yields a rush and a euphoric experience that reinforce the antecedent drug-taking behavior. In addition, the environmental cues associated with substance use become associated with the euphoric state so that long after a period of cessation, such cues (e.g., white powder and paraphernalia) can elicit memories of the euphoric state

and reawaken craving for cocaine.

In cocaine abusers (but not in normal controls), cocaine-related stimuli activate brain regions subserving episodic and working memory and produce electroencephalographic (EEG) arousal (desynchronization). Increased metabolic activity in the limbic-related regions such as amygdala, parahippocampal gyrus, and dorsolateral prefrontal cortex correlated with reports of craving for cocaine, but the degree of EEG arousal did not.

Pharmacological Factors As a result of actions in the central nervous system (CNS), cocaine can produce a sense of alertness, euphoria, and well-being. There may be decreased hunger and less need for sleep. Performance impaired by fatigue is usually improved. Some users believe that cocaine enhances sexual performance.

Mechanisms of Action Cocaine inhibits the normal reuptake of monamines from the synaptic cleft by binding to transporter proteins. Its reinforcing effects are primarily due to its actions at the dopamine transporter, producing high levels of dopamine in the synapse. Evidence suggests that stimulation of both dopamine (D_1) and D_2 receptors plays some role in dopamine's reinforcing and salience-enhancing actions. Cocaine also inhibits reuptake of norepinephrine and serotonin. The increase in norepinephrine concentration is important for some of cocaine's toxic effects.

In animals cocaine is considered the most powerful pharmacological reinforcer of drug-taking behavior known. Given free access, animals choose to self-administer cocaine rather than have food, water, or access to other animals. Death from starvation or drug toxicity is the typical consequence of unlimited cocaine access. With limited access (2 to 6 hours a day), cocaine does not gain such control over behavior, and animals may select food in preference to cocaine, depending on the dose, the amount of work they must do to get the dose, and the type and amount of food offered as alternative reinforcers.

Common Routes of Administration Cocaine can be taken orally, by injection, by absorption via nasal and buccal membranes, or by inhalation and absorption through the pulmonary alveoli. Cocaine hydrochloride, the water-soluble form typically used for snorting or injection, is largely destroyed by the heat of burning and so is not well suited for smoking. Cocaine as freebase sublimates before it is destroyed by heat. The hydrochloride salt can be converted to the freebase form by treatment with alkali and extraction with organic solvents. Inhalation of freebase cocaine produces almost immediate absorption and a rapid onset of effects. In the 1980s users learned to avoid the fire hazard of extracting organic solvents and still produce a crude form of freebase cocaine by heating the cocaine with sodium bicarbonate to yield crack, a hard, white mass that is freebase plus impurities. When smoked, this material gives off a crackling sound. In cocaine-producing countries some users may smoke a crude intermediate product, cocaine sulfate (coca paste, pasta basica, basuca), which is usually contaminated with solvents.

As with the opioids, the rapid onset of cocaine's effects after intravenous injection or freebase inhalation produces an intensely pleasurable sensation, or rush. The cocaine rush lasts only a few minutes, whereas other psychological and physiological effects tend to decline more slowly, in parallel with declining concentrations in plasma.

Metabolism The half-life of a single dose of cocaine in the blood is only about 30 to 90 minutes. It is typically hydrolyzed by butyrylcholinesterase (plasma pseudocholinesterase) and liver esterase into inactive metabolites, most significantly benzoylecgonine and ecgonine methylester. The metabolite is generally detectable in urine for 24 to 72 hours after brief periods of use. With repeated high dosages (e.g., 1 to 2 grams daily), cocaine or its metabolites may accumulate in body compartments (e.g., fat and the CNS), from which it is then slowly released. Consequently, using sensitive measures, cocaine may be detectable in the urine of heavy users for 2 weeks. In a study of cocaine-dependent patients admitted to an inpatient treatment unit, the average time from last reported cocaine use to first negative urine test (using a cutoff of 300 ng/mL) was 105 hours, and 20 percent had positive tests for 120 hours or longer.

The concurrent use of cocaine and alcohol may result in the accumulation of a distinct metabolite, cocaethylene. This metabolite is active and longer lasting than cocaine itself and may account for the enhancement of subjective effects and toxicity when the two are used simultaneously.

Tolerance and Sensitization Patients seeking treatment often report needing progressively more cocaine to get the same effect. In laboratory studies, occasional users of cocaine have more marked cardiovascular, subjective, and endocrine responses to intravenous challenge doses of cocaine than subjects who are cocaine dependent. Despite the evidence for some tolerance to blood pressure–elevating effects, even experienced users may sustain significant cardiovascular toxicity.

Chronic use of cocaine also produces a form of sensitization in which the response to a given dose is actually enhanced. In animals repeated doses of CNS stimulants such as cocaine or amphetamine eventually elicit seizures or stereotyped behaviors not seen with initial doses. Sensitization is produced more reliably by intermittent dosing than by continuous dosing. The sensitization can be long lasting.

The paranoid states and toxic psychoses that commonly develop among chronic cocaine users are believed to be among the phenomena to which sensitization develops. Cocaine psychosis develops more rapidly in those who have been chronic users or had developed psychoses previously.

Withdrawal States The cocaine withdrawal syndrome has aversive qualities (e.g., dysphoria and anhedonia). Although withdrawal anhedonia and fatigue are not generally reported to be the most important reasons for relapse after brief withdrawal, some users who have come to depend on cocaine for high energy or to project a confident persona may be temporarily unable to function without it. For others, withdrawal dysphoria may exaggerate the intensity of an antecedent mood disorder. If a protracted cocaine withdrawal syndrome exists, it is more subtle than the syndrome associated with opioid withdrawal. It is in some ways puzzling that patients do not usually attribute craving for cocaine and relapse to withdrawal, since there is considerable evidence that chronic cocaine use produces significant long-lasting changes in many parts of the brain.

COCAINE-INDUCED BRAIN CHANGES The repeated finding of perfusion deficits in the brains of cocaine-dependent subjects recently withdrawn from cocaine is probably not related to tolerance or withdrawal; however, several other findings probably are. Many, but not all, studies using positron emission tomography (PET) and single positron emission computed tomography (SPECT) to study the brains of cocaine-dependent subjects have found an increased number of dopamine transporters in the striatum, a finding consistent with postmortem studies. Within a few days of withdrawal, cocaine abusers show higher than normal cerebral metabolic rates in orbitofrontal cortex and basal ganglia that correlate with craving. At 1 to 4 weeks and at 3 to 4 months postwithdrawal, cocaine abusers have lower metabolic rates in the frontal cortex that correlate with symptoms of depression, and decreased availability of D_2 receptors that correlates with decreased cerebral metabolic rates and years of cocaine use. An increase in μ-opioid receptor binding after 4 weeks of cocaine abstinence also correlated with severity of cocaine craving.

Chronic cocaine use induces a wide range of changes in the brains of animal models; many of these changes appear to be adaptive responses, while others may be linked to sensitization. After a period of chronic, binge-like cocaine administration, the threshold for reinforcement increases, and dopaminergic and serotonergic transmission in the nucleus accumbens decreases. In addition, the density of D_1 receptors increases. Messenger ribonucleic acid (mRNA) for corticotropin-releasing factor (CRF) increases, μ- and k-opioid receptors are upregulated, and the concentration of mRNA encoding for prodynorphin in the striatum and nucleus accumbens increases. Dynorphin, acting on k-receptors, probably serves as a negative feedback mechanism, dampening excessive dopaminergic activity. When cocaine use ceases, enhanced dynorphin activity could contribute to reduced dopaminergic activity manifested in dysphoria and anhedonia. Neurons bearing dopamine receptors in these same brain areas show upregulation of cyclic adenosine monophosphate (cAMP)-dependent kinase and decreased concentrations of Gi protein. Both of these changes contribute to upregulation of the cAMP pathway and activation of various transcription factors, (e.g., CRE-binding protein [CREB]), which results in the production of long-lasting Fos-like proteins that are distinct from those seen after acute cocaine administration. The persistent changes in the cAMP pathway probably represent one mechanism underlying tolerance.

DIAGNOSIS AND CLINICAL FEATURES

Table 11.6-1 lists the DSM-IV cocaine-related disorders.

Patterns of Use and Abuse There are several patterns of cocaine use and abuse. For example, Indians in the Andes chew coca leaves daily, but apparently very few progress to excessive use or toxicity. Although some cocaine users can use it intermittently without becoming dependent, it is not clear how long such intermittent, nondependent use can continue and for what proportion of users. Cocaine use that does not cause problems for the user does not meet the DSM-IV criteria for either dependence or abuse.

Most cocaine users seeking treatment report initial intermittent use. However, at some stage the use escalated, with episodes of high-dose usage becoming more

frequent. Unlike opioid dependence, daily use is not the most common pattern among persons seeking treatment for cocaine dependence. A small percentage of such patients report using high doses, but for only a few days a month over a long period; such persons may still meet the criteria for dependence. That pattern is atypical, but intermittent use is not. Intermittent use consists of episodes or binges of use, often starting on weekends and paydays and lasting until the drug supply is exhausted or toxicity develops. The runs, or binges, during which the drug may be used every 15 to 30 minutes, can last 7 or more consecutive days but typically are shorter. Although there appears to be little tolerance between binges, changes in the response to the drug occur during the binge. Euphoric effects seem less prominent, and anxiety, fatigue, irritability, and depression increase. Any pause in the drug use causes blood concentrations to drop; typically, there is dysphoria rather than a return to normal mood. If cocaine is still available, it is used to dispel the dysphoria. When the binge is interrupted or supplies have been depleted, a cocaine crash quickly follows. Patients report the sense of needing more cocaine to get the same effect (tolerance) more commonly than the experience of pronounced withdrawal. Some users distinguish between a brief crash and withdrawal. A substantial proportion of cocaine users seeking treatment report daily or almost daily use, often associated with daily heroin use.

In the early stages, cocaine use may cause little interference with normal activities. Some persons may even find that the sense of energy and heightened sense of self-confidence facilitate productive activity. Others may find that the cocaine facilitates social interaction, particularly enhancing sexual arousal and enjoyment, at least initially. The development of sexual dysfunction later in the course of use is better documented than is the enhancement.

In addition to feelings of euphoria, cocaine use may also induce concurrent feelings of anxiety, irritability, and suspiciousness. Users may commit crimes to obtain money to buy cocaine, and such crimes may involve violence. In addition, cocaine can induce paranoid ideation, and there are numerous reports of homicide and attempted homicide during such cocaine-induced toxic states.

Cocaine is an especially powerful reinforcer when it is taken in ways that produce a rapid onset of effects. Not only do intravenous and intrapulmonary routes of administration produce a rapid rise in blood and brain drug concentrations and an intense rush, but especially with the smoking of freebase cocaine, an almost equally rapid decline in blood and brain drug concentration occurs as the cocaine is redistributed and metabolized. Compared with those who use it intranasally, users who inhale freebase cocaine or inject the salt intravenously seem more likely to move from experimentation to regular, compulsive use, limited only by the availability of the drug or the money to buy it. Even in the laboratory setting it can be shown that craving for cocaine is briefly intensified a few minutes after intravenous use when brain and blood concentrations are falling. However, while intravenous and pulmonary cocaine use are far more likely to result in compulsive use and dependence, the intranasal route can also lead to dependence and to the full range of cocaine toxicity (including fatalities).

Cocaine abusers frequently use sedatives or opioids to modulate the stimulant and toxic effects of the cocaine, a practice that can lead to concurrent dependence on sedatives or opioids. Sometimes an opiate, such as heroin, and cocaine are injected intravenously simultaneously; the mixture (speedball) is reportedly especially euphorigenic. Similar synergistic effects are seen when cocaine and buprenorphine (Buprenex) are taken simultaneously. Alcohol is probably the substance most commonly used in conjunction with cocaine, and its use may become associated with cocaine use and can trigger cocaine craving in former users trying to abstain from cocaine.

Cocaine Dependence As the drug use progresses, greater priority is often given to obtaining and using cocaine than to meeting other social obligations or avoiding toxicity or arrest. The user may engage in illegal activities to raise money for cocaine or trade sex for it. At this stage the use of cocaine is considered maladaptive and probably meets the DSM-IV criteria for cocaine abuse or dependence. The DSM-IV criteria for cocaine dependence are the same generic criteria applied to other substances (see Table 11.1-3). A diagnosis of dependence requires a maladaptive drug-use pattern that leads to clinically significant impairment or distress, as indicated by at least three of seven criteria presented in the table. DSM-IV instructs the clinician to specify whether physiological dependence is present (i.e., evidence of either tolerance or withdrawal as defined in the diagnostic criteria).

Drug use to prevent withdrawal is not as dominant with cocaine dependence as with opioid dependence. However, the other criteria for dependence are common among heavy users of cocaine. Tolerance to some drug actions (e.g., euphorigenic effects) can coexist with increased sensitization to other actions (e.g., anxiogenic and psychotogenic effects).

Cocaine Abuse Some cocaine users develop problems or adverse effects related to their drug use (i.e., their use is maladaptive), even though such use does not meet the three-criteria requirement for the diagnosis of dependence. Examples of such recurrent maladaptive patterns include use that leads to multiple legal problems; failure to meet major social, school, or work-related obligations; and continued use despite social or vocational difficulties caused by, or aggravated by, cocaine use. When one or more such substance-related problems occur in a 12-month period but the pattern has never met the criteria for dependence, the diagnosis of cocaine abuse (see Table 11.1-8) should be made.

Cocaine Intoxication Among those who meet the criteria for cocaine abuse or dependence, certain psychiatric toxicities are common. Just as alcohol-dependent persons are frequently intoxicated, cocaine users commonly develop the symptoms of cocaine intoxication during the course of a single binge. The euphoria may be accompanied by increasing suspiciousness, hypervigilance, anxiety, hyperactivity, talkativeness, and grandiosity. Users may engage in stereotyped and repetitive behaviors (e.g., disassembling and reassembling the same object). Typically other signs and symptoms of central stimulation occur, such as tachycardia, cardiac arrhythmias, blood pressure changes, pupillary dilation, perspiration, or chills. Hallucinations may occur, including tactile hallucinations. Judgment is impaired, and confusion may occur, but insight into the drug-induced nature of the hallucinations is retained.

Any of these symptoms following the recent use of cocaine should invoke consideration of cocaine intoxication, provided they are not better accounted for by some other medical or mental disorder and there are at least two of a number of physiological signs commonly seen with cocaine use (e.g., tachycardia and elevated blood pressure). The DSM-IV diagnostic criteria for cocaine intoxication (Table 11.6-2) are identical to the criteria for amphetamine intoxication except for the substitution of the word “cocaine” for the words “amphetamine or a related substance.” Any perceptual disturbances should be specified. In one study of cocaine abusers in the community, just over half reported experiencing paranoia or hallucinations at some time; among those who sought treatment, 63 percent reported those symptoms. Cocaine intoxication may occur in occasional users who do not meet the criteria for abuse or dependence.

A. Recent use of cocaine.
B. Clinically significant maladaptive behavioral or psychological changes (e.g., euphoria or affective blunting; changes in sociability; hypervigilance; interpersonal sensitivity; anxiety, tension, or anger; stereotyped behavior; impaired judgment; or impaired social or occupational functioning) that developed during, or shortly after, use of cocaine.
C. Two (or more) of the following, developing during, or shortly after, cocaine use:
(1) tachycardia or bradycardia
(2) pupillary dilation
(3) elevated or lowered blood pressure
(4) perspiration or chills
(5) nausea or vomiting
(6) evidence of weight loss
(7) psychomotor agitation or retardation
(8) muscular weakness, respiratory depression, chest pain, or cardiac arrhythmias
(9) confusion, seizures, dyskinesias, dystonias, or coma
D. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

Table 11.6-2 DSM-IV Diagnostic Criteria for Cocaine Intoxication

The development of paranoia does not seem to be closely related to cocaine dose. Some cocaine users develop the syndrome at far lower doses than are used by others who do not develop it. Furthermore, a person who has experienced cocaine-induced paranoia is more likely to have it recur with subsequent cocaine use. It is postulated that a change in threshold represents a form of sensitization. Cocaine use has also been linked to development of a panic disorder that outlasts the cocaine use; here too sensitization has been postulated.

Cocaine Intoxication Delirium and Cocaine-Induced Psychotic Disorder Whereas some paranoia or hypervigilance is typical of cocaine intoxication and tactile and other hallucinations may also occur, cocaine use can also induce a toxic delirium and a more persistent toxic psychotic disorder characterized by suspiciousness, paranoia, visual and tactile hallucinations, and loss of insight. The hallucination of bugs (cocaine bugs) or vermin crawling under the skin (formication) is sometimes reported and is often associated with excoriation of the skin. A paranoid syndrome can develop within 24 hours after the beginning of a cocaine binge. When the syndrome develops in the presence of a clear sensorium and the person retains insight into the drug-induced nature of the symptoms, it is called cocaine intoxication,

even when there are hallucinations. When insight is lost but the sensorium is clear, the syndrome is called cocaine-induced psychotic disorder with delusions or with hallucinations. If consciousness is disturbed (i.e., the ability to focus, sustain, or shift attention is reduced) and deficits in memory and orientation exist, the diagnosis is cocaine intoxication delirium.

Cocaine Withdrawal Cocaine withdrawal phenomena have not been as thoroughly studied as those associated with opioids or alcohol. No experimental studies have been conducted in which patients with known baseline characteristics have been stabilized solely on large doses of cocaine and then abruptly withdrawn. Consequently, most data have been derived from interviews and patients' recollections or from observations of hospitalized patients whose level of drug ingestion and prior baseline characteristics can only be estimated.

Emil Erlenmeyer reported in 1886 that depression was likely to be seen when cocaine was stopped, and in *Der Kokainismus* Hans Maier noted depression and apathy upon cessation of cocaine. During the cocaine epidemic of the 1980s about 50 percent of cocaine users reported experiencing some type of withdrawal when drug use was interrupted.

An early description of withdrawal, based on interviews of outpatients, described a three-phase syndrome in which the first phase, the crash, was characterized by agitation, depression, anorexia, and high cocaine craving. This cluster of symptoms was followed by a decrease in cocaine craving, fatigue, depression, and a desire for sleep; followed in turn by exhaustion and hypersomnia, with intermittent awakening, and hyperphagia. The second phase was reported to be heralded by normalized sleep, improved mood, and low levels of craving, but that relatively benign phase was succeeded by a return of anergia, anhedonia, anxiety, and increased cocaine craving, especially in response to stimuli previously associated with cocaine use. A third phase—extinction (which appears to represent a period of extended vulnerability to relapse rather than a phase of an extended withdrawal syndrome)—was also described.

A complex phasic withdrawal has not been reported by others who observed cocaine-dependent patients admitted to clinical and research units. Instead, symptoms of depression and craving for cocaine declined steadily over several weeks. After 3 weeks, sleep, weight, and appetite were mostly comparable to those of normal controls on the same unit. Hypersomnia, disturbed sleep, hyperphagia, and excessive weight gain were not seen, nor was a severe crash observed. The phases and fluctuations in craving previously reported might have been related to environmental stimuli.

Some of the inconsistencies in the findings and symptoms associated with cocaine cessation are probably attributable to differences in the dose and duration of use and to vulnerability factors. In interviews with almost 400 cocaine abusers, including about 100 who were not seeking treatment, some 83 percent reported tolerance to cocaine effects (needing more to get same effect), and 52 percent reported having undergone some type of withdrawal. Those seeking treatment were more likely to report experiencing withdrawal. Available data show no convincing evidence that a protracted cocaine withdrawal syndrome follows resolution of the signs and symptoms associated with abrupt cessation. However, abnormalities of brain function appear to persist for at least 12 weeks, and possibly, subtle withdrawal phenomena increase vulnerability to relapse.

Drug craving, often part of cocaine withdrawal, is not included among DSM-IV diagnostic criteria. While not commonly observed during recent clinical studies, severe depression, sometimes associated with suicidal ideation, is reported in the older literature on cocaine withdrawal and in occasional contemporary clinical reports. To what degree the more severe depressive features are a part of withdrawal or represent the emergence of primary mood disorder is unclear.

The DSM-IV diagnostic criteria for cocaine withdrawal Table 11.6-3 specify that the syndrome follows the cessation (or reduction) of heavy, prolonged cocaine use. Further, the dysphoric mood and other symptoms (e.g., fatigue and sleep disturbances) must be intense enough to cause significant distress or impairment. Thus, the criteria are structured so that the brief dysphoria and fatigue (crash) that follow a single short binge by an occasional user do not lead to a diagnosis of withdrawal.

A. Cessation of (or reduction in) cocaine use that has been heavy and prolonged.
B. Dysphoric mood and two (or more) of the following physiological changes, developing within a few hours to several days after criterion A:
   (1) fatigue
   (2) vivid, unpleasant dreams
   (3) insomnia or hypersomnia
   (4) increased appetite
   (5) psychomotor retardation or agitation
C. The symptoms in criterion B cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

Table 11.6-3 DSM-IV Diagnostic Criteria for Cocaine Withdrawal

Animal Models of Withdrawal Although there is no easily observable animal model of cocaine withdrawal comparable to that for the syndromes seen with alcohol or opioid withdrawal, animal analogues of the postuse dysphoria and anhedonia often seen in humans have been proposed. In rats cocaine typically lowers the threshold for intracranial electrical self-stimulation. After 24 hours of cocaine self-administration, the thresholds for such self-stimulation are elevated above baseline for several days, which suggests a relative dopaminergic deficiency or insensitivity. Rats administered cocaine in a binge pattern had elevated dopamine concentrations in the nucleus accumbens during cocaine administration and below-normal concentrations during withdrawal; after 14 days of drug administration, recovery to pretreatment levels was prolonged.

Other Cocaine-Induced Disorders Other psychiatric syndromes that may develop in the course of cocaine use include cocaine-induced mood disorder, cocaine-induced anxiety disorder, and cocaine-induced sleep disorder. With each of those disorders the clinician should specify whether the onset occurred during intoxication or during withdrawal. DSM-IV also describes cocaine-induced sexual dysfunction and a category of cocaine-related disorder not otherwise specified (Table 11.6-4).

The cocaine-related disorder not otherwise specified category is for disorders associated with the use of cocaine that are not classifiable as cocaine dependence, cocaine abuse, cocaine intoxication, cocaine withdrawal, cocaine intoxication delirium, cocaine-induced psychotic disorder, cocaine-induced mood disorder, cocaine-induced anxiety disorder, cocaine-induced sexual dysfunction, or cocaine-induced sleep disorder.

Table 11.6-4 DSM-IV Diagnostic Criteria for Cocaine-Related Disorder Not Otherwise Specified

Cocaine-induced mood disorder can occur during use, intoxication, or withdrawal. During use and intoxication, the disorder is more likely to simulate a manic, hypomanic, or mixed episode; during withdrawal, it is more likely to involve a depressed mood. Such diagnoses are difficult to make during periods of active drug use or during the first week or two of withdrawal. Because sexual dysfunction, anxiety, and disturbed sleep are seen so commonly during cocaine use and withdrawal, the diagnoses should be made only when the disturbances or dysfunctions are judged to be in excess of that usually associated with intoxication and withdrawal and only when severe enough to require independent treatment or attention. Panic episodes that develop during cocaine use may persist for many months following cessation.

Lasting vulnerability to panic attacks may be linked to sensitization phenomena.

Comorbidity The frequent co-occurrence of other psychiatric disorders and cocaine dependence was noted during the cocaine epidemic in the early part of the twentieth century. The presence of other psychiatric disorders sharply increases the odds of substance dependence, and substance-dependent persons are more likely than the general population to meet the diagnostic criteria for additional psychiatric disorders.

Among cocaine users seeking treatment, the rates of additional current and lifetime diagnoses are regularly found to be elevated. In one study, about 300 patients (69 percent men, average age 28, mostly lower socioeconomic class) were interviewed using the Schedule for Affective Disorders and Schizophrenia (SADS). Symptoms occurring within 10 days after the last drug use were not used in making any diagnoses. The additional psychiatric diagnoses are shown in Table 11.6-5. The most common additional lifetime diagnoses were alcoholism (62 percent), antisocial personality (33 percent), and major depression (30 percent). In this sample, depression preceded the onset of drug abuse in about one-third of the patients, whereas alcoholism preceded the onset of drug abuse in 21 percent.

Psychiatric Diagnosis	Current Disorder	Lifetime Disorder
Major depression	4.7	30.5
Cyclothymia/hyperthymia	19.9	19.9
Mania	0.0	3.7
Hypomania	2.0	7.4
Panic disorder	0.3	1.7
Generalized anxiety disorder	3.7	7.0
Phobia	11.7	13.4
Schizophrenia	0.0	0.3
Schizoaffective disorder	0.3	1.0
Alcoholism	28.9	61.7
Antisocial personality disorder–DSM-III	32.9	32.9
Attention-deficit disorder	—	34.9

Table 11.6-5 Additional Psychiatric Diagnoses Among Cocaine Users Seeking Treatment (New Haven Cocaine Diagnostic Study Results, Percentages)

Some studies have found that cocaine users who seek treatment have higher rates of depression and adverse consequences of drug use than those who do not. Another study found that those not seeking treatment had comparably severe cocaine use and lifetime and current psychiatric disorders, and higher rates of polysubstance use and involvement with the law, but they also tended to minimize the adverse consequence of substance use and lacked pressure to seek treatment.

The prevalence of schizophrenia has generally been reported to be low among patients admitted to cocaine treatment programs, probably largely because people with schizophrenia are excluded from such programs. In fact, persons with schizophrenia commonly use cocaine or amphetamine and develop both dependence and toxic syndromes, although the diagnosis is not routinely made. Depending on the geographical area, an estimated 12 to 30 percent of persons with schizophrenia also abuse cocaine. It has been suggested that they use cocaine and stimulants to alleviate negative symptoms, postpsychotic depressive disorder of schizophrenia, and the side effects of antipsychotics. One nonblinded study did find fewer negative signs and more anxiety and depression among cocaine users with acute schizophrenia who had used cocaine prior to admission. A substantial proportion of schizophrenic patients admit having used cocaine during the months before hospitalization, but many are less candid about recent drug use, and urine tests frequently reveal recent cocaine use unsuspected by clinicians. Patients with schizophrenia who use cocaine tend to be younger and are more likely to be homeless and unemployed than psychotic patients who are not abusing drugs. Special programs involving peer-based support groups seem to be effective in linking substance-using schizophrenic patients to outpatient treatment programs.

Toxicity and Complications High doses of cocaine can cause a wide variety of toxic effects, including cardiac arrhythmias, coronary artery spasms, myocardial infarction, and myocarditis. Other reported cardiovascular toxicities include headache, ischemic cerebral or spinal infarction, and subarachnoid or cranial hemorrhage. Toxic effects on the CNS may include seizures, hyperpyrexia, respiratory depression, and death. Cocaine-related seizures and loss of consciousness are often reported on questionnaires given to heavy users (up to 27 percent); most episodes do not lead to emergency room visits. Rhabdomyolysis, not uncommon after large doses of cocaine, may contribute to renal complications, although vasoconstriction alone may suffice to account for renal damage. Sniffing cocaine can cause ulcers of the mucosa in the nose and perforation of the nasal septum from persistent vasoconstriction. Inhaled cocaine freebase is thought to induce lung damage. Gastrointestinal necrosis, caused by vasoconstriction, has been associated with the rupture of swallowed condoms containing large amounts of cocaine. By producing placental vasoconstriction, cocaine may contribute to fetal anoxia. A list of medical complications associated with cocaine intoxication and abuse is shown in Table 11.6-6.

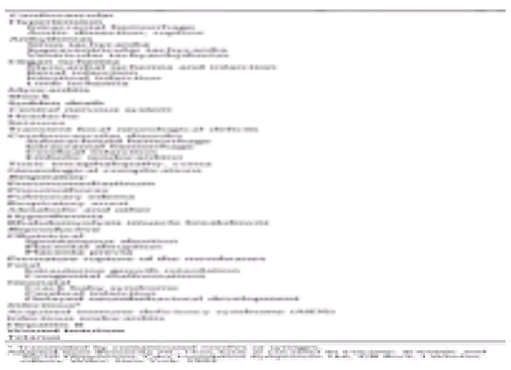

Table 11.6-6 Medical Complications of Cocaine Intoxication and Abuse

Seizures and respiratory depression may be related to cocaine's actions as a local anesthetic, and although the cardiovascular complications are primarily due to its effects on the reuptake of catecholamines in the peripheral nervous system, local anesthetic effects may contribute to myocardial depression. Animal studies reveal significant genetic vulnerability to various kinds of cocaine toxicities, suggesting that some of the observed toxicity in humans may not be predominantly dose dependent and predictable. Furthermore, cocaine elimination is nonlinear at high doses. Probably as a consequence of altered sensitivity of dopaminergic systems in the brain, chronic cocaine users may exhibit abnormal movements such as tics, choreoathetoid movements, and dystonic reactions. They may be particularly sensitive to neuroleptic-induced dystonias.

Cocaine use is frequently associated with increased sexual activity, and sometimes the exchange of sex for cocaine. Such behaviors put cocaine users at elevated risk for venereal diseases, including infection with the human immunodeficiency virus (HIV).

Treatment of Toxicity The treatment of acute cardiac emergencies is aimed at blocking the sympathomimetic effects of the drug and correcting arrhythmias. Some clinicians have recommended using combined a- and b-adrenergic receptor antagonists; however, others have advised against using adrenergic or dopaminergic blockers. Also suggested for myocardial ischemia are calcium channel blockers and nitroglycerine. Grand mal seizures may respond to diazepam (Valium). μ-Agonist opioids reduce cocaine lethality in animals. The fatal hyperpyrexia seen with cocaine shares some features with neuroleptic malignant syndrome and might respond to similar therapy (e.g., dantrolene [Dantrium]). Some researchers advise using ambient cooling.

Pathology and Laboratory Examinations Cocaine metabolites can be detected for varying lengths of time in urine, depending on the dose of cocaine and sensitivity of the assay. They can also be detected in blood, saliva, sweat, and hair. Blood and saliva provide a better index of current concentrations, whereas urine provides a longer window of opportunity for detecting use over the previous few days. Hair analysis can reveal drug use over weeks to months but has little applicability in clinical situations.

Some of the insults to the CNS (e.g., cerebral infarction) are detectable by computed tomography (CT) scans or magnetic resonance imaging (MRI), but most chronic cocaine abusers who do not also abuse alcohol show no evidence of CNS structural damage when examined by these methods. However, studies using PET or SPECT have revealed a variety of functional abnormalities in the brains of recently abstinent cocaine users. Compared with controls, heavy cocaine users showed perfusion defects in the cortex. Considerable improvement in cortical perfusion occurs after several weeks of abstinence, although blood flow in many instances still does not match that of normal controls. Carefully controlled studies have found that brain volumes of cocaine users are slightly smaller (show atrophy) than those of controls who do not use drugs, but do not differ from those of other drug abusers.

Compared with normal controls and patients withdrawn from alcohol, patients withdrawn from cocaine exhibited persistent resting tremor (4 to 6 Hz, similar to that of Parkinson's disease) lasting at least 12 weeks. The tremor is subtle and would not ordinarily be detected by clinical testing; no other cerebellar signs are present. They also exhibit slower reaction times in divided attention tasks that also persisted. Compared with age-matched and education-matched controls, chronic cocaine users are more likely to score in the impaired range on a neuropsychological screening battery. Impairment seems most obvious in concentration and memory, with less impairment in users who had been abstinent longer. To what extent the abnormalities in brain function are causally related to the signs and symptoms associated with cocaine cessation is uncertain.

A few early studies of cocaine addicts reported that almost all patients exhibited hyperprolactinemia lasting several weeks, which seemed consistent with a dopaminergic deficiency. However, several subsequent studies found either no evidence of hyperprolactinemia or a much lower incidence of that effect, and no apparent correlation between high prolactin levels and either cocaine craving or the extent of cocaine use.

DIFFERENTIAL DIAGNOSIS

The disorders associated with the use of cocaine need to be distinguished from both primary mental disorders and disorders induced by other classes of substances. A history of substance ingestion is important in making those distinctions. However, given the unreliability of self-reports about substance use and the likelihood that many users will deny any substance use at all, laboratory testing for drugs in body fluids and histories from collaterals are important. Disorders associated with cocaine use cannot be distinguished from those associated with amphetamines and related substances except by reliable history or laboratory tests. Users of cocaine (and amphetamine and related substances) may exhibit inappropriate optimism, euphoria, expansiveness, excessive talkativeness, and a decreased need for sleep sometimes associated with irritability in the context of a clear sensorium, a pattern also observed in manic and hypomanic episodes of bipolar disorder. However, these symptoms may not be obvious enough to suggest their relation to substance use, and the first indication of substance dependence may be financial difficulties, an arrest for drug sale or possession, or substance-induced toxicity.

Intoxication Cocaine intoxication is diagnosed when the effects of cocaine exceed the mood-elevating effects its users typically seek. The diagnosis of intoxication is appropriate when the effects are problematic enough to require differentiation from hypomanic or manic behavior. Cocaine intoxication can also be confused with amphetamine intoxication and phencyclidine (PCP) intoxication, although the last is usually associated with nystagmus, motor incoordination, and some cognitive impairment. Endocrine disorders (such as Cushing's disease) and excessive use of steroids should also be considered.

Toxic Psychosis Cocaine-induced toxic psychosis can be exceedingly difficult to differentiate from schizophrenia or other psychotic disorders characterized by hallucinations or delusions. The presence of vivid visual or tactile hallucinations should raise suspicion of substance-induced disorder. In areas and populations where cocaine use is common it may be necessary to provide only a provisional diagnosis until the patient can be observed and substance test results are obtained. Even then there may be difficulties because in some urban areas a high percentage of persons with established diagnoses of schizophrenia also use cocaine.

Cocaine-Induced Anxiety Disorder Cocaine-induced anxiety disorder must also be distinguished from generalized anxiety disorder and panic disorder. Panic disorder that has its onset associated with the use of cocaine may persist well beyond the period of cocaine use.

Other Symptoms The symptoms that may emerge during withdrawal—depression, dysphoria, anhedonia, disturbed sleep—need to be distinguished from those of primary mood disorders and primary sleep disorders. Unless the symptoms are more intense or more prolonged than is typical of cocaine withdrawal and so require independent treatment, the diagnosis should be limited to withdrawal, rather than cocaine-induced mood disorder. When a diagnosis of cocaine-induced mood disorder is made, it is important to specify whether the onset was during intoxication or withdrawal. One can also specify the subtype of mood disorder (i.e., with depressive, manic, or mixed features). In differentiating cocaine-induced mood disorder from the primary mood disorders the critical factor is the clinician's judgment that the mood disorder was caused by the cocaine. Generally, a cocaine-induced mood disorder, with onset during intoxication or withdrawal, remits in a week or two. It is appropriate, therefore, to withhold judgment about the diagnosis during the early phase of withdrawal. If depressed mood and related symptoms persist beyond a few weeks, alternative causes should be entertained. In reviewing diagnostic possibilities the clinician should consider the age at which symptoms began and a history of mood episodes that developed before the onset of cocaine use or during any long intervals without significant drug abuse.

COURSE AND PROGNOSIS

Not all cocaine users develop cocaine-related disorders. However, even occasional users can experience cocaine toxicity. Among those who do develop dependence, the time from first use to problematic use ranges from a few months to 6 or more years. The course of cocaine use is often marked by shifts from intranasal to intravenous use and inhalation of freebase forms. In the United States, since most persons who tried cocaine did not become dependent, the decreased cocaine use in the general population in the early 1990s following peak rates of self-reported use in the 1980s does not shed much light on the natural history of cocaine dependence.

Presently little information exists on untreated cocaine dependence, but there are findings on the course of cocaine use among those seeking treatment. A number of short-term (6-month to 2-year) follow-up studies seem to indicate that the course of dependence is more favorable for persons using cocaine who seek treatment than for heroin addicts who seek treatment.

Among veterans on the East Coast randomly assigned to either an inpatient program or a day-hospital program lasting 28 days, 60 percent reported abstinence at 4 months, which was largely maintained at 7 months. About 56 percent of urine specimens were negative for each group at 7 months. In a 1-year follow-up of almost 300 cocaine users, half treated as outpatients and half treated initially as inpatients, both groups showed reductions in self-reported cocaine use during the 30 days before the interview: from an average 17 days per month at admission to 1.1 days for inpatients; from 10 days per month to 5 days for outpatients. Although the data do not give the percentage of those who were entirely abstinent, the improvement levels were substantial and differed from those typically found among heroin-dependent patients seeking treatment. The prognosis appears to be even better for persons with social support.

DRUG ABUSE TREATMENT OUTCOME STUDY (DATOS) In DATOS, the largest recent study of drug users seeking treatment, about 3000 patients from 81 programs were interviewed at entry and 1 year after completion of index treatment. Cocaine dependence was the most frequent primary drug problem, but cocaine was also used by some whose major drug problem involved heroin or alcohol. Among the entire sample of clients 39 percent met criteria for antisocial personality disorder, and 14 percent met criteria for some other DSM-III-R Axis I disorder. At follow-up, weekly or more frequent cocaine use was reported by 35 percent of clients who stayed in long-term residential treatment for less than 3 months and 14 percent of those who stayed longer. For outpatient drug-free programs, the rates were 25 percent for those who stayed less than 3 months and 13.6 percent for those who stayed longer. Weekly or more frequent cocaine use decreased to about 20 percent for short-term inpatient treatment, but the drop was similar for those who stayed more than 2 weeks and those who stayed for a shorter time.

Since baseline levels of cocaine use differed, the results across program types are easier to compare when expressed as percentage reduction from pretreatment levels. Reduction in weekly or more frequent cocaine use for the long-term residential clients was 54 percent for those who stayed less than 3 months and 82 percent for who stayed longer than 3 months; for outpatient drug-free clients, it was 57 percent (less than 3 months) and 87 percent (longer than 3 months); for short-term inpatient clients, 79 percent (less than 2 weeks), and 74 percent (longer than 2 weeks). A substantial proportion of patients were referred for additional social support and treatment after discharge, and many participated in self-help programs. The investigators concluded that there was little difference among program types, but that very different types of patients self-select different treatments.

COCAINE-RETRO This retrospective study identified about 1000 charts of patients treated primarily for cocaine dependence at three types of programs—short-term inpatient, long-term residential, and drug-free outpatient. Some 772 of those patients were interviewed after discharge. Patients in all three types of programs reported substantial reductions not only in cocaine use but also in the use of other drugs. While the self-reports were generally confirmed by drug tests, cocaine use was underreported. About 37 percent of the drug tests were positive for cocaine metabolites (32 percent of the long-term residential patients, 33 percent of the drug-free

outpatients, and 46.4 percent of the short-term inpatients.) The researchers concluded that no significant differences in outcome existed across these three approaches. By self-report, weekly or daily cocaine or crack use was about one third of pretreatment levels for each of the modalities. However, different programs serve different groups. Patients entering these three modalities of treatment differed significantly in terms of gender, age, criminal justice pressure to enter treatment, and the extent and types of support and treatment received after discharge.

VARIETIES OF REMISSIONS Treatment of cocaine dependence may have various outcomes, including, at the extremes, complete relapse to cocaine dependence or total abstinence from cocaine and related drugs for a prolonged period—more than 12 months (sustained full remission). However, sustained partial remissions occur in which, after at least 1 month when no criteria of dependence have been present, one or more criteria of abuse or dependence are again met, but over the course of 12 months fewer cocaine-dependence criteria have been met than the three required for full relapse. There are also situations in which these patterns are observed, but the period of observation is not a full year (early full remission and early partial remission). Any pattern of remission may be observed while the person is in a controlled environment, and that fact should be specified. DSM-IV criteria for both abuse and dependence require maladaptive use associated with distress or impairment. Technically, a person can be in sustained full remission from cocaine dependence despite occasional use, provided the drug use causes no problems or distress and does not escalate. How often such a return to occasional nonproblematic use takes place is unknown.

Cocaine and Crime The typical interactive relation between the use of opioid drugs and crime generally holds true for cocaine users, but some significant differences exist. As with opioid users, considerable heterogeneity exists among cocaine users. Although a history of delinquency or antisocial behavior is often an antecedent to cocaine use, not everyone who uses cocaine or develops cocaine dependence engages in crime, even though the cost of using the drug may create serious financial problems for them. Sometimes, however, a person with no previous criminal behavior will engage in a variety of illegal activities ranging from fraud and white-collar crime to drug selling, prostitution, and predatory crime just to get enough money to buy cocaine. Among persons seeking treatment for any variety of substance abuse, use of cocaine is most highly correlated with income-generating crime.

In a nationwide sample of adolescents 40 percent of serious crimes committed by the entire sample were committed by the 1.3 percent who reported using cocaine. In the late 1980s, when cocaine use declined in the general population in the United States, it rose or merely stabilized among those arrested for a variety of serious offenses. In the late 1990s, however, cocaine use began to decline, especially among younger arrestees.

COCAINE, AGGRESSION, AND VIOLENCE One conceptual framework for thinking about the links between violence and substance (cocaine) use involves three major causal categories: psychopharmacological effects (effects of the substances), economic compulsion (violent crimes committed to obtain money for drugs), and systemic violence (associated with the business methods and lifestyle of drug dealers). Cocaine can induce states of paranoia and aggressive behavior, a common reason why cocaine users are brought to emergency rooms. However, pharmacologically induced aggression is not the major reason why cocaine and crime, and more specifically, cocaine and violence, are linked. Among those arrested for violent crime, the primary predictors of such crime are past arrests for violent crime, poor education, and poor intellectual ability. Past arrest for violence is also associated with antisocial personality disorder. Studies of violent predatory offenders indicate that most had histories of heavy involvement with multiple substance use and with serious crime as juveniles. Among predatory offenders high-frequency substance users were likely to use many substances, particularly heroin and cocaine, and to engage in a variety of crimes, including violent crimes, at high rates. Cocaine also has a nonpharmacologically based link to violent crime; many drug dealers who may not use cocaine routinely themselves resort to violence to protect or expand their customer base.

TREATMENT

Selection of Treatment Setting The general principles of treatment for cocaine dependence do not differ much from those for other varieties of drug dependence. Patient heterogeneity requires careful assessment of the patient and thoughtful selection among alternative treatment approaches. Cocaine dependence severe enough to require formal treatment is often associated with other psychiatric diagnoses. Not all cocaine users require extensive treatment; some who are not severely dependent respond to external pressures, as when employers insist on carefully monitoring substance use. Among the factors influencing selection are the severity of dependence, other drugs being used concurrently, comorbid medical and psychiatric disorders, as well as the preferences of the patient and the alternatives available. Availability, in turn, is often influenced by the policies of managed care companies, the patient's resources, and the types of therapy provided locally.

In general, treatment can be initiated in intensive outpatient settings, although often third party payers do not authorize, and public sector programs cannot provide, the duration of treatment or the intensity shown to be most effective. Some early studies found that inpatient treatment is associated with better outcomes at 1 year than outpatient treatment, even though patients initially treated as inpatients had more-severe cocaine problems. A study using random assignment found that at 4 months, working class veterans treated in a day-hospital program were about as successful in reducing their cocaine use and improving social functioning as those treated in a 28-day inpatient program. However, a somewhat higher proportion of those assigned to the inpatient setting completed the 28-day program. Currently, severe depression with suicidal ideation, psychosis, or substance use that has repeatedly failed to respond to outpatient efforts are the indications for hospitalization. A retrospective study of individuals treated for cocaine dependence in various settings found no advantage in outcome for inpatient treatment lasting longer than 2 weeks.

In many instances, the selection of the setting and type of treatment is made by neither the patient nor the clinician. Patients are often referred (mandated) to treatment by the criminal justice system, which often prefers long-term residential programs (therapeutic communities). The intensity and specificity of services for particular problems (i.e., medical, psychiatric, and vocational) are now considered important determinants of outcome in the specific problem areas.

Detoxification The cocaine withdrawal syndrome is distinct from that of opioids, alcohol, or sedative-hypnotics, since there are no physiological disturbances that necessitate inpatient or residential drug withdrawal. Thus it is generally possible to engage in a therapeutic trial of outpatient withdrawal before deciding whether a more intensive or controlled setting is required for patients unable to stop without help in limiting their access to cocaine. Patients withdrawing from cocaine typically experience fatigue, dysphoria, disturbed sleep, and some craving; some may experience depression. No pharmacological agents reliably reduce the intensity of withdrawal, but recovery over a week or two is generally uneventful. It may take longer, however, for sleep, mood, and cognitive function to recover fully.

Treatment Methods A number of psychological and pharmacological approaches to the treatment of cocaine dependence have been explored. More than 20 different pharmacological agents have been tested in the search for drugs to facilitate withdrawal, reduce postwithdrawal craving, or prevent relapse. In general, no drug with robust therapeutic efficacy has emerged. Psychosocial approaches have included various forms of individual and group psychotherapies, drug counseling, and self-help groups.

It is generally held that total and permanent abstinence from cocaine must be the goal of treatment for those who have developed symptoms of dependence; any use at all is seen as a prodrome to relapse. However, this perspective may underestimate the benefits that accrue from treatment that results in a substantial and prolonged reduction in drug use but falls short of total abstinence. In most studies of treatment effectiveness a significant proportion of patients report substantial reductions in use, even though they are not completely abstinent.

Psychotherapy and Behavior Modification Psychological treatment approaches have used cognitive-behavioral, psychodynamic, and general supportive techniques. One cognitive-behavioral method uses contingency contracting in which it is agreed in advance that for a specified period of time (e.g., 3 months), if the patient uses cocaine (as detected by supervised urine testing) the therapist will initiate actions that will result in serious adverse consequences for the patient, such as informing an employer or a professional credentials board. In one such study 48 percent of potential patients accepted such a contractual arrangement, and 80 percent of those patients successfully abstained from cocaine during the period covered by the contract; many of the successful patients relapsed when the contract expired. Although the technique is not widely used by individual therapists, the general principle of linking drug use and aversive contingencies is central to many employment-based programs and criminal justice programs that use drug (urine) testing. No adequate studies exist comparing such adverse contingency contracts with alternatives.

In contrast, several studies have compared relapse prevention and contingency contracts using positive rewards with 12-step type programs. In these studies, ambulatory cocaine abusers (mostly white, male, white-collar workers) were randomly assigned to either experienced therapists who used 12-step principles or therapists who used behavioral approaches that emphasized contingency management, community reinforcement, and positive rewards (such as vouchers) for cocaine-free urine samples. Retention rates were higher and cocaine use was significantly lower with contingency management and positive rewards. The same researchers found that positive reinforcement was more effective in terms of retention and abstinence than were otherwise identical behavioral treatment methods without positive reinforcement.

Another research group randomly assigned cocaine users (typically white men with more than 12 years of education) to relapse prevention or to a 12-step treatment

that used group techniques. Relapse prevention involved teaching the patient how to recognize high-risk situations and ways of dealing with negative emotions, but it did not offer positive material reinforcement such as vouchers or lottery tickets for cocaine-free urine samples. The 12-step treatment group was led by a man and woman cotherapy team using 3 of the first 12 steps, but it was not Alcoholics Anonymous (AA) or Narcotics Anonymous (NA). The groups did not differ at 6-month follow-up or at end of treatment in retention in treatment or reduction in cocaine use.

In another study, relapse prevention using cognitive-behavioral coping skills training was compared with clinical management in the context of a pharmacotherapy trial comparing desipramine (Norpramin) with placebo. Clinical management was intended to foster a supportive doctor-patient relationship, retention in the protocol, and compliance with medication. Unlike the other two studies, there were more women (27 percent), more minorities (54 percent), fewer high school graduates (24 percent), and fewer patients who were gainfully employed (53 percent). About 40 percent of patients completed the proposed 12-week protocol (mean of 7.2 weekly sessions). Overall, about 70 percent of patients improved, but cognitive-behavioral treatment did not appear better than clinical management. Although there was a trend for more patients receiving relapse prevention or desipramine to complete treatment, the differences were not significant. Relapse prevention appeared to be more helpful with those with more severe cocaine dependence. Desipramine seemed useful primarily for those with less-severe dependence and only early in the course of treatment. There were no differences between the response to drug and placebo at 12 weeks.

Supportive Therapy The specific methods of supportive therapy overlap the techniques used by behaviorists. Patients are helped to separate themselves from drug-using friends and from situations where cocaine is available and which increase drug craving. They are urged to abstain from other substances, such as alcohol and cannabis, because those substances have been reported to increase cocaine craving and the probability of relapse. Patients are also helped to repair the areas of their lives that once provided satisfaction and may have been damaged by the behaviors associated with cocaine use. In addition, patients may be encouraged to participate in Cocaine Anonymous (CA), AA, or NA as a means of gaining control over other substance use.

Psychodynamic, Interpersonal, and Combined Approaches Psychodynamically oriented clinicians emphasize the patient's unconscious motives for using cocaine (e.g., to relieve an inner sense of emptiness or depression). However, experienced clinicians with a wide range of skills believe that a combination of psychological approaches, with the emphasis tailored to the needs of the individual patient, is more effective than treatments that emphasize the principles of only one approach.

Group Psychotherapy Techniques Several distinct approaches to group psychotherapy with cocaine users have been described. Interpersonal group therapy focuses on relationships and uses the group interactions to illustrate the interpersonal causes of individual distress and to offer alternative behaviors. Modified dynamic group therapy is described as emphasizing character, as it manifests itself individually and intrapsychically, and in the context of interpersonal relationships with a focus on affect, self-esteem, and self-care. Both approaches share the view that the group should serve as an interpersonal anchor that leads first to more-stable emotional status and enables members to face unresolved life issues. Both approaches recognize the vulnerability of the patients to narcissistic injury and the need for a supportive, empathetic environment. Some psychotherapists emphasize that the focus in the early months of treatment must be exclusively on the disease and on achieving sobriety and recovery, but modified dynamic group therapy asserts that even early in the process, those goals are not incompatible with attention to characterological problems. Dynamic group psychotherapy assumes that substances are used as self-medication and that the persons most likely to use cocaine include those whose depression, anergia, or boredom is alleviated by it. However, those who place exaggerated value on assertiveness and self-sufficiency may also find cocaine alluring. Since patients must sometimes be abstinent for at least 2 weeks before participating in this type of group therapy, the technique may be more accurately described as relapse prevention rather than treatment to induce initial cessation. Few studies bear on the effectiveness of such group therapy.

Group Counseling Perhaps the most widely used form of psychosocial treatment for cocaine dependence is group counseling, in which the group is open ended with rolling admissions, the group leaders are drug counselors, many of whom are recovering from addiction, and the emphasis is on providing a supportive atmosphere discussing problems in recovery and encouraging participation in 12-step programs. It is unclear if this treatment is properly considered group therapy since the group is continually changing.

Intensive and Eclectic Treatment Most private practitioners who typically work with employed patients of middle and upper socioeconomic class probably use approaches best described as intensive and eclectic and consider the patient's motivation for treatment (stage of change). The goals of treatment and the techniques shift over time, with the initial work focused on forging an alliance with the patient and increasing the motivation to achieve abstinence. Treatment may initially involve several group and individual sessions per week focused on interrupting the substance-use cycle and on developing detailed plans for avoiding exposure to the substances and high-risk situations. Experienced clinicians advise taking supervised urine samples at least weekly, so that patients know that they are accountable for their actions. Results are generally considered measures of progress, not tests designed to catch the patient in lies. Emphasizing shared goals and instilling hope, trust, and confidence may foster the engagement of even resistant patients. While arguing about whether or not the patient is an addict may drive a patient from treatment, since some may not be ready to give up cocaine entirely, clinicians need to be able to work with such patients despite their own doubts that they may be enabling substance-using behavior.

Once abstinence is achieved, the goals of treatment shift to relapse prevention. Slips (occasional use of cocaine), especially during the first 60 days of treatment, should be used as learning experiences, with the focus on how to prevent reoccurrence. In the later stages of treatment a balance must be struck between enabling (tolerating continued use) and being so rigid about use that the patient leaves treatment. Sometimes a temporary suspension from the group, with continued individual sessions, is a therapeutically useful. Generally, the longer the retention in treatment, the better the long-term outcome. Self-help groups can fill the void in the patient's life once occupied by cocaine, but other drug-free alternatives exist.

Cocaine use is often linked to compulsive sexual activity. Some practitioners believe that it is important to ascertain what kinds of sexual behaviors and fantasies are associated with being high on cocaine, since sexual feelings can trigger a craving for cocaine. It may sometimes be appropriate to ask patients to refrain from sex for the first weeks of treatment.

Comparison of Psychotherapy Methods and Programs A large-scale collaborative multisite cocaine treatment study sponsored by the National Institute on Drug Abuse (NIDA) compared different psychosocial treatments. Following a brief period of stabilization, 487 cocaine-dependent patients were randomly assigned to one of four groups: weekly group drug counseling, group counseling plus individual drug counseling based on 12-step principles, group counseling plus individual cognitive therapy, or group counseling plus individual supportive expressive therapy. Group drug counseling was provided for 6 months; individual therapies were provided twice weekly for 3 months, then once weekly for 3 months. Therapy was manual guided, and cognitive therapy and supportive expressive therapists were fully trained professionals. Drug counselors had extensive experience with drug dependence treatment; about one third were in recovery from drug dependence. All patients reported substantial reduced cocaine use, whether measured by Addiction Severity Index composite, days of cocaine use in the past month, or number of months abstinent. Follow-up occurred 1 year after treatment entry (which for some patients was only 6 months after completion). Patients assigned to group drug counseling plus individual drug counseling reported significantly better outcomes; patients assigned to either cognitive therapy or supportive expressive therapy stayed in treatment longer, but outcomes in terms of cocaine use or dependence were not significantly better than those for group drug counseling alone. Among patients assigned to individual counseling, 73 percent achieved 1 month of complete abstinence, and 36 percent achieved 3 consecutive months of abstinence. In the other groups, 17 to 25 percent achieved 3 months of abstinence. By 6 months posttreatment, no delayed benefits of psychotherapy had emerged. Psychiatric severity and the presence of antisocial personality disorder did not significantly affect treatment outcome.

Patients assigned to once-weekly group counseling reported substantially reduced cocaine use starting from the first month of treatment. Although only 23 percent of patients continued for the 6 months of treatment available, the reported improvement in drug use was sustained through the 1 year follow-up. Adding individual sessions of either cognitive therapy or supportive expressive therapy twice weekly (provided by professionally trained therapists) to the weekly group counseling session increased retention in treatment but did not increase the proportion of patients who reported being abstinent or using substantially less cocaine.

In evaluating these outcomes one must know that all patients participated in a stabilization phase lasting 1 to 2 weeks during which they were required to attend one group session and two case-management visits before being assigned to a specific treatment. During that time there was attrition of less motivated patients. The therapists were highly qualified, carefully trained, used a manual to guide therapy, and were supervised. The study population was 77 percent male, 58 percent white and 60 percent employed, with a mean age of 34 and generally low psychiatric severity. Patients taking psychotropic medication, and those with schizophrenia, bipolar disorder, polysubstance dependence, or opioid dependence were excluded. However, 33 percent met criteria for alcohol dependence, 28 percent those for cocaine-induced mood disorder, 14 percent met full criteria for antisocial personality disorder, and 32 percent for adult antisocial personality disorder with history of conduct disorder.

Pharmacological Adjuncts Presently no pharmacological treatments produce decreases in cocaine use that compare with the decreases in opioid use seen when heroin users are treated with methadone, levomethadyl acetate (ORLAAM) (commonly called L-a-acetylmethadol [LAAM]) or buprenorphine. However, a variety of pharmacological agents, most of which are approved for other uses, have been and are being tested clinically for the treatment of cocaine dependence and relapse. Some of these agents are being used routinely by clinicians although little solid evidence exists for their efficacy. The most common premises on which

pharmacological interventions are based are as follows: (1) chronic cocaine use alters dopaminergic systems, so that giving up the drug is associated with a hypodopaminergic state characterized by dysphoria or anhedonia; (2) some cocaine users are using the drug to ameliorate a preexisting psychiatric disorder, such as major depressive disorder, dysthymic disorder, attention-deficit disorder, or cyclothymic disorder; (3) cocaine produces a sensitization, or kindling, effect that somehow predisposes to continued use; and (4) relapse is related to memories of the reinforcing and euphoric effects of cocaine, craving for which can be elicited by stress, other drugs, or environmental stimuli.

Cocaine users presumed to have preexisting attention-deficit/hyperactivity disorder or mood disorders have been treated with methylphenidate (Ritalin) and lithium (Eskalith), respectively. Those drugs are of little or no benefit in patients without the disorders, and clinicians should adhere strictly to maximal diagnostic criteria before using either of them in the treatment of cocaine dependence. In patients with attention-deficit/hyperactivity disorder, slow-release forms of methylphenidate may be less likely to trigger cocaine craving, but the impact of such pharmacotherapy on cocaine use remains to be demonstrated.

Many pharmacological agents have been explored on the premise that chronic cocaine use alters the function of multiple neurotransmitter systems, especially the dopaminergic and serotonergic transmitters regulating hedonic tone, and that cocaine induces a state of relative dopaminergic deficiency. Although the evidence for such alterations in dopaminergic function has been growing, it has been difficult to demonstrate that agents theoretically capable of modifying dopamine function can alter the course of treatment. This has been so even when studies in animal models and open-label studies suggested that they would be successful. In well-designed, controlled trials that obtained objective evidence of drug use, the following agents are among those that have not been found to reduce cocaine use: neurotransmitter precursors, (e.g., dopa; tyrosine); dopaminergic agonists, (bromocriptine [Parlodel]; lisuride; pergolide [Permax]); and antiparkinson drugs that may also affect the dopaminergic system (amantadine [Symmetrel]).

Tricyclic antidepressant drugs such as desipramine and imipramine (Tofranil) have also been tried. Although some double-blind studies that relied heavily on self-reports of drug use yielded some positive results, other studies have not found them significantly beneficial in inducing abstinence or preventing relapse. There is no consensus that the effects of desipramine are robust or reliable enough to justify routine use, but used early in treatment, it may have some transient benefit for patients who are less severely dependent.

Also tried in pilot or open-label studies but not confirmed effective in controlled studies, are other antidepressants, such as bupropion (Wellbutrin), monoamine oxidase (MAO) inhibitors (selegiline [Eldepryl]); selective serotonin uptake inhibitors (SSRIs) (e.g., fluoxetine [Prozac]); mazindol (Sanorex); pemoline (Cylert); antipsychotics (e.g., flupenthixol); lithium; several different calcium channel inhibitors, anticonvulsants (e.g., carbamazepine [Tegretol] and valproic acid [Depakene]). One double-blind study not yet replicated found that 300 mg a day of phenytoin (Dilantin) reduced cocaine use.

Several agents are being developed but have not been tried in human studies. These include agents that would selectively block or stimulate dopamine receptor subtypes (e.g., selective D_1 agonists) and drugs that can selectively block the access of cocaine to the dopamine transporters but still permit the transporters to remove cocaine from the synapse. Another approach is aimed at preventing cocaine from reaching the brain by using antibodies to bind cocaine in the bloodstream (a so-called cocaine vaccine). Such cocaine-binding antibodies do reduce the reinforcing effects of cocaine in animal models. Also under study are catalytic antibodies that accelerate the hydrolysis of cocaine; and butyrylcholinesterase (pseudocholinesterase), which appears to hydrolyze cocaine selectively and is normally present in the body.

Acupuncture Use of auricular acupuncture to treat cocaine and other varieties of dependence behavior has become popular among some groups, including some drug courts and prison-based programs. Controlled studies of its efficacy for treating cocaine dependence (using sham acupuncture) have been conducted but are subject to varying interpretations; large differences in cocaine use (as measured by urine tests) have not been shown. In programs offering treatment in a drop-in outpatient setting, clients typically are instructed to stay as clean and sober as they can and to come in daily for treatment; clinic rules are minimal; treatment usually takes place in groups, with patients sitting in comfortable chairs for about 45 minutes. Dropout rates are generally high. Herbal teas are often consumed as part of the treatment.

Also used for treatment of cocaine dependence are several forms of transcranial electrical stimulation (neuroelectric therapy [NET]). A comparison of NET with sham NET revealed no differences in successful detoxification over a 12-day hospitalization.

Special Populations and Special Considerations

Mixed Addictions

PATIENTS MAINTAINED ON METHADONE Behavioral techniques and pharmacological agents have been used to help patients maintained on methadone reduce their use of cocaine (as measured by urine tests). Some methadone programs use progressive sanctions, such as decreased take-home privileges, a decreased methadone dosage, and finally in some cases, discharge from the program. However, in one comparison study, decreasing the methadone dosage proved far less effective than giving small (5 mg) increases (up to 120 mg a day in some cases) for each cocaine-positive urine test. However, an analysis of the relation between cocaine use and methadone dose at another clinic did not find less cocaine use among patients maintained on higher doses of methadone. Providing small rewards (such as vouchers for goods and services) contingent on submitting a urine specimen negative for cocaine does reduce the frequency of cocaine use.

Other pharmacological agents that have been tried for methadone-maintenance patients who also use cocaine include bromocriptine, amantadine, desipramine, bupropion, carbamazepine, and buprenorphine. In a controlled comparison of amantadine, desipramine, and placebo, self-reports of cocaine use were lower for both medication groups at 4 weeks, but there were no significant differences in cocaine-positive urine tests, and there were no significant group differences at 8 or 12 weeks.

Early animal studies and open-label clinical studies suggested that buprenorphine might help decrease cocaine use among patients dependent on both opioids and cocaine. In three double-blind controlled studies comparing buprenorphine and methadone (one of which was not specifically designed to test effects on cocaine use), cocaine use was not affected, although both buprenorphine and methadone significantly decreased heroin use. In animal models buprenorphine appears to antagonize some of the lethal effects of cocaine and to increase its reinforcing effects. Carbamazepine, which substantially stimulates the metabolism of methadone, has not shown any specific effects on cocaine use in controlled studies. In summary, no pharmacological agent has been shown to have reliably robust effects on cocaine use among patients maintained on methadone.

COCAINE AND ALCOHOL In patients dependent on both cocaine and alcohol, the opioid antagonist naltrexone (Revia) had no effect on cocaine use. In an open-label trial, disulfiram (Antabuse) seemed useful for reducing cocaine use, perhaps because it discouraged the use of alcohol which is often used with cocaine.

Women, Pregnant Women, and Their Children Data suggest that although women who seek treatment tend to be more severely drug dependent, they respond as well to treatment as do men. Women dependent on cocaine have a number of special needs, especially with respect to their physical health. Cocaine use by pregnant women represents a hazard to the fetus.

At the peak of the cocaine epidemic, 10 to 45 percent of women who received obstetrical care in some urban hospitals reported using cocaine at some time during pregnancy. There is some controversy about the frequency and permanence of any damage sustained by the fetus, but there is little question that maternal cocaine use can be associated with some perinatal morbidity and mortality. Separating cocaine effects from the effects of other substances and of other maternal behavior is exceedingly difficult but some toxicity may be due to cocaine-induced hypertension, tachycardia, and vasoconstriction, which lead to impaired placental blood flow and decreased transfer of nutrients and oxygen to the fetus.

Some toxicity also results from direct effects of cocaine on the fetus. Depending on the severity of the placental and fetal effects and when they occur during gestation, the result may be teratogenic, with destruction of developing tissues or overall retardation of fetal growth. Commonly reported abnormalities in fetuses exposed to cocaine are microcephaly and structural abnormalities in brain and urinary tract development. Ischemic and hemorrhagic lesions in the newborn brain have also been reported. Spontaneous abortions, premature birth, placenta previa, and abruptio placenta are complications of pregnancy that are more common among women who use cocaine than among nonusers; low-birth-weight babies are also common.

Despite the risks, only a small percentage of the infants exhibit what might be called a neonatal cocaine exposure syndrome, which consists of poor feeding, irritability, tremor, and abnormal sleep patterns. Those abnormalities are most evident on the second day after birth and last for less than a week or two. Sudden infant death syndrome (SIDS) is reported to be more common among infants exposed to cocaine in utero, but since there are no controls, the evidence for this is not

conclusive. The long-term neurological, cognitive, and developmental consequences of intrauterine cocaine exposure are still not clear, but after the first few months, most of these children appear to be developmentally within normal limits. A follow-up study tested children ages 6 to 9 who were exposed prenatally to cocaine and then compared them with unexposed controls matched for gender, birth weight, ethnicity, and socioeconomic status. Intelligence quotient (I.Q.) scores did not differ and were unchanged when adjusted for caregiver I.Q. and home environment.

There appears to be no contraindication to discontinuing cocaine abruptly during pregnancy (unlike opioids), and prompt abstinence from cocaine should be the goal of treatment.

Patients With Other Psychiatric Disorders Persons with cocaine-dependence who also have mood or anxiety disorders are generally managed in programs that focus on the substance-use problem. Several clinical reports indicate that cocaine users with bipolar disorders generally are not compliant with prescribed lithium.

Patients with a history of attention-deficit/hyperactivity disorder are also likely to have antisocial personality disorder. Although some studies found that patients with antisocial personality disorder and cocaine abuse responded relatively poorly to treatment, more recent studies found that in terms of their cocaine use, improvement was comparable to that of patients who did not have antisocial personality disorder. Up to 10 percent of persons meeting criteria for cocaine abuse also met DSM-IV criteria for adult attention-deficit/hyperactivity disorder. Clinical trials using methylphenidate on the assumption that cocaine use was an attempt to self-medicate attention-deficit/hyperactivity disorder have led to the caution that in most cases, the patient's demand for methylphenidate escalates and craving for cocaine is stimulated. A slow-release form of methylphenidate may be less likely to elicit craving, but its efficacy in reducing cocaine use has not been demonstrated.

PATIENTS WITH DEPRESSION Symptoms of depression are common among patients seeking treatment for cocaine dependence. In studies of tricyclic drugs and SSRIs in patients who were using cocaine, outcomes of those who initially had depressive symptoms and patients who were initially without such symptoms did not differ. In a large-scale study of psychosocial treatment, cocaine-dependent patients who met criteria for any Axis I disorder were less likely to drop out once they became engaged in treatment. The relation of symptoms of depression and of concurrent major depression to treatment outcome needs further clarification. The most sensible course is to treat significant depression with antidepressants only if they persist after cessation of drug use.

PATIENTS WITH SCHIZOPHRENIA Persons with schizophrenia and other psychotic disorders who use cocaine have been managed within either primary drug treatment or psychiatric facilities. In all settings, concurrent use of alcohol and cocaine further complicates treatment. There is a growing consensus that parallel treatment (two separate programs, one treating substance dependence/abuse and the other treating schizophrenia) is less effective than a comprehensive integrated program that deals with both disorders concurrently.

Intensive case management that gives patients access to social services makes it possible to treat patients with schizophrenia who abuse cocaine in the same day-hospital setting as non-substance-abusing patients. However, requiring abstinence for admission or retention may be unrealistic for such patients, and some of the traditional rules concerning substance abuse and poor attendance may need to be relaxed. Most patients are not initially motivated to participate in abstinence-oriented programs, but when attention is paid to a patient's level of motivation, most can be engaged and moved toward active treatment.

The use of cocaine, amphetamines, and cannabis exacerbates schizophreniform disorder, and such use is not an uncommon problem. Among patients receiving public assistance or disability payments, such use seems to increase substantially shortly after they receive monthly checks. Some cocaine (or stimulant) use may represent an attempt to alleviate negative symptoms, depression, or the side effects of antipsychotic agents. The last problem might be dealt with by using newer antipsychotic agents that have fewer extrapyramidal adverse effects.

SUGGESTED CROSS-REFERENCES

See Chapter 1 for discussion of the neural sciences and Chapter 2 for a presentation of neuropsychiatry and behavioral neurology. A classification of mental disorders appears in Chapter 9. An introduction and overview of substance-related disorders is presented in Section 11.1, and amphetamine-related disorders in Section 11.3. Various drugs are discussed in the chapter on biological therapies (Chapter 31), particularly sympathomimetics in Section 31.21. Schizophrenia is discussed in Chapter 12, and other psychotic disorders in Chapter 13. Animal research and its relevance to psychiatry is discussed in Section 5.4. Cognitive-behavioral therapy is discussed in Section 48.3

11.7 HALLUCINOGEN-RELATED DISORDERS

HENRY DAVID ABRAHAM, M.D.

The discovery of lysergic acid diethylamide (LSD) by Albert Hofmann in 1943 proved to be a double-edged sword that simultaneously widened the understanding of central mechanisms of neural regulation and led to the widespread abuse of hallucinogenic drugs. The emergence of this semisynthetic hallucinogen raised important questions about synaptic transmission, the mechanisms of hallucinations, and the phenomenology of the functional psychoses. However, the possibilities of the use and misuse of such hallucinogens was greater than that of botanical hallucinogens such as psilocybin mushrooms and peyote cacti because synthetic hallucinogens are readily made, easily distributed, cheaply sold, and thousands of times more potent than botanical preparations. These factors, among others, led to the abuse of synthetic hallucinogens and to the development of several disorders now seen in psychiatric practice.

DEFINITION

An hallucinogenic drug has been defined by the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) as “any agent which has alterations in perception, cognition and mood as its primary psychobiological actions in the presence of an otherwise clear sensorium. Most commonly this includes indoleakylamines and phenethylamines, and excludes, inter alia, the anticholinergics, the arylcyclohexylamine dissociative anesthestics such as phencyclidine, stimulants such as amphetamine and cocaine, bromism and heavy metal intoxication.” Excluded from this class are agents that produce hallucinations in the context of a delirium. The term *hallucinogen* emphasizes perceptual effects, but the literature supports ample evidence of the effects of hallucinogens on mood and cognition as well. Table 11.7-1 illustrates the representative hallucinogens.

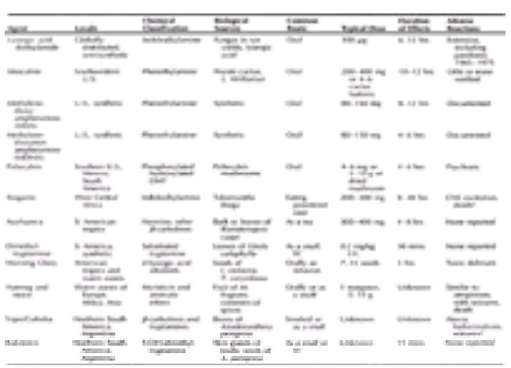

Table 11.7-1 Overview of Representative Hallucinogens

By definition these drugs are intoxicants. Clinically the use of hallucinogenic drugs is associated with panic attacks, hallucinogen persisting perception disorder (flashbacks), psychosis, delirium, and mood and anxiety disorders. Empirical evidence more strongly supports the first three as discussed below. Although DSM-IV defines hallucinogen abuse and dependence with criteria applicable to other agents of abuse, hallucinogens differ from addictive drugs in that cessation after long-term use is not associated with a distinct withdrawal syndrome.

HISTORY

The omnivorous diet of primeval man no doubt led to the discovery of certain plants which, while meager in nutrition, possessed extraordinary abilities to alter consciousness. Thus was introduced to history a class of plants that assumed importance in ritual, religion, and recreation. One of the earliest plants used for its mind-altering properties is the fly agaric mushroom, *Amanita muscaria*, which is thought to have been discovered by aboriginal Siberian hunters who observed intoxicated reindeer. The same plant is believed to have been described as *soma* in the 3500 year old Sanskrit text, the Rigveda. The Eleusian Mysteries of ancient Greece were thought to have used ergot alkaloids in the holy potion, *kykeon*, to induce mystical states. In the Middle Ages women used brooms as medicinal applicators for the vaginal insertion of hallucinogenic ointments, a probable origin of the contemporary association of brooms with witches. In 944 AD the ingestion of ergot-laden rye, produced by the ergot fungus *Claviceps purpurea*, is said to have killed 40,000 people in Europe.

In the nineteenth century the mycologist Mordecai Cubit Cooke discriminated opiates from hallucinogens, a distinction that was more precisely drawn by Ernest Bosc DeVeze and Louis Lewin decades later. A Texas physician, John Briggs, described his self-experimentation with muscale buttons in 1887, the alkaloids of which Lewin described in the following year. Field work began in earnest in the 1920s, leading to the identification of 120 plants possessing hallucinatory properties, 80 percent of which are found in the western hemisphere. In 1928 Heinrich Klüver used mescaline to analyze the formal structure of hallucinations. The ethnobotanical work of Richard Schultes and others documented the use of hallucinogens among contemporary cultures such as the Waiká of Brazil and the Huichol of Mexico. Psychoactive agents were described in the bark of Banisteriopsis (b-carbolines), seeds of the common Morning Glory (lysergic acid), and skin glands of toad Bufo bufo (bufotenine). In 1943 Albert Hofmann discovered LSD by tracking down its identity after he accidentally ingested the drug and suffered a transient psychosis. Over the next 20 years psychiatrists in England and the United States attempted to use LSD as a therapeutic agent for a variety of illnesses, with unconvincing results. By the 1950s the drug was used by academicians, theologians, and the military for a variety of purposes. In the 1960s fascination with the drug, fueled by the American media, exploded in an epidemic of hallucinogen use involving much of Europe and the United States. The residuum of this epidemic continues today as an endemic among the young.

COMPARATIVE NOSOLOGY

DSM-IV lists a number of hallucinogen-related disorders (Table 11.7-2), but contains specific diagnostic criteria only for hallucinogen intoxication and hallucinogen persisting perception disorder (flashbacks). The diagnostic criteria for the other hallucinogen-related disorders are contained in the DSM-IV sections that are specific to each symptom. For example, hallucinogen-induced mood disorder is discussed with other mood disorders. Table 11.7-2 compares several diagnostic systems.

Hallucinogen use disorders
Hallucinogen dependence
Hallucinogen abuse
Hallucinogen-induced disorders
Hallucinogen intoxication
Hallucinogen persisting perception disorder (flashbacks)
Hallucinogen intoxication delirium
Hallucinogen-induced psychotic disorder, with delusions
Specify if:
With onset during intoxication
Hallucinogen-induced psychotic disorder, with hallucinations
Specify if:
With onset during intoxication
Hallucinogen-induced mood disorder
Specify if:
With onset during intoxication
Hallucinogen-induced anxiety disorder
Specify if:
With onset during intoxication
Hallucinogen-related disorder not otherwise specified

Based on American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, ed 4. ©American Psychiatric Association, Washington, DC, 1994.

Table 11.7-2 DSM-IV Hallucinogen-Related Disorders

Differences between the revised third edition of DSM-III-R and DSM-IV are as follows: (1) psychoactive substance abuse was a residual category in DSM-III-R; DSM-IV provides specific diagnostic criteria for substance abuse; (2) the DSM-IV criteria for substance dependence are also modified from those of DSM-III-R; (3) DSM-IV generally permits subtyping of dependence with (or without) physiological dependence, but because hallucinogens produce no withdrawal, that option does not apply here; DSM-IV expands the list of hallucinogen mental disorders to include (4) hallucinogen intoxication delirium and (5) hallucinogen-induced anxiety disorder. Hallucinogen-induced psychotic disorder in DSM-IV is coded as a substance-induced psychotic disorder, developed concurrently with drug use, and is characterized by a longer-than-expected period of psychotic symptoms; as a rule of thumb for hallucinogens this means beyond 48 hours. Hallucinogen persisting perception disorder in DSM-IV applies to intermittent flashbacks, recurring days to years after the last hallucinogen use. This disorder now appears in certain subjects to be both permanent and constant. The 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) makes provision for flashbacks, but confuses the issue by considering them a psychotic disorder, which most authorities do not. DSM-IV provides no diagnosis for persisting hallucinogen-induced psychosis, although the literature now supports the existence of this disorder.

In general, ICD-10 does not draw helpful distinctions between hallucinogen-related disorders. ICD-9 provides for seven hallucinogen-induced diagnoses, but summarily lumps four of them under “nondependent abuse.” The *International Classification of the Diseases, 9th Revision, Clinical Modification* (ICD-9-CM), a U.S. government classification for Medicare and Medicaid billing, calls intoxication “abuse” and provides no separate diagnosis of hallucinogen-induced anxiety disorder or flashbacks. ICD-10 names abuse “harmful use,” and has neither hallucinogen-induced mood disorder nor hallucinogen-induced anxiety disorder diagnoses; in part, these omissions reflect the lack of systematic research of these entities.

EPIDEMIOLOGY

Surveys in the United States and Europe report that the use of hallucinogenic drugs among the young exceeds that of cocaine and heroin use. In the United Kingdom from 1989 to 1993 use of LSD rose from 7 to 11 percent. A survey of 781 German adolescent drug abusers found that 14.1 percent used LSD. A survey of 458 Danish students found that 7.2 percent experimented with a European hallucinogenic mushroom, *P. semilanceata*. Survey data in the United States show higher trends. In an analysis of data from two large universities, 13.7 percent of the students surveyed reported using hallucinogenic mushrooms. Trend data, gathered annually from approximately 15,000 U.S. high school seniors, reveal a precipitous rise in hallucinogen use from 10.3 to 15.1 percent in the decade from 1987 to 1997, beginning in 1991 (Fig. 11.7-1). Demographic data from 18,054 American householders in 1990 shows that LSD use is most likely to occur between the ages of 18 and 25. Use is more common among males, whites, and Hispanics and is more likely to occur in the American Northeast and West. Use is associated with lower levels of employment and education, although the parents of LSD users are more often of a white-collar socioeconomic status. Among American undergraduates the prevalence of the use of 3, 4-methylenedioxy-N-methylamphetamine (MDMA, “ecstasy”) has ranged widely from 2.3 to 24 percent in the first half of the 1990s.

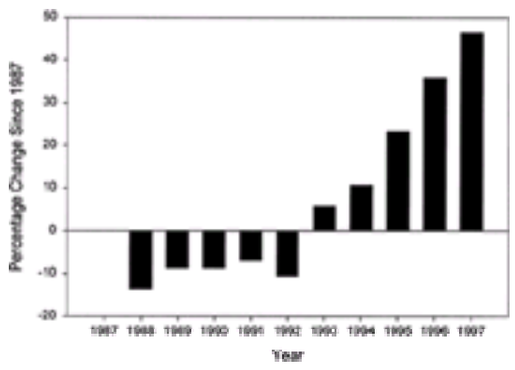

FIGURE 11.7-1 Percentage change in lifetime use of hallucinogen use in U.S. high school seniors since 1987.

PHARMACOLOGY

Several hundred known plants possess hallucinogenic properties. They vary widely in potency, but are orders of magnitude less potent than synthetic agents. Alexander Shulgin has synthesized and screened 179 phenethylamines for these effects in humans. The commonly used hallucinogens are the peyote cactus, containing mescaline, which is indigenous to the American Southwest and northern Mexico; mushrooms producing psilocybin and its active metabolites; and chemically substituted tryptamines such as dimethyltryptamine (DMT) and LSD. Hallucinogens have been classified according to their course of action assuming their usual clinical route of administration. By this schema, parenteral DMT is ultra–short-acting, with an onset when given parenterally of 1 to 5 minutes. Diethyltryptamine is short-acting (15–30 minutes), oral psilocybin is intermediate (30–60 minutes orally), LSD is long-acting (4–10 hours), and oral 2, 5-dimethoxy-4-methyl-amphetamine (DOM) and ibogaine are considered ultra–long-acting, lasting as long as 24 hours.

Of the hallucinogens the pharmacology of LSD has been studied most extensively. The drug is active orally in doses of 50 to 100 µg. It is readily absorbed through the mucous membranes and exerts its psychological effects within 20 minutes. The drug is marketed illicitly as single crystals, drops deposited on blotter paper, or in sugar cubes. A drop of LSD when placed on a piece of blotter paper is for all practical purposes invisible. To mark its location, the spot is often stamped with an image of a cartoon character or New Age design. The drug's potency is underscored by the report of a drug dealer who was apprehended after he accidentally became psychotic from sitting on a wet surface with a sheet of “blotter acid” in his back pocket. Because of such potency the drug is seldom injected. Although it can cause a toxic psychosis lasting 6 to 12 or more hours, only 1 percent of the ingested drug reaches the central nervous system. Hallucinogenic drugs bind to multiple synaptic receptors in the brain. It has been shown that hallucinogenic potency is associated with binding affinities at the serotonin type 2 (5-hydroxytryptamine [5-HT $_2$]) receptor where these drugs act as partial agonists. Repeated administration of LSD in rats downregulates the density of 5-HT $_2$ binding sites, further implicating this receptor in the drug's mechanism of action. In monkey brain LSD is anatomically distributed maximally in the pituitary, pineal, the visual and auditory cortex, the hypothalamus, and the limbic cortex. This parallels the finding of high concentrations of 5-HT $_2$ receptors in human cerebral cortex.

Studies in animals have produced mixed results on toxicity. Animals as a rule do not self-administer hallucinogens as they do reinforcing agents such as heroin and cocaine, possibly reflecting the drugs' predilection for affecting higher cortical centers that are less developed in nonhuman mammals. The LD $_{50}$ of LSD in mice is 150,000 µg/kg, whereas an elephant was killed by an LSD injection of 100 µg/kg. Accidental ingestion of between 10,000 and 100,000 µg LSD by eight persons resulted in confusion, hallucinations, and hemorrhage, but no deaths.

However, fatalities have been documented with MDMA and 3,4-methylenedioxy-N-ethylamphetamine (MDEA, “Eve”). These drugs are ring-substituted isopropylamines. Drug discrimination studies in rats suggest that MDMA is “amphetamine-like.” Although MDMA was first synthesized in 1914, the drug achieved prominence in 1986 when clinicians claimed that the drug enhanced psychotherapy and improved social function. The following year widespread use was reported on

college campuses. In the following decade serotonergic neurotoxicity was described in numerous animal models for both MDMA and 3,4-methylenedioxy-N-amphetamine (MDA). MDMA deaths have been associated with drug-induced compulsive dancing, hyponatremia, and hyperthermia. Autopsy studies reveal massive hepatic necrosis and changes of heat stroke. Serotonergic cells appear particularly sensitive to MDMA; for these cells the drug is cytotoxic in rodents and monkeys, with effects lasting as long as 18 months. The coadministration of either selective serotonin uptake inhibitors or 5-HT $_2$ antagonists in animals appear to attenuate MDMA neurotoxicity.

LSD is readily metabolized by the liver through hydroxylation and conjugation. Although tolerance occurs after 2 to 3 days of serial use, there is no withdrawal syndrome from hallucinogens, and no physiological dependence. Psychological dependence has been clinically observed. Cross-tolerance occurs between LSD, mescaline, and psilocybin, but not between these agents and amphetamines or marijuana. Phenylalkylamines, however, may elicit both hallucinogenic and amphetamine properties in varying ratios depending on the nature of the substituted moieties.

PSYCHOPHARMACOLOGY

The classic description of the psychological effects of LSD remains that by Albert Hofmann, recalled in retrospect after an attempt to record his experiences ended with the entry into his journal, “Beginning dizziness, feeling of anxiety, visual distortions, symptoms of paralysis, desire to laugh—”

In addition to these symptoms, there are signs of sympathetic arousal, including mydriasis, hypertension, hyperreflexia, tachycardia, and tremor. Following this period of arousal, visual illusions and hallucinations may occur. They can be in any sensory modality, but visual events predominate. Synesthesia, in which one sensory modality stimulates a second one, (seeing sounds or hearing colors) is clinically rare, and probably reflects heightened connectivity between adjacent cerebral regions. Mood changes, by comparison, can be profound or can or reflect preexisting emotional conflicts. Feelings of terror, depression, and panic, described by Hofmann, may present to the clinician as a psychiatric emergency. As these perceptual and affective components of the trip subside, the user may be left with cognitive states of transcendence or paranoia. The entirety of the trip seldom lasts more than 12 hours (Table 11.7-3).

DSM-IV	DSM-III-R	ICD-9	ICD-9-CM	ICD-10
Hallucinogen abuse	Hallucinogen abuse	Nondependent abuse of hallucinogens	Hallucinogen abuse	Hallucinogen harmful use
Hallucinogen dependence	Hallucinogen dependence	Hallucinogen dependence	Hallucinogen dependence	Hallucinogen dependence syndrome
Hallucinogen intoxication	Hallucinogen hallucinosis	Nondependent abuse of hallucinogens	Hallucinogen abuse	Hallucinogen acute intoxication
Hallucinogen intoxication delirium		Acute confusional state	Drug-induced delirium	Hallucinogen acute intoxication
Hallucinogen-induced mood disorder	Hallucinogen mood disorder	Nondependent abuse of hallucinogens	Drug-induced organic affective syndrome	
Hallucinogen-induced anxiety disorder		Nondependent abuse of hallucinogens	Hallucinogen abuse	
Hallucinogen-induced psychotic disorder	Hallucinogen delusional disorder	Hallucinogen paranoid and/or hallucinatory state	Drug-induced organic delusional syndrome	Hallucinogen psychotic disorder
Hallucinogen persisting perceptual disorder	Posthallucinogen perception disorder			Hallucinogen residual psychotic disorder (flashbacks)
Hallucinogen-related disorder NOS	Hallucinogen organic mental disorder NOS		Unspecified drug-induced mental disorder	Other or unspecified mental or behavioral disorder induced by hallucinogen

Table 11.7-3 Hallucinogen Diagnoses, DSM and ICD

Initial studies compared the above hallucinogen-induced psychotic disorder to schizophrenia, but clinical and single photon emission tomography (SPECT) studies now clearly differentiate hallucinogen-induced psychotic states from schizophrenic states. The type of hallucinogenic experience is strongly influenced by the personality of the user, the instructional set, the setting in which the drug is used, and the chemical structure of the drug. More severe reactions occur when the patient is given the drug surreptitiously.

ETIOLOGY

The rising trend of hallucinogen use among high school students in the United States since the late 1980s attests to the interplay of several factors in their use. Longitudinal studies show that hallucinogenic drugs like LSD occupy a midrange position in the progression of many drug use careers, in that many adolescents experiment first with legal drugs (alcohol and tobacco), fewer progress to misdemeanor drugs (marijuana and hallucinogens), and fewer still to felony drugs (cocaine and heroin). Accessibility is a key factor in drug use, and is high for LSD. A student can purchase a single dose of LSD for a few dollars, a fraction of the cost of a first-run Hollywood movie. The ease with which the synthetic hallucinogens can be manufactured in illegal laboratories keeps the price down. Facilitating the distribution of hallucinogens is their efficacy in microgram quantities, permitting them to be smuggled at will into any quarter of society, including schools, hospitals, and prisons, and almost as a routine, into rock concerts. The drugs are also attractive because of their prolonged effects and the absence of withdrawal symptoms and other stigmata of addiction.

PSYCHIATRIC DISORDERS

With the excitement that accompanied the discovery of LSD in 1943 came a spate of experiments attempting to glean therapeutic benefits from this new agent. A review of all human studies published from 1960 to 1994 listed in *Index Medicus* revealed that favorable reports of LSD's effects in humans predominated from 1960 to 1965. But beginning in 1968, the Summer of Love in the United States that arguably was the modal peak in the LSD epidemic of the 1960s, adverse reports began to outnumber positive ones, initiating a legal, psychiatric, and social reaction against the use of this class of drugs; this reaction has persisted into the present (Fig. 11.7-2). The figure describes a curve that can be applied not only to the trends found in the literature of LSD, but to any number of enthusiasms that mark the history of ideas, each characterized by initial excitement followed by sober reassessment. DSM-IV lists ten disorders associated with hallucinogenic drugs. (Table 11.7-2). Of these, the commonest adverse reactions to hallucinogens are intoxication, hallucinogen-induced anxiety disorder, hallucinogen persisting perception disorder, and hallucinogen-induced psychotic disorders. Clinical reports also support the diagnosis of hallucinogen-induced mood disorder.

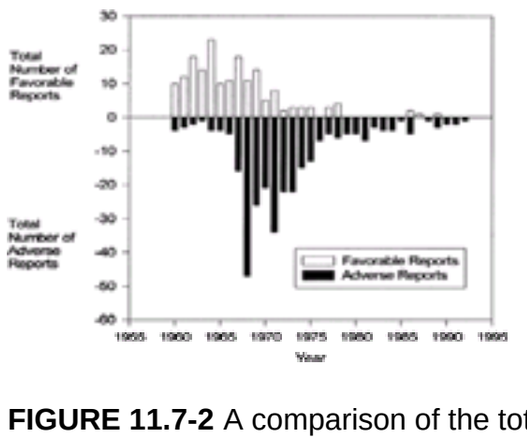

FIGURE 11.7-2 A comparison of the total number of clinically favorable and adverse reports on LSD appearing in the scientific literature between 1960 and 1995.

Hallucinogen Abuse and Dependence

Diagnosis and Clinical Features The diagnosis of an abuse of hallucinogens is determined by DSM-IV criteria used for other forms of substance abuse, namely, the recurrent use of an hallucinogen in a maladaptive pattern associated with physical risks or adverse impact on psychosocial function. Dependence is diagnosed when three or more of the following are present: tolerance, increasing drug consumption, unsuccessful efforts to cut down, drug-seeking behaviors, reduction in psychosocial function, and continued use despite knowledge of adverse consequences. The latter diagnosis is uncommon, given the time-limited course of

hallucinogen use in most patients.

Differential Diagnosis The patient presenting with a clinical picture of the sudden onset of inappropriate affect, visual hallucinations, and paranoid ideation suggests hallucinogen toxicity. Confusing this picture may be toxicity arising from other agents, including phencyclidine, anticholinergics, inhalants, and numerous other drugs. Laboratory tests screening for amphetamines, tetrahydrocannabinol, opiates, cocaine, benzodiazepines, and barbiturates are widely available. The presence of visual hallucinations or pseudohallucinations almost invariably points to a toxic, metabolic, vascular, epileptic, or neoplastic etiology in the central nervous system, rather than to schizophrenia. Hallucinations may also arise from within the eye as entoptic phenomena, but the patient with cataracts or retinal disease is likely to be older than the hallucinogen-abusing person.

Course, Prognosis, and Treatment The lifetime character of hallucinogen abuse is commonly described as a bell curve characterized by initial experimentation with the drug in adolescence, followed by a rising frequency of use, and finally a decline and end to use because of disinterest or the onset of chronic psychopathology. Of note is that few persons appear for treatment of hallucinogen abuse or dependence, but do present with the comorbid symptoms of anxiety, depression, psychosis, and suicidal ideation following the use of hallucinogens. Although clinical observation relates the onset of these disorders to the use of hallucinogens, the etiological role of hallucinogen abuse in mood and psychotic disorders has not been established by controlled studies. However, data suggest that substance use in general and hallucinogen use in particular is associated with adolescent suicide. The risk of suicide in the patient with psychosis following hallucinogen use is not inconsiderable. A clinical rule of thumb is that any patient suffering a chronic illness following hallucinogenic drugs, such as a perceptual, mood, or psychotic disorder, should be considered at higher than general risk for suicide for the duration of time that the disorder is present.

Hallucinogen Intoxication

Diagnosis and Clinical Features The characteristic feature of hallucinogen intoxication is the rapid onset of alterations in mood, cognition, and perception in the presence of a clear sensorium and following the ingestion of a drug in a commonly distributable form. Because memory is preserved, the details of the trip may be retained. This has led to a number of extraordinary personal descriptions of drug-altered states of consciousness, including those by William James, Aldous Huxley, and others. Psychological distress is more likely the hallmark of the hallucinogen user who presents for psychiatric help. Such cases may present with a variety of perceptual and conceptual phenomena leading to anxiety and panic. The DSM-IV diagnostic criteria for hallucinogen intoxication are listed in Table 11.7-4.

A. Recent use of a hallucinogen.
B. Clinically significant maladaptive behavioral or psychological changes (e.g., marked anxiety or depression, ideas of reference, fear of losing one's mind, paranoid ideation, impaired judgment, or impaired social or occupational functioning) that developed during, or shortly after, hallucinogen use.
C. Perceptual changes occurring in a state of full wakefulness and alertness (e.g., subjective intensification of perceptions, depersonalization, derealization, illusions, hallucinations, synesthesias) that developed during, or shortly after, hallucinogen use.
D. Two (or more) of the following signs, developing during, or shortly after, hallucinogen use:
(1) pupillary dilation
(2) tachycardia
(3) sweating
(4) palpitations
(5) blurring of vision
(6) tremors
(7) incoordination
E. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

Table 11.7-4 DSM-IV Diagnostic Criteria for Hallucinogen Intoxication

Differential Diagnosis The patient presenting to an emergency service with a possible adverse reaction to hallucinogens should routinely be screened for other toxic agents capable of presenting with psychosis or delirium. These include the abuse of substituted amphetamines, cocaine, and PCP, as well as withdrawal from alcohol and benzodiazepines. Screens of urine can eventually rule out abuse of other drugs, which may present with psychosis, but depend on cooperation from the patient. Although drug detection technology can identify LSD in such cases, tools including gas chromatography and mass spectroscopy are not universally available to clinicians. The single best diagnostic tool remains a careful history and physical examination. Often, the history must be obtained from a less disturbed friend. A nettlesome issue in the differential diagnosis of hallucinogen intoxication is the possibility of PCP intoxication. Discriminating LSD from PCP effects is important because the treatment for one disorder may exacerbate the other disorder. One useful technique is the palm test. The examiner holds up his or her own hand and asks the patient to name all the colors visible in the palm. If the patient is using LSD, the response will be a stream of improbable colors and occasional images; if the user has taken PCP, he or she will remain mute or attack the examiner's hand. Examiner agility is helpful in the latter case.

Other features in the differential diagnosis include historical evidence of ingestion of an hallucinogen in an epidemiologically common form, the time of onset of toxic symptoms, and consensual validation of the drug history from companions. A physical examination will reveal marked mydriasis and other signs of autonomic arousal consistent with the acute drug state, in contrast to the miosis observed in PCP intoxication. Cases may be complicated by adulteration of the hallucinogen, mistaken attribution, or supplementation of the hallucinogen with marijuana, alcohol, cocaine, or other drugs.

Course and Prognosis The natural history of the “bad trip” is benign, tending to end, depending on the nature of the hallucinogen used, with a resolution of psychotic symptoms 6 to 12 hours following the time of ingestion.

Treatment Persons have historically been treated for hallucinogen intoxication by psychological support for the remainder of the trip. This is a time-consuming and potentially hazardous undertaking given the lability of a patient with hallucinogen-related delusions. Accordingly, treatment of hallucinogen intoxication is the oral administration of 20 mg of diazepam (Valium). This medication brings the LSD experience and any associated panic to a halt within 20 minutes, and is to be considered superior to “talking down” the patient over a period of hours, or to administering antipsychotic agents. The marketing of lower doses of LSD and a more sophisticated approach to treatment of casualties by drug users themselves have combined to reduce the appearance of this once-common disorder in psychiatric treatment facilities.

Hallucinogen-Induced Mood Disorder DSM-IV provides a diagnostic category for hallucinogen-induced mood disorder (see Table 14.6-18). Unlike cocaine-induced mood disorder and amphetamine-induced mood disorder, in which the symptoms are somewhat predictable, mood disorder symptoms accompanying hallucinogen abuse can be variable. Abusers may experience manic-like symptoms with grandiose delusions or depression-like feelings and ideas or mixed symptoms. As with the hallucinogen-induced psychotic disorder symptoms, the symptoms of hallucinogen-induced mood disorder usually resolve once the drug has been eliminated from the person's body.

However, depression, and suicide have been reported following the use of MDMA. Weekend use of MDMA has been shown to be followed by depression midweek, similar to the crashing syndrome of amphetamines and cocaine. The suggestion that hallucinogens may induce a chronic mood disorder is controversial, because patients may use mood-altering drugs to self-medicate a preexisting depressive disorder.

Hallucinogen-Induced Anxiety Disorder One feature of this class of drugs that invites use is the unmasking and amplification of pleasurable affect. Feeling states appear unbidden, but are seldom under the user's control. When the affects are frightening, they may cause the user to fly into a drug-induced panic. Such patients are likely to be found terrified on the fringes of the rock concert or in the waiting rooms of psychiatric emergency centers.

> A 20-year-old man had a 7-year history of polysubstance abuse, including having used LSD an estimated 400 times. While driving with his girlfriend he ingested an unknown quantity of LSD and became intoxicated; he reported using no other drugs at this time. Within minutes after ingestion, he began to experience visual hallucinations that intensified as he drove. When he attempted to speak to his girlfriend, he saw that she had become a giant lizard. He became terrified and attempted to kill her by crashing the car, injuring himself and his passenger. By the time of discharge from the hospital 3 days later, his panic had resolved.

Treatment is the use of oral benzodiazepines as described for hallucinogen intoxication.

Hallucinogen Persisting Perception Disorder Prolonged visual disturbances following LSD have been described for over 40 years. They may occur contiguously

with the trip or spontaneously recur days to weeks following cessation of drug use. Visual symptoms that occur sporadically after drug use and last for a second or two are usually designated “flashbacks.” Those that linger continuously, with minor fluctuations in intensity, are more properly considered to be hallucinogen persisting perception disorder (Table 11.7-5).

A. The reexperiencing, following cessation of use of a hallucinogen, of one or more of the perceptual symptoms that were experienced while intoxicated with the hallucinogen (e.g., geometric hallucinations, false perceptions of movement in the peripheral visual fields, flashes of color, intensified colors, trails of images of moving objects, positive afterimages, halos around objects, macropsia, and micropsia).

B. The symptoms in criterion A cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

C. The symptoms are not due to a general medical condition (e.g., anatomical lesions and infections of the brain, visual epilepsies) and are not better accounted for by another mental disorder (e.g., delirium, dementia, schizophrenia) or hypnopompic hallucinations.

Table 11.7-5 DSM-IV Diagnostic Criteria for Hallucinogen Persisting Perception Disorder (Flashbacks)

Such recurrences may involve somatic and emotional symptoms, but perceptual ones predominate. These may include geometric hallucinations, false fleeting perceptions of movement in the peripheral fields, flashes of color, and afterimagery. Common complaints are the persistence of trailing images as an object moves through the patient's visual field. Brighter objects such as auto tail lights induce trails more easily, although these may be induced simply by moving the examiner's hand across the patient's visual field, a maneuver with high sensitivity and specificity for hallucinogen persisting perception disorder. The entire visual field in many cases may be described as reticulated, grainy, or filled with numerous vibrating pinpoint-sized dots, to the extent that patients complain that they can see the air. This phenomenon of “aeropsia” also appears to be highly specific for hallucinogen persisting perception disorder. Comorbidly occurring secondary conditions include depressive and anxiety disorders; alcohol dependence may occur secondarily. Less frequently, psychosis may be present although the vast majority of patients with flashbacks have preserved reality testing, and understand that their new perceptual burden is “not real” and is more properly considered a form of pseudohallucinations.

A 16-year-old girl presented with a complaint of “never being happy.” She had used LSD for the first time at the age of 13, and used the drug a total of 30 times until 3 months prior to her consultation. Occasional LSD trips had been notable for panic attacks, but she denied spontaneous panic. At the age of 14 she noted the onset of depression, which coincided insidiously with the onset of continuous visual symptoms. These included images of faces on the floor and walls (*pareidolias*), dots too numerous to count hovering in the air, flashes of color and white light, trails of moving objects, positive afterimages, boxes on walls, and occasionally, a face or its outline floating in space. At 15 she attempted suicide; major depression was diagnosed. A sleep electroencephalography (EEG) with sphenoidal leads was unremarkable although a year later a quantitative EEG showed abnormal sensory evoked potentials.

A 19-year-old college student presented with a complaint of “feeling high all of the time.” His past history was positive for daily marijuana use from ages 15 to 17. In that period he also used LSD 13 times. He was asymptomatic for 3 years until he experienced an attack of anxiety, visual disturbances, and hyperacusis. The initial spell lasted several hours, and was characterized by the experience of continuous visual trails and auditory reverberations in passing stimuli. He felt distant from his body, and had a sense of impending doom. The anxiety attack subsided, but the visual disturbances continued without abatement. Among them was a complaint of seeing “millions” of clear dots in the air, “like I can see the molecules.” A computerized tomogram of the cerebrum and an EEG were negative. A brief trial of thioridazine (Mellaril) made the visual symptoms worse, but chlordiazepoxide (Librium) was effective in reducing but not obliterating his visual symptoms. The visual symptom of “seeing” the air was intensified on gazing at the sky, but seemed to remit spontaneously in the following 2 years. Visual and auditory trailing persisted, however, as have occasional episodes of panic attacks.

A 26-year-old male was referred for an evaluation of possible LSD-related disorder. His past medical history was negative for preexisting disorders of the central nervous system. His family history was negative for psychiatric illness. The patient's first use of LSD occurred at age 14 with an alleged dose of 100 micrograms. In the next year he used the drug on approximately 30 occasions, and used marijuana frequently as well. Drug use coincided with family conflict, truancy, and running away from home. At the age of 15 on the day following a dysphoric LSD experience, he awoke with a sense that “something snapped” on the left side of his head. He suffered progressive dysphoria, depression, and withdrawal. Peering into a friend's eyes generated LSD-like feelings and panic. He hallucinated yellow geometric forms and the trails of passing objects. He became irrationally afraid of people, was unable to attend school, and 2 months later was hospitalized in a psychotic state. He was treated with chlorpromazine (Thorazine) with partial relief from paranoid delusions. Over the next 9 years his major symptom was depression in a context of constant visual pseudohallucinations. He saw trails of objects and auras around people. When listening to music he generated internal geometric imagery. He was able to visualize “the air,” which he described as yellow dots hovering in space. These images persisted daily for 12 years.

Course and Prognosis Roughly half the patients with hallucinogen persisting perception disorder recover completely in 5 years, but others may irreversibly continue to have symptoms. The appearance of this disorder is not dose dependent; it may arise from a single LSD ingestion. The disorder is exacerbated by autonomic arousal, including psychostimulants such as amphetamines, cocaine, cold tablets containing pseudoephedrine, and caffeine; also by marijuana use, including passive inhalation; excessive fatigue, overexercise, and intercurrent infections. Symptoms are commonly precipitated by entering a dark environment. The disorder is associated with vivid visual hallucinations during alcohol withdrawal. Psychophysical evidence is consistent with the hypothesis that this disorder is associated with disinhibition of visual information processing; that is, once stimulated, the visual system is slow to return to a resting baseline. Quantitative electroencephalography also reveals evidence of visual disinhibition in these patients. Auditory responses are delayed (Fig. 11.7-3). It is noteworthy that these findings closely parallel those EEG findings described during the acute administration of LSD to a variety of species, including humans. Thus, the patient's claim that he is “still tripping” is borne out neurophysiologically.

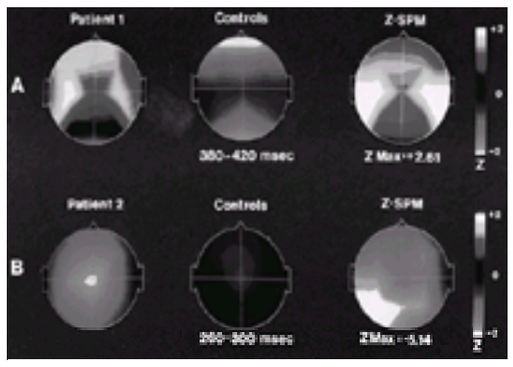

FIGURE 11.7-3 Illustrative cases of quantitative EEG abnormalities in hallucinogen persisting perreotion disorder (flashback). **Patient 1:** A 26-year-old computer programmer used LSD at the age of 18 on 15 occasions; 31 months later the patient experienced the abrupt onset of intense, LSD-like set of visual and affective disturbances lasting all night. At 25 he suffered the spontaneous onset of hourly flashing white lights centrally and black dots in his peripheral fields, which have continued for the past 10 years. Topographic brain maps are shown during the 380-420 msec epoch of the visually evoked potential in row **A**. The upper left map represents the subject's data. The upper middle map shows control subjects for the same poststimulus latency epoch. The right upper image is a significance probability map (SPM) showing *Z*-scores resulting from a comparison of the data from the left and middle upper maps. The patient shows an enhancement in the visually evoked signal involving both temporal regions of the cerebrum. **Patient 2:** A 23-year-old musician used LSD on 16 occasions over a 4-month period at the age of 20. Within 2 months he began to notice a progressive, continuous visual disorder characterized by flashes of color, persisting afterimages, haloes around objects, a grainy texture to the sky, and the lingering trails of objects as they passed through his visual field. The graininess in the visual field interfered with night vision. Topographic brain mapping is illustrated during the 260-300 msec epoch of auditory evoked potentials in row **B**. Note the region of reduced electrical activity in

the left posterior temporal region in the lower right map. (Reprinted with permission from Abraham HD, Duffy FH: Stable quantitative EEG difference in post-LSD visual disorder by split-half analysis: Evidence for disinhibition. Psychiatry Res *67:*173, 1996.) (See Color Plate 6.)

Treatment Treatment for hallucinogen persisting perception disorder is palliative. The first step in the process is correct identification of the disorder; it is not uncommon for the patient to consult a number of specialists before the diagnosis is made. Pharmacological approaches include long-lasting benzodiazepines such as clonazepam (Klonopin), and to a lesser extent anticonvulsants including valproic acid (Depakene) and carbamazepine (Tegretol). No drug is yet completely effective in ablating symptoms. Antipsychotic agents should only be employed in the treatment of hallucinogen-induced psychoses. It is not uncommon for these agents to exacerbate the disorder within the first 72 hours of administration. Case reports suggest sertralin and naltremene may be beneficial. Serotonin type 2 antagonists such as risperidone (Risperdal) have also been shown to exacerbate the intensity of visual symptoms. A second dimension of treatment is behavioral. The patient must be instructed to avoid gratuitous stimulation in the form of over-the-counter drugs, caffeine, alcohol, and avoidable physical and emotional stressors. Marijuana smoke is a particularly strong intensifier of the disorder, even when passively inhaled. Finally, three comorbid conditions are associated with hallucinogen persisting perception disorder—panic disorder, major depression, and alcohol dependence. All these conditions require primary prevention and early intervention.

Hallucinogen-Induced Psychotic Disorders

Diagnosis and Clinical Features If psychotic symptoms are present in the absence of retained reality testing, a diagnosis of hallucinogen-induced psychotic disorder may be warranted (see Table 13.3-4). DSM-IV also allows clinicians to specify whether hallucinations or delusions are the prominent symptoms.

Because the ingestion of an hallucinogen induces a toxic mental state analogous to a psychosis, it is useful operationally to define a posthallucinogen psychotic disorder as one that continues for more than 48 hours following ingestion. Attack rates of such disorders among those using hallucinogens are reported to occur in a range of 0.08 to 4.6 percent, with a trend of higher rates occurring in psychiatric patients and lower ones in healthy volunteers. Patients may suffer the onset of a psychosis immediately on ingestion of the drug, or may have a lucid interval of days to months before the onset. In the former case the hallucinogen is linked more convincingly as the cause of the psychosis than in the latter situation. The patient presenting with a prolonged psychosis following the verified ingestion of LSD or other hallucinogen should raise a strong suspicion of a substance induced disorder.

Differential Diagnosis Prior to diagnosis the clinician must consider preexisting psychotic disorders like schizophrenia; mistaken attribution in samples of LSD that are in fact amphetamines, phencyclidine, or other drugs with psychotic potential; or sources of delirium such as alcohol withdrawal. Posthallucinogen psychotic symptoms include mood swings with euphoria and grandiosity, multimodal hallucinations, and hyperreligiosity. When compared to non–drug–using schizophrenia patients, patients with posthallucinogen psychosis have earlier ages of onset, more visual hallucinations, more depression, and a higher prevalence of families with mood disorder. Clinically they are more likely to suffer the positive symptoms of psychosis in the context of schizoaffective disorder. Finally, individuals claiming to have developed a lifelong psychosis following a single dose of LSD without being able to describe the symptoms of a typical trip are more likely to be suffering from a paranoid rather than a postdrug disorder.

> A 19-year-old musician used LSD on three occasions. Following the third trip, he failed to regain his pre-drug mental state. Instead, he experienced auditory and visual hallucinations, rapid and incoherent speech, sleeplessness, zoophilic delusions, and suicidal ideation. He acted out his psychotic fears aggressively, showering with his clothes on, ripping towel racks from the wall, and requiring four-point restraints. This disorder continued for 2 months during which time he was unsuccessfully treated with lithium carbonate (Eskalith), lorazepam (Ativan), propranolol (Inderal), haloperidol (Haldol), benztropine (Cogentin), and diphenhydramine (Benadryl). His symptoms slowly abated with a combination of lithium and perphenazine (Trilafon).
>
> A 22-year-old female photography student presented to the hospital with inappropriate mood and bizarre thinking. She had no prior psychiatric history. Nine days prior to admission she ingested one or two psilocybin mushrooms. Following the immediate ingestion, the patient began to giggle. She then described euphoria, which progressed to auditory hallucinations and belief in the ability to broadcast her thoughts on the media. Two days later she repeated the ingestion, and continued to exhibit psychotic symptoms to the day of admission. When examined she heard voices telling her she could be president, and reported the sounds of “lambs crying.” She continued to giggle inappropriately, bizarrely turning her head from side to side ritualistically. She continued to describe euphoria, but with an intermittent sense of hopelessness in a context of thought blocking. Her self-description was “feeling lucky.” Haloperidol was begun, 10 mg twice a day, along with benztropine 1 mg three times a day and lithium carbonate 300 mg twice a day. On this regimen her psychosis abated after 5 days.

Another variety of posthallucinogen psychosis presents with catatonia, confusion, and multimodal hallucinations, supporting the concept of hallucinogenic delirium.

> A 23-year-old undergraduate was premorbidly a sociable, outgoing individual with no prior history of drug use. Over a 3-day period he used LSD on three occasions, and continued to act in a bizarre manner. He described auditory and visual hallucinations, including images of his estranged father on the ceiling, which fixated his gaze upwardly for long periods. He was disoriented and his gait was reduced to 3-inch steps. Speech was reduced to rare one- and two-word sentences. He could not follow simple commands. Generalized apraxia was present. Pauses of 30 to 60 seconds were noted between an examiner's question and his verbal response. A screen of his urine was negative for toxins. An awake EEG showed generalized slowing in the theta range. The catatonia, delusions, and hallucinations were partially reduced with antipsychotic medications, fluoxetine (Prozac), and electroconvulsive therapy, but the patient continued to exhibit psychotic symptoms chronically.

This uncommon case shares features of hallucinogen-induced psychotic disorder, hallucinogen intoxication delirium, and schizophrenia. The continuity of a drug state with an enduring psychotic disorder suggests the first, though whether this class of drugs activates a pre-existing schizophrenogenic trigger remains to be shown.

Treatment Treatment of hallucinogen-induced psychosis does not differ from conventional treatment for other psychoses. However, in addition to antipsychotic medications, a number of agents have been reported to be effective including lithium carbonate, carbamazepine, and electroconvulsive therapy. Antidepressant drugs, benzodiazepines, and anticonvulsant agents may each have a role in treatment as well. One hallmark of this disorder is that, as opposed to schizophrenia, in which negative symptoms and poor interpersonal relatedness may commonly be found, patients with hallucinogen-induced psychosis exhibit the positive symptoms of hallucinations and delusions while retaining the ability to relate to the psychiatrist. Medical therapies are best applied in a context of supportive, educational, and family therapies. The goals of treatment are the control of symptoms, a minimal use of hospitals, daily work, the development and preservation of social relationships, and the management of comorbid illnesses including alcohol dependence, depression, and suicide. The preservation of insight in these patients permits a painful comparison of their lives to those of their healthy contemporaries as the latter reach milestones of the life cycle while the former do not. Optimizing psychological and social development of the patient with psychosis is the central strategy for treatment.

Hallucinogen Intoxication Delirium DSM-IV allows for the diagnosis of hallucinogen intoxication delirium (see Table 10-22), a relatively rare disorder beginning during intoxication in those who have ingested pure hallucinogens. Hallucinogens are often mixed with other substances, however, and the other components or their interactions with the hallucinogens can produce a clinical delirium.

Hallucinogen-Related Disorder Not Otherwise Specified Chronic users of hallucinogenic drugs may present a number of symptoms and behaviors that do not easily conform to the preceding classification. Cerebral edema, has been reported following the use of MDMA. Not uncommonly, patients who have used LSD in the past may describe a constellation of symptoms suggestive of a disorder of the temporal lobes, including hyperreligiosity, sexual dysfunction, and occasionally hallucinations (Table 11.7-6).

The hallucinogen-related disorder not otherwise specified category is for disorders associated with the use of hallucinogens that are not classifiable as hallucinogen dependence, hallucinogen abuse, hallucinogen intoxication, hallucinogen persisting perception disorder, hallucinogen intoxication delirium, hallucinogen-induced psychotic disorder, hallucinogen-induced mood disorder, or hallucinogen-induced anxiety disorder.

Table 11.7-6 DSM-IV Diagnostic Criteria for Hallucinogen-Related Disorder Not Otherwise Specified

This syndrome must be differentiated from schizophrenia because the global, social, and occupational dysfunction of schizophrenia is absent in this patient. Not uncommonly hyperreligiosity may be coupled with organizational abilities so that the patient may present as a minister of a church of his own creation, a benign enough species of psychological diversity. On rare occasions, however, persons such as Charles Manson, combining drug use with quasireligious dogma, may form cults with lethal outcomes.

SUGGESTED CROSS-REFERENCES

A general discussion of substance use disorders (intoxication, withdrawal, abuse, dependence, and persisting disorders) is found in Section 11.1. Section 12.7 on schizophrenia highlights differences in the clinical presentation and course between schizophrenia and hallucinogen abuse and hallucinogen, dependence, and Section 11.10 on phencyclidine (and related substances) clarifies differences from disorders involving those compounds.

11.8 INHALANT-RELATED DISORDERS

THOMAS J. CROWLEY, M.D.

Inhalant drugs (sometimes called “volatile substances”) are widely available and frequently misused, especially by adolescents. About 20 percent of American eighth-grade students report that they have used these substances for psychoactive effects, more than the number who have tried marijuana. Most adolescents who try inhalants apparently discontinue them after one or a few times. However, for a smaller group of adolescents, especially those with comorbid conduct disorder, inhalant use may foreshadow many years of polysubstance abuse or dependence, including drug injections. Most of these persons eventually shift to other drugs, although some continue daily use of inhalants themselves for many years, suffering major behavioral and organ pathology from the drugs' chronic toxicity. A still smaller number of adolescents die from acute inhalant toxicity, often during their first use of the drugs. Indeed, in Great Britain where detailed records are available, inhalants have become a leading cause of adolescent death because, although such deaths are infrequent, adolescent deaths generally are uncommon.

Inhalants are volatile hydrocarbons, such as toluene, *n*-hexane, methylbutyl ketone, trichloroethylene, trichloroethane, dichloromethane, gasoline, and butane. They make up four commercial classes: (1) solvents for glues and adhesives; (2) propellants for aerosol paint sprays, hair sprays, frying pan sprays, and shaving cream; (3) thinners (e.g., for paint products and typing correction fluids); and (4) fuels.

DEFINITION

The section on inhalant-related disorders in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) “includes disorders induced by inhaling the aliphatic and aromatic hydrocarbons... Less commonly used are halogenated hydrocarbons... and other volatile compounds containing esters, ketones, and glycols.” DSM-IV provides two broad categories of inhalant-related disorders (Table 11.8-1). The first category is inhalant use disorders (inhalant abuse and inhalant dependence), which are characterized by maladaptive patterns of inhalant use (e.g., frequency, dose, danger). The second category, inhalant-induced disorders (such as inhalant intoxication), result from the toxic effects of inhaled substances. Because of epidemiological and pharmacological differences, DMS-IV excludes from the inhalant-related disorders conditions related either to anesthetic gases or to amyl and butyl nitrites, classifying these as other (or unknown) substance-related disorders; some disorders associated with those compounds are briefly discussed at the end of this chapter. Although fumes of such combustible drugs as crack cocaine and tobacco also are inhaled, DSM-IV similarly places disorders related to those drugs in separate categories.

Inhalant use disorders
Inhalant dependence

Table 11.8-1 DSM-IV Inhalant-Related Disorders

COMPARATIVE NOSOLOGY

The section on inhalant-related disorders in DSM-IV lists three major categories: inhalant abuse, inhalant dependence, and inhalant intoxication. The other inhalant-related disorders have their diagnostic criteria specified in the DSM-IV sections that specifically address the major symptoms. For example, inhalant-induced psychotic disorder is included with other psychotic disorders.

The 10th revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) refers to inhalants as “volatile substances.” ICD-10 does not use the term “abuse,” which is in DSM-IV, offering instead the term “harmful use.” DSM-IV provides no diagnosis of inhalant withdrawal (which clinicians describe, but which probably is rare), whereas ICD-10 includes that diagnosis, but gives no diagnostic criteria.

EPIDEMIOLOGY

The 1995 United States National Household Survey estimated that 5.7 percent of Americans had used an inhalant at some time in their lives. The prevalence was 8.0 percent among males and 3.5 percent among females. The figures were highest for males 18 to 34 years of age; almost 15 percent of them reported using an inhalant at some time. The overall prevalence rates for use of inhalants at any time in one's life were 6.7 percent among whites, 3.5 percent among Hispanics, and 1.8 percent among blacks.

A large annual survey has examined trends in drug use among American high school students. It shows that many adolescents have used inhalants. Among eighth-grade students inhalants are the most commonly used drug (except for alcohol and tobacco); about 20 percent of eighth-graders report having used an inhalant, while only about 17 percent report having used marijuana. Native-American students on reservations may be especially vulnerable to inhalant use; one large survey found that 34 percent of reservation-dwelling Native-American eighth-grade students had used an inhalant.

In 1976 about 10 percent of interviewed high school seniors reported some use of inhalants. The figure peaked at 18 percent in 1990, and remained at about 17 percent in 1996. The number of students using inhalants more frequently is reflected in the proportion of high school seniors who report using an inhalant in the last 30 days. That figure gradually rose from about 1 percent of students in 1976 to 2.5 percent in 1996.

In relation to other abused drugs inhalants are not a major cause of morbidity or mortality in the United States. Inhalants accounted for only 0.3 to 0.4 percent of drug-related episodes in federally monitored emergency rooms between 1991 and 1994. Similarly, inhalants contributed to only about 1.4 percent of federally

reviewed medical-examiner death reports for 1994.

For inhalant males and whites (in comparison to females and blacks) were overrepresented in both medical-examiner reports and emergency-room visits. However, age distributions differed between patients in emergency rooms and those deceased. In 1994 the peak prevalence for inhalant-related emergency-room episodes was among patients 12 to 17 years of age (40 percent of all inhalant-related episodes), whereas the peak prevalence of deaths occurred in the age range 35 to 44 years (35 percent of inhalant-related death reports).

Medical examiners considered over 40 percent of inhalant-related deaths to be suicides. Similarly, a suicide attempt was part of the presentation in 38 percent of inhalant-related emergency visits. Thus, it appears that inhalant intoxication often is associated with suicidality.

In Great Britain inhalants are among the leading causes of death in adolescents and are the single most common cause in those 15 years old. First-time users there are the most likely to die, perhaps because they are inexperienced at this dangerous pastime. Comparable data are not available for the United States. In several developing countries heavy use of inhalants is common in groups of street kids, who live with no ties to adults.

American data show widespread experimentation with inhalants, relatively few current users, and still fewer inhalant emergencies or deaths, suggesting that most users try the drugs a few times and stop without mishap. Most of these users probably will not develop further drug problems, but nevertheless the odds of such problems are much greater among them. For example, inhalant use is associated with increased odds of later injection-drug use, a risk factor for infection with the human immunodeficiency virus (HIV). In a general population survey, persons reporting any use of inhalants were 45 times more likely, and those who had used both inhalants and cannabis were 89 times more likely, than others to have injected drugs. Similarly, a prospective study of inner-city youths found that those who had used inhalants in adolescence were nine times more likely to use heroin later.

The available data suggest that most adolescents who survive a brief experimentation with inhalants and who do not have conduct disorder soon abstain from inhalants and avoid pathological outcomes. However, among adolescents with conduct disorder, perhaps half will develop adult antisocial personality disorder. Inhalant problems in these youths often herald serious alcohol and polysubstance use in adulthood, and a few of these youths will become chronic, deteriorated, inhalant-dependent adults.

PHARMACOLOGY AND TOXICOLOGY

Data on inhalant choice in the United States are limited, but of some 20 abused compounds, toluene and gasoline may be the most popular. Various authorities recommend industrial exposure limits for toluene of 50 to 100 parts per million (ppm), although a recent study showed that a 6-hour exposure to 100 ppm produced a temporary neuropsychological performance decrement of about 10 percent. By comparison, inhaled concentrations from a glue-containing bag may reach 10,000 ppm, and vapors from several tubes of glue may be inhaled each day. About 15 to 20 breaths of 1 percent gasoline vapor produce several hours of intoxication. Sniffing vapor through the nose or huffing (taking deep breaths) through the mouth leads to transpulmonary absorption with very rapid drug access to the brain. Breathing through a solvent-soaked cloth, inhaling fumes from a glue-containing bag, huffing vapor sprayed into a plastic bag, or breathing vapor from a gasoline can are common.

Toluene concentrations in blood in hospitalized intoxicated persons reportedly range from 0.8 to 8 µg/g. Exposure at the industrial maximum of 100 ppm produces blood levels around 0.5 µg/g, although moderate exercise may triple these levels through increased respiration. Brain and fat achieve higher concentrations than blood because lipophilic compounds preferentially distribute there. The coadministration of alcohol dramatically raises toluene concentration in blood, increasing toxicity, probably through competition for hepatic metabolizing enzymes.

About 20 percent of a toluene dose is excreted unchanged in the breath, but most is metabolized in the liver to hippuric acid before urinary excretion. Breath concentrations of toluene fall by half within a few minutes after the end of a prolonged exposure. Blood concentrations fall more slowly, becoming undetectable 4 to 10 hours after exposure. Urinary hippuric acid remains measurable somewhat longer; hippurate-creatinine ratios above 1 gram per gram suggest toluene use, but benzoic acid food preservatives may generate false-positive hippuric acid concentrations.

The cellular mechanisms of inhalant action are unclear. Hypotheses include cell membrane fluidization or interactions at g-aminobutyric acid (GABA)-gated chloride channels, but data are very sparse. Behavioral actions in animals suggest that inhalants act like alcohol, barbiturates, and other depressants of the central nervous system (CNS). Like depressants they produce motor stimulation at lower doses and motor suppression at higher doses, as well as ataxia and loss of righting reflex. Inhalants also have anticonvulsant actions and show depressant-like effects in certain behavioral paradigms. Animals will work to self-administer inhalants, and animals trained to press one lever when injected with alcohol or pentobarbital and another when injected with saline will press the depressant-appropriate lever after exposure to toluene vapor, suggesting that the subjective experience after toluene or a depressant is similar. Moreover, alcohol and benzodiazepines potentiate inhalant effects.

Rodents develop withdrawal seizures after several days' exposure to trichloroethane, a frequently abused inhalant. The seizures are blocked by toluene, ethanol, pentobarbital, and midazolam (Versed), a benzodiazepine. Thus, inhalants can produce physical dependence, and they show cross-dependence with familiar CNS depressants.

In human subjects low-dose (0, 75, or 150 ppm) toluene exposures for several hours produce dose-related decrements in tests of perception, memory, and manual dexterity, with increased headaches, mucosal irritation, thirst, and sleepiness.

Organ Pathology Inhalants are associated with many potentially serious adverse effects. The most serious of these is death, which can result from respiratory depression, cardiac arrhythmias, asphyxiation, aspiration of vomitus, or accident or injury (e.g., driving while intoxicated with inhalants). Placing an inhalant-soaked rag and one's head into a plastic bag, a common procedure, may cause coma and suffocation.

Chronic inhalant users may have numerous neurological problems. Computed tomography and magnetic resonance imaging reveal diffuse cerebral, cerebellar, and brainstem atrophy with white-matter disease, a leukoencephalopathy. Several studies of house painters and factory workers who have been exposed to solvents for long periods also have found evidence of brain atrophy on computed tomography scans, with decreased cerebral blood flow. Neurological signs and symptoms may include hearing loss, peripheral neuritis, headache, paresthesias, cerebellar signs, persisting motor impairment, parkinsonism, and lead encephalopathy. The combination of organic solvents with high concentrations of copper, zinc, and heavy metals has been associated with the development of brain atrophy, temporal lobe epilepsy, decreased intelligence quotient (I.Q.), and a variety of electroencephalographic (EEG) changes.

Other serious adverse effects associated with long-term inhalant use include irreversible hepatic disease or renal damage (tubular acidosis) and permanent muscle damage associated with rhabdomyolysis. Additional adverse effects include cardiovascular and pulmonary symptoms (e.g., chest pain and bronchospasm) as well as gastrointestinal symptoms (e.g., pain, nausea, vomiting, and hematemesis). Several reports suggest that in utero exposure to toluene may produce an embryopathy similar to fetal alcohol syndrome. Fortunately, there is no convincing evidence that toluene, the best-studied inhalant, produces genetic damage in somatic cells.

ETIOLOGY

Multiple factors contribute to the etiology of inhalant-related disorders. First, availability is important in determining the prevalence of abuse or dependence on a drug. Inhalants are cheap, available in several forms in most households, easily concealed, legal to possess, and simple to take. Second, inhalant use apparently is rewarding, both through direct pharmacological action and through the drugs' social effects. As mentioned, under certain circumstances animals repeatedly self-administer inhalants, showing that these substances have innate reinforcing properties. In addition adolescents usually gather in small groups to use inhalants and being a user gains entry to the group, socially reinforcing the use. Third, inhalant users often can evade detection or punishment by parents or school authorities, since the drugs quickly produce a high that passes within a few hours. Fourth, inexpensive inhalants may be one of the few exciting and novel experiences available to youths in impoverished communities providing few other reinforcers. This may help to explain the high prevalence of inhalant use on some Indian reservations.

In addition to those extrinsic factors at least one intrinsic factor contributes to inhalant problems. A risk-taking propensity may lead some persons to the at-the-brink excitement and danger of inhalant intoxication. Persons with adolescent conduct disorder or adult antisocial personality disorder are prone to taking extreme risks, and many inhalant users have those disorders. Several studies suggest an association of inhalant use and conduct problems. Among youths in grades 7 through 12, inhalant users (compared with others who used no drugs or who used only cannabis or alcohol) had many characteristics suggesting conduct disorder. They accepted

cheating more readily, admitted to more stealing, perceived less objection to drug use from their families, liked school less, and reported more sadness, tension, anger, and a feeling of being blamed by others. In addition, school surveys showed that solvent users were more likely to be involved with other drugs. Similarly, among youths referred to court-mandated education for minor alcohol offenses, those who also had used inhalants reported fewer school honors and more expulsions, truancy, academic failures, criminal offenses, running away, and associations with troubled peers, as well as many more drug and alcohol problems. More of them also had mothers or siblings with alcohol- or drug-related problems. Some families are burdened by antisocial personality disorder and substance dependence in the adults and by conduct disorder and substance use disorders (often including inhalant abuse or dependence) in the adolescent children, and there is growing evidence that genetics plays a role in these familial disorders.

A group home referred a 16-year-old single Hispanic female to a university substance-treatment program for evaluation and recommendations regarding inhalant problems. The patient had been ordered to the group home for auto theft, menacing with a weapon, and being out of control by her family. By age 15 she had regularly been using inhalants and drinking alcohol heavily. She had tried typewriter erasing fluid, bleach, tile cleaner, hairspray, nail polish, glue, and gasoline, but preferred spray paint. She had huffed paint many times each day for about 6 months at age 15, using a maximum of eight paint cans per day. The patient said, “It blacks out everything.” Sometimes she had lost consciousness, and she believed that the paint had impaired her memory and made her “dumb.”

The patient reported sexual abuse by an older, nonparental male relative beginning at age 3 and continuing for many years. By fifth grade she had begun showing extensive conduct problems, eventually including fighting, truancy, multiple runaways, gang involvement, and bringing weapons to school. Her family reportedly permitted gang meetings in their home. The patient reported stabbing one person with a screwdriver, another with a knife, and beating another unconscious with a bat. She said that her violence was greatest when she was intoxicated. The patient listed as her strengths and abilities as drawing, cooking, staying clean, fighting, and giving good tattoos. In formal testing her thinking seemed slow, and she had some difficulty understanding questions. Her I.Q. scores were Verbal, 72; Performance, 87; and Full Scale, 77. She met diagnostic criteria for inhalant dependence, alcohol abuse, and conduct disorder.

The evaluating program recommended (1) individual and group substance treatment, emphasizing the adverse cognitive and health effects of huffing; (2) urine monitoring; (3) further neurological and neuropsychological assessment; (4) family evaluation and treatment addressing the patient's anger about sexual abuse and her rebelliousness; (5) specific attention in treatment to the patient's anger and aggression; (6) psychoeducation concerning contraception and protection from sexually transmitted diseases; and (7) active support for continued schooling, with consideration of placement in special education. The patient returned to the group home for several months, and it is unclear which of these recommendations were implemented. She then rejoined her parents in a distant community. One year after the evaluation the patient and two others died when their speeding car hit a tree. An investigating officer said, “It appears that all of them had been sniffing or huffing paint.”

INHALANT DEPENDENCE AND INHALANT ABUSE

Diagnosis and Clinical Features A diagnosis of inhalant abuse or inhalant dependence should be considered in persons showing intermittent changes compatible with substance intoxication, together with an odor of organic solvents, inhalation paraphernalia, or the occasionally present perioral or perinasal papular glue-sniffers' rash. The cardinal feature of inhalant abuse is repeated use of inhalants in ways that produce a physical hazard or adverse social consequences for the user (see Table 11.1-8). Inhalant dependence is characterized by repeated use resulting in some combination of adverse consequences, loss of control of the drug use, and tolerance or withdrawal (see Table 11.1-3). Although DSM-IV provides no diagnosis for inhalant withdrawal, 17 percent of inhalant users in DSM-IV's substance field trial complained of withdrawal symptoms after inhalant use. Thus, despite the absence of a separate inhalant withdrawal diagnosis, patients' complaints of withdrawal symptoms probably should be counted toward a diagnosis of inhalant dependence. ICD-10 uses the category of volatile substance dependence syndrome for inhalant dependence. ICD-10 does not include the diagnostic category of inhalant abuse, offering instead the category of harmful use of volatile substances, which is defined as a pattern of use causing damage to health.

Differential Diagnosis Three conditions should be considered. First, most adolescents who experiment with inhalants stop spontaneously after one or a few episodes of use, never meeting criteria for diagnoses of inhalant abuse or inhalant dependence. Although such use is dangerous and occasionally fatal (most often on the first try), the many spontaneous resolutions support recommendations of minimalist, nonalarmist interventions for adolescent users who do not meet criteria for diagnoses of inhalant use disorders; parents also should be involved. Second, polysubstance use is common in adolescent patients, and abuse or dependence on drugs other than inhalants is established through history, physical findings, and toxicological screens. Such disorders may exist in addition to, or instead of, inhalant abuse or dependence. Third, uncontrolled and impulsive behavior during repeated inhalant intoxications may mimic aspects of, or be comorbid with, conduct disorder or antisocial personality disorder. Antisocial behavior before the onset of inhalant abuse or dependence, or in periods of abstinence, suggests the presence of these disorders.

Course and Prognosis The relatively high prevalence of inhalant use in high school surveys, and its relatively low prevalence in adulthood, led one expert to state that inhalant use “should be regarded as a passing phase or fad.” However, although most inhalant users probably do not progress to serious adult disorders, the risk of such progression is much greater for those who have used inhalants than for those who have not. Studies indicate that inhalant use is associated with increased risk for future diagnoses of antisocial personality disorder and other substance use disorders. Among adult substance-dependent patients, a history of inhalant use indicated a significantly enhanced risk for antisocial personality disorder, social phobia, polysubstance use, and injection drug use. Among a group of adult heroin addicts, those who had been inhalant users appeared to be a “marginal group with particularly unfavorable developmental conditions and a specific course of addition.”

Most adolescents who progress from inhalant use to inhalant abuse or dependence eventually shift to other drugs, but some continue active inhalant dependence into adulthood. Such chronic patients may use the drugs for extended periods each day for many years; they demonstrate moderate criminal activity, weight loss, medical disease, slow and slurred speech, impaired attention and memory, and often are both dirty and louse-ridden.

Tolerance occurs and, less commonly, mild withdrawal involving sleep disturbance, irritability, shakiness, sweating, fleeting illusions, and nausea. One observer reported tachycardia, delusions, and hallucinations during withdrawal.

Medical problems in chronic users may include (1) muscle weakness, sometimes with myoglobinuria and rhabdomyolysis; (2) gastrointestinal problems, such as pain, nausea, vomiting, or hematemesis; (3) renal dysfunction, often with severe electrolyte imbalance; (4) cardiomyopathy; (5) hepatotoxicity; (6) pulmonary disorders (pulmonary hypertension, increased airway resistance, and acute respiratory distress); and (7) hematopoietic disorders (including elevated carboxyhemoglobin levels, methemoglobinemia, hemolytic anemia, aplastic anemia, and even acute myelocytic leukemia). Neurological problems include (1) headache, (2) paresthesias with peripheral neuropathy, (3) reversible cerebellar signs or cerebellar degeneration, (4) radiological abnormalities of widened sulci and basal cisterns, and (5) dementia (e.g., lead encephalopathy from leaded gasoline or white matter dementia from toluene).

Researchers have examined individual patients or small series of mothers who regularly used toluene during pregnancy. The studies, although they need large-scale replication, strongly suggest that such inhalant use, often with accompanying distal renal tubular acidosis in the mother, has devastating effects. Mothers may experience nausea, vomiting, abdominal pain, elevated blood pressure, and early contractions. Preterm delivery is common, and even after correction for gestational age, the infants show intrauterine growth retardation. Growth retardation continues postnatally. Dysmorphic facies, similar to those of the fetal alcohol syndrome, may occur. Perinatal infant deaths are not infrequent. The management of pregnancy in women with inhalant abuse or inhalant dependence should aim at abstinence with attention to the early detection of renal tubular acidosis, preterm labor, and fetal growth retardation.

Treatment No controlled studies guide the treatment of adults or adolescents who meet criteria for inhalant abuse or inhalant dependence. Obviously, appropriate medical care is required for the disorders' medical sequelae. In addition vigorous treatment is needed for adolescent patients who progress from experimentation to inhalant abuse or dependence. Most of these youths have comorbid conduct disorder and are at serious risk for adverse outcomes.

One authority recommends that a comprehensive treatment plan include eight aspects: detoxification; a peer advocate system; assessment of physical, cognitive, and neurological deficits; building on existing strengths; developing new strengths; therapists trained in solvent abuse; attention to personal and family issues; and assistance in returning back to the community.

The author and his colleagues provide day-treatment and nonhospital residential programs for adolescents 13 to 19 years of age with combined substance dependence and conduct disorder. About 20 percent of males and 6 percent of females admitted have diagnoses of inhalant abuse or dependence. However,

treatment for these polysubstance-dependent, delinquent youths is not specific by drug category (e.g., inhalants), but instead targets substance use and conduct problems generally. Most referrals are from social-service and juvenile-justice agencies, which pay for the treatment. Currently suicidal youths and those with recent fire-setting are excluded, although many patients have past histories of these problems, together with considerable violence and gang involvement.

Treatment in these programs begins with detailed interviews addressing use and establishing diagnoses of abuse or dependence for each drug category in DSM-IV. Most patients meet criteria for dependence on several substances. Interviews also address diagnoses of disorders commonly comorbid in this group: conduct disorder attention-deficit/hyperactivity disorder, major depressive disorder, dysthymic disorder, and posttraumatic stress disorder. Interviews also address experiences of abuse or neglect, which are very common in these patients. Group and individual therapy is behaviorally oriented, with immediate rewards for progress in treatment and punishments for lapses to previous behaviors. Patients attend onsite schools with special education teachers, together with planned recreational activities. The programs provide birth control consultations with Planned Parenthood as well as a nursery for the babies of adolescent female patients. The patients' parental families, often very chaotic, are engaged in a modification of structural family therapy. Participation in 12-step programs is required. Treatment interventions are coordinated closely with interventions by community social workers and probation officers. No medications are prescribed for inhalant abuse or dependence per se, but a child-and-adolescent psychiatrist often prescribes antidepressants for depression, disulfiram (Antabuse) for comorbid alcohol dependence, or pemoline (Cylert) for attention-deficit/hyperactivity disorder. Progress is monitored with urine and breath samples at intake and frequently during treatment. Patients who fail to abstain in day treatment may transfer to residential care. Treatment usually lasts 3 to 12 months. Termination is considered successful if the youth has practiced a plan to stay abstinent in a supportive, drug-free environment; to interact with the family in a more productive way; to work or attend school; and to associate with drug-free, nondelinquent peers. In many cases, of course, these goals are only partially accomplished. As with all other treatments for inhalant abuse or dependence, controlled studies of long-term outcomes are lacking.

Laboratory Examinations Therapy for substance use disorders often uses repeated tests of biological samples to validate patients' reports of abstinence or use. However, with inhalants such tests may be difficult to interpret. First, these volatile compounds have a relatively brief sojourn in the body and may be detected in urine for only a few hours after use. Second, even if the compounds occur in urine, they may volatilize out of samples during transfer or storage. Third, although hippuric acid, a toluene metabolite, can be detected longer than toluene, hippuric acid also may be produced from foods, raising a question of false-positive findings. Fourth, inhalants may bind to, or pass through, the plastic of urine cups or breath collection bags, reducing concentrations and making the compounds undetectable. Thus, the most careful monitoring of inhalant use would involve frequent urine samples (e.g., two or three per week) at random times, collected in tightly sealed glass containers with little or no air space, and carefully refrigerated until analysis. Analyses would be both for inhalants themselves and for the ratio of hippuric acid to creatinine. However, even under these ideal conditions, the short half-life of inhalants makes inhalant monitoring much less valuable clinically than monitoring for many other substances.

Similarly, breath samples may be collected in specially designed glass traps or in Tedlar (not Mylar) bags. However, the half-life of inhalants in alveolar air apparently is a matter of minutes, and so breath samples may be useless for monitoring treatment progress in patients who show no current signs of intoxication.

INHALANT INTOXICATION

Diagnosis and Clinical Features Inhalant intoxication should be considered in persons showing an acute onset of behavioral disturbance, coupled with the characteristic odor of organic solvents or the presence of inhalation paraphernalia. Inhalant intoxication is an inhalant-related, clinically significant maladaptive behavioral disorder that develops during or immediately after inhalant use and (assuming survival) clears a few hours later. Intoxication signs initially may include vomiting and motor stimulation, followed by slowing, ataxia, depressed reflexes, slurred speech, disorientation, impaired judgment, lethargy, or coma. Bronchospasm, chest pain, cardiac arrhythmias or arrest, trauma, accidental burns, seizures, aspiration of vomitus, or suffocation in a plastic bag may result. Users often show slowed speech, elated mood, fearfulness, illusions, auditory and visual hallucinations, delusions, and perceptions of altered body size. The DSM-IV diagnostic criteria are listed in Table 11.8-2. ICD-10 provides a comparable diagnostic category of acute intoxication due to use of volatile substances.

A. Recent intentional use or short-term, high-dose exposure to volatile inhalants (exc halling anesthetic gases and short-acting vasodilators).
B. Clinically significant maladaptive behavioral or psychological changes (e.g., belligerence, assaultiveness, apathy, impaired judgment, impaired social or occupational functioning) that developed during, or shortly after, use of or exposure to volatile inhalants.
C. Two or more of the following signs, developing during, or shortly after, inhalant use or exposure:
(1) dizziness
(2) nystagmus
(3) incoordination
(4) slurred speech
(5) unsteady gait
(6) lethargy
(7) depressed reflexes
(8) psychomotor retardation
(9) tremor
(10) generalized muscle weakness
(11) blurred vision or diplopia
(12) stupor or coma
(13) euphoria
D. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

Table 11.8-2 DSM-IV Diagnostic Criteria for Inhalant Intoxication

Laboratory Examinations As noted above, random, intermittent monitoring of biological samples has modest value for confirming self-reported abstinence in nonintoxicated patients with inhalant abuse or dependence, because inhalants are so briefly detectable in the body. However, patients showing behavioral signs of inhalant intoxication do, in most cases, have detectable concentrations of inhalants in urine and breath. Confirming their presence may have later clinical or forensic value. Urine samples should be collected in glass vessels with little or no air space, sealed tightly, and refrigerated until analysis for inhalants themselves and for the ratio of hippuric acid (a toluene metabolite) to creatinine. Alternatively, breath samples may be collected in specially-designed glass traps or in Tedlar (not Mylar) bags, and they should be analyzed for inhalants within a few hours.

Differential Diagnosis Differentiation from other intoxications is aided by a history of inhalant use, the presence of inhalant odor and residues on the skin or clothing, a characteristic perioral rash from contact with organic solvents, and toxicological examination of body fluids. Polysubstance use is common among solvent users, and concurrent intoxications with other drugs may be assessed by history and toxicological examinations. Despite evidence of inhalant intoxication, in comatose patients other explanations (e.g., closed head injury) must be sought. Dextrose 50 percent for injection (50 grams) and naloxone (Narcan) 2 mg intravenously help rule out coma of diabetic or narcotic origin. If delirium develops in the course of an intoxication with inhalants, the diagnosis is inhalant intoxication delirium, rather than inhalant intoxication. If a mood disturbance, anxiety, or psychosis appear very prominently during an intoxication and if those symptoms are severe enough to warrant independent clinical attention, the diagnosis should be inhalant-induced mood disorder, inhalant-induced psychotic disorder, or inhalant-induced anxiety disorder, respectively.

Course and Prognosis The onset of intoxication is almost instantaneous after the inhalation of volatile hydrocarbons, given the rapid absorption of those inhalants across pulmonary membranes and their quick distribution into the brain and other lipids. Inhalant drugs are rapidly metabolized and excreted, and inhalant intoxication usually lasts a few hours or less. Unless trauma, hypoxia, cardiac arrest, burns, or other problems ensue, there probably are no lasting effects from one or a few intoxications, except that each use of these reinforcing drugs increases the probability of further use. Prolonged, repeated use causes persisting effects.

Treatment Inhalant intoxication, like alcohol intoxication, usually receives no medical attention and resolves spontaneously. However, effects of the intoxication, such as coma, bronchospasm, laryngospasm, cardiac arrhythmias, trauma, or burns, need treatment. Otherwise, care primarily involves reassurance, quiet support, and attention to vital signs and level of consciousness. Some evidence suggests that physical agitation during inhalant intoxication may precipitate cardiac arrhythmias or cardiac arrest, so the environment should be calming and reassuring. However, sedative drugs, including benzodiazepines, are contraindicated, since they may potentiate inhalant effects. Because of the short half-life of inhalants, inhalant intoxication usually improves considerably after about 30 minutes of abstinence, unless other drugs were also consumed. Following resolution of the intoxication a careful evaluation is needed with appropriate intervention or referral for inhalant abuse or dependence, other substance use disorders, conduct disorder, or antisocial personality disorder.

INHALANT INTOXICATION DELIRIUM

DSM-IV provides a diagnostic category for inhalant intoxication delirium (see Table 10-22). Inhalant intoxication delirium is a disturbance of consciousness and a

change in cognition that results from intoxication with inhalants and is not better explained by dementia. The course and treatment are like those of inhalant intoxication but the additional confusion requires special attention to patient safety. If the delirium results in severe behavioral disturbances, short-term treatment with a dopamine receptor antagonist—for example, haloperidol (Haldol)—may be necessary. Benzodiazepines should be avoided because of the possibility of adding to the patient's respiratory depression. ICD-10 provides a comparable diagnostic category, “acute intoxication due to use of volatile substances, with delirium.”

INHALANT-INDUCED PERSISTING DEMENTIA

Diagnosis and Clinical Features Studies of inhalant-caused cognitive impairment have been equivocal and have been beset by numerous methodological problems, including a focus on adolescent users with briefer lifetime exposures. But clinical and some research evidence suggests that some inhalant-using adults develop inhalant-induced persisting dementia. For example, among toluene users (average age, 29 years) studied with magnetic resonance imaging, the neuropsychological deficits correlated strongly with the severity of cerebral white matter abnormalities.

The cardinal feature of the disorder is dementia resulting from the use of inhalants (see Table 10-31). Nearly all of these persons also meet the criteria for inhalant dependence. Patients with inhalant-induced persisting dementia have memory impairment and at least one of the following: aphasia (language disturbance), apraxia (impaired ability to carry out motor activities despite intact motor function), agnosia (failure to recognize or identify objects despite intact sensory function), and disturbed executive functioning (planning, organizing, sequencing, abstracting). The symptoms must significantly impair social or occupational functioning, represent a decrement from earlier functioning, not occur exclusively in the course of a delirium, and persist beyond the usual duration of inhalant intoxication. The ICD-10 category of dementia in other specified diseases classified elsewhere includes inhalant-induced persisting dementia.

Differential Diagnosis Nearly all of these patients have inhalant dependence and many are dependent on alcohol, which also produces dementia. Moreover, histories of head injury are very common among such patients. Thus, despite clear evidence of prolonged inhalant use, this disorder requires a full evaluation for the multiple causes of dementia.

Course and Prognosis Few of these patients have been studied prospectively. Despite some reports of improvement when patients abstained from inhalants, it seems likely that most neuropsychological deficits that persist for days or weeks after intoxication will continue or worsen. Moreover, as dementia progresses, patients become more difficult to treat, and each relapse adds to their cerebral toxicity.

Treatment There is no established treatment for the cognitive and memory problems of inhalant-induced persisting dementia. Low-key street outreach and extensive social service support have been offered to severely deteriorated inhalant-dependent homeless adults. Patients may require extensive support within their families or in foster or domiciliary care.

INHALANT-INDUCED PSYCHOTIC DISORDER

The essential features of inhalant-induced psychotic disorder are prominent hallucinations or delusions judged to be due to the direct physiological effect of inhalant substances. Such psychotic symptoms sometimes develop during intoxication with inhalants, so this diagnosis applies to patients who meet criteria for inhalant intoxication but who also have psychotic symptoms in excess of those usually associated with inhalant intoxication. The psychotic symptoms must be severe enough to warrant independent clinical attention. This diagnosis is not made in the presence of inhalant intoxication delirium. The clinician can specify whether hallucinations or delusions predominate (Table 13.3-4).

The course and treatment of inhalant-induced psychotic disorder are like those of inhalant intoxication. The disorder is brief, lasting a few hours to (at most) a very few weeks beyond the intoxication. Vigorous treatment of such life-threatening complications as respiratory or cardiac arrest, together with conservative management of the intoxication itself, is appropriate. Confusion, panic, and psychosis mandate special attention to patient safety. Severe agitation may require cautious control with haloperidol (5 mg per 70 kg intramuscularly, repeated once in 20 minutes if needed). Sedative drugs, including benzodiazepines, may potentiate and worsen inhalant intoxications.

Despite similarities in name, DSM-IV's inhalant-induced psychotic disorder differs from ICD-10's residual and late-onset psychotic disorder due to volatile substance use. The former is a variant of inhalant intoxication, while the later is conceptualized as persisting long after direct psychoactive substance effects abate. Controversy continues as to whether inhalants produce persisting psychotic states. In ICD-10, acute intoxication due to use of volatile substances includes patients with marked psychotic symptoms arising in the course of the intoxication.

INHALANT-INDUCED MOOD DISORDER

The essential feature of inhalant-induced mood disorder (see Table 14.6-18) is a prominent disturbance of mood judged to be due to the direct physiological effect of inhalant substances. Such mood symptoms sometimes develop during intoxication with inhalants, so this diagnosis applies to patients who meet criteria for inhalant intoxication but who also have mood symptoms in excess of those usually associated with inhalant intoxication. The mood symptoms must be severe enough to warrant independent clinical attention. The clinician can specify one of the following subtypes: with depressive features (probably the more common subtype), with manic features, or with mixed features. This diagnosis is not made in the presence of inhalant intoxication delirium. In ICD-10, acute intoxication due to use of volatile substances includes patients with marked affective symptoms arising in the course of the intoxication.

The course and treatment of inhalant-induced mood disorder are like those of inhalant intoxication. Inhalant-induced mood disorder is brief, lasting a few hours to (at most) a very few weeks beyond the intoxication. Although antidepressant or antimanic drugs are seldom appropriate for these relatively brief disorders, a history and psychosocial attention to suicide are important. Suicide has been implicated in 40 percent of inhalant-related medical examiners' death reports and in 38 percent of inhalant-related visits to hospital emergency departments.

INHALANT-INDUCED ANXIETY DISORDER

The essential features of inhalant-induced anxiety disorder (see Table 15.6-18) are prominent anxiety symptoms judged to be due to the direct physiological effect of inhalant substances. Such anxiety symptoms sometimes develop during intoxication with inhalants, so this diagnosis applies to patients who meet criteria for inhalant intoxication but who also have anxiety symptoms in excess of those usually associated with inhalant intoxication. The anxiety symptoms must be severe enough to warrant independent clinical attention. This diagnosis is not made in the presence of inhalant intoxication delirium. The clinician can specify one of the following subtypes: with generalized anxiety, with panic attacks, with obsessive-compulsive symptoms, or with phobic symptoms; generalized anxiety and panic attacks are probably most common. In ICD-10, acute intoxication due to use of volatile substances includes patients with marked anxiety symptoms arising in the course of the intoxication.

The course and treatment of inhalant-induced anxiety disorder are like those of inhalant intoxication. Sedative and antianxiety drugs are contraindicated, since they worsen inhalant intoxication, which precipitates inhalant-induced anxiety disorder.

INHALANT-RELATED DISORDER NOT OTHERWISE SPECIFIED

The diagnosis of inhalant-related disorder not otherwise specified is reserved for inhalant-related disorders that do not fit into one of the above diagnostic categories (Table 11.8-3).

The inhalant-related disorder not otherwise specified category is for disorders associated with the use of inhalants that are not classifiable as inhalant dependence, inhalant abuse, inhalant intoxication, inhalant intoxication delirium, inhalant-induced persisting dementia, inhalant-induced psychotic disorder, inhalant-induced mood disorder, or inhalant-induced anxiety disorder.

Table 11.8-3 DSM-IV Diagnostic Criteria for Inhalant-Related Disorder Not Otherwise Specified

NITROUS OXIDE–RELATED DISORDERS

DSM-IV includes nitrous oxide–related disorders among other substance-related disorders because of differences in modes of action and associated problems. Nitrous oxide was introduced for clinical practice in 1844 and is still a widely used inorganic gas anesthetic. It also is a propellant in whipped-cream dispensers. Not surprisingly, nitrous oxide misuse seems to appear most commonly among the health-care and food-service workers who use these preparations, although there is little scientific information on its epidemiology. The drug has a rapid onset and offset of action. It is mostly excreted in the breath with little or no biotransformation. Some users experience euphoria and a pleasant dreamlike state with nitrous oxide, but several studies show that it is not a reinforcer for most research subjects who have been exposed only a few times. Chronic use may produce diffuse polyneuropathy and myelinopathy with extensive, although sometimes reversible, neurological symptoms mimicking those of vitamin B_{12}–related pernicious anemia. Active vitamin B_{12} requires reduced cobalt, but nitrous oxide irreversibly oxidizes cobalt, suppressing the activity of an important enzyme, methionine synthase.

A 35-year-old male dentist with no history of other substance problems complained of problems with nitrous abuse for 10 years. This had begun as experimentation with what he had considered a harmless substance. However, his rate of use increased over several years, eventually becoming almost daily for months at a time. He felt a craving before sessions of use. Then, using the gas while alone in his office, he immediately felt numbness, a change in his temperature and heart rate, and an alleviation of depressed feelings. “Things would go through my mind. Time was erased.” He sometimes fell asleep. Sessions might last a few minutes, or up to 8 hours; they ended when the craving and euphoria ended. He had often tried to stop or cut down, sometimes consulting professionals about the problem.

Cases in the literature strongly suggest that nitrous oxide intoxication, dependence, and abuse do occur. Considering the drug's brief duration of action and users' intermittent inhalation patterns, nitrous oxide appears unlikely to produce clinically significant withdrawal. It is not clear, however, whether nitrous oxide produces other substance-related disorders. There are no clinically practical urine or breath tests for the presence of nitrous oxide. Misusers of the drug who develop neurological symptoms may have low serum concentrations of vitamin B_{12}, and remission of neurological symptoms has followed combined administration of B_{12} and folate, together with abstinence from nitrous oxide. In the absence of controlled studies of treatment for nitrous oxide use disorders, general principles for treating other substance use disorders should guide the treatment of these patients.

AMYL AND BUTYL NITRITE–RELATED DISORDERS

DSM-IV includes amyl and butyl nitrite–related disorders among other substance-related disorders. The vapors of amyl nitrite, a volatile liquid, produce vasodilation and smooth muscle relaxation. Supplied in easily “popped” glass vials, amyl nitrite found wide use as acute inhalation therapy for angina pectoris between 1867 and about 1980. Sublingual nitroglycerin tablets now have superseded that use. Amyl nitrite and its close relative, butyl nitrite, enjoyed a flurry of use as recreational drugs during the 1970s and 1980s. Reports from that time suggest that the use mainly was among adolescents, users of other drugs, and homosexual men. The latter group especially reported using the drugs to enhance orgasm, and these nitrites also were considered to produce a high, a feeling of wild abandon, or an altered state of consciousness. Nonmedical users called amyl nitrite vials “poppers.” Those vials' availability declined with their declining medical use. Butyl nitrite was then increasingly sold as a “room odorizer” (but really for inhalation) under suggestive names such as Rush or Locker Room.

In one study of patients who had misused these drugs, most experienced dizziness, lightheadedness, cardiac palpitations, blurred vision, and a feeling of warmth immediately after the inhalation. Others complained of immediate headache, nasal burning, nausea, cough, dyspnea, or syncope. Nearly half found the experience not at all pleasant, and the others rated it only as “fair to good.”

A few case reports document severe, but nonfatal methemoglobinemia after nitrite inhalation by persons genetically deficient in methemoglobin reductase. There also are reports of rapidly fatal methemoglobinemia after oral ingestion (not inhalation) of these compounds by genetically normal persons. Some epidemiological studies further suggested that among homosexual men nitrite use might increase the risk of HIV infection or of developing Kaposi's sarcoma after HIV infection. However, those observations were heavily confounded, since nitrite users tended to have more partners and to pursue unsafe sexual practices more frequently.

Considered together, the lack of a compelling instantaneous high, the immediate unpleasant feelings, and the longer-term risks from amyl and butyl nitrite seem to have reduced the prevalence of their use. In 1979 an annual national survey of high school seniors found that 6.5 percent reported using these drugs in the previous year, but that percentage fell to 1.2 percent by 1997. Similarly, among Americans over 12 years of age living in households, only 2 percent said in 1996 that they ever had used amyl nitrite “for kicks or to get high.”

No studies have examined users of amyl or butyl nitrite with modern diagnostic procedures, and it is unknown how many (if any) meet criteria for intoxication, abuse, or dependence. Some persons with sustained industrial exposures to nitrites experience withdrawal headaches on weekends or vacations, but it seems unlikely that intermittent, brief exposures to these short-acting drugs would produce clinically significant withdrawal in recreational misusers of nitrites. There are no studies of the treatment of amyl or butyl nitrite–related disorders, and so such treatment should follow general principles for the treatment of other substance-related disorders.

SUGGESTED CROSS-REFERENCES

An overview of substance-related disorders is given in Section 11.1, hallucinogen-related disorders are discussed in Section 11.7, and phencyclidine-related disorders are discussed in Section 11.11. Mood disorders are discussed in Chapter 14. Chapter 15 reviews anxiety disorders, and Chapter 13 covers psychotic disorders.

11.9 NICOTINE-RELATED DISORDERS

JOHN R. HUGHES, M.D.

Nicotine dependence is the most prevalent, most deadly, most costly, yet most treatable of the substance dependencies. In the past psychiatrists have often not participated in the diagnosis and treatment of nicotine dependence, perhaps because of the incorrect notion that most smokers do not need treatment or that psychiatric patients are unlikely to respond to smoking cessation treatment because most health insurers or organizations do not reimburse for treatment of smoking. There is increasing recognition that smoking is usually a form of substance dependence and that treatment for smoking is highly cost effective. In addition, persons who continue to smoke despite significant social pressure appear to be those who are severely nicotine dependent or who have significant psychiatric problems that interfere with cessation. These two trends—increasing legitimization of treatment and a selection bias toward highly dependent smokers with comorbid mental disorders—suggest that psychiatrists will play a larger role in treating smoking cessation.

DEFINITION

Nicotine dependence and withdrawal are the two defined nicotine-related disorders in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). The essential feature of any substance dependence disorder in DSM-IV is that "the individual continues use of the substance despite significant substance-related problems." Because 50 percent of smokers die of a smoking-related illness, this definition clearly is applicable to nicotine use. The essential feature of withdrawal is "a substance-specific maladaptive behavioral change... that is due to the cessation of, or reduction in, heavy and prolonged substance use." Because nicotine withdrawal produces an observable, well-defined, time-limited syndrome in over half of smokers, this definition also appears appropriate.

Nicotine abuse is not included in DSM-IV because abuse is confined to significant psychosocial but not physical problems and the former is rare with nicotine use. The 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) includes harmful use, a category similar to abuse but that includes continued use that causes physical problems; thus, harmful use from the nicotine-containing products often occurs. Nicotine intoxication is very rare; it is included in ICD-10 but not DSM-IV.

HISTORY AND COMPARATIVE NOSOLOGY

Tobacco use in the New World dates back to at least 600 AD and was introduced into European culture in the sixteenth century. Early on, most tobacco use was via pipes, smokeless tobacco, or cigars. The cigarette became popular beginning in the early 1900s with the invention of the cigarette-making machine and the use of acidifying agents to permit nicotine to enter the lower respiratory tract where it could be rapidly absorbed into the arterial circulation. Cigarette use grew dramatically in the first half of the twentieth century. The first reports of the association of smoking and disease began in the 1950s and culminated with the 1964 *Surgeon General's Report on Smoking and Health*. Use in the United States fell slightly after this but then began to decline dramatically in the 1970s but has plateaued recently. However, in the 1990s use has stabilized plus noncigarette products such as cigars and smokeless tobacco use have increased. Although tobacco use in other Western nations has declined somewhat, use in developing countries is actually increasing.

Nicotine dependence was widely accepted but not codified until the 1980 third edition of DSM and (DSM-III) and the ninth revision of the International Statistical Classification of Diseases (ICD-9) included tobacco dependence and withdrawal as disorders. The revised third edition of DSM (DSM-III-R) and the 1988 U.S. Surgeon General's *The Health Consequences of Smoking—Nicotine Addiction* concluded that smoking was a form of substance dependence.

EPIDEMIOLOGY

In 1998 25 percent of Americans smoked, 25 percent are former smokers, and 50 percent have never smoked cigarettes. The prevalence of pipe, cigar, and smokeless tobacco use is less than 2 percent. The prevalence of smoking in the United States was decreasing about 1 percent a year but it has not changed in the last 4 years because of increased initiation and decreased cessation.

The mean age of onset of smoking is 16 and few persons start after 20. Dependence features appear to develop quickly. Classroom and other programs to prevent initiation are only mildly effective and increased taxation does decrease initiation.

Over 75 percent of smokers have tried to quit, about 40 percent try to quit each year. On a given quit attempt only 30 percent remain abstinent for even 2 days and only 5 to 10 percent stop permanently. However, most smokers make 5 to 10 attempts such that eventually 50 percent of eversmokers quit. In the past, 90 percent of successful quit attempts involved no treatment. However, with the advent of over-the-counter (OTC) and nonnicotine medications in 1998, about one third of all quits were due to use of medication.

In terms of the diagnosis of nicotine dependence per se, about 20 percent of the population develops nicotine dependence at some point, making it the most prevalent psychiatric disorder. Approximately 85 percent of current daily smokers are nicotine dependent. Nicotine withdrawal occurs in about 50 percent of smokers who try to quit.

Smoking is now as common in women as in men. Smoking is more prevalent in those with lower education and income, in most ethnic groups, and is especially high in psychiatric patients (50 percent), including those with other substance use disorders (80 percent).

ETIOLOGY

Both nicotine and acetylcholine interact with nicotinic-cholinergic receptors. Originally these receptors were thought to be confined to the ganglia and neuromuscular junction but have now been found in several areas of the central nervous system (CNS). These receptors are unusual in that they quickly desensitize. This phenomena plus the fact that repeated use of nicotine increases, not decreases, the number of receptors suggests that nicotine may actually act much as an antagonist as an agonist at this receptor.

The dependence-producing effects of nicotine appear to be modulated by dopamine (e.g., nicotinic-cholinergic receptors lie on dopamine neurons, nicotine increases dopamine, and dopamine blockers attenuate nicotine self-administration). Nicotine also increases norepinephrine, epinephrine, and serotonin and these increases may modulate some of the reinforcing effects from cigarettes.

Nicotine via cigarettes is rapidly absorbed directly into the arterial circulation and reaches the CNS in less than 15 seconds. Peak behavioral and cardiovascular effects occur within a few minutes. Nicotine is metabolized via the liver and has a half-life of about 2 hours. Nicotine levels from smoking typically rise in the morning, plateau in the evening, and fall to near zero in the night. This pattern causes an acute tolerance such that the first cigarettes of the day are more potent than later cigarettes.

Nicotine improves performance on long, fatiguing, boring tasks. It decreases anger and stabilizes mood. It decreases hunger and food intake and increases metabolic

rate. When a smoker experiences these effects, it is often not clear how much of them result from nicotine combating withdrawal and bringing the smoker back to normal and how much is actual improvement above the norm. Some of nicotine's effects (e.g., performance enhancement) appear to occur independent of withdrawal relief.

Nicotine use, like most substance use, begins because of social reinforcement. However, with repeated exposure, many young users find the pharmacological effects of nicotine well suited to help them with the demands of adolescence. In addition, a physical dependence on nicotine begins so that periods of nonuse become uncomfortable.

Children more likely to start smoking are those who have a high need to conform, low academic performance, rebelliousness, depressive symptoms, and poor self-esteem. Both peer and family influences are paramount. Attention deficit, conduct, and alcohol or drug use disorders increase the risk of initiation and maintenance of smoking.

Although not widely known, initiation and cessation of tobacco use are as heritable as alcoholism (alcohol dependence or abuse). Some of the genetic effects are shared with alcohol and some are specific to tobacco (Table 11.9-1). The biological and behavioral mechanisms for genetic effects on tobacco use are not known.

	Genetic Variance		
Substance	Common to Both Substances	Substance-Specific	Total
Tobacco	36%	20%	56%
Alcohol	17%	32%	49%

Table 11.9-1 Percent of Variation in Cigarette Smoking and Alcohol Consumption, Attributable to Genetic Sources

DIAGNOSIS AND CLINICAL FEATURES

Table 11.9-2 lists the DSM-IV nicotine-related disorders. Most of the generic criteria for substance dependence readily apply to nicotine (e.g., tolerance, a withdrawal syndrome, use to avoid withdrawal, inability to stop despite repeated attempts, and continued use despite knowing that use is harmful) (Table 11.9-3). Because nicotine is legal and easily available, spending a great deal of time to procure the drug and giving up activities to use the drug are rare.

Table 11.9-2 DSM-IV Nicotine-Related Disorders

Criteria	Examples
Tolerance	Absence of nausea, dizziness, etc; most smokers escalate use to 1 pack/day or more by age 25
Withdrawal	See Table 11.9-4
The substance is often taken in larger amounts or over a longer period than was intended	Most smokers do not intend to smoke 5 years later, but over 70% continue to use
Persistent desire or unsuccessful effort to stop	5–10% of self-quitters are successful on each attempt; 50% of smokers have not been able to stop despite repeated attempts
A great deal of time is spent to obtain, use, or recover from the drug	Leaving work site to smoke
Important activities are given up or reduced because of substance use	Not taking a job because of smoking restrictions in the workplace
Use continues despite knowledge of problems caused by substance	Many smokers have heart disease, chronic obstructive pulmonary disease, or ulcers and continue to smoke

Table 11.9-3 Examples of DSM-IV Nicotine Dependence Criteria

There are several reasons smoking can produce such a severe dependence: (1) nicotine produces many different effects that can be used in many different situations (2) with pulmonary; absorption, nicotine reaches the brain in a few seconds producing a rapid effect; (3) smoking allows the user to titrate the dose; (4) smoking is an intense habit >200 puffs/day × 20 years); (5) there are many environmental cues eliciting smoking (e.g., others smoking and advertisements); and (6) nicotine use almost never impairs the user via intoxication.

Nicotine withdrawal (Table 11.9-4) is manifested by changes in mood, insomnia, difficulty concentrating, restlessness, decreased heart rate (average decline is 8 beats per minute [bpm]), and weight gain (average is 2 to 3 kg). The insomnia appears to be specific to increased awakenings and intense dreaming. Postcessation weight gain is due both to increased eating and the loss of nicotine stimulation of metabolism. Craving is common and increased coughing and poor performance on vigilance tasks can occur. The syndrome is typically worse in cigarette smokers, intermediate in users of smokeless tobacco, and mild in users of nicotine replacement products. Most withdrawal symptoms peak at 1 to 3 days and last 3 to 4 weeks; however, 40 percent of smokers have withdrawal that lasts for more than 4 weeks. In addition, craving and weight gain often persist for 6 months or more.

A. Daily use of nicotine for at least several weeks.
B. Abrupt cessation of nicotine use, or reduction in the amount of nicotine used, followed within 24 hours by at least four of the following signs: (1) dysphoric or depressed mood (2) insomnia (3) irritability, frustration, or anger (4) anxiety (5) difficulty concentrating (6) restlessness (7) decreased heart rate (8) increased appetite or weight gain
C. The symptoms in criterion B cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

Table 11.9-4 DSM-IV Diagnostic Criteria for Nicotine Withdrawal

Abstinence can also have pharmacokinetic effects. Nonnicotine chemicals in tobacco smoke activate cytochrome P450 enzymes, thereby decreasing the levels of several medications. As a result, smoking cessation increases the concentrations of these medications. Many of these medications are psychiatric medications and often the increase can be clinically significant (e.g., haloperidol [Haldol], clozapine [Clozaril], and fluvoxamine [Luvox] concentration increase 30 to 40 percent with abstinence) (Table 11.9-5).

Abstinence Increases Blood Concentrations			
Clomipramine	Desmethyldiazepam	Haloperidol	Nortriptyline
Clozapine	Doxepin	Imipramine	Propranolol
Desipramine	Fluvoxamine	Oxazepam	
Abstinence Does Not Increase Blood Concentrations			
Amitriptyline	Ethanol	Midazolam	
Chlordiazepoxide	Lorazepam	Triazolam	
Effects of Abstinence Unclear			
Alprazolam	Chlorpromazine	Diazepam	

Table 11.9-5 Effect of Abstinence From Smoking on Blood Concentrations of Psychiatric Medicines

Smoking (and particularly nicotine dependence) is two to three times more prevalent among patients with mood, substance use, and other psychiatric disorders. Conversely, these psychiatric disorders are two to three times more common among current smokers than among never or exsmokers. There are several possible reasons for this association—for example, shared genetic influences on smoking and psychiatric disorders, modeling other psychiatric patients, and boredom. Among adolescents the number of depressive symptoms predicts both the likelihood of starting to smoke and the probability of becoming dependent. Recent work suggests that more than nicotine may be responsible for this association. Tobacco smoke and extracts of smokeless tobacco contain substances other than nicotine that inhibit monoamine oxidase type A (MAO_A) and MAO_B, and recent work using positron emission technology has shown less MAO_B activity in the brains of cigarette smokers. The nature of the chemical entity is not known but in in vitro models, this inhibition, like that of most clinically available MAO inhibitors, is irreversible. This suggests that MAO inhibition would persist until the body synthesizes new enzymes, a process that usually takes several weeks. Psychiatric patients may have a special need for the anxiolytic, anorexic, antiaggression, antidepressant, and improved concentration effects of nicotine. Nicotine also increases the self-administration of alcohol, which may predispose smokers to alcoholism. Finally, smokers with a current or past history of a depressive disorder have more withdrawal upon cessation and a lower rate of smoking cessation. DSM-IV also includes a residual category of nicotine-related disorders not otherwise specified (Table 11.9-6).

The nicotine-related disorder not otherwise specified category is for disorders associated with the use of nicotine that are not classifiable as nicotine dependence or nicotine withdrawal.

Table 11.9-6 DSM-IV Diagnostic Criteria for Nicotine-Related Disorder Not Otherwise Specified

DIFFERENTIAL DIAGNOSIS

Many of the symptoms of nicotine withdrawal can mimic, exacerbate, or mask the symptoms of psychiatric disorders or the adverse effects of psychiatric medications (e.g., akathesia, anxiety, depression, irritability, insomnia, and weight gain). Some recent data suggests that cessation of smoking can reinitiate a psychiatric (including substance use) disorder in a subgroup of smokers; however, other data refute this.

COURSE AND PROGNOSIS

About half of smokers finally stop smoking; however, half do not and many of those who stopped had unfortunately done so having already developed smoking-related diseases. Twenty percent of all mortality in the United States is due to smoking. About 45 percent of smokers will die of a smoking-related disease resulting in over 410,000 deaths a year in the United States. Smoking is a huge risk for lung cancer, accounting for over 90 percent of all deaths from lung cancer. Smoking doubles the risk for cardiovascular disease deaths, but because this disease is more prevalent, it accounts for more smoking deaths than lung cancer. Other common smoking-related diseases include chronic obstructive pulmonary disease, low–birth-weight, perinatal complications, other cancers (e.g., throat, breast, and pancreas) and ulcers. Second-hand smoke increases the risk of cancer and heart disease in spouses and the incidence of respiratory and ear problems in children.

The tar in cigarette smoke is responsible for the cancers. Irritants and ciliotoxins appear to be responsible for lung diseases. Carbon monoxide and clotting factors appear to be the most likely causes of cardiovascular disease. The role of nicotine in cardiovascular disease is actually not well defined and how many perinatal problems are caused by carbon monoxide or by nicotine is debatable.

Cessation of smoking almost eliminates the risk of heart disease in 5 years and of lung cancer in 20 years. Although cross-sectional epidemiological data suggest that switching to low-tar cigarettes should decrease cancer, this is still not firmly established. Whether decreasing the number of cigarettes decreases risk has also not been directly tested.

Nicotine intoxication causes abdominal pain, dizziness, headaches, nausea, pallor, palpitations, sweating, vomiting, and weakness. Intoxication is rare although mild

symptoms can occur with nicotine replacement; treatment is supportive.

Epidemiological, biochemical, and clinical trial data suggest that nicotine may be beneficial for dementia of the Alzheimer's type, Parkinson's disease, Tourette's disorder, and ulcerative colitis disorders.

TREATMENT

Psychiatrists are urged to read the two guidelines for the treatment of smoking published in 1996 by the Agency for Health Care Policy Research and by the American Psychiatric Association. All patients should be assessed for smoking status, motivation to quit, and motivators for and barriers to quitting. Smoking status includes current, exsmoker, or neversmoker; type of tobacco used; and frequency of use. Motivation to quit can be classified as *precontemplation* (no plans to quit), *contemplation* (thinking about quitting but no plans), and *preparations* (plans to quit in near future). Common motivators to quit are health concerns, effects of smoking on others, and social pressure. Common barriers to cessation are withdrawal, fear of failure, and fear of weight gain.

Psychiatrists should advise all patients who are not in crisis to quit smoking. Many psychiatric patients are precontemplators and thus the psychiatrist's role is often to use the patient's concerns as motivators for cessation and to suggest ways to decrease barriers to cessation. The psychiatrist should also reintroduce cessation at later visits.

Among patients who are ready to stop smoking, it is best to set a quit date. Most clinicians and smokers prefer abrupt cessation but because there is no good data that abrupt cessation is better than gradual cessation, patient preference for gradual cessation should be respected. Brief advice should focus on the need for medication or group therapy, weight gain concerns, high-risk situations, making cigarettes unavailable, and so forth. Because relapse is often rapid, the first follow-up phone call or visit should be 2 to 3 days after the quit date. These strategies have been shown to double self-initiated quit rates (Table 11.9-7). The psychiatrist should also inform the patient about existing therapies (Table 11.9-8), which can be done by giving the patient the APA booklet *Treatment Works*.

Therapy	Rate (%)
Self-quit	5
Self-help books	10
Physician advice	10
Over-the-counter patch or gum	15
Medication plus advice	20
Behavior therapy alone	20
Medication plus group therapy	30

Table 11.9-8 Scientifically-Proven Treatments for Smoking

Ms. H. was a 55-year-old patient with schizophrenia who smoked 35 cigarettes a day and smoked each cigarette very intensely. She began her cigarette use at around the age of 20 during the prodromal stages of her first psychotic break. Over the next 35 years she had several psychotic breaks and was treated with conventional antipsychotic agents. During the first 30 years of treatment, no psychiatrist or physician advised her to stop smoking, largely because they believed she could not stop.

At age 53 she was diagnosed with diabetes and early ischemic heart disease. At that time her primary care physician recommended smoking cessation. The patient attempted to stop on her own but lasted only 48 hours, partly because her housemates and friends smoked. After a second failure on her own, she became discouraged and concluded that she could not stop smoking. During a routine medication check, her psychiatrist recommended that she stop smoking and the patient described her prior attempts. The psychiatrist and the patient discussed ways to avoid smokers and had the patient announce her intent to quit and request her friends to try not to smoke around her and to offer encouragement for her attempt to quit. The psychiatrist also noted that she became irritable, slightly depressed, restless, and insomniacal during prior cessation attempts, and thus recommended medications and used the APA brochure *Treatment Works* to help the patient decide which medication was best for her. The patient chose a nicotine patch.

The psychiatrist had the patient call 2 days after her quit attempt. At this point the patient stated that the patch and gum were helping but she still felt “left out” when her friends smoked and talked. One week later the patient returned after having relapsed back to smoking. The psychiatrist praised the patient for not smoking for 4 days. He suggested that the patient contact him again if she wished to try to stop again. Seven months later during another medication check the psychiatrist again asked the patient to consider cessation but she was reluctant.

Two months later the patient called and said she wished to try again. She met with the psychiatrist and this time the psychiatrist and patient listed several activities the patient could do to avoid being around friends who smoked, phoned the patient's boyfriend to ask him to assist the patient in stopping, asked the nurses on the inpatient ward to call the patient to encourage her, plus decided to enrol the patient in a support group for the next 4 weeks. The nicotine patch was used again but this time, the nonnicotine medication buproprion (Zyban) was added. The patient was followed with 15-minute visits for each of the first 3 weeks and two phone calls thereafter. She had two “slips” when she became angry with her boyfriend but did not go back to smoking and remained an exsmoker. An unexpected result of her successful cessation was an improvement in the therapeutic alliance between the patient and her psychiatrist.

Discussion Most psychiatrists fail to diagnose and treat nicotine dependence. Unfortunately, sometimes psychiatrists find that although they have adequately treated the disorder that brought the patient into treatment, the patient has such morbidity or mortality from smoking that he or she cannot reap the benefits of psychiatric treatment. Ms. H.'s psychiatrist was correct in using pragmatic plans to help the patient overcome specific problems, in following the patient with short visits or phone calls, and in recommending nicotine replacement. The total amount of time spent with the patient on smoking was about 3 hours. Although this was not reimbursed, the psychiatrist knew that his intervention was an important contribution to the patient's health and was unlikely to be given by other care providers.

Psychosocial Therapies Behavior therapy is the most widely accepted and well-proven psychological therapy for smoking. Behavior therapy consists of several techniques, three of which are supported by good evidence to support them. *Skills training* and *relapse prevention* identifies high-risk situations and plans and practices behavioral or cognitive coping skills for these situations. *Stimulus control* refers to eliminating cues for smoking in the environment. *Rapid smoking* has smokers repeatedly smoke to the point of nausea, etc. in sessions to associate smoking with unpleasant rather than pleasant sensations. This last therapy appears

effective but requires a good therapeutic alliance and patient compliance.

Often behavior therapy is conducted in group settings to promote social support and save on costs. Typically, several sessions are conducted prior to the quit date and several are scheduled for early after the quit date. Although group therapy for alcohol dependence is widely accepted, most smokers believe that they should be able to quit without help. Even those who seek treatment find that smoking cessation treatments are generally not reimbursable, only voluntary agencies and wellness programs offer treatment and, in most locales, treatment is offered only a few times a year. In addition, these programs are only in larger cities and require patient payment. As a result of these barriers, less than 5 percent of smokers enrol in behavior therapies.

Although written materials are the most common self-help format, telephone systems that tailor treatment to patient concerns have recently been found to be more effective and more acceptable. These systems are available free of charge from pharmaceutical firms and some state health departments and industries.

Psychopharmacological Therapies

Pharmacotherapy The AHCPR and the APA guidelines recommends that all smokers be offered medication to aid in smoking cessation. All the medications approved by the Food and Drug Administration (FDA) for smoking cessation appear equally effective, and they all double the quit rate (similar to results obtained with behavior therapy) (Table 11.9-7). With all these medications few produce side-effects; less than 5 percent of patients stop medication due to adverse effects. Although there are many theories, there are no empirically-verified methods to match smokers to specific therapies. Most clinicians believe that patients should be informed of the various therapies and allowed to choose the therapy they believe will be most helpful. In other substance use disorders, psychosocial therapy is thought to be essential and pharmacotherapy is used as an aid to psychosocial therapy. In nicotine dependence the opposite is true: pharmacotherapy is the treatment to be offered to all, and psychosocial therapy should be added when desirable and feasible.

Nicotine Replacement Therapies All nicotine replacement therapies double cessation rates, presumably because they reduce nicotine withdrawal. These therapies can also be used to reduce withdrawal in patients on smoke-free wards. Replacement therapies use a short period of maintenance (6 to 12 weeks) often followed a gradual reduction period (6 to 12 weeks).

Nicotine gum (Nicorette) is an over-the-counter product that releases nicotine via chewing and buccal absorption. A 2-mg (for <25 cigarettes/day smokers) and a 4-mg gum variety (for ³25 cigarettes/day smokers) are available. Smokers are to use 1 to 2 pieces of gum per hour after abrupt cessation. Venous blood concentrations from the gum are $^{1}/_{3}$ to ½ that of between-cigarette levels. Acidic beverages (coffee, tea, soda, and juice) should not be used before, during, or after gum use because these decrease absorption. Compliance with the gum has often been a problem. Adverse effects are minor and include bad taste and sore jaws. About 20 percent of those who quit use the gum for long periods but 2 percent use gum for longer than a year, plus long-term use does not appear to be harmful. The major advantage of nicotine gum is its ability to provide relief in high-risk situations.

Nicotine patches, also sold over the counter are available in a 16-hour no-taper preparation (Habitrol) and a 24- or 16-hour tapering preparation (Nicoderm CQ). Patches are administered each morning and produce blood concentrations of about half those of smoking. Compliance is high and the only major adverse effects are rashes and, with 24-hour wear, insomnia. Long-term use does not occur. Using gum and patches in high-risk situations increases quit rates by another 5 to 10 percent. Whether 24-hour versus 16-hour or taper versus no-taper patches are better has not been tested.

Nicotine nasal spray (Nicotrol), available only by prescription, produces blood concentrations more similar to a cigarette and appears to be especially helpful for heavily dependent smokers. However, the spray causes rhinitis, watering eyes, and coughing in over 70 percent of patients. Although there was initial data suggesting abuse liability, further trials have not found this.

Nicotine inhaler a prescription product, was designed to deliver nicotine to the lungs but the nicotine is actually absorbed in the upper throat. Resultant nicotine levels are low. The major asset of the inhaler is that it provides a behavioral substitute for smoking. The inhaler also provides double quit rates. These devices require frequent puffing, which can cause minor adverse effects.

Nonnicotine Medications Nonnicotine medications may be helpful to smokers who object philosophically to the notion of replacement therapy and to smokers who fail replacement therapy. Buproprion (Zyban) (marketed as Wellbutrin for depression) is an antidepressant medication that has both dopaminergic and adrenergic actions. Dosages of 300 mg a day reliably double quit rates in smokers with and without a history of depression. In one study, combined buproprion and nicotine patch had higher quit rates than either alone. Adverse effects include insomnia and nausea, but these are rarely significant. Seizures have not occurred in smoking trials. Interestingly, nortriptyline (Pamelor) appears to be effective for smoking cessation.

Clonidine (Catapres) decreases sympathetic activity from the locus ceruleus and is thereby thought to abate withdrawal symptoms. Whether given as a patch or orally, 0.2 to 0.4 mg a day of clonidine appears to double quit rates; however, the scientific database for the efficacy of clonidine is not as extensive nor as reliable as that for nicotine replacement; also, clonidine can cause drowsiness and hypotension.

Combined Psychosocial and Pharmacological Therapy Several studies have shown that combining nicotine replacement and behavior therapy increases quit rates over either therapy alone (Table 11.9-8).

Use in Special Populations Use of nicotine replacement during pregnancy is debatable. On the one hand, the concentrations of nicotine from these medications are much lower than those from smoking, plus no carbon monoxide and tar exposure occurs. However, nicotine has been implicated in low-birth–weight and in sudden infant death syndrome. Nicotine replacement is effective in the elderly without excess complications; it has not been tested in smokers under the age of 18. There are no known effective psychosocial or pharmacological treatments for adolescents.

Smokers who have been recently diagnosed with cancer or heart disease often quit on their own; thus, more intensive therapy probably should be reserved for those who fail; however, recently diagnosed smokers should be followed closely so that such therapy can be offered if they do fail.

Psychiatric patients who are trying to stop smoking should be encouraged to undertake both psychosocial and pharmacological therapies because these patients suffer greater withdrawal symptoms and have a poorer ability to stop. In addition, these patients should be followed weekly to detect any possible exacerbation of their psychiatric problem.

Whether alcoholics should stop smoking along with or soon after stopping drinking is debatable. Current evidence suggests that for the large majority of patients, stopping smoking does not threaten sobriety. Whether smokers with a history of alcoholism or other substance abuse need more intense therapy or different content therapy for smoking cessation is unclear.

Patients on smoke-free psychiatric wards can have withdrawal symptoms that require treatment. Because wards often lack cues for smoking, withdrawal is usually not as problematic as anticipated; thus, treatment should usually be reserved until the emergence of symptoms. If the smoker will be taking passes and smoking, nicotine gum is preferred because it can be used intermittently. If the smoker will be confined to the ward or is using the hospitalization to stop smoking, nicotine patches should be used because they are associated with improved compliance. All smokers should be told that the rationale for the smoke-free ward is not a moral one, but rather to protect nonsmokers from second-hand smoke and to prevent tempting exsmokers under stress from returning to smoking.

SUGGESTED CROSS-REFERENCES

Section 11.1 provides an overview of substance abuse and substance-related disorders. Section 11.2 is devoted to alcohol-related disorders; Chapter 20 discussed eating disorders, and Chapter 21 on sleep disorders and Chapter 39 on attention-deficit disorders are of related interest. Anxiety disorders are the subject of Chapter 15, and mood disorders are presented in Chapter 14. Bupropion is discussed in Section 31.11.

11.10 OPIOID-RELATED DISORDERS

JEROME H. JAFFE, M.D. AND ARI B. JAFFE, M.D.

Throughout the world more than 20 chemically distinct opioid drugs are in clinical use. In the developed countries the opioid drug most frequently associated with abuse and dependence is heroin—a drug that is not used for therapeutic purposes in the United States. Dependence on opioid drugs other than heroin is seen mostly in persons who have become dependent in the course of medical treatment, in health care professionals who have easy access to opioids, and in persons who use drugs that have been diverted from treatment programs. Virtually all the opioid dependence and abuse seen clinically is associated with prototypical μ-agonist opioids. All the μ-agonists produce similar subjective effects. However, the patterns of opioid use and some aspects of toxicity are powerfully influenced by the route of administration and the metabolism of the specific opioid, as well as by the social conditions that determine its price and purity and the sanctions attached to nonmedical use.

DEFINITIONS

The fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) divides *opioid-related disorders* into *opioid-use disorders* (opioid abuse and opioid dependence) and nine other *opioid-induced disorders* (e.g., intoxication, withdrawal).

Opioid dependence is a cluster of physiological, behavioral, and cognitive symptoms, which taken together indicates repeated and continuing use of opioid drugs despite significant problems related to such use. Drug dependence in general has also been defined by the World Health Organization (WHO) as a syndrome in which the use of a drug or class of drugs takes on a much higher priority for a given person than other behaviors that once had a higher value. These brief definitions each have as their central features an emphasis on the drug-using behavior itself, its maladaptive nature, and on how the choice to engage in that behavior has shifted and becomes constrained as a result of interaction with the drug over time.

Opioid abuse is a term used to designate a pattern of maladaptive use of an opioid drug leading to clinically significant impairment or distress and occurring within a 12-month period, but one in which the symptoms have never met the criteria for opioid dependence.

The *opioid-induced disorders* as defined by DSM-IV include such common phenomena as opioid intoxication, opioid withdrawal, opioid-induced sleep disorder, and opioid-induced sexual dysfunction. Opioid intoxication delirium is occasionally seen in hospitalized patients. Opioid-induced psychotic disorder, opioid-induced mood disorder, and opioid-induced anxiety disorder, by contrast, are quite uncommon with μ-agonist opioids, but have been seen with certain mixed agonist-antagonist opioids acting at other receptors. DSM-IV also includes *opioid-related disorder not otherwise specified* for situations that do not meet the criteria for any of the other opioid-related disorders.

HISTORY

Opiates have been used for at least 3500 years, mostly in the form of crude opium or in alcoholic solutions of opium. Morphine was first isolated in 1806 and codeine in 1832. Over the next century, pure morphine and codeine gradually replaced crude opium for medicinal purposes, although nonmedical use of opium (as for smoking) still persists in some parts of the world. The first semisynthetic opium derivative—diacetylmorphine or heroin—was introduced into medicine in 1898. The first purely synthetic drugs with morphine-like opioids, meperidine (Demerol) and methadone (Dolophine), were introduced into medical practice in the 1940s. The term “opioid” was coined to include the naturally occurring drugs derived from opium (morphine and codeine), the semisynthetic drugs produced from opium derivatives, and a wider range of totally synthetic agents bearing little chemical resemblance to morphine.

Opioid dependence, or at least opioid withdrawal, was first recognized in 1700. Opioid dependence was common by the middle of the nineteenth century, but it was not until later in the century that it came to be seen as an important medical problem. There was public concern about opium smoking by Chinese immigrants and the severe forms of dependence associated with the newly introduced hypodermic needle and syringe. Growing awareness of the problems created by opioid-containing patent medicines sold over the counter or casually dispensed by practitioners with minimal training generated media attention and public debate. In the United States this debate, combined with international political considerations, led to legislation at the state and federal levels restricting opioid use to medically recognized purposes and requiring legitimate prescriptions for most use. The Harrison Act of 1914 had a profound impact on persons who were already addicted because it was interpreted to exclude the provision of opioids to addicts as a legitimate use. Clinics that had been established specifically to provide morphine to addicts were closed, the last in 1923. Doctors were encouraged to avoid opioid addicts entirely. Detoxification efforts were a disappointment to both physicians and patients because relapse was typical. An illicit traffic in opioids arose, providing drugs (mostly morphine and heroin) to persons who could no longer get them through medical channels. Addicts were arrested both for possession and sale. In the early 1930s the United States Public Health Service established two federal hospitals—at Lexington, Kentucky, and Fort Worth, Texas—to deal with the growing number of federal prisoners who were addicted. These hospitals provided long-term residential treatment for prisoners and for some voluntary patients. Later follow-up studies found that relapse rates were very high despite long periods of treatment. Although increasingly harsh penalties for the sale or possession of opioids were enacted, hero in addiction persisted and its prevalence rose following World War II. By the early 1960s some thoughtful observers recommended remedicalizing heroin distribution as a way to reduce crime associated with heroin addiction.

However, several new developments in treatment techniques sharply altered the general perception of opioid dependence as an essentially untreatable disorder. They included the development of therapeutic communities based on the Synanon model (an organization that began in California in 1958); the creation of large-scale civil commitment programs in California (1961) and New York (1965); demonstration of the effectiveness of maintenance on oral methadone in decreasing crime and heroin use; and the development of long-acting opioid antagonists such as cyclazocine, along with the finding that some addicts were willing to take them.

Starting in the late 1960s federal and state sources increased support for research and treatment. In response to the outbreak of heroin addiction among United States military personnel in Vietnam, federal support for treatment was greatly expanded and accelerated in the early 1970s. This support was not merely monetary, but included legislation providing for the legitimate use of methadone and for protection of the confidentiality of patient records.

In the mid-1970s the four dominant treatment modalities were brief detoxification, methadone maintenance, therapeutic communities, and a heterogeneous category generally designated as drug-free outpatient care. Civil commitment declined in influence and support. In the early 1980s, with the expansion of private insurance to cover treatment for alcohol abuse and drug dependence, in-hospital treatment programs based on the 12-step model pioneered in Minnesota proliferated. Although these programs were initially developed as treatments for alcohol abuse, they were gradually broadened to deal with a wider range of dependence, including opioid dependence. For a brief period, “chemical dependence” programs became an additional significant option in the array of treatments available to persons who were dependent on opioids. By the late 1980s, however, the rising cost of treatment and growing government deficits stimulated the emergence of managed care. The impact of managed care on the support for the treatment of opioid dependence has not yet been fully felt, but the availability even of short-term hospital-based treatment has virtually disappeared.

COMPARATIVE NOSOLOGY

The DSM-IV criteria for opioid dependence are the same generic criteria as are applied to other psychoactive drugs. The notion of a generic concept of dependence is shared with the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10). In the diagnosis of opioid dependence, there generally is a high level of agreement between DSM-IV and ICD-10: they employ similar concepts (the dependence syndrome varying in degree of severity), although the wording of the criteria for determining the presence and severity of the syndrome differs. Both require that three elements of the syndrome occur within a 12-month period.

There is a major difference between DSM-IV and ICD-10 in how substance abuse is defined. ICD-10 does not use the term “abuse.” Instead, it includes a category of harmful use that is substantially different from the concept of abuse in DSM-IV. But the concept of harmful use is limited to physical and mental health (e.g., hepatitis, overdose, skin abscess) and specifically excludes social impairments. ICD-10 states: “Harmful patterns of use are often criticized by others and frequently associated with adverse social consequences of various kinds. The fact that a pattern of use or a particular substance is disapproved of by another person or by the culture, or may have led to socially negative consequences such as arrest or marital arguments is not in itself evidence of harmful use.”

DSM-IV and ICD-10 also have distinctly different coding systems. ICD-10 separates for record-keeping purposes mental and behavioral disorders due to use of opioids from those caused by other categories of drugs. DSM-IV limits the number of distinct drug-induced syndromes that can be recorded (except under the categories *other* and *unspecified*) as disorders induced by opioids.

EPIDEMIOLOGY

Opioid use in the United States experienced a resurgence in the early 1990s, with emergency department visits related to heroin abuse doubling between 1990 and 1995. This increase in heroin use was associated with an increase in heroin purity and a decrease in its street price. Methods of administration other than injecting, such as smoking and snorting, have been increasing in popularity. The number of current heroin users has been questionably estimated to be between 600,000 and 800,000. The number of people estimated to have used heroin at any time in their lives (‘lifetime users') is estimated at approximately 2 million.

There are a number of activities aimed at estimating the extent and consequences of psychoactive drug use in the United States. All the regularly recurring estimating techniques have sampling limitations, and none apply standardized diagnostic criteria to substance-use patterns or adverse effects. Consequently, although they provide a picture of substance use over time, the methods do not reveal changes in the incidence and prevalence of specific substance-related disorders, such as substance dependence and substance abuse.

The annual Monitoring the Future project (“High School Senior Survey”) has found lifetime rates of heroin use increasing significantly from the low levels reported at the start of the 1990s. Lifetime use rates for heroin peaked at 2.8 percent in 1975, fell to 0.9 percent in 1991, and rose again to 2.1 percent in 1997. The lifetime use rate for other opiates (which has always been higher than for heroin) fell from a peak of 10.3 percent in 1977 to 6.6 percent in 1991, and rose again to 9.7 percent in 1997. For both categories of opioids, past-year and past–30-days use rates were substantially lower. For the population as a whole ages 12 and older, the 1997 National Household Survey on Drug Abuse (NHSDA) found the use of heroin within the past year to be 0.3 percent, and use within the past 30 days was 0.2 percent; recent (past 30 days) nonmedical use of analgesics was 0.7 percent.

Two population surveys have been conducted using accepted criteria to measure the extent of drug abuse and dependence: the Epidemiologic Catchment Area (ECA) Study carried out in the early 1980s using criteria from the third edition of DSM (DSM-III), and the National Comorbidity Survey (NCS) carried out from 1990 to 1992 using the revised third edition of DSM (DSM-III-R) criteria. The NCS found the lifetime prevalence of heroin use to be 1.5 percent overall, but with a prevalence of 2.7 percent among 35-year-olds to 44-year-olds, probably reflecting the peak of the heroin epidemic among adolescents and young adults in the late 1960s and early 1970s. Heroin dependence (lifetime) was 0.4 percent overall, but 0.8 percent among 35-year-olds to 44-year-olds. Those findings indicate that about 32 percent of those who used heroin at the peak of the epidemic became dependent at some time in their lives.

Lifetime history of extramedical use of opioid analgesics (other than heroin) was 9.7 percent, with the highest prevalence among 15-year-olds to 34-year-olds, suggesting a different pattern from that of heroin. Overall, only 7.5 percent of those who used opioid analgesics outside of a medical context developed dependence as defined by DSM-III-R. Obviously, the 6-month and current prevalence rates of dependence would be lower than these lifetime rates.

The use and dependence rates derived from national surveys do not accurately reflect fluctuations in drug use among opioid-dependent and previously opioid-dependent populations. When the supply of illicit heroin increases in purity or decreases in price, as seemed to be the case in 1994, use among that very vulnerable population tends to increase, with subsequent increases in adverse consequences (emergency room visits) and requests for treatment.

Recent increases in the purity of street heroin and users' concern about the risks of HIV transmission have led to a resurgence of heroin snorting as well as smoking (“chasing the dragon”). Casual users may persist in such routes of administration; however, with long-term use and increasing pharmacological tolerance, economic imperatives often lead users to switch to the more efficient parenteral routes. Injecting drug users are also more likely to experience a “rush” than those using other routes of administration.

ETIOLOGY

Opioid dependence is currently seen as a biopsychosocial disorder in which multiple factors interact to influence initiation of use, continued use, and relapse after periods of abstinence. Those factors—pharmacological, social, environmental, personality, psychopathology, genetic, and familial—are the same that must be considered when looking at abuse and dependence on other categories of drugs. What changes in the case of the opioids is the balance of the various factors. For example, as reinforcers of drug-taking behavior, benzodiazepine anxiolytic agents are not as powerful as either opioids or cocaine. Consequently, medical attitudes, prescribing patterns, and pre-existing psychopathology are more dominant as causative factors in the dependence on benzodiazepines whereas pharmacological factors (i.e., intense euphorigenic and reinforcing effects, the avoidance of aversive withdrawal states, and perhaps the persistence of some low-level protracted abstinence) play a larger role in dependence on opioids.

For opioids, as for most substances, it is largely social and cultural factors that influence availability and initial use. In the case of opioid drugs, however, pharmacological factors—the initial effects and their consequences—are believed to play very important roles in the perpetuation of use and of progression to dependence. Opioids have potent mood-elevating and euphorigenic actions in humans and are powerful reinforcers in animal models. This is particularly true when the effects are rapid in onset, such as when the opioids are injected or inhaled. Perhaps more than any other category of drugs, the opioids can induce a variety of physical dependence that results in an aversive withdrawal syndrome when brain opioid levels decline. This aversive syndrome appears to play a key role in perpetuating opioid use and in relapse after brief periods of withdrawal.

Pharmacological Factors Because the reinforcing and physical-dependence–inducing effects of opioid drugs play such an important role in the genesis of dependence (as well as in opioid-induced disorders), the pharmacology of the opioids is briefly summarized here.

Opioids and Opioid Receptors The discovery of multiple, stereospecific opioid receptors and endogenous ligands for those receptors made it easier to understand the multiple actions of morphine-like drugs and of some of the drugs that only partially resembled morphine. Those discoveries, however, also made it necessary to redefine the term “opioid.” An opioid agonist is now defined as any exogenous substance that binds specifically to any of several subtypes of opioid receptor and produces some action. While many opioids produce actions very similar to that of morphine (a prototypical μ-agonist), others may bind to various receptor subtypes in a pattern distinct from that of morphine, producing a dissimilar profile of actions, and may not suppress the morphine abstinence syndrome. Drugs that bind to any of the subtypes of receptors but initiate no actions are opioid antagonists at those receptors.

Several opioid receptor subtypes have been described and characterized. These include: μ, where classic opioids such as morphine bind preferentially and produce actions; k, where the endogenous opioid dynorphin exerts some of its effects; and d, which appears to be the preferential binding site for the endogenous pentapeptide met-enkephalin, as well as for several synthetic peptides. With the development of more specific ligands and modern molecular techniques, subtypes of the μ-, d-, and k-receptors have also been identified. These major receptor subtypes have been cloned in the laboratory.

Cloning studies have recently identified a new receptor with a high degree of homology to traditional opioid receptors. An endogenous ligand to this initially “orphan” receptor has been identified and termed orphanin FQ or nociceptin. The peptide has been demonstrated to have both analgesic and pronociceptive effects in vivo,

depending on site of administration; additional effects on the vasculature and fluid homeostasis have also been noted.

The s receptor was named for the benzomorphan derivative SKF-10, 047 which, in dogs induced excitation and hallucinatory effects but little or no analgesia. Because binding to the s receptor is not antagonized by naloxone (Narcan), it is no longer considered an opioid receptor. As is the case with the opioid receptors, several subtypes of s receptor have been identified. Since phencyclidine (PCP) may exert some of its actions through this family of receptors, they are discussed at greater length in connection with that drug.

The actions of μ-agonist opioids are exerted primarily at receptors on neural tissues in the central nervous system (CNS), the autonomic nervous system, and to some degree on opioid receptors on white blood cells. The actions of opioids include analgesia, respiratory depression, changes in mood (euphoria in some persons), indifference to anticipated distress, drowsiness, decreased ability to concentrate, changes in endocrine and other functions regulated by the hypothalamus, and increased tone of smooth muscle in the gastrointestinal tract. μ-Agonists also induce tolerance and neuroadaptive changes in the CNS that result in distressing withdrawal phenomena when the agonist is stopped after days or weeks of continuous use. In contrast, drugs that act at k receptors, such as U-50, 4884, produce some dysphoria and no significant pupillary change but still induce analgesia. Also in contrast to μ-agonists, which produce dopamine release by neurons originating in the ventral tegmental area, k-agonists inhibit dopamine release in this pathway.

Most of the opioid drugs associated with opioid abuse and dependence are typical μ-agonists, having pharmacological profiles that are quite similar to morphine and differing primarily in terms of metabolism and pharmacokinetics. Thus heroin is more potent and more lipid soluble than morphine, thereby crossing the blood-brain barrier more rapidly, producing a more rapid onset of subjective effects and less general pruritus an adverse effect of morphine. However, heroin is hydrolyzed quite rapidly (half-life of about 3 minutes) to 6-monoacetylmorphine and morphine. Its actions are probably exerted primarily through those metabolites binding to μ receptors, although 6-monoacetylmorphine may bind to d receptors as well.

Codeine (3-methoxymorphine) occurs naturally (0.5 percent) in opium. Codeine is probably a prodrug; after absorption, it is transformed to some degree into morphine, which accounts for its opioid effects. This biotransformation is dependent on the cytochrome P450 isoenzyme CYP 2D6. This enzyme is relatively inactive in 7 percent of Causasians, who probably get minimal analgesia from codeine. The activity of CYP 2D6 can also be inhibited by such drugs as quinidine (Cardioquin), fluoxetine (Prozac), and paroxetine (Paxil). Codeine itself does not bind with great affinity to μ receptors, but it does cause some toxicity, and that probably accounts for its relatively low abuse potential. Hydrocodone and oxycodone (Roxicodon) may also be prodrugs that require metabolic conversion for full activity. Methadone appears to be a typical μ-receptor agonist, but with an extended duration of action after repeated administration. Meperidine (Demerol), has numerous μ-receptor actions, but it probably has some actions at other receptors as well and may enhance the actions of dopamine, most likely by a nonopioid action at the dopamine transporter. One of its metabolites, normeperidine, has convulsant properties, and addicts who use excessive amounts may achieve high enough levels of the metabolite to experience delirium and frank seizures. Similar toxicity may be seen in patients receiving meperidine for pain when the excretion of normeperidine is reduced by impaired renal function. In patients who are taking monoamine oxidase inhibitors (MAOIs) meperidine can cause serious toxicity, including fatal hyperthermia.

In the United States most of the μ-agonists drugs are included in either Schedule (Control Level) I (prohibited for clinical use) or Schedule II (clinical use under the most restrictive prescribing controls) of the Controlled Substances Act (CSA), although some mixtures (e.g., codeine and aspirin) are in the less restrictive Schedules III and IV. Buprenorphine (Buprenex), a partial μ-agonist now included in Schedule V, was misused by opioid addicts in Europe when it was introduced there without restrictions. Abuse or dependence is occasionally seen with opioids that are not prototypical μ-agonists but also have actions at other opioid receptors, such as the mixed agonist-antagonists pentazocine (Talwin) and nalbuphine (Nubain). Such agents, if they are included in the CSA, may be in Schedules III, IV, or V.

Opioid receptors are typical G-protein coupled receptors. Receptors can be linked either to second messenger systems or directly to ion channels. μ-Receptors, for example, can act via G_i or G_o to directly increase potassium flux or to inhibit the action of adenylate cyclase. Subsequent decreases in the activity of cyclic adenosine monophosphate (cAMP)-dependent protein kinases can have immediate effects on phosphorylation-dependent cellular proteins as well as long-term effects on gene expression via decreased phosphorylation of cAMP-dependent transcription factors, such as cAMP response element binding protein (CREB).

Several analgesics now available have actions at more than one receptor type. Some have antagonist actions at one type and agonist actions at another. For example, pentazocine has reinforcing properties and is self-administered by animals and some addicted persons, but it does not appear to exhibit a significant degree of cross-tolerance with μ-agonists and does not suppress μ-agonist withdrawal to any significant degree. It may be a very weak μ-agonist and k-agonist.

Buprenorphine is a partial agonist at the μ-receptor. It supports μ-receptor physical dependence when the degree of physical dependence is low to moderate but precipitates withdrawal when the degree of dependence is high. Because most opioid-dependent persons have a low to moderate level of dependence, buprenorphine typically suppresses withdrawal and maintains dependence. It generally produces neither typical μ-agonist effects nor precipitated withdrawal in patients maintained on doses of methadone below 30 mg. Some withdrawal may occur when methadone doses are above 60 mg, but rapid transfer from lower doses to buprenorphine is usually easily accomplished.

Endogenous Opioid Substances Three distinct neurobiological opioid peptide systems or families have now been well described. A recently discovered fourth family (orphanin FQ) is a topic of active research. Each of the three well-described systems has a distinct genetic basis, separate biosynthetic pathways, and distinct precursor molecules. The anatomical distributions of the cells that produce and release the respective endogenous peptides are also distinct, but there is sometimes considerable overlap. These three systems are usually referred to as (1) the pro-opiomelanocortin (POMC) system, (2) the proenkephalin system, and (3) the prodynorphin system. Each precursor protein produces more than one active peptide that can be detected in body tissues.

The POMC precursor molecule is a 265–amino-acid protein that contains the 91 amino acid peptide b-lipotropin (b-LPH), as well as adrenocorticotropin hormone (ACTH) and melanocyte-stimulating hormone (MSH). Peptides 61 to 91 in b-lipotropin make up beta-endorphin, one of the active opioid fragments produced by the POMC family. The enkephalin system consists primarily of the pentapeptides met-enkephalin (tyr-gly-gly-phe-met) and leu-enkephalin (tyr-gly-gly-phe-leu). In proenkephalin, a 263-amino-acid protein, met-enkephalin or met-enkephalin extended peptides are six times as prevalent as leu-enkephalin. Several additional opioid peptides are also derived from proenkephalin. From the parent pro-dynorphin, the dynorphin system produces the 17-amino-acid peptide dynorphin and several other active dynorphin peptides, all of which are C-terminal extensions of leu-enkephalin. They include dynorphin A (1 to 17), dynorphin A (1 to 8), dynorphin B (1 to 13), a-neoendorphin, b-neoendorphin, and others.

The processing of the precursor molecules to smaller peptides is tissue specific. For example, in the rat the POMC precursor is processed to different peptides by the anterior and intermediate lobes of the pituitary.

The various endogenous peptides tend to bind preferentially to one or more of the opioid receptor subtypes. For example, met-enkephalin appears to prefer d-receptors, and most members of the dynorphin family of peptides display their highest affinity for k-receptors. However, b-endorphin binds to both μ-receptors and d-receptors and does not appear to be as selective as the other endogenous ligands are. Preferential binding is not the same as exclusive binding. Peptides that bind preferentially to one set of receptors can, in high enough concentrations, exert actions at receptors for which they have lower affinities. Thus far, no endogenous peptide has been found that binds as preferentially to the μ-receptor as do such drugs as morphine. Several laboratories have confirmed the presence of morphine and codeine in mammalian brain and adrenal gland and in human cerebrospinal fluid (CSF). Highest concentrations are found in adrenal glands and spinal cord. Since no exogenous sources could be identified, the morphine and codeine so identified are thought to be of endogenous origin, although the synthetic pathways and possible biological function of those nonpeptide substances are still uncertain. Other findings not yet fully explored are the isolation from brain of natural cleavage products of beta-endorphin, which are more potent than naloxone as opioid antagonists; the capacity of certain dynorphin fragments to modify opioid withdrawal; and the likelihood that some of those dynorphin fragments act at nonopioid receptors.

Tolerance and Physical Dependence (Opioid Neuroadaptation) Tolerance does not develop uniformly to all the actions of opioid drugs. There can be high levels of tolerance to some actions of opioids (such that it requires a hundredfold increase in dose to produce the original effect) when responses to other drug actions show only modest tolerance. With μ-agonist opioids there can be remarkable tolerance to their analgesic, respiratory-depressant, and sedative actions. Patients in Swiss heroin clinics have injected as much as 300 mg intravenously as a single dose. Markedly less tolerance develops to the miotic and constipating actions of opioids on the bowel. Intermediate degrees of tolerance to endocrine actions develop, and there appears to be less tolerance to the capacity of opioids to lower the threshold for electrical self-stimulation of the brain. Opioids occupying the same receptor types exhibit a considerable degree of cross-tolerance, but tolerance and physical dependence appear to be specific for each major receptor type.

When tolerance to a given action develops to a μ-agonist, such as morphine, some cross-tolerance will be seen with other μ-agonists. However, when tolerance

develops to a selective k-agonist, such as the investigational drug U-50,488, there is no cross-tolerance to μ-agonists. Similarly, opioid withdrawal phenomena can be suppressed by any opioid that acts at the same receptor, but not by one that acts at another receptor; k-agonists do not suppress withdrawal from μ–agonist-induced physical dependence. Furthermore, physical dependence induced by k-agonists has distinct characteristics and a different pattern of withdrawal signs and symptoms.

Physical (Physiological) Dependence Physical dependence is a substance-induced change in a biological system that becomes manifest by a characteristic response pattern, the withdrawal syndrome, when the drug is removed from the body or displaced from its receptor. In general, responses are opposite in direction to the acute agonistic effects of the drugs, that is, they are rebound hyperexcitabilities. The neuroadaptive changes induced by the repeated administration of opioids occur in cells bearing opioid receptors and in neural systems widespread throughout the organism. In humans the changes begin with the first few doses. For example, if single intramuscular doses of 15 to 18 mg of morphine are given to opioid naive subjects or abstinent former opioid users, large doses of naloxone (10 to 30 mg) given within 24 hours will precipitate a mild μ-agonist withdrawal syndrome. However, some period of continuous receptor occupation is required before the syndrome produced by abrupt cessation reaches an intensity level high enough to be obvious to the clinical observer. Withdrawal phenomena are more intense and more readily detectable when the opioid is rapidly removed from its receptor, as happens with opioid antagonist administration.

A distinction between opioids and other classes of pharmacological agents is that physical dependence not only develops rapidly, but there also appears to be a protracted period of physiological abnormality that follows the acute opioid withdrawal syndrome. This long-lasting *protracted abstinence* syndrome, characterized by hypophoria, irritability, mood instability, and recurrent urges to use opioids, is postulated to result from opioid-induced alterations in endogenous opioid peptide systems, opioid receptors, or other intracellular proteins that are produced in neurons exposed to opioids over long periods. However, long-lasting neuronal changes can also result from indirect actions of opioids. A reduction in the size of dopaminergic neurons in the ventral tegmental area (VTA) has been observed in animals administered morphine over long periods. It is postulated that the protracted abstinence syndrome is responsible for the high rate of relapse observed when well-motivated patients on high doses of methadone are withdrawn from the drug.

Mechanisms of Tolerance and Physical Dependence A variety of mechanisms have been put forth to account for the general observation that opioid tolerance and physical dependence tend to develop in parallel and that withdrawal phenomena tend to be opposite in direction to the acute effects produced by the drugs. Among the mechanisms that have been proposed are variations in receptor number or affinity, alterations in intracellular second messengers and ion concentrations, and changes in the levels of endogenous opioid peptide agonists and antagonists. These are not mutually exclusive but appear to be complementary, and supportive data exist for several of the mechanisms. Opioid drugs can alter the expression of the genes encoding the opioid neurotransmitters. For example, the repeated administration of morphine results in downregulation of proenkephalin expression in striatal neurons whereas administration of opioid antagonists up-regulates proenkephalin expression. There is also considerable evidence that the cAMP second messenger system plays an important role in the development of opioid tolerance. Acute administration of μ or d opioids results in inhibition of adenylyl cyclase and a decrease in cAMP concentrations. With chronic administration, there appears to be a compensatory increase in the expression of adenylate cyclase and the cAMP-dependent protein kinase probably mediated by effects on cAMP-responsive transcription factors such as CREB. When the opioid is removed, these changes result in transiently higher cAMP concentrations. Some aspects of withdrawal, such as excess sympathetic nervous system activation, have been attributed to the hyperexcitability that results from such an upregulation of the cAMP system in the noradrenergic neurons of the locus coeruleus. These neurons express opioid receptors and their activity is inhibited by opioid administration. Other effects of repeated opioid administration may be attributable to the functional decoupling of opioid receptors from their mediating G-proteins. Long-term administration of opioids can upregulate G protein receptor kinases, which in turn can produce a densensitization of opioid receptors (Fig. 11.10-1).

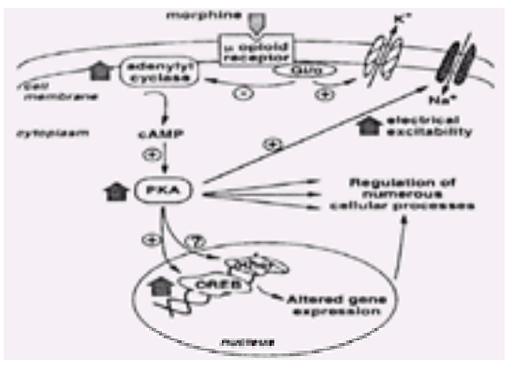

FIGURE 11.10-1 Scheme illustrating opioid actions in the locus coeruleus (LC). Opiates acutely inhibit LC neurons by increasing the conductance of a K^+ channel (light cross-hatch) via coupling with subtypes of G_i and/or G_o and by decreasing a Na^+-dependent inward current (dark cross-hatch) via coupling with $G_{i/o}$ and the consequent inhibition of adenylyl cyclase. Reduced levels of cAMP decrease PKA activity and the phosphorylation of the responsible channel or pump. Inhibition of the cAMP pathway also decreases phosphorylation of numerous other proteins and thereby affects many additional processes in the neuron. For example, it reduces the phosphorylation state of CREB, which may initiate some of the longer-term changes in LC function. Upward bold arrows summarize effects of repeated morphine administration in the LC. Repeated morphine administration increases levels of adenylyl cyclase, PKA, and several phosphoproteins, including CREB. These changes contribute to the altered phenotype of the drug-addicted state. For example, the intrinsic excitability of LC neurons is increased via enhanced activity of the cAMP pathway and Na^+-dependent inward current, which contributes to the tolerance, dependence, and withdrawal exhibited by these neurons. This altered phenotypic state appears to be maintained in part by upregulation of CREB expression. (Reprinted with permission from Nestler EJ: Molecular mechanisms underlying opiate addiction: Implications for medications development. Semin Neurosci *9:*84, 1997.)

Chronic treatment with opioids induces supersensitivity in several distinct transmitter circuits, including the dopaminergic, noradrenergic, cholinergic, and serotonergic systems. The effects of opioids on the noradrenergic neurons of the locus coeruleus have already been noted. The observation that certain a_2-adrenergic agonists such as clonidine (Catapres) can, like opioids inhibit the activity of neurons in the locus ceruleus formed the background for the clinical trials of clonidine in opioid withdrawal. The finding that *N*-methyl-D-aspartate (NMDA) antagonists can suppress a number of opioid withdrawal symptoms has generated interest in the interaction between opioid neurotransmitter systems and the glutaminergic system. NMDA antagonists, most of which are limited in their clinical utility by their phencyclidine-like side-effects, appear to attenuate changes induced by opioid withdrawal in the amygdala and basal forebrain, but not in the locus coeruleus. Further, NMDA antagonists as well as agents that inhibit nitric oxide synthase appear to retard the development of opioid tolerance. It has been suggested that D-methadone, which is not active as a μ-agonist, actually delays the development of tolerance to the active levorotatory isomer component of racemic methadone by actions at the NMDA receptor. Dextromethorphan, commonly used as a cough suppressant, also acts at the NMDA receptor. It has been combined with morphine for use as an analgesic in clinical studies. The mixture enhances the analgesic but not the euphorigenic effects of morphine.

Opioids as Reinforcers In laboratory experiments animals will self-administer μ-opioid and d-opioid agonists, but not k-agonists. Former heroin addicts given opioids report reduced anxiety, increased self-esteem, a better ability to cope with everyday problems, and a decreased sense of boredom. Given intravenously, opioids produce a “rush” or “flash,” a sudden, brief sensation that is reported to be exceedingly pleasurable. Although the rush was customarily described as being much like an orgasmic sensation felt in the abdomen, in more recent interviews addicts have described it in much more varied terms, although still as a much desired experience. The rush, a far shorter phenomenon than a general sense of euphoria, lasts only a minute or two, and is experienced only with rapid drug intake, as with intravenous or intrapulmonary routes. Heroin addicts who self-administered heroin in a research setting seemed to develop tolerance to the anxiety-relieving and mood-elevating effects of opioids and, over a period of several weeks, developed various somatic complaints and reported feeling increasingly anxious and dysphoric. Nevertheless, they were able to experience brief periods of mood elevation for 30 to 60 minutes each time they received single injections. The loss of mood-elevating effects and the appearance of hypophoria and hypochondriasis have also been observed with the long-term administration of methadone in a research setting.

Tolerant opioid users do not continue to self-administer opioids solely to prevent the highly aversive withdrawal phenomena. Interviews with heroin users indicated that they continue to experience a brief euphoric effect immediately following an injection, despite some tolerance to many of the drug effects.

Opioids are synergistic with either amphetamine or cocaine in lowering self-stimulation thresholds in animals and in inducing euphoria in humans. The neurobiological mechanisms of reinforcement of these drugs also appear to overlap. The mesolimbic dopaminergic system, which is thought to play a role in regulating responses to natural forces such as sex and food, is affected by both acute and repeated drug administration. Acutely, opioids increase dopaminergic signals along this pathway from the ventral tegmental area to the nucleus accumbens, in the basal forebrain. This is an indirect action that results from opioid inhibition of GABA-ergic neurons,

which normally act to inhibit the dopaminergic neurons in the ventral tegmental area; opioids can also act directly on neurons in the nucleus accumbens.

Repeated administration of opioids can upregulate the cAMP system in the nucleus accumbens and ventral tegmental area, just as has been described for the locus coeruleus. Just as rebound effects of the cAMP system in the locus coeruleus have been linked to some of the physical symptoms of withdrawal, analogous effects in the nucleus accumbens and ventral tegmental area have been hypothesized to play a role in the aversive motivational states (dysphoria, anhedonia) associated with the withdrawal of drugs. Further evidence for the convergence of drug reinforcement systems is provided by studies of brain glucose metabolism and cerebral blood flow in human volunteers. These studies have found striking similarities in the way that different drugs that induce euphoria alter brain function. When subjects experienced euphoria induced by either opioids or cocaine, euphoria was correlated with decreased brain glucose metabolism, especially in orbito-frontal cortex and thalamus.

Psychological and Social Factors Social attitudes, peer pressure, and drug availability are the major determinants of experimentation with the less socially disapproved drugs. Generally, the use of tobacco, alcohol, and cannabis precedes the use of cocaine and opioids. Since in most cases the earlier substance use continues, most opioid or cocaine users are really multiple drug users. The presence of a significant number of opioid users in a neighborhood, town, or city creates a subculture supportive of experimentation, and continuing use of the drug usually follows. In the United States, areas where availability of illicit opioids is high also have high crime rates, high unemployment rates, and demoralized school systems. These factors all contribute to the sense of hopelessness and the low self-esteem that reduce resistance to drug use and militate against a good prognosis once dependence develops. Along with family factors, these factors may contribute to disproportionately high rates of heroin addiction currently seen among African-American and Hispanic minorities.

A unique natural experiment in which the influence of vulnerability, social norms, and particularly of availability could be observed, was provided by the experience of U.S. service personnel who used heroin in Vietnam. During the period between 1970 and 1972, high-grade, low-cost heroin was readily available to young men separated from their families and usual social norms. Among U.S. Army enlisted men, about 42 percent tried heroin and about half of those who did became physically dependent. Very few of these men, however, continued to use heroin after their return to civilian life. The importance of availability in the genesis of addiction to opioids is also illustrated by the high rates of opioid addiction among physicians, dentists, and nurses compared to other professionals with comparable educational achievement but less easy access to opioids.

Psychodynamic Factors and Psychopathology The psychodynamic perspective is that psychopathology is the underlying motivation for initial drug use, drug dependence, and relapse after a period of abstinence. Recent psychoanalytic formulations postulate ego defects, which are manifest in the addict's inability to manage painful affects (guilt, anger, anxiety), and to avoid preventable medical, legal, and financial problems. Some addicts also appear to have great difficulty in differentiating and describing what they feel, a difficulty that has been aptly called *alexithymia* (i.e., no words for feelings). It is postulated that both pharmacologically and symbolically opioid use helps the ego control those affects and that drug use can be viewed as a form of self-medication.

Epidemiological studies find that persons who use illicit drugs, especially those who use opioids, tend to place more value on independence and less on academic achievement. They are also more tolerant of deviance, and a very substantial number showed significant signs of delinquency before their first experimentation with opioids. A significant proportion of opioid users meet the criteria for antisocial personality disorder, even when those items that are related to illicit drug use are not applied. In Vietnam, where heroin was readily available, the use of heroin by American service personnel was powerfully predicted by the same factors that predicted use in the United States: the frequency and severity of preservice fighting, truancy, drunkenness, arrest, and school expulsion. The ECA Study and the National Comorbidity Study both found that persons with a diagnosis of either drug dependence or alcohol abuse were much more likely than were those without such a diagnosis to also have at least one other mental disorder that was present in the absence of drugs or alcohol. The rates of coexistent psychiatric disorders and substance abuse and findings of high rates of coexistent psychiatric disorders among opioid users seeking treatment do not prove causality; drug use could and does increase the risk of psychopathology. However, these data strongly support the argument that many persons will be left at higher risk for initial treatment failure or relapse if treatment efforts are aimed solely at the drug-using behavior itself and do not address comorbidity.

Family Factors More than 50 percent of urban heroin addicts come from single-parent families, and poor parental functioning has been consistently reported as a risk factor for opioid addiction. A retrospective study of urban males in an East Coast city compared heroin addicts, never-addicted peer controls who were associates of the addicts at age 11, and never-addicted members of the community who were not associates of the addicts. Family risk factors involving deviant behaviors among family members and disruption of family structure (biological parents who had never lived together or were divorced, separated, or died before the subject reached 11 years of age) was 50 percent higher among the heroin addicts before they were age 11.

Typically, even in two-parent families there are disturbed family relationships, with one parent, usually of the opposite sex, intensely involved with the addict and the other parent distant, absent, or punitive. Cross-generational alliances between the drug user and one parent against another parental figure are common. The disability of the drug-using member of the family often serves as a focus for communication among other members, and sometimes may be the main motive for their remaining together; thus, the family equilibrium may be threatened by the addict's recovery.

Despite their seeming rebelliousness and precocious efforts to be independent, opioid users often remain dependent on and in close communication with families of origin well into adulthood. Interestingly, both male and female heroin addicts believe that members of their families of origin or their in-laws would be the most helpful to them in their efforts to give up drugs. Rates of alcohol and drug abuse, mental illness, and antisocial personality disorder are higher in the families of heroin users. Relatives of depressed opioid addicts tend to have higher rates of depression and anxiety, but not of other disorders.

Other Factors It has been postulated that some antecedent metabolic deficiency, such as endogenous opioid dysregulation or one induced by long-term opioid use, may increase vulnerability to becoming opioid dependent but no evidence for such defects has yet emerged. There is now evidence for common and drug-specific, genetically transmitted, vulnerability factors that increase the likelihood of developing drug dependence. Individuals who abuse a substance from any category are more likely to abuse substances from other categories. The common vulnerability factor is influenced by family and nonfamily environmental factors. In a study of Vietnam-era veterans, monozygotic twins were more likely than dizygotic twins to be concordant for opioid dependence. Multivariate modeling techniques indicated that not only was the genetic contribution high for heroin abuse in this group, but also a higher proportion of the variance due to genetic factors was not shared with the common vulnerability factor—that is, it was specific for opioids.

Learning and Conditioning Opioids are positive reinforcers of drug self-administration. They can also reinforce drug-seeking behavior by terminating noxious or aversive states, such as pain, anxiety, or depression (negative reinforcement). In some social situations the use of the drug can also be reinforcing if it results in gaining special status among friends, and such social reinforcement can serve to maintain drug use until the effects of primary reinforcement or reinforcement by alleviation of withdrawal symptoms come into play. Typically, each time the drug is used, reinforcement occurs. It may be the rush, drug-induced euphoria, alleviation of disturbed affect or of withdrawal symptoms, or any combination of those effects. Use of a short-acting opioid, such as heroin, causes such reinforcement to occur several times a day, day after day, creating a powerfully reinforced habit pattern. Eventually the paraphernalia and hustling associated with drug use can become secondary reinforcers as well as cues that signal drug availability, and in their presence craving or desire to experience drug effects increases.

In addition to this operant reinforcement of drug-using and drug-seeking behaviors, classical or Pavlovian conditioning probably plays a role in relapse. In both laboratory animals and human volunteers, opioid withdrawal phenomena can be conditioned to environmental or interoceptive stimuli. Animals that exhibit marked tolerance to the effects of opioids given repeatedly in one situation may exhibit toxicity when the same dose is administered in a novel environment. For long periods following withdrawal, former opioid addicts may experience conditioned withdrawal or conditioned craving when exposed to environmental stimuli previously linked to drug use or withdrawal. Conditions such as watching someone else use heroin or being offered a drug by a friend, rather than conditions associated with withdrawal, elicit the most intense craving.

DIAGNOSIS AND CLINICAL FEATURES

Table 11.10-1 lists the DSM-IV opioid-related disorders.

Opioid use disorders
Opioid dependence
Opioid abuse
Opioid-induced disorders
Opioid intoxication
Specify if: With perceptual disturbances
Opioid withdrawal
Opioid intoxication delirium
Opioid-induced psychotic disorder, with delusions
Specify if: With onset during intoxication
Opioid-induced psychotic disorder, with hallucinations
Specify if: With onset during intoxication
Opioid-induced mood disorder
Specify if: With onset during intoxication
Opioid-induced sexual dysfunction
Specify if: With onset during intoxication
Opioid-induced sleep disorder
Specify if: With onset during intoxication/with onset during withdrawal
Opioid-related disorder not otherwise specified

Table 11.10-1 DSM-IV Opioid-Related Disorders

Opioid Intoxication DSM-IV criteria for opioid intoxication are shown in Table 11.10-2. Intoxication can vary in severity. In severe cases of opioid overdose there is usually coma, severely depressed respiration, and pinpoint pupils. There may be gross pulmonary edema with frothing at the mouth, but X-ray evidence of pulmonary changes is seen even in less severe cases. Pulmonary edema is an opioid effect and is sometimes seen with overdoses of oral opioids that have been medically prescribed. Depending on when the patient is seen, there may also be cyanosis, cold clammy skin, and decreased body temperature. Blood pressure is decreased, but only falls dramatically with severe anoxia, at which point the pupils may dilate. Cardiac arrhythmias have been reported and may be related either to anoxia or to the presence of quinine as an adulterant in the opioid.

A. Recent use of an opioid.
B. Clinically significant maladaptive behavioral or psychological changes (e.g., initial euphoria followed by apathy, dysphoria, psychomotor agitation or retardation, impaired judgment, or impaired social or occupational functioning) that developed during, or shortly after, opioid use.
C. Pupillary constriction (or pupillary dilation due to anoxia from severe overdose) and one (or more) of the following signs, developing during, or shortly after, opioid use: (1) drowsiness or coma (2) slurred speech (3) impairment in attention or memory
D. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.
Specify if: With perceptual disturbances

Table 11.10-2 DSM-IV Diagnostic Criteria for Opioid Intoxication

Opioid Withdrawal The opioid withdrawal syndrome can vary greatly in intensity, depending primarily on the dose of the opioid used, the degree to which the opioid effects on the CNS were continuously exerted, the duration of use, and the rate at which the opioid is removed from the receptors. These generalizations appear to apply as well to other categories of drugs, such as barbiturates and benzodiazepines. The DSM-IV diagnostic criteria for opioid withdrawal are shown in Table 11.10-3.

A. Either of the following: (1) cessation of (or reduction in) opioid use that has been heavy and prolonged (several weeks or longer) (2) administration of an opioid antagonist after a period of opioid use
B. Three (or more) of the following, developing within minutes to several days after criterion A: (1) dysphoric mood (2) nausea or vomiting (3) muscle aches (4) lacrimation or rhinorrhea (5) pupillary dilation, piloerection, or sweating (6) diarrhea (7) yawning (8) fever (9) insomnia
C. The symptoms in criterion B cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

Table 11.10-3 DSM-IV Diagnostic Criteria for Opioid Withdrawal

The clinical syndrome observed consists of purposive behavior, which is dependent on the observer and environment (e.g., complaints, pleas, and manipulations directed at getting more drug), and nonpurposive behavior (e.g., piloerection and dilated pupils), which is not goal oriented and is relatively independent of the observer and environment. The opioid withdrawal syndrome, while often exquisitely uncomfortable and distressing, is not, in contrast to withdrawal from alcohol or barbiturates, life-threatening, in healthy adults. Deaths have occurred during abrupt opioid withdrawal in debilitated patients with other medical disorders.

In the case of short-acting drugs, such as morphine or heroin, the first symptoms may be seen within 8 to 12 hours after the last dose of drug. In the least severe cases or very early in withdrawal, symptoms may consist only of dysphoria, irritability, restlessness, and general achiness, with few objective signs. In mild syndromes the signs and symptoms may be limited to craving, anxiety, dysphoria, yawning, perspiration, lacrimation, rhinorrhea, and restless and broken sleep. In more severe cases, as the syndrome progresses, additional signs and symptoms that may be seen include increasingly dilated pupils; piloerection (waves of gooseflesh, from which comes the term “cold turkey” to describe withdrawal); and hot and cold flashes. In severe syndromes, which in the case of heroin and morphine generally reach peak severity about 48 hours after the last dose, the patient may also experience nausea, vomiting, diarrhea, weight loss, fever (usually low grade), and increased blood pressure, pulse, and respiratory rate. Also often observed are twitching of muscles and kicking movements of the lower extremities (whence comes the phrase “kicking the habit.”) It is important to remember that substantial subjective distress can develop before the more obvious physical signs. Also, when so motivated, opioid-dependent patients in early withdrawal may exaggerate the severity of distress in the hope that it will elicit higher doses of drugs for relief.

With short-acting drugs, the acute phase of the syndrome, if untreated, runs its course in 7 to 10 days. In research subjects the acute phase was followed by a more subtle but longer-lasting phase, the protracted abstinence syndrome, that persisted for many weeks.

During this phase many physiological variables reached subnormal values, such as hyposensitivity to the respiratory stimulant effects of carbon dioxide. There was also disturbed sleep, overconcern about bodily discomfort, poor self-image, and a decreased capacity to tolerate stress. It is frequently assumed that the protracted abstinence syndrome plays a role in relapse to opioid use.

With longer-acting drugs, such as methadone or levomethadyl acetate (ORLAAM), which is also known as a-acetylmethadol (LAAM), the onset of withdrawal may be delayed for one to three days following the last dose. Although the syndrome is qualitatively similar, peak symptoms may not occur until the third to eighth day, and the symptoms may persist for several weeks.

Withdrawal from methadone, and presumably from levomethadyl acetate, is also followed by a protracted abstinence syndrome that may last for more than 6 months. If naloxone is given to a patient dependent on methadone, thereby displacing the drug abruptly from the receptors, the withdrawal is immediate in onset, can be quite

severe, and persists until the naloxone is metabolized and the residual methadone reoccupies the receptors.

Withdrawal from analgesics that are presumed to act in part as k-receptor agonists (e.g., pentazocine, nalbuphine) is generally rapid in onset, mild, and lasts a few days. The syndrome bears some similarities to the μ-receptor withdrawal syndrome, but there are also some distinct elements. Withdrawal from pure k-agonists is not associated with drug-seeking behavior. Since drug-seeking behavior is sometimes seen with pentazocine, it is likely that it has some low-level agonist actions at μ-receptors.

Withdrawal symptoms after several weeks of administration of buprenorphine, a partial μ-agonist, at doses of 8 mg daily parenterally or sublingually, are generally not severe in intensity but some patients are uncomfortable enough to request drugs for relief of discomfort and for insomnia. After sublingual administration (8 mg daily), withdrawal symptoms are experienced within a few days after drug use is stopped, and symptoms of the acute phase reach baseline levels by 7 to 10 days. It is usually mild and consists primarily of subjective effects, such as muscle aches, dysphoria, and insomnia, rather than more dramatic autonomic signs such as piloerection or diarrhea. If very large doses of buprenorphine (16 to 32 mg sublingually) have been taken, the drug effect persists for several days, with onset of wthdrawal symptoms at 72 to 96 hours.

Opioid Abuse and Opioid Dependence Opioid abuse (see Table 11.1-8) is a pattern of maladaptive use of an opioid drug leading to clinically significant impairment or distress and occurring within a 12-month period, but one in which the symptoms have never met the criteria for opioid dependence.

Opioid dependence (see Table 11.1-3 and Table 11.1-4) is inferred from behaviors that indicate some decrease in volitional control over the use of an opioid drug. DSM-IV specifies the criteria to be used by the clinician to decide whether the patient exhibits such a decrease in volitional control. These criteria are not specific for opioids, but are believed to apply for all psychoactive agents. DSM-IV does not require that any single criterion be met, and none is given special weight. Thus, the presence of tolerance and physical dependence (withdrawal) is not required. However, according to DSM-IV, if tolerance and physical dependence are present, that should be noted specifically.

Because tolerance develops to many of the actions of opioid drugs after long-term use, opioid effects are not readily detected by even the careful observer. Patients maintained on large oral doses of methadone function quite normally. Physicians, nurses, and other medical personnel who use opioids, even by injection, may go undetected by their colleagues for months or years. Thus, a candid history obtained from the patient or a reliable informant is needed to make a diagnosis of dependence, although evidence of recent and long-term use can be developed by testing urine or hair for the presence of opioids.

Opioid Intoxication Delirium Opioid intoxication delirium is most likely to happen when opioids are used in high doses, are mixed with other psychoactive compounds, or are used by a person with preexisting brain damage (see Table 10-22).

Certain opioids, such as meperidine, have toxic metabolites that can accumulate, causing delirium and sometimes seizures. Impaired renal function increases the likelihood of accumulation.

Opioid-Induced Psychotic Disorder Opioid-induced psychotic disorder can begin during opioid intoxication. The DSM-IV diagnostic criteria are contained in the section on schizophrenia and other psychotic disorders (see Table 13.3-4). Clinicians can specify whether hallucinations or delusions are the predominant symptoms.

Opioid-Induced Mood Disorder Opioid-induced mood disorder (see Table 14.6-18), can begin during opioid intoxication, or withdrawal and can result from chronic use. (see Table 11.10-3). Opioid-induced mood disorder symptoms may be of a manic, depressed, or mixed nature. A person coming to psychiatric attention with opioid-induced mood disorder usually has mixed symptoms, combining irritability, expansiveness, and depression.

Some degree of depressed mood (hypophoria) typically occurs during and for several weeks following withdrawal. Opioid-induced mood disorder should not be diagnosed unless the severity of mood disturbance exceeds what is normally encountered or persists for more than a few weeks and is of sufficient intensity to warrant independent clinical attention.

Opioid-Induced Sleep Disorder and Opioid-Induced Sexual Dysfunction Opioid-induced sleep disorder (see Table 21-18) and opioid-induced sexual dysfunction (see Table 19.1a-20) are diagnostic categories in DSM-IV. Hypersomnia is likely to be a more common sleep disorder among those given opioids therapeutically, but disturbed sleep (insomnia) is a common complaint of patients maintained on opioid agonists such as methadone. The most common sexual dysfunction is likely to be impotence, but patients maintained on methadone may complain of inability to achieve orgasm, rather than impotence.

Opioid-Related Disorder Not Otherwise Specified DSM-IV includes diagnoses for opioid-related disorders with symptoms of delirium, abnormal mood, psychosis, abnormal sleep, and sexual dysfunction. Clinical situations that do not fit into these categories are examples of appropriate cases for the use of the DSM-IV diagnosis of opioid-related disorder not otherwise specified (Table 11.10-4).

The opioid-related disorder not otherwise specified category is for disorders associated with the use of opioids that are not classifiable as opioid dependence, opioid abuse, opioid intoxication, opioid withdrawal, opioid intoxication delirium, opioid-induced psychotic disorder, opioid-induced mood disorder, opioid-induced sexual dysfunction, or opioid-induced sleep disorder.

Table 11.10-4 DSM-IV Diagnostic Criteria for Opioid-Related Disorder Not Otherwise Specified

Psychiatric Comorbidity The high prevalence of additional psychiatric disorders among treated opioid-dependent patients has now been repeatedly confirmed. Currently no subtypology of opioid-dependent patients based on psychopathology has been proposed. However, the type and severity of those additional diagnoses can influence the course of the disorder and the kind of treatment that is most likely to be effective.

Among opioid addicts seeking treatment at a program in New Haven in the 1980s, 87 percent met the research diagnostic criteria (RDC) for a psychiatric disorder, in addition to opioid dependence, at some point in their lives. Other substance-related diagnoses, such as alcohol dependence were considered additional disorders. A study of addicts seeking methadone treatment in Baltimore in the early 1990s found (using DSM-III-R criteria) a 24 percent lifetime prevalence of non–substance-related Axis I disorders, a 35 percent lifetime prevalence of Axis II disorders, and a total prevalence of additional non–substance-related diagnoses of 47 percent. In both studies, the most common diagnoses were mood disorders, alcoholism, antisocial personality disorder, and anxiety disorders (Table 11.10-5, Table 11.10-6, Table 11.10-7). In the Baltimore study, cocaine dependence (65 percent) was actually higher than alcohol dependence (50 percent). Multiple psychiatric diagnoses for a given patient were common. Researchers in Europe and Australia report similar overall distributions of psychiatric disorders among opioid users seeking treatment.

Diagnostic Category*	Lifetime Rates % (Current Rates %)		
	Men (N = 378)	Women (N = 338)	Total
Any Axis I disorder	15.6 (5.0)	33.4 (11.2)	24.0 (8.0)
Mood disorder	11.4 (2.1)	27.5 (5.3)	19.0 (3.6)
Major depressive disorder	8.7 (1.3)	23.7 (5.3)	15.8 (3.2)
Dysthymic disorder	2.4 (2.4)	4.4 (4.4)	3.4 (3.4)
Bipolar I disorder	0.8 (0.8)	0.0 (0.0)	0.4 (0.4)
Anxiety disorder	6.1 (3.4)	10.7 (6.8)	8.2 (5.0)
Simple phobia	1.9 (1.9)	5.3 (3.6)	3.5 (2.7)
Social phobia	1.9 (0.8)	3.6 (2.7)	2.7 (1.7)
Panic disorder	2.1 (0.3)	1.8 (0.9)	2.0 (0.6)
Agoraphobia	0.0 (0.0)	0.6 (0.3)	0.3 (0.1)

Table 11.10-7 Personality Disorders in Opioid Users

Among women, depression, anxiety disorders, and borderline personality disorder were significantly more common than among male patients, and alcoholism, cannabis misuse, and antisocial personality disorder were significantly less common. The rate of current psychiatric illnesses are obviously lower than lifetime rates and vary with the treatment setting. Among the methadone patients in the Baltimore study, 5 percent of men and 11.2 percent of women met criteria for a current diagnosis of a non–substance-related Axis I disorder, most commonly a mood or anxiety disorder. Forty percent of the sample had a current diagnosis of cocaine dependence, and 25 percent suffered concurrently from alcoholism. Other studies have confirmed rates of current major depressive disorder in the range of 17 to 20 percent and concurrent rates of alcoholism (alcohol abuse or dependence) of 20 to 30 percent. Although stimulant dependence (other than cocaine dependence) was not seen among the patients in Baltimore, it occurs frequently in the western United States where methamphetamine use is more prevalent.

The presence of a comorbid psychiatric condition has been shown to be associated with more severe substance abuse in some studies. In the Baltimore study, patients with comborbid psychiatric conditions were more likely to suffer from polysubstance abuse and to have begun abusing drugs at an earlier age. This was particularly true of patients with antisocial personality disorder.

The high rates of psychiatric comorbidity in the methadone maintenance population are by no means unique to this modality of treatment. Similar patterns of additional psychiatric disorders have been found by workers at other public clinics and by clinicians in private practice. Among patients in therapeutic communities, 60 percent reported depressive symptoms during the year before entry, 28 percent had contemplated suicide, and 13 percent had made at least one suicide attempt. And, although opioid abusers who have current psychiatric problems are more likely to seek treatment, it should not be assumed that those who do not seek treatment are free of comorbid psychiatric problems. Among the respondents in the community-based ECA study, about half of those with a substance (other than alcohol) use disorder had one or more additional psychiatric disorders (odds ratio 4:5); anxiety disorder, 28.3 percent (odds ratio 2:5); mood disorder, 26.4 (odds ratio 4:7); antisocial personality, 17.8 percent (odds ratio 13:4); schizophrenia, 6.8 percent (odds ratio 6:2). The probability of comorbidity is higher for those with a lifetime diagnosis of an opioid or cocaine disorder than for those who abuse cannabis. Widespread comorbidity was again found in the similar NCS study: 59 percent of those with a lifetime history of illicit drug abuse or dependence also met DSM-IV criteria for another mental disorder, and 71 percent met the criteria for a lifetime alcohol use disorder.

PATHOLOGY AND LABORATORY EXAMINATION

In opioid abuse and opioid dependence there may be no abnormal laboratory findings at all. Urine tests can usually detect short-acting opioids, such as heroin, for 12 to 36 hours after use. Very potent opioids, such as fentanyl, may not be detected by standard opioid screens. Standard tests for heroin actually test for its main metabolite, morphine. A urine test positive for morphine can also be caused by therapeutic doses of codeine or by the ingestion of modest amounts of poppy seeds (of the type and amount used to flavor bagels and other breads and pastries).

Persons who have shared injection implements often test positive for hepatitis (B and C) and for the human immunodeficiency virus (HIV). Other liver enzymes may be elevated if there is active hepatitis. There may be positive and false-positive tests for syphilis. Chest X-rays may show evidence of pulmonary fibrosis if the person has been using injection materials contaminated with microcrystalline talc or cotton particulates. During withdrawal white blood cell counts and cortisol levels may be elevated.

Physical findings may be unremarkable if opioids are ingested orally; snorting (insufflation) of heroin may irritate nasal membranes. Drug injectors, however, may show widespread evidence of having used unsterile injection equipment. There may be needle tracks over veins on the arms, legs, and, in some cases, the backs of the hands and the femoral and jugular veins. Infections and venous scleroses and lymph obstruction may lead to severe edema of the hands and feet. There may be skin abscesses or scars on accessible skin surfaces as a result of unsterile subcutaneous injections (Fig. 11.10-2). There may be rock-like hardening of subcutaneous and muscle tissue as a result of repeated intramuscular injections of meperidine (often seen among health professionals). Endocarditis may produce fever and heart murmurs. In addition, a variety of neurological sequelae of intravenous heroin use may be detected.

FIGURE 11.10-2 Skin popper. Circular depressed scars often with underlying chronic abscesses, can result from skin popping. (Courtesy of Michael Baden, M.D.)

DIFFERENTIAL DIAGNOSIS

The diagnosis of opioid dependence can be relatively straightforward when the patient is willing to be candid. It can be quite taxing when the patient is motivated to conceal past patterns of opioid use, as is frequently the case among health care professionals or persons who obtain opioids from medical sources by simulating disease or greatly exaggerating the painful nature of disease actually present.

The diagnosis of opioid withdrawal is easier when the opioid is short-acting and the symptoms are accompanied by obvious physiological signs. This is not the typical case, and the clinician is often confronted by a patient complaining of various aches, pains, anxiety, and insomnia in the absence of obvious signs of withdrawal. Patients who are dependent on opioids may withhold information on the use of other classes of drugs. Because opioid withdrawal does not generally cause tremulousness, confusion, delirium, or seizures, the presence of those signs or the failure of insomia and anxiety to respond to reasonable doses of an opioid should raise the possibility of dependence on alcohol, sedatives, or benzodiazepines.

Opioid intoxication must be differentiated from mixed intoxications in which opioids play only a minor role. In general, a failure to respond to modest doses of naloxone suggests that intoxication is caused by a nonopioid. Some patients, more typically the elderly, may respond to therapeutic doses of a μ-agonist with dysphoria and confusion; such reactions are generally short-lived. They are seen more commonly with mixed agonist-antagonists. They should be considered atypical opioid intoxications rather than opioid-induced intoxication delirium or opioid-induced psychotic disorders, which although listed in DSM-IV are quite rare. One possible exception is the state associated with the accumulation of toxic meperidine metabolites. However, even in that case the syndrome does not usually outlast the metabolites and should probably be considered an intoxication.

COURSE AND PROGNOSIS

It was once commonly believed that experimentation with illicit opioids invariably led to dependence, but it is now apparent that only a fraction of those who briefly experiment with illicit opioids develop serious problems. It is still true that those who use opioid drugs heavily—at least once a week—usually go on to use daily, at least for a brief period. Data from national surveys suggest that about one third of those who experimented with heroin during the epidemic of the 1960s and 1970s became dependent on it at some point. It is likely, however, that many who go on to develop some degree of dependence recover without ever seeking formal treatment. In the St. Louis ECA study, only 20 percent of those with a lifetime history of opioid abuse had any symptom during the year prior to the interview.

Some persons apparently can use opioids occasionally (e.g., several times a month) over periods of months or years without becoming drug dependent. It may be that self-imposed limits on the time and place they use drugs may help prevent progression to addiction, but drug injectors are still at risk for death from overdose, as well as for infections and other medical complications. When addiction does develop, the subsequent course of the syndrome depends on environmental factors, the characteristics of the user, the route of administration, and the specific opioid being used.

Heterogeneity of Lifestyle Opioid addicts seeking or entering treatment in the United States and the United Kingdom exhibit a surprising heterogeneity of lifestyles, attitudes toward conventional values, and criminality. Some addicts, except for their drug use, are quite conventional, avoid criminality, work at legitimate occupations, and do not identify with the addict subculture. At the other extreme, some addicts live exclusively by illicit activities and are highly involved with other addicts. A third group appears to identify with both cultures, engaging in some criminal activities and interacting with other addicts, but living primarily on legitimate earnings. A fourth group of addicts seems not to be involved in either the conventional culture or the addict subculture. They tend to be unemployed and to live on welfare rather than on criminal earnings and often have high levels of psychopathology. Health professionals and those who become addicted to opioids in the course of medical treatment probably constitute additional distinct subgroups.

Slips and Relapses In the early stages of opioid use the most typical course for the user of illicit opioids is one of periods of abstinence, either voluntary or forced (by imprisonment or hospitalization) and lasting from a few weeks to many months, followed by relapse to opioid use and readdiction. Among the addicts who enter abstinence-oriented treatments, relapse occurs most often in the first 3 months; a number of studies show that at least two out of three patients relapse within 6 months. Depression and life crises (especially arguments and interpersonal losses) are associated with relapse to illicit drug use; those factors are additive. The impact of those risk factors is reduced by treatment in drug abuse programs.

The theme running through the many specific reasons given for periods of voluntary abstinence is a desire to change life patterns and a weariness with the constant difficulty of trying to obtain illicit opioids. At the time of reentry into treatment, addicts are often less seriously impaired than when first treated, suggesting some residual benefit from intermittent treatment. With successful treatment episodes and with age the duration of each opioid episode tends to shorten.

Repeated relapse is not an inevitable consequence of opioid dependence. Eighty-eight percent of United States Army enlisted personnel who became addicted during a tour of duty in Vietnam did not become readdicted at any time during the 3 years following their return to the United States; 56 percent did not use opioids at all. Of the soldiers who did become readdicted in the first year, 70 percent were no longer addicted in the following 2 years. Only 2 percent of the soldiers who used opioids in Vietnam (6 percent of those who tested positive for opioids at time of departure) entered treatment following their return to the United States. However, the relapse rates for those who did enter treatment were as high as for civilians, with two thirds relapsing within less than a year. It is possible that among those who become dependent on opioids, the ones who cannot stop without formal help have a more severe form of the disorder.

In considering the natural history of opioid addiction, a distinction must be made between the course of all those who report a period of dependence (e.g., among respondents to a household survey) and the course of those who enter treatment. Those who enter treatment may have additional problems or a more severe addiction. Further, opioids are rarely the sole drug class used. During the 1980s a high proportion of opioid-dependent patients also abused or became dependent on cocaine. Depression was found to be a risk factor for continued cocaine use among patients in opioid treatment programs, and cocaine use itself predicted continued heroin use and earlier discontinuation of methadone treatment. Abstinence from opioids or recovery from opioid dependence does not mean that the person has no drug problems. Standard methadone maintenance treatment programs do not appear to have any major effect in preventing cocaine use, and abuse of alcohol and other nonopioid drugs is common among patients in these programs who are no longer using other opioids.

Long-Term Prognosis Studies from both the United States and the United Kingdom support the view that opioid addiction is a disorder that eventually ends for many of those addicts who survive. This seems to be so even for those who seek treatment, a group that may have a more severe variety of the disorder. For a substantial number of these persons, it is prolonged incarceration that ends their opioid use; others stop using opioids but continue to abuse other drugs. Although there are some old opioid addicts in the United States, their numbers are few. Opinion remains divided as to just how many opioid addicts eventually achieve abstinence outside of an institution. One review of long-term follow-up studies found abstinence rates between 10 and 19 percent for drug-free treatment and between 9 and 21 percent following treatment with methadone. A 24-year follow-up of narcotic addicts remanded to the California Civil Commitment Program in the early 1960s interviewed 354 survivors. Seventeen percent had not used narcotics and had no other serious drug problems over the preceding 36 months; 13 percent had been abstinent from narcotics but not from other drugs and had not been incarcerated. The largest group (41 percent), had avoided incarceration but used narcotics and other drugs. The next largest group (29 percent), were incarcerated, and many had used drugs during the 12 months prior to interview. Thus, of those still alive 30

percent were free of opioids, although some used other classes of drugs.

The usual measures of treatment outcome—legitimate work, crime, drug use, family relationships, psychological adjustment—are best predicted by different pretreatment variables. Thus, pretreatment history of high levels of criminal activity most accurately predicts posttreatment criminal activity, and previous stable work history is more predictive of posttreatment gainful employment. Severity of psychological problems at the beginning of treatment, however, is a predictor of outcome on all dimensions. Opioid addicts with the least severe psychological problems appear to respond better to all treatments on all outcome measures.

In long-term follow-ups no important differences in outcome have been found among patients treated initially by different modalities, although over shorter follow-up periods, methadone maintenance, therapeutic communities, and drug-free programs were significantly superior to detoxification programs. Differences—or lack thereof—among different forms of treatment may be affected by pretreatment characteristics of the patient population. For example, studies from the United States and Australia suggest that addicts electing detoxification are younger and have less psychopathology than those entering more lengthy forms of treatment.

Although a period of prolonged abstinence is a good predictor of long-term outcome, a study of heroin users in Texas found that 33 percent of those who reported 3 years of abstinence eventually relapsed. The long-term outcome for opioid dependence among persons with additional major psychiatric disorders, such as schizophrenia or bipolar I disorder, is not generally known. However, one study that specifically examined the efficacy of additional psychiatric care for dual-diagnosis subjects in an outpatient drug dependence clinic found that while they initially had significantly greater percentages of positive urine toxicologies than patients without comorbid psychiatric conditions, they had higher retention rates in treatment and after 6 months of treatment had comparable success rates as the single-diagnosis group. The course of opioid dependence among medical personnel supervised by state-level organizations is far less bleak than that of heroin users who enter public sector treatment programs.

Opioids and Crime The statistical relation between the use of illicit opioids and crime in the United States is unquestionable. Persons who use illicit opioids commit crimes more frequently than do nonusers. There are, however, questions about the degree to which one behavior causes the other. The direct tranquilizing actions of opioids ought to reduce criminal activity rather than increase it.

Throughout much of history in countries where crude opioids (e.g., opium, tincture of opium) were inexpensive and socially acceptable and were either smoked or taken by mouth there was little relation between opioid use and criminal behavior. The association between opioid use and crime emerges primarily in countries, such as the United States, that have tried to restrict the use of opioids to legitimate medical indications but have been unable to eliminate illicit opioid traffic.

Most addicts' crimes are directed at generating income for drugs by shoplifting, petty theft, and selling drugs; however, recently more addicts seem to be engaging in crimes, such as robbery, that involve the potential for violence. However, the relationship between drug use and crime is not one of simple cause and effect. In the United States and the United Kingdom more than 50 percent of heroin addicts interviewed in prisons and jails or treatment programs had been arrested prior to their first opioid use.

In a study in Baltimore, adolescent boys (11 to 14 years old) who later became opioid addicts exhibited substantially more criminal behavior than did peers or age-matched nonpeers from the same community. As noted previously, there is a high incidence of antisocial personality disorder among drug users, even when the diagnostic criteria for this disorder are limited to exclude antisocial behavior engaged in solely because of the need for drugs. Although it might be argued from these data that the criminal behavior seen after the onset of addiction is merely a continuation of a criminal lifestyle, criminal activity does increase sharply after the onset of opioid addiction. Arrest rates for nondrug offenses increase from 1.5-fold to threefold after the onset of addiction, and self-reported property crimes increase to a comparable degree. However, it has also been suggested that crime is a better predictor of opioid use than opioid use is of crime, and that rather than heavy use causing crime, day-to-day success in crime enables the escalation to heavier opioid use.

Further evidence pointing to a causal relationship between opioid use and crime is the sharp reduction in both self-reported criminal activity and arrests during periods of less than daily illicit opioid use. The decrease in crime is seen whether the decrease in opioid use is a result of effective treatment, probation, parole, or spontaneous cessation. When criminal behavior antedates opioid use, however, it is unrealistic to expect the successful treatment of opioid dependence to eliminate criminal behavior entirely. Addicts who were criminally active prior to opioid dependence are more likely to persist in criminal acts when abstinent. It is postulated that only more comprehensive treatment directed at social, psychological, and vocational factors, rather than just at illicit drug use, is likely to alter antisocial lifestyles.

Toxicity, Morbidity, Medical Complications, and Life Expectancy Opioids used orally are relatively nontoxic. Whereas long-term use, as in methadone maintenance, is associated with minor endocrine abnormalities, constipation, and some sleep disturbance, no major damage to internal organs has been noted and no significant impact on longevity would be expected. The cognitive impairment seen with long-term alcohol and sedative use is not generally found with long-term use of oral opioids. Nevertheless, the life expectancy of opioid addicts, especially heroin addicts, is markedly reduced.

Before the emergence of HIV infection among opioid injectors, estimates ranged from a twofold to a threefold increase in the expected mortality rate for older addicts to a twentyfold increase in the expected rate among young addicts. Follow-ups of treated opioid addicts in the United States indicate an overall death rate of 1 to 1.5 percent a year. A substantial proportion of those deaths were due to drug overdose, drug-related infections, and suicide. Homicide is also a common cause of death among urban opioid addicts in the United States. The death rate at British clinics providing clean injectable drugs to young addicts was estimated at 2 to 3 percent a year, at least twenty-fold higher than the death rate of comparably aged contemporaries. Mortality rates far higher than for age-adjusted controls were also observed in Italy during a period when heroin use was not a criminal offense. The suicide rate among opioid addicts is estimated to be three times higher than in the general population. This is probably an underestimation because it is difficult to determine how many overdose deaths are to some degree intentional.

The advent of HIV has changed the patterns of mortality among drug users. In some areas of the United States and Europe, acquired immune deficiency syndrome (AIDS) is now a leading killer of injecting drug users. HIV seroprevalence among users has a wide geographic variability. Although the death rate of heroin addicts in treatment remains higher than that of age-adjusted controls, it is substantially lower than the rate for untreated addicts.

Medical Complications Opioid drugs, properly administered, are associated with few serious medical complications. Most complications associated with opioid abuse are those associated with the route of administration. Because opioid addicts—even physicians who have access to drugs and sterile materials—tend to neglect the hygienic aspects of injecting, infections of skin and systemic organs are quite common. Filtering illicit opioids through cigarette filters or wads of cotton and injecting materials intended for oral use allows starch, talc, and other particulate contaminants to enter into the bloodstream. These particulates can cause pulmonary emboli, which can eventually result in angiothrombotic pulmonary hypertension and right ventricular failure. Staphylococcal pneumonitis may also be related to septic emboli. Endocarditis and septicemia involving lesions either of the tricuspid or of the aortic and mitral valves is a frequent complication. Less frequent but equally serious complications are meningitis and brain abscess. Other frequently seen infections that can be related to injecting the substance or the sharing of needles include viral hepatitis, malaria, tetanus, osteomyelitis, and HIV. Syphilis transmission has also been associated with sharing of needles, although most cases are probably acquired in the usual fashion. False-positive tests for syphilis are also not uncommon among injecting drug abusers. Many opioid addicts who inject have a low-level chronic hepatitis without jaundice and may have abnormal liver function tests. Seroprevalence surveys conducted by the Centers for Disease Control (CDC) found some marker of hepatitis B infection in sera from 60 to 80 percent of drug injectors. Rates of hepatitis C infection are similarly elevated. Abnormal liver function tests, which are found in about two out of three heroin addicts, may persist for long periods after the cessation of injection. Comborbid alcoholism may in some cases contribute to the liver disease.

Other complications associated with poor intravenous injecting technique include chronic edema of extremities (e.g., puffy hands), probably due to lymphatic obstruction caused by contaminants and sclerosis of veins caused by the drugs or their dilutants. Chronic lymphadenopathy was common among addicts even before the advent of HIV and was also thought to be related to particulate contaminants. Subcutaneous or intracutaneous injection (“skin popping”) may cause widespread ulceration and disfigurement as a result of chemical necrosis or infection (see Fig. 11.10-2). These injecting techniques may be used by addicts who have sclerosed their major veins. Some drug users, determined to experience the effects of the drug used intravenously, switch to the use of femoral and jugular veins when the surface veins of the arms and legs have become unusable. Complications associated with injection of particulate contaminated material include pulmonary hypertension—sometimes leading to cor pulmonale—occasionally seen in heroin smokers.

Additional medical complications are likely to be due to contamination of illicit opioids with other chemical substances. A number of changes found at autopsy, such as degernation of the globus pallidus and necrosis of spinal gray matter, may fall into this category. Occasionally there are clinical manifestations in those users surviving overdose experiences. Examples are transverse myelitis, amblyopia, plexitis, peripheral neuropathy, parkinsonian syndromes, intellectual impairment, and personality changes. Pathological changes in muscles and degeneration of peripheral nerves have also been seen. Illicit laboratories sometimes produce opioid-like agents that are extremely toxic or are so potent that even small doses are lethal. For example, 1-methyl,4 phenyl,1,2,3,6-tetrahydropyridine (MPTP), a contaminant of

illegally produced meperidine, produces a severe form of parkinsonism by selective destruction of dopaminergic neurons. While not technically a contaminant, the illicit fentanyl analog, 3-methylfentanyl (“China White”), is 1000 times more potent than morphine and may have been responsible for several hundred overdose deaths.

HUMAN IMMUNODEFICIENCY VIRUS In 1989 it was estimated that from 5 to 33 percent of intravenous drug users in the United States were infected with HIV. However, despite comparable rates of sharing of injection equipment, there is wide regional variation. Seroprevalence rates during the 1990s remained highest in the northeastern United States and Puerto Rico (10 to 65 percent), and lowest (less than 5 percent) in the west, midwest, and south. Risk of infection appeared to be higher among Hispanics and African-Americans. Infection was far lower among former heroin users who had been continuously in methadone treatment. High rates of HIV infection among drug injectors is also found in many countries of Europe and Southeast Asia.

The finding that not all drug users who shared needles were infected with HIV stimulated vigorous prevention efforts aimed at recruiting patients into treatment and teaching them how to avoid infection by cleaning injection equipment properly, not sharing equipment, and not participating in high-risk sex. Outreach by community workers, coupled with specific instruction, reduces self-reported equipment sharing but has far less effect on high-risk sexual behavior. The question of whether providing injecting drug users with sterile equipment at little or no cost would substantially slow the spread of HIV infection is still controversial, but the available evidence indicates that those who inject drugs will use sterile equipment in order to avoid disease if the equipment is available at reasonable cost. Even in the absence of available syringes, many addicts have proven receptive to outreach programs that teach needle sterilization techniques. This recognition has led to the establishment of a number of syringe exchange programs, first in Europe and now in the United States. These programs can be stand-alone sites, incorporated into other kinds of drug treatment centers, operated in mobile units, or via community pharmacies. Additionally, a number of states have begun to liberalize their needle and syringe possession laws, making it possible for addicts to purchase and possess clean needles. In many areas the prevalence of HIV now appears to be declining as those with AIDS succumb and as the noninfected reduce the frequency of sharing injection equipment.

TUBERCULOSIS. Even before the HIV epidemic the incidence of tuberculosis was higher among heroin addicts than in the general population. Now a reemergence of tuberculosis poses a major problem for many treatment programs. Patients with compromised immune systems are far more vulnerable to developing active tuberculosis once infected, and poor compliance with antitubercular medication has led to the emergence of drug-resistant strains of the tubercle bacillus. Studies indicate that 4 to 21 percent of AIDS patients are infected with tuberculosis.

OPIOIDS AND THE IMMUNE SYSTEM. μ-opioid actions at CNS receptors can produce immunosuppressive effects (e.g., decreased natural killer cell activity). Opioid receptors are also found on lymphocytes and naloxone-reversible opioid effects can be demonstrated on white cells in vitro. However, the concentrations required are quite high; it seems unlikely that direct actions on white cells mediate effects on the immune system. In heroin addicts there are changes in the ratio of helper-to-suppressor T-cells and a suppression of cell-mediated immunity. The relation to opioid use is still unclear; the effects are probably more related to unhygienic injection practices. Natural killer cell activity and immunoglobulin G and M are within normal limits in former heroin users maintained for several years on methadone, although abnormalities are typically observed among heroin addicts.

TREATMENT

Treating Intoxication (Overdose) The first task is to ensure an adequate airway. Tracheopharyngeal secretions should be aspirated; an airway may be inserted. The patient should be ventilated mechanically until naloxone, a specific opioid antagonist, can be given. Naloxone is administered intravenously at a slow rate—initally about 0.8 mg per 70 kg of body weight. Signs of improvement—increase in respiratory rate and pupillary dilation—should occur promptly. In opioid-dependent patients, too much naloxone may produce signs of withdrawal as well as reversal of overdosage. If there is no response to the initial dosage, naloxone maybe repeated after intervals of a few minutes. In the past it was thought that if no response was observed after 4 to 5 mg the CNS depression was probably not due solely to opioids. However, buprenorphine is difficult to antagonize with naloxone and higher doses may be required. The duration of action of naloxone is short compared with that of many opioids, such as methadone and levomethadyl acetate, and repeated administration may be required to prevent recurrence of opioid toxicity.

Withdrawal (Detoxification) Currently oral methadone is the opioid drug most often used to ameliorate the severity of withdrawal. Until the recent introduction of levomethadyl acetate, methadone was the only opioid approved for this purpose by federal regulations. Buprenorphine, a partial μ-agonist opioid, is likely to gain approval for treatment of opioid dependence in the near future. Theoretically, however, any opioid can be administered and then gradually reduced. In general, the objective of treating patients hospitalized for detoxification is to make the withdrawal experience tolerable rather than to suppress all symptoms; patients should be told to expect some discomfort.

For patients who have been using street drugs, the initial dosage of methadone is usually 10 to 20 mg orally. If signs of withdrawal persist, the dose can be repeated after about 2 hours. As a general rule, initial stabilization does not require more than 40 mg of methadone during the first 24 hours. Physician addicts and others who had access to pure drugs are exceptions to that general rule and may require higher doses. If the usual daily dose of opioid (heroin, meperidine, hydromorphone) is known, the equivalent withdrawal-suppressing dose of methadone can be calculated. For example, methadone is approximately 3 times as potent as morphine in suppressing withdrawal. Because the objective of treatment is to prevent severe withdrawal, the current tendency is to base dosage on clinical history rather than to wait for obvious withdrawal or to precipitate withdrawal with naloxone. Caution should be used when giving doses above 40 mg of methadone daily because the accumulation of methadone can lead to serious toxicity. Once the patient is stabilized, the dose can be gradually reduced. If patients are hospitalized, this can usually be accomplished within 10 days by reducing the dose by 10 to 20 percent per day.

In some cases of low-level to moderate dependence, the withdrawal process can be accomplished within 1 or 2 days by giving repeated doses of naloxone to precipitate symptoms and ameliorating discomfort with diazepam (Valium) or clonidine. This technique permits rapid transfer to naltrexone (ReVia). If the detoxification process is to be successful with outpatients, the time required may have to be extended considerably. Some clinicians recommend 10 percent a week as the maximum rate of reduction from high dosage and reductions of 3 percent a week when the daily dosage is below 20 mg. Patients may be unwilling to accept such a long period of treatment and financial considerations may preclude this approach.

Despite the best efforts of clinicians and the use of slow detoxification, all studies to date indicate that many patients drop out before completing outpatient detoxification and that relapse rates following successful outpatient or inpatient detoxification are high. Relapse rates are particularly high for users of street heroin who attempt to detoxify on an outpatient basis. For such patients, extending the period of withdrawal from 3 weeks to 6 weeks or using a longer-acting drug, such as levomethadyl acetate, does not appear to alter a pattern of almost universal and rapid return to illicit opioid use. Federal regulations now permit the clinical use of levomethadyl acetate for detoxification. Despite the problems of initial stabilization, the less frequent need for clinic visits may make levomethadyl acetate useful for very slow detoxification schedules.

In an early study in which drug users were detoxified over a 90-day period with either methadone or low doses (2 mg) of sublingual buprenorphine, both groups did equally poorly in terms of dropping out of treatment and reverting to use of illicit opioids. Subsequent studies using higher doses of buprenorphine for detoxification found high patient acceptance, good 30-day retention comparable to that with methadone, reduction in illicit opioid use, and withdrawal symptoms that were generally quite mild. The use of buprenorphine may facilitate the transfer to naltrexone. Buprenorphine has not yet been approved for the treatment of opioid dependence, but studies have shown that patients can be transferred from heroin to buprenorphine even in a primary care setting. Opioid withdrawal can be suppressed for 48 to 72 hours when higher doses of buprenorphine are used. In general, patients who form a good relationship with a therapist or who have been maintained for some time on methadone have a far better prognosis for completing detoxification.

Nonopioid Agents for Detoxification Clonidine, an a_2-adrenergic receptor agonist originally marketed as an antihypertensive agent, has been shown to suppress some elements of the opioid withdrawal syndrome. Patients stabilized on relatively low doses of opioids—for example, 30 to 40 mg of oral methadone a day—can abruptly discontinue the opioids and clonidine can be used to attenuate withdrawal. Clonidine is given orally, starting at doses of 0.1 to 0.3 mg three to four times a day. In outpatient settings a total dosage above 1 mg a day is not recommended, although higher doses (1.5 to 2.5 mg) have been used with hospitalized patients. The major adverse effects are hypotension, which can be quite extreme, and sedation, and the dosage must be carefully individualized. Patients in outpatient clinics who have been stabilized on methadone and have developed a relationship with their therapists were found to be more successful in achieving abstinence when treated with clonidine than patients who were taking illicit heroin when clonidine treatment was begun. Some studies have found that outpatient detoxification with clonidine is almost as successful as detoxification using decreasing doses of methadone. In hospitalized patients clonidine permits more rapid detoxification from opioids than does the gradual withdrawal of methadone and patients are more likely to complete the detoxification process.

Clonidine appears to be least effective in suppressing postwithdrawal muscle aches, lethargy, insomnia, restlessness, and craving. There is no evidence that it is useful in preventing relapse after the completion of detoxification. Clonidine does appear to facilitate the detoxification of patients maintained on methadone and their

subsequent stabilization on naltrexone. Properly used, the combination of clonidine and naltrexone can shorten the period of hospitalization required for detoxification to less than 5 days. The clonidine to naltrexone technique has also been used in a day-hospital outpatient setting. Heroin addicts were given oral clonidine 3 times on the first day, with dosages ranging from 0.1 to 0.3 mg adjusted on the basis of dependence severity and blood pressure response; naltrexone was started on the second day. The initial naltrexone dose of 1 mg (orally) was gradually increased so that patients were receiving 40, 50, and 150 mg by days 3 to 5 respectively.

Lofexidine is another a_2-agonist that is used to ameliorate opioid withdrawal. It is not approved for this use in the United States, but in the United Kingdom it is more widely used than clonidine because it is believed to produce less hypotension.

a_2-Agonists can be used in conjunction with intravenous naloxone to accelerate or precipitate detoxification of heroin-using or methadone-maintained patients. This is accomplished by first briefly stabilizing the patient on buprenorphine and then increasing the doses of naloxone and naltrexone to adjust for the greater affinity of buprenorphine for opioid receptors. Starting patients on oral naltrexone soon after naloxone-precipitated withdrawal symptoms subside does not appear to cause any additional withdrawal symptoms.

Ultrarapid Detoxification The duration of the acute phase of opioid withdrawal can be markedly shortened by using opioid antagonists to remove opioid agonists from opioid receptors. Such a procedure results in a withdrawal syndrome far more intense than that which occurs with mere abrupt discontinuation (cold turkey). Building on the work of researchers who used small doses of naloxone along with benzodiazepine sedation to precipitate withdrawal and initiate naltrexone treatment, several groups of investigators developed methods to make tolerable and further shorten the duration of acute withdrawal. Researchers at Yale used clonidine to reduce withdrawal symptoms associated with starting naltrexone. Others added sedatives to the clonidine-naltrexone regimen. It was reported that the acute withdrawal syndrome could be shortened to less than 2 days if the procedure was initiated under full thiopentone or methohexitone anesthesia lasting 3 to 4 hours. Since these early studies, the procedure of precipitating withdrawal with opioid antagonists under anesthesia (sometimes called *ultrarapid opioid withdrawal* or *detoxification*) has become more widely used and also in many cases commercialized.

The basic technique consists of premedication with several adjunctive medications to reduce vomiting and bowel activity (e.g., octreotide [Sandostatin], ondansetron [Zofran], cimetidine [Tagamet]) and modulate autonomic activity (clonidine), following which the patient is sedated and intubated, and light general anesthesia is induced with midazolam (Versed) or propofol (Diprivan). Patients are then given naltrexone by nasogastric tube. Anesthesia is maintained for 4 to 8 hours, after which patients are allowed to recover. While some patients experience minimal withdrawal upon awakening, many still feel achy and washed out for an additional 24 to 72 hours. Patients are immediately started on a regimen of oral naltrexone.

There have been a number of variations on this general theme, with some practitioners using nalmefine (Revex) instead of naltrexone and others varying the premedications, the anesthetic, or both. Sometimes patients are taken off full μ-agonist opioids and put on buprenorphine, after which withdrawal is precipitated under heavy sedation without use of endotracheal or nasogastric intubation.

There is little reliable follow-up data on people who have undergone this detoxification procedure and there is little reason to believe that ultra-rapid detoxification would by itself be more efficacious than detoxification over 4 to 10 days. However, most commercial organizations offering this service state that they provide more than just detoxification under anesthesia. Most include in the price for the service a number of visits for weekly counseling and naltrexone to be taken orally. Some encourage the family to oversee the ingestion of naltrexone. Since it is typically the family that pays the very high charge for ultra-rapid detoxification, the family is usually motivated to participate in the postdetoxification treatment.

Many clinicians have expressed the view that since opioid detoxification using conventional methods is almost never fatal, ultra-rapid detoxification subjects patients to unnecessary risks. However, it must also be recognized that some patients are extremely reluctant to undergo withdrawal (either inpatient or ambulatory) and many who begin never complete the process. Further research is needed to determine if there is any benefit to the use of this expensive and intensive method.

Other Techniques Because opioid withdrawal is rarely life-threatening in healthy adults, a variety of nonpharmacological approaches to drug abstinence have been and continue to be utilized. Abrupt withdrawal (cold turkey) is used in some countries (e.g., Singapore) as a matter of policy because it is believed that experiencing severe withdrawal is a deterrent to relapse. Abrupt withdrawal, coupled with considerable emotional support, is still used in some therapeutic communities. Because withdrawal stress fatalities can occur in debilitated persons (e.g., those with advanced AIDS, tuberculosis, or heart disease), some caution is indicated in selecting accelerated withdrawal or nontreatment for them.

Acupuncture has also been utilized to alleviate opioid withdrawal. The acupuncture-stimulated release of endogenous opioids provides some rational basis for this approach. Whether opioid withdrawal is substantially alleviated by various electrical devices that purport to stimulate the CNS is still not certain despite efforts at controlled studies.

Herbal medicines aimed at ridding the body of toxic substances are sometimes used in a religious or semireligious context (Fig. 11.10-3). There is no evidence to indicate that when those traditional approaches are used in their own cultural settings the outcome is any better or worse than with the more medically sophisticated approaches typically used in the United States.

FIGURE 11.10-3 Treatment of addicts at Tham Krabok Monastery in Thailand results in a 70 percent success rate, according to its records. The 10-day free treatment begins with a vow to Buddha never to use narcotics again. Then patients are given an herbal medicine that makes them vomit immediately. (Reprinted with permission from White PT, Raymer S: The poppy—For good and evil. Natl Geogr *167:*187, 1985.)

Treatment of Dependence Following detoxification, the treatment process may involve outpatient, inpatient, residential, day-care settings, or prisons. The staff may consist solely of former addicts with considerable personal experience but minimal formal training, formally trained health care professionals, correctional officers, or some combination of these personnel. The program may emphasize group, individual, or family interactions; all drugs may be banned in some programs whereas other programs may be centered on the use of a single drug, such as methadone, or may be designed specifically to target special populations selected by age, sex, culture, race, or special status (e.g., pregnant women). Some of the treatment alternatives to be described, such as opioid maintenance, are not currently available in many other countries and not all options are equally accessible in all parts of the United States. Theoretically, many different combinations of environment, staffing, philosophy, target populations, and pharmacological agents are possible, but in practice there are only a handful of major program varieties, each of which may have a few subvarieties.

Despite a tendency toward a greater diversity of programs for the treatment of addiction in general, most of the opioid users treated annually in the United States are treated in one of four types of programs: detoxification (ambulatory or residential), usually followed by outpatient counseling; opioid maintenance and (methadone, levomethadyl acetate); residential or therapeutic communities; and outpatient drug-free programs. Opioid dependence is also treated in chemical-dependency programs based largely on 12-step principles. Many opioid users benefit from participation in such self-help groups as Alcoholics Anonymous (AA) or Narcotics Anonymous (NA), coupled with participation in a formal program or individual psychotherapy.

For individuals who become dependent on opioids in the context of medical treatment, the subsequent course of the disorder depends largely on the medical

problems that generated the opioid use, the willingness of doctors to continue to prescribe drugs for them, and whether the drug is used orally or by injection. Patients who use opioids orally and whose pain is controlled by adequate doses of legitimately prescribed medication may experience little interference with normal function for many years. If pain is uncontrolled, demands for increased or altered medication schedules sometimes leads to repeated diagnostic workups, surgery, and other procedures, punctuated by attempts at withdrawal—voluntary and coerced—and treatment for depression.

General Principles A person's willingness to accept treatment may change over time as life circumstances, family relationships, and the severity and complications of the dependence change. Consideration should be given not only to the characteristics, wishes, and previous experiences of patients but also to how they are likely to react to the particular treatments that are economically and geographically feasible.

The clinician should make it clear that treatment requires a commitment to a long-term change in life-style, attitude, family dynamics, and sometimes even geographic location, and that the responsibility for making the changes belongs to the patient. If resources permit, the clinician should not rest content with making a diagnosis of opioid dependence, but should make a complete psychiatric assessment and take a thorough drug-use history. Most opioid users have additional psychiatric disorders and other substance-related disorders (Table 11.10-5, Table 11.10-6, and Table 11.10-7). The severity of psychological difficulties (e.g., mood disorders, anxiety disorders, paranoid ideation) and patterns of using drugs other than opioids are predictors of outcome in treatment. Patients should also understand, however, that although antecedent stress, environmental conditions, and underlying psychological difficulties may have played important roles in the genesis of their drug dependence, once it is established, opioid dependence will not resolve spontaneously even if those conditions are improved. Clinicians must communicate the necessity for treating the pathological drug use as a disorder in its own right. Opioid addicts who enter therapeutic communities under pressure from the criminal justice system are almost as likely to benefit from treatment as are those who enter for other reasons. Court pressure enhances retention in treatment, and retention for more than 90 days is a predictor of positive outcome.

Detoxification as Treatment Because brief detoxification alone is generally followed by relapse, some experts believe that detoxification should be provided only as part of a more comprehensive treatment effort. Others believe that brief detoxification should be available for those addicts who want only a limited service. At present it is not clear whether extended ambulatory detoxification (i.e., 180 days) should be viewed as detoxification or a distinct treatment approach.

Counseling Counseling and family and individual psychotherapy following opioid withdrawal are usually used but have not been evaluated satisfactorily. Each of these therapeutic techniques has been evaluated in the context of methadone maintenance treatment programs, where scheduled counseling has been shown to reduce illicit drug use substantially and to increase prosocial behaviors. The efficacy of counseling is further supported by studies showing that the quality of counseling and rapport between patient and counselor have a significant impact on outcome measures. When the dosage of methadone was held constant (e.g., at 60 mg), the addition of drug counseling on a regular basis was distinctly more effective than was emergency counseling in reducing opioid and cocaine use. When patients were provided with on-site medical, psychiatric, employment, and family counseling, the outcome was improved still further. It is reasonable to assume that the quality of counseling, psychiatric, and social services can have an impact on how opioid users not being maintained on methadone respond to treatment. In one study, detoxified heroin addicts who participated in a support group where they learned how to avoid or to cope with situations that provoked drug cravings or feelings of withdrawal (relapse prevention) had lower relapse rates than those assigned to control groups.

Self-Help NA is a self-help group of abstinent drug addicts modeled on the 12-step principles of AA. Such groups now exist in most large cities and can provide useful group support. The outcome for physicians treated in 12-step programs is generally good, but the anonymity that is at the core of the 12-step model has made detailed evaluation of its efficacy in treating opioid dependence difficult.

Opioid Antagonists The use of opioid antagonists to treat opioid dependence was originally based on the assumption that classically conditioned withdrawal symptoms and operantly reinforced drug-seeking behavior contribute to the high relapse rate typically seen after withdrawal from opioids. Theoretically, by blocking the euphoric effects of opioids, treatment with antagonists would lead to the extinction of operantly reinforced drug seeking; by preventing the reestablishment of physical dependence, treatment with antagonists also leads to the eventual extinction of conditioned withdrawal phenomena. These drugs do produce the expected blockade of opioid effects and their toxicity is low. Recent treatment with antagonists has been based on empirical and laboratory observations that patients taking naltrexone experience less craving in the presence of opioid-related cues, presumably because on a cognitive basis they are aware that they are unable to experience the opioid effects.

Naltrexone has been used in a number of clinical trials, but in each of them the dropout rate has been high. Curiously, these very low compliance rates have not been characteristic of alcohol abusers treated with naltrexone.

Naltrexone would appear to be an ideal drug for use in therapy. It is orally effective and when given three times a week (100 mg on weekdays and 150 mg on weekends) it completely blocks the effects of substantial doses of heroin. When naltrexone was tested in a multiclinic, double-blind study, however, very few of those patients who initially expressed an interest in the drug actually took a single dose. At the 6-month follow-up few differences were noted between the naltrexone group and the placebo control group, although the naltrexone group had fewer urine specimens positive for opioids while they were in treatment. In other clinical trials patients continued to take naltrexone for an average of 6 to 8 weeks. A double-blind study in Spain found no differences in drug use or retention in treatment between naltrexone and placebo groups. Former opioid users sometimes report dysphoria, an adverse effect not reported when the drug is given to alcohol abusers. The only consistent side effect reported is a somewhat higher incidence of nausea.

Experienced clinicians do not think that double-blind placebo-controlled trials are the most appropriate way to assess the utility of long-acting antagonists. They believe that a period of 30 to 60 days of treatment with naltrexone immediately after detoxification reduces the probability of relapse to opioid use. In open studies of opioid users on probation who volunteered to take naltrexone, those on active drug were far less likely than those randomly assigned to placebo to violate probation and be reincarcerated. In studies conducted in Israel and Portugal, special efforts were made to involve family members in supporting patients' compliance with naltrexone treatment, resulting in 30 to 40 percent continued abstinence rates at 1-year follow-up. However, in a controlled study conducted in New Haven, Connecticut, neither family therapy nor cash-equivalent vouchers provided contingently improved compliance. New techniques for facilitating the transfer from heroin or methadone to naltrexone (ultrarapid detoxification, clonidine, or buprenorphine and clonidine) may increase the ease of initiating naltrexone treatment, but low compliance and high dropout rates remain unsolved problems. Depot preparations of naltrexone and a somewhat longer-acting antagonist, nalmefine, are under study. In a small number of volunteers a single injection of naltrexone encased in microcapsules has been found to produce blood concentrations adequate to block the effects of street-quality heroin for about 30 days.

Opioid Maintenance In the United States about 750 outpatient methadone maintenance programs operating in 40 states and territories are now providing treatment with methadone or levomethadyl acetate to more than 110,000 patients at any given time. Methadone maintenance is also used in the United Kingdom, Australia, Hong Kong, and a number of European countries. In France, opioid addiction is now being treated with buprenorphine. Thus, opioid maintenance is a major modality for treating opioid dependence throughout much of the world.

Initiated by Vincent Dole and Marie Nyswander in 1964, the maintenance approach postulated that high doses of methadone would alleviate drug hunger and simultaneously block, by means of cross-tolerance, any euphoria produced by self-administered heroin. Thus, opioid users would be freed from the preoccupation with drug-seeking behavior and, with help and rehabilitation, could channel their energies into more productive avenues. Dole and Nyswander further postulated that opioid dependence is unrelated to antecedent psychological difficulties and that most of the traits of instability and unreliability seen in addicts are the consequence rather than the cause of their opioid addiction. Although the results obtained by other programs using methadone were often less dramatic as program criteria for entry were broadened, more disturbed and less motivated patients were admitted, and lower doses of methadone were prescribed, patients still showed substantial decreases in drug use and criminality and increases in health and social functioning.

General Pharmacology Given acutely, methadone is a typical μ-receptor agonist producing euphoria, analgesia, and other typical morphine-like effects. Given long-term by the oral route, however, methadone has several interesting properties that make it unusually useful in maintenance programs. These qualities include its reliable absorption and bioavailability after oral administration, the delay of peak plasma levels until 2 to 6 hours after ingestion, and the apparent nonspecific binding to tissues that creates a large reservoir of methadone in the body. The large reservoir, combined with slow time-to-peak effects, buffers the patients against sharp peaks in subjective effects after ingestion, which in any event are highly attenuated as a result of tolerance. The reservoir of methadone also tends to minimize any sharp declines that would induce withdrawal. Thus, not only is the administration of methadone on a once-a-day schedule possible, but minor variations in dosage over short periods do not induce major changes in biological effects. Although the mean plasma half-life in naive subject is about 15 hours, it ranges from approximately 22 to 56 hours in methadone-maintained patients depending on the measurement technique used. A number of commonly used therapeutic agents can induce liver enzymes and thereby result in more rapid metabolism of methadone and in half-lives significantly shorter than 22 hours; some agents can inhibit metabolism.

Standard Procedures and Government Regulations Since 1972 opioid maintenance programs have been required to operate according to detailed federal, state, and, sometimes, local regulations. Under recently revised federal regulations, opioid-dependent persons who have been dependent (i.e., physiologically addicted) for less than 1 year can be detoxified using opioids, but cannot be maintained beyond the detoxification period without an opioid-free interval. Persons less than 18 years old must have had two prior treatment failures and verified opioid dependence (i.e., physiological dependence) at admission, and have parental consent. Currently, regulations also govern maximum take-home dosage and the duration of daily clinic treatment before take-home dosage may be provided.

These regulations and the entire rationale for special regulations were the subject of a study by the Institute of Medicine (IOM) of the National Academy of Sciences and of a National Institutes of Health (NIH) Consensus Development Conference on the Effective Treatment of Heroin Addiction. The IOM concluded that federal regulations overestimated the danger of diversion of methadone or levomethadyl acetate, overregulated medical practice, and restricted access to treatment. The IOM report recommended sharply reducing the extent of federal regulation and the substitution of guidelines for regulations. The Department of Health and Human Services (HHS) is now proposing to test a new model of federal supervision in which programs and individual practitioners would be accredited by organizations such as the Joint Commission on the Accreditation of Health Care Organizations (JCAHO) and Commission for Accreditation of Rehabilitation Facilities (CARF) using standards based on expert medical opinion. Accredited programs would then be licensed by the Drug Enforcement Agency (DEA), which would retain its independent statutory authority to oversee the security of opioid drugs used by narcotic treatment programs. Since many states and local jurisdictions also have detailed regulations for opioid maintenance programs, the benefit that would flow from a reduction of federal regulations would vary from state to state. It is possible that the accreditation process will provide for opioid maintenance treatment by qualified individual practitioners.

Methadone Dose and Philosophical Differences Among Programs Methadone maintenance programs vary with respect to dosage, attitudes toward continued antisocial behavior, medical and social services provided, and long-term goals. The original programs emphasized methadone dosage sufficient to suppress opioid drug hunger and to induce a cross-tolerance blockade of the effects of illicit opioids, usually 80 to 120 mg a day. Patients were encouraged to remain on methadone indefinitely on the assumption that the return of opioid drug hunger following detoxification would lead to relapse and the loss of any gains achieved during treatment.

Other programs used lower doses of methadone (20 to 60 mg), which were often adequate for partially suppressing drug-seeking behavior, but not for producing adequate cross-tolerance to large doses of heroin. Such programs generally viewed maintenance as a transitional stage to eventual detoxification. Although patients may remain in treatment in these programs indefinitely, the ambience is often more supportive of efforts at gradual withdrawal. Empirically, patients maintained on lower doses of methadone are far more likely to discontinue treatment, and those who do so are unlikely to achieve sustained abstinence from opioids. In a six-program study in the United States the number of patients using intravenous heroin steadily increased after treatment was discontinued. By 12 months 80 percent reported heroin use in the month prior to the interview. Since only a small percentage of these persons were actually discharged as having completed treatment, the figure is perhaps a better illustration of what happens to those who drop out.

Since the publication of the findings on the importance of dose in reducing opioid use and increasing retention in treatment, more programs are prescribing daily doses of methadone of 60 mg or higher. However, the proper dose is not a matter of reaching some arbitrary number. There are wide variations in rates of methadone metabolism, and some experts believe that more attention should be given to using laboratory measures of plasma levels to adjust daily dosage. Data suggest that an average level of 400 ng/mL seems adequate and that trough levels below 150 ng/mL are likely to be associated with some degree of withdrawal or drug hunger. Clinicians should be aware that a variety of therapeutic agents can cause a decrease in plasma levels of methadone by inducing hepatic enzymes (CYP 3A4) that metabolize methadone. Among those are rifampin (Rifadin), phenytoin (Dilantin), barbiturates, carbamazepine (Tegretol), and ethyl alcohol. Valproic acid does not accelerate metabolism. Agents that can inhibit methadone metabolism include erythromycin, cimetidine, and ketoconazole. Zidovudine (Retrovir) does not alter methadone metabolism, but patients on methadone tend to have higher zidovudine levels than do controls. More methadone is excreted when urinary pH is low than when it is high; stress and other factors that lower urinary pH can result in lower plasma levels of methadone.

In both high-dosage and low-dosage methadone programs there is often a continuing struggle with patients over take-home medication. Patients who do not respond to treatment generally continue to use opioid and nonopioid illicit drugs, use alcohol to excess, attend the programs very irregularly, or exhibit combative behavior at the clinic. Such patients pose a dilemma for both types of methadone maintenance programs because they would probably fare worse if discharged. However, permitting them to remain demoralizes the staff and the other patients and often increases drug use among the latter.

Long-Term Effects The relative safety of methadone maintenance in terms of organ toxicity has been firmly established. Tolerance to many of the opioid agonist actions of methadone is incomplete, however, and continuing pharmacological effects are observed. Many of these effects, such as euphoria, drowsiness, and somnolence, are more prominent in the first weeks of treatment; if the dosage level is increased too rapidly, the effects even become manifested at later points in treatment. Some effects, however, persist even after many months of treatment. Among the most common long-lasting effects are constipation, which can sometimes result in fecal impaction and intestinal obstruction; excessive sweating; complaints of decreased libido; and sexual dysfunction, e.g., an inability to sustain an erection. Opioids reduce plasma levels of testosterone and follicle-stimulating hormone for which tolerance is often incomplete, but the correlation between abnormally low plasma levels of hormones and sexual dysfunction is not high.

In general, however, indexes of hypothalamic-pituitary-adrenal axis function are normal in patients maintained on long-term methadone, in contrast with the deranged function typical of active and recently detoxified heroin users. Both sleep abnormalities (insomnia and nightmares) and altered electroencephalogram (EEG) sleep patterns frequently are found during the first months of methadone treatment; the EEG sleep patterns appear to return to baseline, but complaints of sleep abnormalities may persist. For a substantial percentage of patients, even those participating in programs where dosage is adjusted, the major adverse effect is mild to moderate withdrawal symptoms prior to the next dose.

Tolerance does not develop in all patients to the mood-elevating effects of methadone. In double-blind studies some patients regularly report a greater sense of well-being a few hours after ingesting their daily dose; for some patients this effect may be an important factor in retention in treatment.

In-Treatment Outcome The majority of patients treated in methadone programs show significantly decreased opioid and nonopioid drug use, criminal behavior, and symptoms of depression and increased gainful employment. Significant differences in effectiveness across programs are due in some measure to the characteristics of patients treated, but certain program features tend to make some programs more effective than others. In 1980 the average retention rate for a group of methadone clinics participating in a national prospective study was 81 percent at 1 month, 67 percent at 3 months, and 52 percent at 6 months. Higher retention rates are associated with the provision of high-quality social services (especially within the first months), higher doses of methadone (60 mg or more) and allowing patients to know their dosage, the ease of accessibility, no fees or very low fees, and the use of supportive rather than confrontational techniques.

It bears repeating that the effectiveness of opioid maintenance treatment is powerfully influenced by the quality of the additional services provided. Effective individual drug counseling (e.g., one session per week) can result in significantly better outcome in terms of illicit opioid and cocaine use, needle-sharing, crime, employment, and psychological well-being. Treatment outcome can be further improved by the provision of psychiatric services, employment counseling, and family therapy. However, such additional services increase the overall cost of treatment, and in terms of overall improved outcomes it is more cost effective to ensure that all patients have competent standard drug counseling. Providing additional group therapy to patients in maintenance programs does not appear to produce better outcomes.

It has been confirmed repeatedly that positive behavioral change, including decreases in illicit drug use and other criminal behavior, does not typically occur immediately upon entry into treatment but takes place over a period of many months. Treatments lasting less than 90 days usually have little or no impact; consequently, retention in treatment is critical. Several studies have shown a direct relation between methadone dose and the probability of treatment retention.

In Australia patients on doses of 80 mg or higher were twice as likely to remain in treatment as those receiving 60 to 79 mg, who were twice as likely to remain as those receiving less than 60 mg. Dosage has also been shown to have a profound effect on whether or not patients will continue to use illicit heroin. In a study of 6 clinics in the United States there was an inverse relation between methadone dosage (over the range from 20 to £ 80 mg daily) and the percentage of patients using heroin. Although some programs persist in using low doses that have been shown to correlate with both high dropout rates and continued heroin use, their number has decreased as the data on the importance of adequate dosage has become more generally accepted.

Other program factors that influence outcome and retention are the perceived range and quality of the social services provided to the patient early in the course of treatment, whether the program is flexible or confrontational and punitive about occasional illicit drug use, and the competence and quality of the program leadership and the counselors. Outcome correlates with services actually delivered and the degree to which patients perceive that the services are those they believe are important to them. Some of the better-funded programs with better staff-patient ratios did not deliver as many services as did less well-endowed programs. The retention of drug users in treatment programs and the successful reduction of injecting drug use are particularly important in an era when such drug use often results

in transmitting or acquiring HIV infection. Older, black, married, and employed patients tend to remain in methadone programs longer; patients with extensive criminal backgrounds tend to drop out sooner and to perform more poorly while in treatment. The severity or duration of opioid use does not correlate with retention or performance in treatment, and patients who enter treatment under what they perceive as legal coercion show improvement comparable to that of patients who report no such external pressure.

Detoxification and Long-Term Outcome The percentage of patients remaining abstinent from opioids 12 to 36 months after successful detoxification from opioid maintenance has ranged from 12 to 28 percent for unselected samples of patients, some of whom were discharged for violation of clinic rules. When analysis is restricted to those patients who elected to be withdrawn (with staff and patient consensus that treatment was completed), abstinence rates were substantially higher, at least over the first 6 to 12 months. Predictors of retention and positive outcome in treatment do not necessarily predict success in achieving abstinence or long-term positive outcome once withdrawal has been completed.

In general, patients with shorter drug histories, longer time in maintenance treatment but at lower dosages seem to have more success detoxifying. In one national, multiclinic follow-up study 40 percent of former methadone patients interviewed were not using any illicit opioids and did not have any other significant drug problems 6 years after the completion of initial treatment. Other follow-up studies have found a smaller proportion of former maintenance patients who were opioid abstinent.

Although the percentage of heroin addicts maintained on methadone who eventually achieve long-term stable abstinence is not high, there is no convincing evidence that the likelihood of abstinence is higher among those treated in other modalities once adjustment is made for various pretreatment predictors of outcome. In one study where methadone treatment appeared to impair eventual abstinence, that disadvantage was offset by substantially lower rates of incarceration among methadone-treated patients.

Other Opioid Maintenance Drugs

LEVOMETHADYL ACETATE This drug is a μ-receptor agonist. It was approved for use in the treatment of opioid dependence in 1993. Levomethadyl acetate is similar to methadone in its pharmacological actions, and it is converted into the active metabolites nor-acetylmethadol and di-nor-acetylmethadol that have very long biological half-lives, (e.g., 48 to 96 hours for di-nor-acetylmethadol). Figure 11.10-4 shows that the plasma levels of nor-levomethadyl acetate and di-nor-levomethadyl acetate persist for many hours after a single dose. Consequently, levomethadyl acetate can be given as infrequently as three times a week, thereby reducing the inconvenience of attending a clinic daily to ingest the drug and simultaneously reducing concerns about illicit diversion. When levomethadyl acetate is abruptly discontinued, the withdrawal syndrome is slow in onset and relatively mild in intensity but it is at least as protracted as that of methadone. Since the mid-1970s in double-blind as well as large-scale, multicenter, open studies, levomethadyl acetate has been shown to be equivalent to methadone in suppressing illicit opioid use and encouraging productive activity. Prior to its approval by the Food and Drug Administration (FDA) a consistent finding was that retention in treatment was lower with levomethadyl acetate than with methadone; more recently clinicians are reporting that some patients prefer levomethadyl acetate.

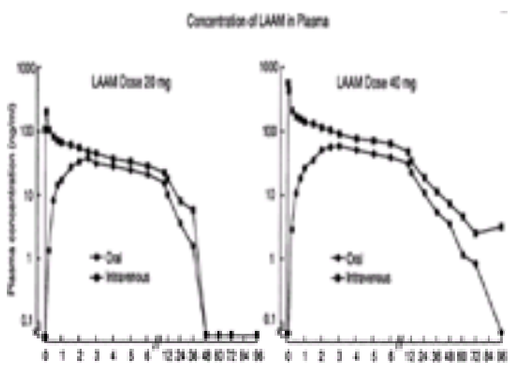

FIGURE 11.10-4 Mean (*N* = 6) concentrations of nor-LAAM and dinor-LAAM after single doses (oral and intravenous) of 40 mg LAAM. The hatch marks on the x-axis indicate a change from 30-minute intervals to 12-hour intervals. (Adapted from Walsh PT, Johnson RE, Cone EJ, Bigelow GE: Intravenous and oral L-alpha-acetylmethadol: Pharmacodynamics and pharmacokinetics in humans. J Pharmacol Exper Ther *285:*71, 1998.)

A random assignment study comparing three dose levels of levomethadyl acetate (25, 25, and 35 mg; 50, 50, and 70 mg; and 100, 100, and 140 mg—all given three times a week) demonstrated that the higher doses were more effective in suppressing heroin use. Patients receiving the medium dose were less likely to drop out of treatment, probably because those on the highest dose felt oversedated. In most cases it is unnecessary to first stabilize heroin users on methadone, and levomethadyl acetate can be used as the initial treatment agent.

Levomethadyl acetate is more complex pharmacologically than methadone and its use demands a more skilled clinician than does methadone. Currently the conditions attached to its use prohibit take-home doses of levomethadyl acetate. This restriction is likely to reduce its utility, except in situations such as long-term detoxification and interim maintenance where no take-home methadone is permitted currently.

BUPRENORPHINE This is a partial μ-receptor agonist that is now available as an analgesic and has been proposed as an alternative to methadone in the treatment of heroin addiction, both for detoxification and for maintenance. It has also been explored in the treatment of concurrent cocaine and opioid dependence. Buprenorphine produces morphine-like effects at low doses, but even when the dose is increased, the intensity of its actions does not seem to exceed that achieved with 30 to 60 mg of morphine. When buprenorphine is given sublingually, morphinelike subjective effects appear to reach a ceiling at about 8 to 12 mg, with only modest increases in effects at 16 and 32 mg. Over this dosage range, significant respiratory depression was not observed. Because of this apparent ceiling, the risk of overdose may be limited. After repeated administration, buprenorphine attenuates or blocks the subjective effects of parenterally administered morphine or heroin. When buprenorphine given sublingually 8 mg a day for several weeks is abruptly discontinued, a generally mild opioid withdrawal syndrome develops.

Buprenorphine has been compared with methadone as a maintenance agent in several double-blind outpatient studies. Although optimal dose ranges have not been established, one study found 8 mg of buprenorphine sublingually to be comparable to 60 mg of methadone orally on measures of retaining patients in treatment and suppressing heroin use. Withdrawal symptoms when buprenorphine was discontinued were mild. In similar studies 8 mg of buprenorphine was significantly less effective than was 80 mg of methadone and was about comparable to 30 mg of methadone; in another study 8.9 mg of buprenorphine was comparable to 54 mg of methadone. In none of those double-blind studies did buprenorphine show superiority in reducing cocaine use. Some patients express a clear preference for buprenorphine over methadone. With higher doses (e.g., 16 to 32 mg sublingually), some patients experience no withdrawal for 48 to 72 hours, permitting a reduction in clinic visits. Buprenorphine may become the treatment drug of choice for most heroin users, although because of its ceiling effects there may be patients who will still require full agonists such as methadone or levomethadyl acetate. In France buprenorphine is now the most widely used maintenance drug for opioid dependence, with about 40,000 patients in treatment.

A formulation combining buprenorphine and naloxone in a 4:1 ratio (SuboxoneR), has completed clinical testing and will be submitted for approval to the FDA. Given sublingually, the naloxone has virtually no effects in opioid-dependent patients; however, if an attempt is made to inject the combintion, the naloxone precipitates withdrawal symptoms. This formulation will have a lower abuse liability than buprenorphine alone.

In a large multisite, random-assignment, double-blind study, 8 mg of sublingual buprenorphine was found to be significantly better than 1 mg. Patients treated with 16 mg were more likely to have 13 weeks of consecutive urine tests negative for illicit opioids than those receiving 1 mg or 4 mg; patients on 16 mg per day were also somewhat less likely to drop out of treatment.

Heroin Maintenance Versus Methadone. Intravenous heroin and oral methadone were compared in a random-assignment study at a London clinic. Most patients given heroin continued to inject opioids and stayed involved with the drug culture. Some of the heroin patients sold part of their prescriptions; others supplemented clinic supplies with opioids from illicit sources. Some of the patients assigned to oral methadone maintenance refused to participate in the study and left treatment immediately; many others left subsequently. At 12 months only 29 percent of oral methadone patients were still at the clinic; of those who left, 40 percent (28 of those initially assigned to oral methadone) were no longer using opioids regularly at the 1-year follow-up. Over the 12-month period more heroin patients than oral

methadone patients died or were admitted to hospitals for drug-related problems. A strong relation was found between criminal activity and continued illicit opioid use, although differences in baseline rates of criminality make it difficult to evaluate the net impact of the two types of treatment on crime.

HEROIN TRIALS. In the early 1990s Switzerland experienced a very sharp rise in heroin use and drug-related crime. This occurred in spite of (or perhaps because of) a policy of toleration begun in 1986 that provided addicts with areas where they could use drugs without fear of arrest (Platzspitz in Zurich and other “needle parks” elsewhere). This seemed only to have acted as a magnet for European drug users. Addiction rates continued to rise along with overdose deaths and the incidence of HIV infection. Efforts to reverse the trend by strict law enforcement and by expanding residential treatment were also less than fully successful in slowing the rise in crime and overdose deaths. In addition, methadone maintenance programs had tripled between 1986 and 1990. With the closing of Platzspitz in 1992, the various Cantons initiated low-threshold methadone prescribing, but many heroin users did not avail themselves of these treatment opportunities.

It was in this context that the Swiss government initiated a research program to test the feasibility of prescribing heroin to confirmed heroin addicts. An initial random-assignment phase indicated that patients strongly preferred intravenous heroin to intravenous morphine or methadone. During the demonstration phase, which began in 1993, patients admitted to 18 treatment centers in several Swiss cities came to specialized clinics several times a day and injected as much heroin as they wished. For most patients heroin dosage first escalated rapidly but after several weeks or months seemed to stabilize, albeit in some cases at up to 900 mg a day intravenously. Most patients came to clinic several times a day. Medical and psychiatric care as well as social work support were readily available. Some patients were given subsidized jobs; all were eligible for welfare assistance. Investigators reported that patients' overall physical and mental health improved. Earnings improved somewhat, and criminal activity declined from 69 to 10 percent, as indicated by police records. Since urine was tested for drugs only every 8 weeks, it is not certain that illicit drug use actually decreased, but patients reported a very sharp decrease in illicit heroin and cocaine use. Reported use of benzodiazepines declined very slowly, and alcohol and cannabis use declined very little. The dropout rate was relatively low, with 69 percent retention at 18 months. Eleven new cases of HIV or hepatitis were recorded, probably due to illicit cocaine use. The annual death rate of 1 percent was far lower than for untreated addicts and lower than for many other treatment programs. Because of the extensive support services and the long clinic hours, the overall cost of operating these clinics, (about $23 per patient a day), was several times higher than the cost of comparable oral methadone maintenance programs. Similar programs would seem to be inappropriate except in areas where there is already easy access to all other forms of treatment. evertheless, the governments of The Netherlands and Australia have been seriously considering the initiation of similar “research” projects.

Therapeutic Communities The underlying philosophy of the more than 300 therapeutic communities that have evolved from Synanon is that the drug addict is emotionally immature and requires total immersion in a specialized social structure in order to modify lifelong, destructive behavioral patterns. The goal is to effect a complete change of lifestyle, including abstinence from drugs, the development of personal honesty and useful social skills, and the elimination of antisocial attitudes and criminal behavior.

To achieve these objectives, the addict was expected to live in the therapeutic community for approximately 12 to 18 months and to participate in frequent group sessions devoted to mutual criticisms of the attitudes and behavior of the participants. The community also acts in many respects as a substitute family. Assumption of responsibility within the community is rewarded with increased personal freedom, material comfort, and the respect of peers. Deviation from community expectations, in terms of behavior or attitude, frequently results in harsh criticisms by staff or sometimes by the entire community. Violence and any form of drug use are totally prohibited and may result in expulsion from the community—the ultimate punishment. Although most therapeutic communities avoid the use of drugs even to ease initial withdrawal, some are more flexible regarding treatment with drugs for heavily dependent new entrants. More recently, some therapeutic communities have recognized that a high percentage of addicts have psychopathology in addition to drug dependence and thus may permit the use of prescribed antipsychotic or antidepressant medication.

Present-day therapeutic communities vary considerably in their attitudes toward professionals and in actual staffing patterns. In every community, however, at least a few exaddicts are employed as key personnel on the staff; the exaddicts serve as role models and visible evidence that recovery and acceptance are possible and expected. Some therapeutic communities, such as Phoenix House, Odyssey, and Second Genesis, are or were directed by psychiatrists and employ a number of health professionals in key positions. Quite recently a number of federally supported programs have begun to develop individualized treatment plans and to use health care professionals, such as physicians, psychologists, or master's degree–level counselors or social workers, to make initial assessments.

Although many therapeutic communities still expect residents to return to the general community after 12 to 18 months, some are experimenting with shorter periods of residence, sometimes because of pressure from funding sources. Because they require so long a period of residence, therapeutic communities obviously have little appeal to those opioid addicts who have stable and gainful employment and satisfactory personal relationships. Currently, a substantial proportion of entrants into therapeutic communities are referred by the criminal justice system. Criteria for entry have thus been modified and external pressure to remain in treatment has been increased. Despite the external pressure, dropout rates are still high: 30 to 40 percent in the first 90 days and 50 percent within 6 months. Furthermore, the percentage of new entrants with severe psychopathology has been gradually increasing. There is substantial variation in drop-out rates among ostensibly similar therapeutic communities, even after adjusting for patient characteristics.

Residence in the therapeutic community results in major reductions in drug-use problems; indicators of depression also decrease significantly. Follow-up studies of graduates and dropouts indicate that patients remaining 90 days or longer exhibit significant decreases in self-reported antisocial behavior, illicit drug use, and recorded arrests, as well as substantial increases in legitimate employment. Improvement was seen in patients who met DSM-III-R criteria for antisocial personality to about the same extent as those who do not. In general, for those without severe psychopathology there is a consistent time-in-program effect up to about 12 months; patients who stay longer exhibit better outcomes along all dimensions at 12-month and 5-year follow-up intervals. In some cases patients found to be doing well have had additional treatment in other programs since leaving the therapeutic community.

Outpatient Drug-Free Programs Such treatment programs often subscribe to the same goals as the residential or therapeutic communities, but they attempt to achieve those goals in a less than 24-hour-a-day setting. The programs vary widely in staffing patterns, philosophy, and program content; they range from highly organized daytime therapeutic communities to drop-in centers offering conversational sessions and recreational activities. Outpatient drug-free programs tend to deal more with multiple-substance abusers than with confirmed heroin addicts, although some programs treat both. Long-term follow-up studies suggest that these programs have an impact beyond what is seen with detoxification alone, but differences in patient characteristics make valid comparisons difficult.

Supplements and alternatives to outpatient drug-free therapies must always be mentioned. They include self-help groups, such as AA and NA, as well as group therapies focusing on cognitive skills for coping with crises and avoiding situations that engender craving (relapse prevention).

Psychotherapies As measured by use of illicit drugs, need for ancillary psychiatric medicines, scores on scales of psychological distress, and amount of legitimate money earned, patients in methadone maintenance programs appear to benefit more when individual, analytically oriented, supportive-expressive, or cognitive-behavioral psychotherapy is added to standard drug counseling than from counseling alone. With such therapy the very bleak prognosis for patients with the most severe psychopathology can be improved. To best engage patients in individual therapy, the therapy should be started early and be an integral part of the program. In general, patients with antisocial personality disorder without depression do not derive additional benefit, but even among that group, those who seem capable of developing an alliance with the therapist appear to do better than those who do not.

Among patients maintained on methadone, one controlled study suggests that skillful family therapy in conjunction with urine monitoring is superior to standard drug counseling in fostering decreased illicit drug use. However, from a public health perspective, such additional psychotherapy for patients treated with adequate doses of methadone does not appear to be as cost effective as providing standard therapy (weekly drug counseling) to more patients.

There are no controlled studies on the efficacy of individual psychotherapy in treating opioid-using patients not stabilized on methadone. Experienced clinicians believe that psychotherapy can influence outcome in opioid users. Most experts now believe that therapists should not be passive but rather should be willing and able actively and empathetically to help patients look at their vulnerabilities. They also need to be flexible and to be able to communicate respect, empathy, and even admiration. At the same time, therapists must be alert to complex countertransferences that drug-using patients typically provoke. Therapists who see drug-dependent patients in office practice settings are increasingly recognizing the need to involve the family and to develop a supportive network to aid in their treatment. The therapeutic interventions in such cases are based less on individual psychoanalytic concepts than on cognitive-behavioral techniques that recognize the role of emotional and environmental cues in triggering craving and predisposing to slips and relapses. Although these techniques have been shown to be of value in controlled studies, their efficacy when transferred to the office practice setting remains unclear.

Treatment of Special Populations

Criminal Justice Clients The criminal justice system has complex interactions with drug-dependence treatment systems. Many patients now enter or remain in treatment because of direct coercion by the courts or correctional system.

Conversely, some patients on probation or parole may enter treatment against the wishes of their probation officers or in violation of some condition of parole. The impact of such coercion on retention in treatment or on outcome has been difficult to estimate because of baseline differences between criminal justice and noncriminal justice patients.

In addition to their relation to the major modalities of treatment, probation, parole, or both can be viewed in their own right as techniques that modify drug-using behavior. Close supervision and drug testing of parolees result in a substantial reduction in daily drug use. The efficacy of such testing and supervision depends in part on the way in which sanctions against use are arranged and the consistency with which such sanctions are exercised. Probation programs that involve use of naltrexone seem to reduce relapse to opioid use.

Civil commitment programs for opioid users involving long periods of institutional care, although still on the law books in some states, have lost popularity. They were exceedingly expensive as compared with all other treatment modalities and there is no evidence of their long-term efficacy. In contrast, there is renewed interest in treating people in jails and prisons who have been drug dependent. Former prisoners who, while incarcerated, participated in programs based on therapeutic community principles tend to have lower rates of recidivism than do matched controls, especially if they receive additional treatment in the community immediately following release.

Pregnant Women In general, opioid use during pregnancy is associated with decreased fetal growth but not with any teratological effects. What is clear, however, is that most women who continue to use heroin while pregnant do not get prenatal care and deliver low-weight babies with an elevated risk for morbidity and mortality. Babies who survive may be infected with HIV and other diseases as a result of maternal high-risk behavior. Most of these risks can be substantially reduced if the mother can be retained in treatment and provided with prenatal care. Sometimes this can be accomplished in drug-free outpatient or residential programs. Utilizing such programs usually requires initial detoxification, which must be undertaken with considerable caution because severe opioid withdrawal early in pregnancy (before 14 weeks) can induce abortion and late in pregnancy (after week 32) can induce fetal distress. If a woman is already maintained on methadone, it is not necessary to undertake withdrawal, but if withdrawal is elected, it should be done slowly (5 mg every other week) and, if possible, in collaboration with clinicians experienced in perinatal addiction. Dose adjustments (increases) may be needed for pregnant women maintained on methadone because of changes in blood volume and metabolism. Babies born to mothers who have been maintained on methadone usually require treatment for neonatal opioid withdrawal. However, if the use of illicit drugs an be eliminated and adequate prenatal care provided, infant mortality and morbidity are reduced, and in the long run the development and cognitive functioning of the baby are not likely to be impaired.

Health Professionals. Health professionals often come to treatment when their drug use is discovered by colleagues or by drug enforcement agencies. Treatment generally consists of a contingency contract under which they agree to frequent drug testing and the certain revocation of their license to practice if they continue to use drugs. This contract is typically supplemented by encouragement to participate in a 12-step program or other therapy. Supervised naltrexone may occasionally be part of the regimen. Under supervision, most (up to 85 percent) of these patients recover and are able to return to practice. Returning to specialties with easy access to opioids can pose a serious hazard to continued abstinence. For example, in one study only 34 percent of anesthesiology residents who were abusing opioids were able to return to their specialty. For a significant percentage of the residents, the first sign of relapse was a fatal overdose.

Other Special Populations. Certain groups of drug users are more likely to enter treatments that seem designed to deal with particular problems, as well as with drug use. For example, some women may feel that only a women's treatment program will deal adequately with issues of childhood sexual abuse, spousal physical abuse, or fears of losing custody of children. Native Americans, Hispanic Americans, or Americans of African or Asian descent may feel more comfortable in programs designed to be sensitive to their cultural values. To what degree such programs are more effective than less specialized programs in retaining patients in treatment or producing long-term behavioral change remains undetermined.

Opioid Dependence With Additional Psychopathology The severity of psychological disturbances—depression, anxiety, paranoid ideation—tends to predict the overall outcome of treatment for opioid dependence. Other predictors of outcome include alcohol abuse and the use of illicit nonopioid drugs, such as cocaine. Furthermore, patients in methadone programs who meet criteria for additional nonsubstance abuse Axis I diagnoses consistently exhibit substantially higher rates of lifetime and current diagnoses of dependence on drugs other than opioids. However, the literature is not entirely consistent on the prognostic significance of additional psychopathology. In a number of studies patients with additional psychopathology, including antisocial personality disorder, appear to do about as well in methadone programs or therapeutic communities as those without such diagnoses, at least in terms of reduced drug use.

Mood Disorders Some form of affective dysregulation is the most common Axis I psychiatric disorder not related to substance abuse found among opioid addicts in treatment (Table 11.10-5). Clinicians agree that those addicts with bipolar I or bipolar II disorders can benefit from treatment with lithium (Eskalith). Lithium has been used in combination with methadone without adverse interactions.

Although clinicians in private practice often prescribe antidepressant medications for opioid-dependent patients with major depressive disorder and minor depression, publicly supported programs often do not. The reasons for this vary. In the past, therapeutic communities were biased against the use of psychoactive agents; they seem to be less so now, and some therapeutic communities have psychiatric consultants and permit psychoactive medication when indicated. Methadone programs do not have a bias against pharmacotherapy, but many still do not commonly assess depressive symptoms, responding only when these symptoms become clinically obvious. Studies of the efficacy of antidepressant agents in the treatment of depressed opioid-dependent patients have yielded inconsistent results. It is possible that adequate antidepressant plasma concentrations may not have been achieved or that patients were not carefully selected.

In methadone-maintained patients whose depression antedated substance use or persisted for more than a month after admission to treatment, a double-blind study found that imipramine (Tofranil) produced significant improvements in mood, as well as self-reported decreases in the use of illicit drugs. However, as measured by urine tests, few patients achieved abstinence. In this study the imipramine dosage was gradually increased, depending on adverse effects and response, to a maximum of 300 mg a day.

Opioid addicts tend to experience a decrease in depressive symptoms after entering treatment, regardless of whether the treatment is an opioid maintenance program or a therapeutic community. Not every patient shows spontaneous improvement, however. Since the severity of psychological impairment is a predictor of overall treatment success, the conscientious clinician will pay particular attention to persistent depression.

Anxiety Disorders Anxiety disorders rarely receive specific treatment in programs devoted to opioid dependence. A very high percentage of addicts with an anxiety disorder also have dysphoria. When treatment seems indicated, antidepressant medications would appear to be the drugs of choice because several of these have antianxiety, antipanic, and antidepressant effects. Also, patients with anxiety disorders may abuse benzodiazepines, and cocaine use can cause cocaine-induced anxiety disorder with panic attacks that persist beyond the period of use. It is not yet clear what effect the use of cocaine by opioid users will have on the prevalence of anxiety disorders among that population.

Alcohol Abuse Alcoholism (alcohol abuse or dependence) is common among opioid addicts in treatment, with lifetime diagnosis rates of 25 to 40 percent. Most opioid addicts who also have alcohol abuse or dependence disorder have some form of mood disorder as well. Several studies suggest that there is an inverse relation between alcohol use and heroin use, with alcohol use increasing as heroin use decreases as a result of treatment—a situation that reverses with relapse. In one methadone program, neither twice-weekly sessions with special AA counselors nor behavioral modification sessions with psychologists were more helpful than a control condition of standard maintenance. However, most alcohol abusers decreased their alcohol consumption as well as their heroin use after entering treatment, and patients and counselors who participated in treatment were enthusiastic about group sessions and expressed the belief that they were beneficial. Disulfiram (Antabuse) can be combined with methadone without adverse effects. In small experimental studies, program privileges, such as take-home doses of methadone, have been made contingent on the ingestion of disulfiram. In controlled studies, however, disulfiram was not superior to placebo in modifying alcohol abuse or dependence among methadone-maintained patients. In some programs methadone itself was made contingent on results of breath alcohol tests. However, making a medicine for one disorder contingent on recovery from another disorder is controversial. Thus, although alcohol abuse or dependence while in treatment is reported to be a major predictor of reversion to opioid abuse following detoxification from maintenance methadone, it appears that there is no specific intervention that is demonstrably effective. In programs that do not use methadone, continued participation in a residential program sharply reduces alcohol use, but data on long-term outcome are lacking. Both outpatient drug-free and residential programs may employ AA and 12-step approaches to controlling alcohol abuse or dependence along

with procedures aimed at opioid use and behavioral change.

Schizophrenia and Other Psychotic Disorders A high percentage of patients (up to 48 percent in some reports) treated in urban hospitals for psychotic disorders, including schizophrenia, also meet the criteria for a substance-use disorder. In most instances, patients are abusing or are dependent on alcohol, cocaine, cannabis, or some combination of those drugs. Even in east coast urban areas where opioid abuse is common, opioid dependence is relatively uncommon among patients hospitalized for schizophrenia. Two hypotheses have been offered to account for that relatively low level. Either people with schizophrenia are not organized enough to be able to deal with the demands and stresses of obtaining and using heroin, or opioids have some ameliorative effects and help persons with schizophrenia avoid hospitalization—in contrast to alcohol, cocaine, and cannabis, which tend to exacerbate schizophrenia. There are case reports but as yet no controlled studies of opioid users whose psychotic or paranoid states responded to opioids but responded only poorly to more traditional antipsychotic agents. The endogenous opioids interact with dopaminergic systems, and it has been postulated that methadone has antimanic and antipsychotic actions. Methadone added to antipsychotic medication produces improvement in antipsychotic-resistant patients with paranoid schizophrenia. Heroin addicts treated with methadone may develop tolerance to these postulated antipsychotic effects of opioids so that after a period on methadone psychosis may break through again. Although lifetime rates for schizotypal features are 6 to 8 percent of patients in drug-abuse clinics, schizophrenia is uncommon—less than 1 percent. For those patients with schizophrenia, dopamine receptor antagonists are probably useful and can be combined with methadone. Some clinicians believe that underlying rage and hostility may play causal roles in opioid dependence and that some addicts use the opioids to control those affects. Clinicians have also observed that, although psychotic patients are reassured by the structure of the usual methadone clinic, patients with borderline personality disorder make the structure and the rules the objects of an all-out war, leading to their rapid and premature discharge from the clinic program.

Opioid Dependence With Other Substance Abuse Many opioid users regularly self-administer some other drug or drugs, (e.g., amphetamines, cocaine, alcohol, barbiturates, benzodiazepines, or cannabinoids). In general, multi-drug users have a greater range and severity of psychiatric problems. In therapeutic communities they create more behavior problems, drop out of treatment sooner, and have poorer posttreatment outcomes. Many polysubstance users are sufficiently dependent on heroin or other opioids to qualify for treatment in methadone programs. Competent counseling has been shown to decrease cocaine use, as has the provision of positive rewards such as vouchers or lottery tickets contingent on urine tests negative for cocaine.

A retrospective study of treatment outcome for polysubstance abuse as a function of the category of drugs abused and the treatment received compared male veterans enrolled in therapeutic community treatment with those in methadone maintenance. All subjects had greater-than-average psychopathology in addition to polysubstance abuse. The groups were further categorized into opioid-stimulant, opioid-depressant, and opioid-only users. At 6-month follow-up the opioid-only group had better outcomes on all measures than either of the other groups, with no clear superiority of either treatment approach. The opioid-stimulant group did significantly better in methadone maintenance and the opioid-depressant group did significantly better after treatment in a therapeutic community. The researchers inferred that recovery from the depression and cognitive impairment that typically accompany the abuse of sedatives was facilitated by the prolonged abstinence afforded by treatment in a therapeutic community. Specialized facilities using therapeutic community approaches have evolved to provide treatment to drug abusers with serious psychiatric disorders, especially those who are also homeless. Their results suggest that major reductions in drug use and rehospitalization can be achieved.

SUGGESTED CROSS-REFERENCES

An overview of substance-related disorders is given in Section 11.1. Alcohol-related disorders are discussed in Section 11.2, amphetamine-related disorders in Section 11.3, and cocaine-related disorders in Section 11.6. Drug and alcohol abuse among the elderly is discussed in Section 51.3h. Posttraumatic stress disorder is discussed in Chapter 15 and sexual dysfunction in Section 19.1a.

11.11 PHENCYCLIDINE (OR PHENCYCLIDINE-LIKE)-RELATED DISORDERS

STEPHEN R. ZUKIN, M.D.

Phencyclidine (1-1 (phenylcyclohexyl)piperidine; PCP), also known as “angel dust,” entered the illicit street market in 1965. In the late 1970s it became one of the leading illicit drugs. Although its popularity subsequently declined, it remains a prominent drug of abuse in a number of American cities. It acts by a novel mechanism, has a long duration of action, and is very potent by any route of administration. PCP use carries a high risk of behavioral, physiological, and neurological toxicity and is highly reinforcing.

COMPARATIVE NOSOLOGY

Table 11.11-1 illustrates the similarities and differences between the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) and International Classification of Diseases (ICD) with respect to PCP-related disorders. Compared with the revised third edition of DSM (DSM-III-R), the fourth edition of DSM (DSM-IV) is more specific and more comprehensive. PCP-induced anxiety disorder is a category unique to DSM-IV. Because of the unusually complex pharmacodynamic and pharmacokinetic properties of PCP and related drugs, fluctuations among categories over time are common in the clinical situation as are PCP-induced states that fail to correspond to any established category.

Table 11.11-1 Nosology of Phencyclidine-Related Disorders

HISTORY

PCP was developed in the 1950s as a potential general anesthetic by Parke-Davis under the trade name Sernyl. Clinical trials in anesthesia were promising in that PCP did not depress vital cardiovascular and respiratory functions. By contrast to conventional general anesthetics, which induce a state of relaxed sleep, PCP induced a state of apparent catatonia, including flat facies, open mouth, fixed staring, rigid posturing, and (sometimes) waxy flexibility. Patients seemed dissociated from the environment without classical unconsciousness. For this reason, PCP was termed a *dissociative anesthetic*.

As many as half of patients given PCP anesthesia showed severe adverse reactions during emergence, such as agitation and hallucinations. Psychotic reactions persisting for up to 10 days then ensued in many of these patients. For this reason, PCP was abandoned for human anesthesia in favor of ketamine Ketalar), a less potent PCP derivative with a shorter duration of action. PCP was used as an experimental probe of psychotomimetic mechanisms in normal and schizophrenic subjects during the late 1950s and early 1960s. Given PCP's well-documented dysphoric and aversive properties in surgical patients, it seems surprising that it attracted so many illicit users beginning in 1965. In the late 1970s it was one of the most prevalent abused drugs in the United States; relatively infrequent but flamboyant and destructive episodes of PCP-induced aggressive and violent behaviors captured the public imagination and the attention of the press. The manifold and severe medical complications of PCP abuse led to an explosion of medical literature on this topic during the late 1970s and the 1980s. The fundamental mechanism of action of PCP, interaction with a unique high-affinity brain binding site, was discovered in 1979. PCP abuse continues to be a serious public health problem in a number of American cities. In recent years there has been a significant increase in abuse of ketamine, also known as “special K.” Although ketamine is less potent than PCP and has a shorter duration of action, they share the same fundamental mechanism of action. Unlike PCP, ketamine has not been scheduled under the Controlled Substances Act and can be found in hospital pharmacies, from which diversion has frequently occurred.

EPIDEMIOLOGY

PCP, a phenylcyclohexylamine, is easily synthesized from piperazine, cyclohexanone, and potassium cyanide. The synthesis proceeds through the intermediate 1-piperidinocyclohexanecarbonitrile (PC), which is reacted with phenylmagnesium bromide to form PCP. The simplicity of this reaction, which requires almost no training or equipment, suggests that PCP production may have an economic advantage over drugs derived from natural products or drugs that are difficult to synthesize. PCP is often misrepresented as another illicit substance (e.g., tetrahydrocannabinol [THC]), cocaine, methamphetamine, or a lysergic acid diethyamine [LSD]-like psychedelic drug). Marijuana is frequently adulterated with PCP by dealers. Thus PCP intoxication may be seen in patients who are not aware that they have taken PCP.

PCP has had many street names, including angel dust, devil's dust, dust, crystal, cyclones, embalming fluid, wet, killer weed, mintweed, peace pill, goon, jet fuel, surfer, black whack, Illy, crazy Eddie, purple rain, and milk. In combination with other drugs it has been called beam me up Scottie or tragic magic (crack dipped in PCP); love boat (marijuana dipped in PCP), and blunt (marijuana and PCP in a cigar wrapper). Its abuse was first reported in 1965, when it had limited popularity. In the early 1970s PCP was usually mixed with other drugs; by the late 1970s most street samples analyzed were pure PCP. The most common routes of administration are smoking and snorting; every conceivable route of administration has been reported, including injection. Regional differences in typical routes of administration have been reported, with snorting predominating in Philadelphia and Chicago, both smoking and snorting in Miami, and smoking in Seattle.

PCP abuse peaked between 1973 and 1979, with a smaller peak between 1981 and 1984. It is estimated that in 1976, 9.5 percent of persons between 18 and 25 had ever used PCP, increasing to 13.9 percent in 1977 and 14.5 percent in 1979. For 12- to 17-year-olds the corresponding figures were 3.0, 5.8, and 3.9 percent. By 1988, these figures had declined to 1.2 percent for those 12 to 17 and 4.4 percent for those 18 to 25. Since 1985 the highest rates of use have been in those between 26 and 34 years of age. Some 12.8 percent of high-school seniors reported PCP use in 1979; this declined to about 3 percent from 1987 through 1995. The 1994 survey data indicate that 4.3 percent of household residents aged 12 years and older, or about nine million people, had used PCP at least once in their lives, up from 2.9 percent in 1985. In 1994 478,000 people (0.02 percent) were estimated to have used PCP at least once in the prior year. Although this number is dwarfed by annual rates of marijuana (8.5 percent), cocaine (1.7 percent), inhalant (1.1 percent), and crack (0.6 percent) use, it is still significant.

PCP-related emergency room mentions increased more than fivefold between 1974 and 1979, then declined; by 1991 PCP ranked 27th among drugs mentioned. In

order, the leading cities for PCP emergency room mentions were Los Angeles, Chicago, Washington, New York City, San Francisco, Baltimore, and Philadelphia. Legal and policy changes contributed to the decline in PCP use during the 1980s. PCP was reclassified from Schedule III to Schedule II under the Controlled Substances Act. Reporting of production of piperidine, a major PCP precursor, was mandated. Penalties for PCP possession with intent to sell were significantly increased.

For 1994 high school seniors asked when they had begun to use PCP, the mode was within the 2 to 3 years prior to interview (while in grades 10 and 11). The same survey also showed that PCP ranked as the seventh most-often-discontinued drug after inhalants (56 percent), heroin (50 percent), methamphetamine (47 percent), steroids (46 percent), tranquilizers (44 percent), and methaqualone (43 percent).

Although information on use is not available for 8th and 10th graders, questions on their questionnaires concerned perceptions regarding the difficulty in obtaining PCP. In 1994, about 18 percent of the 8th graders, 24 percent of the 10th graders, and 31 percent of the 12th graders thought that PCP was “fairly easy” or “very easy” to obtain. The proportion of 8th and 10th graders who thought PCP was easy to get was similar to those who thought heroin and crystal methamphetamine were easy to obtain.

In 1995 the Community Epidemiology Work Group (CEWG), supported by the National Institute on Drug Abuse (NIDA), issued reports indicating increases in PCP use in Washington, D.C., Philadelphia, and New York City (emergency rooms); in Washington, D.C., and Chicago (juvenile arrestees); and in Miami (treatment admissions, particularly in conjunction with marijuana).

ETIOLOGY AND PSYCHOPHARMACOLOGY

Phencyclidine and N-methyl-D-aspartate Receptors The unique primary central nervous system (CNS) actions of PCP result from binding to high-affinity PCP receptors that are highly selective for drugs (from a variety of chemical classes) that elicit PCP-like behavioral effects. The relative potencies of such drugs in eliciting PCP-like behaviors are proportional to their potencies in competing for radioligand binding to the PCP receptor. By virtue of the location of the PCP binding site within the ionophore of the *N*-methyl-D-aspartate (NMDA) receptor, drugs that bind to PCP receptors also block NMDA-activated channels in electrophysiological assays. The rank order of potency of such drugs as channel blockers parallels their behavioral potencies and their potencies in binding to the PCP receptor. The highest densities of PCP receptors are found in the dentate gyrus and the CA1 and CA2 subfields of the hippocampus and in anterior forebrain areas, including neocortex, consistent with the ability of PCP to disrupt learning, memory, and higher cortical functions.

Unlike the other types of glutamate receptor channels, NMDA channels are permeable to both Ca_{2+} and Na_{+}. Following NMDA receptor activation, NMDA-mediated Ca_{2+} flux may lead to stimulation of calmodulin-dependent kinases with activation of postsynaptic second-messenger pathways. A unique functional property of the NMDA channel is that it is blocked in a voltage-dependent manner by the endogenous Mg_{2+} ion. The dual voltage- and ligand-dependence of NMDA receptors permits them to function in a “Hebbian” manner to integrate information from multiple input streams. One stream is represented as a modulation of presynaptic glutamate release, while additional streams are reflected in modulation of resting membrane potential on the postsynaptic NMDA–receptor bearing dendrites. Ca_{2+} flow through open, unblocked NMDA channels may trigger long-term potentiation, which in turn may represent the neurophysiological substrate underlying learning and memory formation. In rodents, PCP and other NMDA antagonists induce profound memory disturbances linked to inhibition of hippocampal long-term potentiation. In humans, amnesia can be seen in both PCP intoxication and ketamine anesthesia.

NMDA receptors possess two distinct agonist binding sites, one for glutamate and other excitatory amino acids (e.g., aspartate) and another for glycine and other structurally similar amino acids such as D-serine. In vivo, glutamate and glycine/D-serine have distinct roles in receptor activation. Like most classical neurotransmitters, glutamate is released from presynaptic nerve endings in pulsatile fashion and then rapidly deactivated. By contrast, glycine in forebrain is neither concentrated in presynaptic nerve endings nor released in response to electrical stimulation. Furthermore, endogenous glycine concentrations are typically at or above the affinity constant of the NMDA-associated glycine site for these agents, indicating that activity-stimulated release of glycine is not required for neurotransmission. Rather, the local glycine concentration appears to set the tonic level of NMDA excitability, thus determining the degree to which presynaptic glutamate release (triggered by presynaptic glutamate release) leads to postsynaptic excitation. Glycine thus functions more as a neuromodulator than as a classical neurotransmitter. D-Serine is the only D-amino acid present in high concentration in brain. Thus D-serine, like glycine, may help regulate the tonic excitability level of NMDA excitability. The NMDA receptor-associated glycine site is anatomically, pharmacologically, and functionally distinct from the classical strychnine-sensitive glycine receptor found primarily in hindbrain, which binds D-serine with low affinity.

Opening the NMDA channel facilitates access of PCP to its receptor, accelerating the rate at which PCP-induced blockade of NMDA receptor-mediated neurotransmission takes place relative to the rate in the absence of NMDA-receptor activation. In the former case, PCP gains access to its binding site rapidly via the open channel pore; in the latter case, the highly lipophilic PCP molecule gains access to its binding site via slow diffusion through the lipid bilayer.

Molecular Characterization of the PCP Receptor The NMDA receptor complex is heteroligemeric, consisting of combinations of NMDAR1 and NMDAR2 subunits. NMDAR1 is the key subunit in the formation of the receptor complex. All functional NMDA receptor complexes contain an NR1 subunit; complexes may also contain variable numbers of modulatory subunits (NR2A-D). The glycine binding site is contained within the NR1 subunit; thus all NMDA receptors show glycine sensitivity. However, glycine affinity is modulated by NR2 subunits; thus receptors containing 2D subunits appear more sensitive to glycine than those containing 2B subunits, which in turn are more sensitive than those containing 2A subunits. Eight variants of NMDAR1 (NMDAR1a–h) have been identified, which reflect alternative mRNA splicing. Receptors containing such variants may also have distinct sensitivities to agonists, antagonists, Zn_{2+}, and polyamines.

NMDA receptors are primarily found postsynaptically and occur on both projection- and interneurons. However, NMDA subunit composition varies both among brain regions and among cell types within a region. In some brain regions, especially in target areas of the mesolimbic-mesocortical system, NMDA receptors may also be localized presynaptically and thus may regulate release of dopamine from presynaptic terminals. It has been suggested that such receptors consist solely of NR1 subunits and thus may have a different pharmacological profile from postsynaptic receptors.

Additional CNS Actions of PCP At doses at least 10 times those at which it exerts its unique behavioral effects by blocking NMDA receptor–mediated neurotransmission, PCP also blocks presynaptic monoamine reuptake, thus directly increasing synaptic levels of dopamine and norepinephrine. Concentrations sufficient to block monoamine reuptake may be achieved during high-dose intoxication and may contribute to the stimulatory behavioral and physiological effects of PCP seen at those doses. Ketamine, even at high dose, fails to block monoamine transporters. This observation may explain why the incidence of episodes of extreme agitation and violence following ketamine intoxication is lower than that after PCP intoxication. At doses associated with extremely high dose intoxication, PCP blocks neuronal Na_{+} and K_{+} channels as well as muscarinic cholinergic receptors. Such effects may be relevant to the seizures observed following PCP overdose. PCP also interacts with a variety of other CNS receptors including opiate and g-aminobutyric acid (GABA) benzodiazepine receptors. However, most such effects take place at concentrations unlikely to be encountered in clinical situations.

Neurotoxicity of PCP In animals, neurotoxic effects of PCP are observed at doses (e.g., 5 to 50 mg/kg) significantly above those required for behavioral activity. At those doses in the rat, PCP induces neuronal vacuolization, particularly in neurons in rat posterior cingulate/retrosplenial cortex. Similar vacuolization is observed following administration of dizocilpine (i.e., MK-801) or ketamine, indicating that the effect is probably mediated at NMDA receptors. The effect is initially observed in layers III and IV of cortex. At lower doses (e.g., 5 mg/kg), the effect is transient, reaching a peak approximately 12 hours after PCP or dizocilpine administration and then resolving over 12 to 18 hours. Much higher doses of PCP may lead to neuronal necrosis, which is apparent even 48 hours after drug administration and is seen in hippocampus and other limbic areas as well as in the posterior cingulate retrosplenial cortex (PCRS). Administration of high-dose PCP also leads to increased glucose uptake and expression of heat shock and glial fibrillary acidic protein (GFAP). Vacuolization can be inhibited by prior administration of anticholinergic, GABAergic, or antipsychotic agents and is potentiated by administration of pilocarpine. Direct evidence of similar neurotoxic effects in humans is lacking, despite the large number of patients who have undergone ketamine anesthesia for surgery.

Toxicity of 1-Piperidinocyclohexanecarbonitrile (PC) During the 1970s significant percentages of analyzed street samples of PCP were found to be contaminated by dangerously high amounts of residual PC, the intermediate compound in PCP synthesis. In physiological saline, PC decomposes to hydrocyanic acid (HCN). When PC-contaminated PCP is smoked, about 58 percent of the PC breaks down to cyanide and organic byproducts. Although devoid of PCP-like pharmacological activity, PC is thus more toxic and may be implicated in some PCP-related fatalities.

Behavioral Pharmacology of PCP Considerable species variation exists in the behavioral effects of PCP. In rodents, PCP induces a characteristic syndrome of hyperactivity and stereotypical movements, which is only partially reversible by neuroleptics but can be more robustly antagonized by agents such as glycine that

augment NMDA receptor-mediated neurotransmission. Because the serum half-life of PCP is shorter and its volume of distribution is larger in rodents than in primates, rodents typically require higher weight-adjusted doses of PCP than primates to elicit behavioral effects. Sensitization to the behavioral effects of PCP has been detected after daily administration in rodents. PCP also inhibits rodents' social behavior, an effect that is not reversed by either typical or atypical antipsychotic agents.

PCP-induced hyperactivity in rodents appears to reflect increased dopaminergic neurotransmission within nucleus accumbens, since this effect can be selectively inhibited by lesions in that brain area. Other components of the PCP-induced behavioral syndrome (e.g., alterations in social behavior, stereotypy) are not affected by lesions of the accumbens, suggesting that those behaviors are mediated by other brain regions. NMDA receptors are also present in substantia nigra (A9) and ventral tegmental area (A10). Glutamatergic innervation of substantia nigra from prefrontal cortex strongly influences dopaminergic activity levels; NMDA receptors appear to be the primary mediators of glutamate-induced stimulation of midbrain dopaminergic neurons. To the extent that NMDA receptors stimulate A9 and A10 neurons, PCP would, paradoxically, be expected to diminish dopaminergic outflow from striatum and accumbens. However, direct application of PCP to A10 does not inhibit dopamine cell firing or alter dopamine release in accumbens, although it does prevent NMDA-induced neuronal activation. Thus, the behavioral effects of PCP in rodents appear to stem predominantly from its interactions within dopamine terminal fields rather than within dopaminergic midbrain nuclei.

Gross behavioral effects of PCP in nonhuman primates more closely resemble the effects of the drug in humans. In monkeys, a PCP dose of approximately 0.5 mg/kg produces tranquilization in which animals appear awake but unresponsive to the environment. At 1.0 mg/kg, PCP induces a cataleptoid state in which animals show waxy flexibility and rigidity resembling catatonic schizophrenia. Doses of 2.5 mg/kg lead to stupor; 5.0 mg/kg, to surgical anesthesia; and 15 mg/kg, to convulsive seizures.

In all species tested, PCP profoundly disrupts learning and memory. In rodents, PCP-like drugs disrupt spatial delayed alteration performance; this effect is reversible by type 2 dopamine (D_2) receptor antagonists. Thus in cortex as in striatum, the effects of PCP-like drugs in part reflect secondary dysregulation of dopaminergic neurotransmission. In monkeys, PCP-like drugs induce impairments in learning and working memory performance that are not reproduced by amphetamine, demonstrating that the effect cannot be attributed entirely to increased dopaminergic neurotransmission. However, NMDA antagonists potentiate the disruptive effects of amphetamine on learning in monkeys, indicating that interactions between the NMDA and dopamine systems are important.

Pharmacokinetics of PCP PCP is highly lipid soluble and has a volume of distribution of 6.2 L/kg in humans. Significant brain concentrations are rapidly attained after inhaled, smoked, or topical administration (PCP intoxication has been documented after inadvertent wearing of clothing on which a PCP solution had been spilled). A typical street dose is about 5 mg (one pill, joint, or line), which results in a serum PCP concentration between 0.01 and 0.1 µM. Psychotic reactions have been observed in association with undetectably low serum concentrations (<0.02 µmol), while concentrations above 0.4 µmol induce gross impairment of consciousness. Serum concentrations above 1.0 µM are strongly associated with coma, seizures, respiratory arrest, and death. The highest recorded serum and cerebrospinal fluid (CSF) concentrations are in the range of 1.0 to 2.0 µM. Users typically titrate dosage in an effort to maximize the high while avoiding unconsciousness. Failures of judgment or variations in purity of supplies often result in inadvertent overdose, which may lead to severe medical complications. The serum half-life of PCP varies considerably among individuals, averaging about 20 hours. The half-life of ketamine in humans is about 2 hours. The lipophilicity of PCP facilitates accumulation in fatty body tissues, including the brain. PCP concentrations in brain and in adipose tissues may be more than 10 times those in plasma. Mobilization of adipose stores (e.g., during exercise) may release sequestered PCP, leading to flashbacks.

Metabolism of PCP is predominantly hepatic; hydroxylase metabolites are secreted renally. PCP (pK_a = 8.5) is largely ionized in the stomach or the urinary tract. Passing through the pyloric valve, PCP enters a nonacidic environment in the small intestine in which it becomes largely nonionized and readily absorbed across the mucosal membrane, whereupon enterohepatic recalculation can account for the fluctuating clinical course so often observed in PCP intoxication.

REINFORCING EFFECTS OF PCP

Experimental monkeys avidly self-administer large doses of PCP intravenously or orally. Monkeys given unlimited access to PCP maintain nearly continuous intoxication. This pattern resembles that seen with opiates and CNS depressants but differs from that seen with classical stimulants. Furthermore, in contrast to findings on opiate self-administration, monkeys will self-administer doses of PCP high enough to cause marked behavioral effects. Given the similarities between behavioral effects of PCP in monkeys and humans, this research validates the clinical impression of avid human self-administration of PCP. PCP-like drugs stimulate brain reward areas, lowering the threshold for intracranial self-stimulation. Such effects, which define a classical profile for drugs abused by humans, are shared by such other abused compounds as opiates, stimulants, and benzodiazepines, despite their differing mechanisms of action.

TOLERANCE TO PCP

In rats and monkeys, repeated administration of PCP daily or more frequently leads to two- to fourfold rightward shifts in dose-response curves. The major determinant of this moderate tolerance appears to be biodispositional. Much greater tolerance is induced by continuous self-administration than by intermittent dosing. Limited human data exist on PCP tolerance, but tolerance has been reported in burn patients given repeated doses of ketamine for analgesia.

PHYSICAL DEPENDENCE ON PCP

After unlimited-access self-administration of PCP for a month or longer, severe withdrawal reactions were observed in monkeys when the drug was discontinued, including vocalizations, bruxism, oculomotor hyperactivity, diarrhea, piloerection, somnolence, tremor, and seizures. Similarly severe reactions might be expected following PCP binges by human abusers. Despite a paucity of controlled studies of tolerance and dependence in humans, the animal literature suggests that PCP must be considered comparable to classical drugs of abuse in this respect.

DSM-IV DISORDERS

Table 11.11-2 lists the DSM-IV PCP-related disorders. Clinical presentations of PCP-induced disorders frequently fail to fit within any established diagnostic category. Mixtures of features of several categories are quite common. Frequently, the presentation varies over time as serum PCP levels fluctuate. Therefore, even the most careful single examination cannot be definitive. The absence of serious medical complications at a single time does not preclude development of such complications hours later. Delirium and psychotic features often come and go several times during intoxication. Unless serious medical complications cause irreversible cardiovascular, renal, or neurological damage, complete recovery from PCP intoxication is usually seen within 24 to 72 hours. Even in prolonged phencyclidine-induced psychotic disorder, complete recovery is usually seen within 6 weeks.

Based on American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, ed 4. Washington, DC, American Psychiatric Association, 1994.

Table 11.11-2 DSM-IV Phencyclidine-Related Disorders

A 17-year-old male was brought to the emergency room by the police, having been found disoriented on the street. As the police attempted to question him, he became increasingly agitated; when they attempted to restrain him, he became assaultive. Attempts to question or examine him in the emergency room evoked increased agitation. Initially it was impossible to determine vital signs or to draw blood. Based upon the observation of horizontal, vertical, and rotatory nystagmus, a diagnosis of PCP intoxication was entertained. Within a few minutes of being placed in a darkened examination room, his agitation markedly decreased. Blood pressure was 170/100; other vital signs were within normal limits. Blood was drawn for toxicological examination. The patient agreed to take 20 mg of diazepam (Valium) orally. Thirty minutes later, he was less agitated and could be interviewed, although he responded to questions in a fragmented fashion and was slightly dysarthric. He stated that he must have inadvertently taken a larger-than-usual dose of "dust," which he reported having used once or twice a week for several years. He denied use of any other substance and any history of mental disorder. He was disoriented to time and place. The qualitative toxicology screen revealed PCP and no other drugs. Results of neurological examination were within normal limits but very brisk deep tendon reflexes were noted. Some 90 minutes after arrival his temperature, initially normal, was elevated to 38°C, blood pressure had increased to 182/110, and he was poorly responsive to stimulation. He was admitted to a medical bed. His blood pressure and level of consciousness continued to fluctuate over the ensuing 18 hours. Results of hematological and biochemical analyses of blood, as well as urinalyses, remained within normal limits. A history obtained from his family revealed that the patient had had multiple emergency-room visits for complications from PCP use during the previous several years. He had completed a 30-day residential treatment program and had participated in several outpatient programs but had consistently relapsed. The patient was discharged after vital signs and level of consciousness had been within normal limits for 8 hours. At discharge, nystagmus and dysarthria were no longer present. A referral to an outpatient treatment program was made.

Phencyclidine Abuse and Phencyclidine Dependence There have been no systematic studies of PCP abuse, dependence (see Table 11.11-2), or withdrawal states in humans, but primate research gives every reason to expect that they are clinically significant. Patterns of PCP use have been documented in specific populations in which users self-administer multiple, high daily doses continuously for weeks, months, or years. The avidity with which many users return to PCP use immediately after treatment for severe PCP intoxication or psychosis suggests that intense craving is experienced after medically supervised withdrawal. No specific treatments have been developed for PCP abuse or dependence. Relapse can reportedly be averted with antidepressant treatment in selected patients, suggesting that some users are attracted to PCP by its antidepressant properties.

Phencyclidine Intoxication, Phencyclidine Intoxication Delirium

Diagnosis And Clinical Features The cornerstone of diagnosis of PCP intoxication (Table 11.11-3) is a history of PCP use, detection of PCP in body fluids, or both. A number of assays for PCP are available; however, for several reasons, it can be dangerous to rely on them. First, the combination of PCP's lipophilicity, long duration of action, and pK_a predict that prominent clinical effects may be present in the absence of measurable concentrations of PCP in blood or CSF. This is particularly true for acute psychotic reactions, which have been observed at serum PCP concentrations undetectable by most assay systems. A positive assay for PCP should generally be used only qualitatively; it is particularly important not to assume that a low measured concentration predicts an uneventful recovery. pK_a considerations in relation to varying urinary and intestinal pH and enterohepatic recirculation indicate that concentrations can be expected to fluctuate. Clinical indications of significant neuronal hyperexcitability, hypertension, hyperthermia, or other physiological dysregulation should be interpreted as indicating a possible impending medical emergency. Reliance upon history may also yield many false negatives, because PCP may have been misrepresented as another drug or used as an adulterant by the dealer. As PCP levels fluctuate, various mixtures of symptoms of intoxication, delirium, and psychosis are seen.

A. Recent use of phencyclidine (or a related substance).
B. Clinically significant maladaptive behavioral changes (e.g., belligerence, assaultiveness, impulsiveness, unpredictability, psychomotor agitation, impaired judgment, or impaired social or occupational functioning) that developed during, or shortly after, use of phencyclidine.
C. Within an hour (less when smoked, "snorted," or used intravenously), two (or more) of the following signs:
   (1) vertical or horizontal nystagmus
   (2) hypertension or tachycardia
   (3) numbness or diminished responsiveness to pain
   (4) ataxia
   (5) dysarthria
   (6) muscle rigidity
   (7) seizures or coma
   (8) hyperacusis
D. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

With perceptual disturbances

Table 11.11-3 DSM-IV Diagnostic Criteria for Phencyclidine Intoxication

Physiological Bases of Intoxication, Delirium and Medical Complications The range of clinical effects of PCP can be correlated with dose, serum PCP concentration, and interaction with several molecular target sites (Fig. 11.11-1). The CNS NMDA receptor complex would be the only system affected significantly at very low PCP doses. Serum PCP concentrations up to about 0.1 µM correspond to a clinical state manifesting psychotomimetic symptoms and impaired cognition without physiological disturbances of vital functions other than nystagmus, hypertension, tachycardia, dysarthria, or hyperacusis. Serum concentrations just above about 0.1 µmol correspond to a state of delirium and at about 0.3 µM to incipient dissociative anesthesia, with prominent numbness or diminished responsiveness to pain. At still higher doses, as additional types of receptors are occupied, acute brain syndrome accompanied by prominent neurological and cardiovascular complications is seen. Deaths from hyperthermia, status epilepticus, and hypertensive crisis have been reported. At high doses, PCP exerts direct excitatory effects upon skeletal muscle endplates. These effects may underlie the many reports of superhuman strength from the late 1970s. Together with the behavioral effects of high-dose PCP, these effects probably account for muscle trauma, which in a number of patients has resulted in rhabdomyolysis, myoglobinuria, and renal failure. Serum concentrations of 1.0 µmol and above are associated with coma and death. PCP-induced delirium (see Table 10-22) and coma result from the combination of noncompetitive inhibition of the PCP-NMDA receptor, blockade of the reuptake sites for catecholamines and indolamines, and blockade of sodium and potassium channels and nicotinic and muscarinic cholinergic receptors.

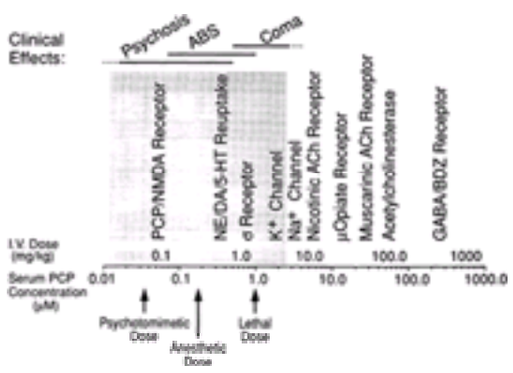

FIGURE 11.11-1 Dose range of PCP effects. The relation of dose, serum concentration, molecular target sites, and clinical effects are shown. The *shaded area* represents clinically relevant interactions. (Reprinted with permission from Javitt DC, Zukin SR: Recent advances in the phencyclidine model of schizophrenia. Am J Psychiatry *148:*1301, 1991.)

NEUROLOGICAL MANIFESTATIONS The vast majority of PCP-intoxicated patients manifest horizontal, vertical, or rotatory nystagmus, which can help distinguish PCP intoxication from a naturally occurring psychotic state. Neuronal hyperexcitability is dose dependent, ranging from increased deep tendon reflexes, through opisthotonos, to focal or generalized seizures, to status epilepticus. Focal neurological findings may arise from cerebral vasoconstriction. Coma can occur at any point during intoxication.

BEHAVIORAL MANIFESTATIONS Clinically urgent short-term behavioral complications of PCP abuse stem from behavioral disinhibition, which can be coupled with

severe agitation, panic, rage, and aggression. The disruption of sensory input by PCP can cause unpredictable, exaggerated, distorted, or violent reactions to environmental stimuli. Such reactions are more common with somewhat higher doses, at which some delirium as well as neurological symptoms and other medical complications are observed. The behavioral manifestations can severely compromise the clinician's ability to treat the medical complications.

CARDIOVASCULAR MANIFESTATIONS PCP-induced hypertension is dose dependent. Mild hypertension is seen in all patients with PCP intoxication. With increasing PCP dose, the panoply of sympathomimetic responses is seen; hypertensive crisis is common in association with high doses and may lead to cerebral hemorrhage.

AUTONOMIC MANIFESTATIONS Severe hyperthermia has been observed, which can be delayed, fatal, or both. The anticholinergic properties of PCP can evoke the full spectrum of atropine-like toxicity in a dose-dependent manner and can be managed accordingly.

Differential Diagnosis Even when PCP is detected in body fluids, remember that PCP is frequently taken in combination with another drug or drugs. Depending upon the analytic method used, an assay for PCP may fail to detect an intoxicating concentration of PCP. While not conclusive or totally specific for PCP intoxication, the constellation of nystagmus, ataxia, and mild hypertension is typically observed even in mild, low-dose PCP intoxication.

Treatment Treatment of PCP intoxication aims to reduce systemic PCP levels and address significant medical, behavioral, and psychiatric issues. For both intoxication and PCP-induced psychotic disorder, while resolution of current symptoms and signs is paramount, the long-term goal of treatment is prevention of relapse to PCP use. PCP levels may fluctuate over many hours or even days, especially after oral administration. Therefore, a prolonged period of clinical observation is mandatory before concluding that no serious or life-threatening complications will ensue.

Trapping of ionized PCP in the stomach has led to the suggestion of continuous nasogastric suction as a treatment for PCP intoxication. However, this strategy can be needlessly intrusive and can induce electrolyte imbalances. Administration of activated charcoal is safer, and it binds PCP and diminishes toxic effects of PCP in animals.

Trapping of ionized PCP in urine has led to the suggestion of urinary acidification as an aid to drug elimination. However, this strategy may be ineffective and is potentially dangerous. Only a small portion of PCP is excreted in urine; metabolic acidosis itself carries significant risks; and acidic urine can increase the risk of renal failure secondary to rhabdomyolysis. Because of the extremely large volume of distribution of PCP, neither hemodialysis nor hemoperfusion can significantly promote drug clearance.

No drug is known to function as a direct PCP antagonist. Any compound binding to the PCP receptor, which is located within the ion channel of the NMDA receptor, would block NMDA receptor–mediated ion fluxes as does PCP itself. NMDA receptor mechanisms predict that pharmacological strategies promoting NMDA receptor activation (e.g., administration of a glycinelike drug) would promote rapid dissociation of PCP from its binding sites. Evidence indicates that oral glycine in massive doses can antagonize PCP-induced behaviors in the mouse. Large doses (80 grams a day) of glycine administered experimentally to schizophrenic patients have shown no significant toxicity; however, no clinical trials for PCP intoxication in humans have been carried out to date. Therefore, treatment must be supportive and directed at specific symptoms and signs of toxicity. Classical measures should be used for medical crises including seizures, hypothermia, and hypertensive crisis.

Because PCP disrupts sensory input, environmental stimuli can cause unpredictable, exaggerated, distorted, or violent reactions. A cornerstone of treatment is therefore minimization of sensory inputs to PCP-intoxicated patients. Patients should be evaluated and treated in as quiet and isolated an environment as possible. Precautionary physical restraint is recommended by some authorities, with the risk of rhabdomyolysis from struggle against the restraints balanced by the avoidance of violent or disruptive behavior. Pharmacological sedation can be accomplished with oral or intramuscular antipsychotics or benzodiazepines; there is no convincing evidence that either class of compounds is clinically superior. Because of the anticholinergic actions of PCP at high doses, neuroleptics with potent intrinsic anticholinergic properties should be avoided.

Course and Prognosis Complete recovery from PCP intoxication is the rule, in the absence of major medical complications. However, many patients relapse to PCP use immediately after discharge from treatment, even for severe PCP-related complications. Intoxication usually occurs in the context of abuse, dependence, or both. Unfortunately, no specific behavioral treatments for PCP abuse and dependence have been described. Case reports indicate successful responses to residential and intensive outpatient treatment regimens with long-term follow-up including urine monitoring with or without contingency contracting.

Phencyclidine-Induced Psychotic Disorder

Diagnosis and Clinical Features Minute, single intravenous doses (0.05 to 0.1 mg/kg) of PCP administered to normal volunteers can rapidly induce a psychotic state, lasting 4 to 6 hours, characterized by withdrawal, autism, negativism, inability to maintain a cognitive set, and concrete, impoverished, idiosyncratic, and bizarre responses to proverbs and projective testing. Some subjects show catatonic posturing. These schizophrenia-like alterations in brain functioning extend beyond the symptom level; in formal studies of neuropsychological function, PCP can induce a spectrum of specific disturbances in attention, perception, and symbolic thinking strikingly similar to those seen in schizophrenia. The most severe impairment caused by PCP was observed in tests requiring selective attention and paired-association learning. An important clinical correlate of these data is that any person under the influence of even a small dose of PCP or a similar drug may have profound alterations of higher emotional functions affecting judgment and cognition, even in the absence of gross neurological findings. Well-formed hallucinations and delusions are relatively uncommon.

Challenge experiments involving recompensated schizophrenic subjects found that a single low dose of PCP can rekindle the presenting symptomatology for as long as 6 weeks, without evoking any symptoms or signs not typical of schizophrenia. Thus schizophrenia or preschizophrenia patient abusing a PCP-type drug run an extremely high risk of severe and prolonged psychiatric morbidity, continuing well beyond the time when PCP is present in the system. While in most cases PCP-induced psychosis closely resembles schizophrenia, a number of reports of mania-like psychotic states, both acute and prolonged, induced by PCP have appeared. Patients with an existing or incipient bipolar disorder are probably particularly sensitive to this complication.

In retrospective studies of patients hospitalized for complications of PCP use during the 1970s, the presenting symptoms could not distinguish PCP-intoxicated patients from schizophrenic patients. In the clinical situation one must recognize that acute PCP-induced psychosis can persist longer than the signs required for formal diagnosis of PCP intoxication in DSM-IV, particularly after low drug doses. By the time a patient comes to medical attention, psychosis may be the only notable finding. PCP-induced psychosis may remit after 4 to 6 hours or can persist for up to 6 weeks after signs of acute physiological reactions have cleared. For both acute and prolonged psychotic disorders induced by PCP, DSM-IV criteria for PCP-induced psychotic disorder (see Table 13.3-4) may fail to be met because of the absence of delusions or hallucinations, despite the presence of severe thought disorder.

Differential Diagnosis For several reasons, the differential diagnosis of PCP-induced psychotic disorder may prove challenging. First, the patient as well as other informants may be unaware that PCP has been used, because it may have been misrepresented as another drug or used as an adulterant. Second, PCP-induced psychosis can persist long beyond the time when PCP is detectable in lood and beyond the time when neurological and cardiovascular symptoms and signs of PCP intoxication are present. Third, careful retrospective analyses have demonstrated that frequently PCP-induced psychosis cannot be distinguished from naturally occurring schizophrenia on the basis of presenting symptoms and signs. Detection of PCP still leaves open the possibility that the patient suffers from a preexisting psychotic disorder that has been exacerbated by PCP, a possibility that can be ruled out only by following the patient's future course.

Course and Prognosis In most cases, once any acute medical complications are successfully treated, both peripheral and CNS complications, including psychosis, resolve completely within 24 to 72 hours. In the case of prolonged PCP-induced psychotic disorder, the rule is complete recovery within 4 to 6 weeks, regardless of whether antipsychotics have been administered. However, the rate of subsequent relapse to PCP use is very high. Persistence of a psychotic disorder beyond 8 weeks indicates the possible presence of an underlying psychotic disorder exacerbated, but not caused, by PCP.

Treatment For either acute or prolonged psychotic reactions, neuroleptics are commonly prescribed. The literature suggests that they are ineffective for most patients, but no systematic studies of this issue have been performed. Both neuroleptics and benzodiazepines have been reported to be moderately effective against the agitation and behavioral disinhibition that may be present. However, the psychotic symptoms themselves often fail to respond to pharmacological treatment. As a consequence, inpatient treatment may be required throughout the course of the psychotic reaction

Phencyclidine-Induced Mood Disorder PCP-induced mood disorder (see Table 14.6-18) is a somewhat elusive category. A relatively small percentage of patients display a prominently elevated mood verging on hypomania after exposure to PCP. Symptoms and signs may clear as PCP concentrations decline or may progress to

a PCP-induced manic state with psychotic features. In patients with a bipolar disorder, the intrinsic antidepressant properties of PCP may provoke a hypomanic or manic reaction.

Phencyclidine-Induced Anxiety Disorder The literature provides little or no support for PCP-induced anxiety disorder (see Table 15.6-17) as a distinct clinical entity. Preclinically, PCP and related drugs fit an anxiolytic and antidepressant profile. Distinguishing anxiety from the agitation and behavioral disinhibition observed in many patients with PCP intoxication would be difficult.

PCP-Related Disorder Not Otherwise Specified The diagnosis of PCP-related disorder not otherwise specified is the appropriate diagnosis for a patient who does not fit into any of the previously described diagnoses (Table 11.11-4).

The phencyclidine-related disorder not otherwise specified category is for disorders associated with the use of phencyclidine that are not classifiable as phencyclidine dependence, phencyclidine abuse, phencyclidine intoxication, phencyclidine intoxication delirium, phencyclidine-induced psychotic disorder, phencyclidine-induced mood disorder, or phencyclidine-induced anxiety disorder.

Table 11.11-4 DSM-IV Diagnostic Criteria for Phencyclidine-Related Disorder Not Otherwise Specified

SUGGESTED CROSS-REFERENCES

Other substance-related disorders are treated in Chapter 11. Schizophrenia, a disorder related symptomatically and pathophysiologically to phencyclidine-induced psychotic disorder, is discussed in Chapter 12. Delirium and its differential diagnosis are covered in Chapter 10. Amino acid neurotransmitters are covered in Section 1.5.

11.12 SEDATIVE-, HYPNOTIC-, OR ANXIOLYTIC-RELATED ABUSE

DOMENIC A. CIRAULO, M.D., AND OFRA SARID-SEGAL, M.D.

Sedative, hypnotic, or anxiolytic dependence is influenced by several factors: the most important is the pharmacology of drugs. Dependence is also affected by the beliefs and values of physicians, who must be aware of their attitudes toward dispensing drugs of this class. Finally, patients, and society at large, are influenced by the moral, economic, and political views of the time. Taken together these factors influence medical care, sometimes to the detriment of patients, who may be denied appropriate medication because of such biases.

DEFINITION

Determining Abuse Liability Any study of sedative, hypnotic, or anxiolytic dependence is limited by the operational definitions of abuse and dependence. Drug abuse is a behavioral and social phenomenon, albeit with significant pharmacological origins and medical consequences.

Abuse liability is established by asking a series of questions about a drug or class of drugs. Questions that originate in society's values lead to studies of illicit trafficking; population surveys of nonprescription use; audits of prescribing practices; monitoring of diversion from physicians' offices, pharmacies, or manufacturing sites; emergency room treatment; and overdose deaths. Questions regarding pharmacological characteristics also predict abuse liability: drug-induced euphoria and the development of tolerance, an abstinence syndrome, or cross-tolerance with known abusable substances may all predict risk of abuse. Finally, a number of ingenious methods for determining drug preferences in humans and animal models have been developed to determine abuse liability.

The terms “abuse” and “misuse,” refer to the use of a drug in a manner that is not consistent with generally accepted medical practice or social and legal custom (e.g., use without a valid prescription or deliberately to produce intoxication, pleasure, or a high). The fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) defines abuse as a “maladaptive pattern of substance use manifested by recurrent and significant adverse consequences related to repeated use.” Some authorities limit *use* to situations in which a drug is taken for a legitimate medical or psychiatric disorder but is used in a way that is not consistent with medical practice. The distinction between *abuse* and *misuse* is not widely accepted, and the terms are used interchangeably here. *Recreational use* refers to use of drugs solely for their hedonic value. According to DSM-IV, substance dependence is “a cluster of cognitive, behavioral, and physiological symptoms indicating that the individual continues use of the substance despite significant substance-related problems. There is a pattern of repeated self-administration that usually results in tolerance, withdrawal, and compulsive drug-taking behavior.” The term *physiological dependence* is used according to the definition of the World Health Organization (WHO): a pathological state brought about by repeated administration of a drug and that leads to the appearance of a characteristic and specific group of symptoms (i.e., an *abstinence syndrome* or *discontinuance syndrome* when the drug is discontinued or, in the case of certain drugs, significantly reduced. The abstinence syndrome has specific characteristics referable to the autonomic nervous system (e.g., tremor, sweating, tachycardia, and startle response) and must be clearly distinguished from recurrence of the features of the underlying disease for which the drug was originally given. It can be reversed or attenuated by readministering the discontinued drug or administering a drug with cross-tolerance. Some authorities reserve the *discontinuance syndrome* for withdrawal syndromes that develop with therapeutic agents, to distinguish physiological dependence that develops in the course of treatment from dependence that develops as part of drug abuse. The terms are used interchangeably here.

Substances The drugs discussed in this section are referred to as anxiolytic or sedative-hypnotic drugs. The terminology for that group of drugs is not clearly established. Their sedative or calming effects are on a continuum with their hypnotic or sleep-inducing effects. Anxiolytic drugs cover a wide spectrum of pharmacological agents, and the terminology implies more specificity than actually exists. For most of these drugs, the differentiation of their sedative, hypnotic, and anxiolytic activities has more to do with marketing than with pharmacology. The broad group of drugs that historically has been included in that class exhibits considerable variation in clinical utility, toxicity, risk for abuse, and potential for diversion or recreational use. The abuse liability of those agents is classified in this section as follows: (1) benzodiazepine receptor agonists (2) barbiturates, and (3) miscellaneous sedative-hypnotic drugs with limited clinical use (meprobamate [Miltown], chloral hydrate [Noctec], ethchlorvynol [Placidyl], glutethimide, and methaqualone). In the practice of both psychiatry and addiction medicine, the drugs that are most important clinically are the benzodiazepines.

H3>ETIOLOGY AND NEUROPHARMACOLOGY

The benzodiazepines, barbiturates, and barbiturate-like substances all have their primary effects on the g-aminobutyric acid (GABA) type A ($GABA_A$) receptor complex, which contains a chloride ion channel, a binding site for GABA, and a well-defined binding site for benzodiazepines. The barbiturates and barbiturate-like substances are also believed to bind somewhere on the $GABA_A$ receptor complex. When a benzodiazepine, barbiturate, or barbiturate-like substance does bind to the complex, it increases the affinity of the receptor for its endogenous neurotransmitter, GABA, and increases the flow of chloride ions through the channel into the neuron. Benzodiazepines have little or no effect in the absence of GABA. At high doses, barbiturates directly activate chloride channels. The influx of negatively charged chloride ions into the neuron is inhibitory, since it hyperpolarizes the neuron relative to the extracellular space.

Although all the substances in this class induce tolerance and physical dependence, the underlying mechanisms are best understood for the benzodiazepines. Long-term benzodiazepine use attenuates the receptor effects caused by the agonist. Specifically, after long-term benzodiazepine use, GABA stimulation of the $GABA_A$ receptors results in less influx of chloride than it did before benzodiazepine administration. Benzodiazepine agonists lead to several processes that result in downregulation of the $GABA_A$ receptor. Benzodiazepine agonists produce acute desensitization of the receptor (tachyphylaxis) and promote $GABA_A$ receptor sequestration in cortical neurons. Chronic administration uncouples the GABA and benzodiazepine binding sites. μ-Receptor mechanisms underlying uncoupling are unknown, although changes in phosphorylation, altered subunit composition, and conformational changes in the receptor have been suggested. Contradictory findings have been reported with respect to alterations in receptor density. Binding affinity is not altered by chronic administration, although receptor alterations leading to uncoupling are almost certainly important in tolerance development. The changes in $GABA_A$ function do not completely explain the clinical phenomenon. For example, although patients develop tolerance to the sedative effects of benzodiazepines, the antianxiety and amnestic effects of these drugs are relatively persistent.

ABUSE LIABILITY

Surveys of prescribing practices, patient-initiated dosage changes, and recreational or nonmedical benzodiazepine use along with reports from emergency rooms, medical examiners, and law enforcement agencies all suggest that benzodiazepine abuse is not a major public health problem. They are rarely used for recreational purposes, and most studies suggest that they are not commonly the sole drug of abuse. The vast majority of medical and psychiatric patients use benzodiazepines appropriately, although they may be abused by patients dependent on alcohol or other drugs.

Abuse liability is evaluated, in part, by measuring the reinforcing properties of the drug. If its pharmacological effects increase a behavior (e.g., self-administration of a dose or the work required to permit self-administration), then the drug is a positive reinforcer and has abuse liability. Both animal and human studies have assessed the reinforcing properties of the benzodiazepines.

Animal Studies Animal studies demonstrated that benzodiazepines have minimal reinforcing effects. Although a few studies show that animals self-administer benzodiazepines more frequently than other drugs, they are consistently less potent in that regard than are drugs of abuse (e.g., cocaine) or even many other

sedative-hypnotics drugs, including most barbiturates.

Animal studies using schedule-induced polydipsia (the use of intermittent food administration to the experimental animal, which promotes ingestion of fluids, including drug solutions) indicate that midazolam (Versed) is ingested more often than water, but self-administration of chlordiazepoxide (Librium) and flurazepam (Dalmane) does not differ significantly from that of water. Prior exposure to ethanol or sedative-hypnotic drugs may increase the reinforcing effects of benzodiazepines, but some studies do not support that finding. Baboons clearly prefer ethanol but not diazepam or triazolam (Halcion) in the schedule-induced polydipsia model.

Another animal model predicting abuse liability consists of drug infusion in response to activity by the animal, such as lever pressing (Fig. 11.12-1). Drug infusion may allow either continuous or intermittent drug availability, and rates of administration of the drug are compared with those of the vehicle, other sedative-hypnotic drugs, and standard drugs of abuse such as cocaine. Studies with continuous drug access suggest that triazolam, diazepam (Valium), midazolam, clobazam, and chlordiazepoxide have reinforcing effects; studies with intermittent drug availability show that diazepam, midazolam, triazolam, alprazolam (Xanax), lorazepam (Ativan), chlordiazepoxide, and bromazepam maintain responses at a level higher than vehicle, which indicates abuse liability. With the possible exception of triazolam and midazolam, in studies using this model, the benzodiazepines consistently demonstrate lower abuse liability than do barbiturates other than phenobarbital, which also has relatively low abuse liability. Partial benzodiazepine receptor agonists, such as abecarnil and bretazenil, have low abuse liability in those models.

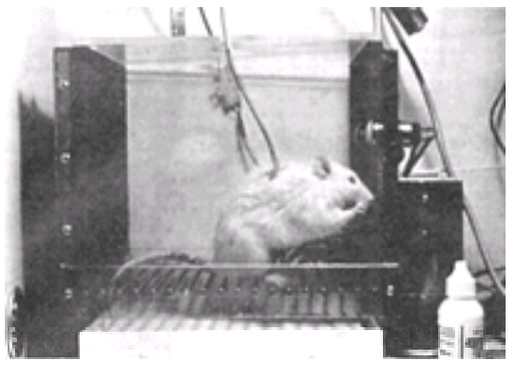

FIGURE 11.12-1 Animal in an operant chamber self-administers a drug by pressing a bar to receive an infusion of a predetermined dose that is delivered from a syringe pump via a cannula implanted in its jugular vein. (Courtesy of Conan Kornetsky, Boston University School of Medicine.)

Animal studies support lower abuse liability for the benzodiazepines than for most barbiturates. Among the benzodiazepines some evidence suggests that triazolam and midazolam may have the greatest potential for abuse, but more studies are required to define differences within the class.

Human Studies The assessment of abuse liability in humans relies on two predictive models: self-administration of benzodiazepines by experimental subjects who have a history of drug abuse and subjective responses that correlate with high abuse potential. In the first paradigm, one type of study allows subjects with a history of sedative-hypnotic dependence to self-administer orally (i.e., sample) different color-coded drugs and placebo under double-blind conditions in a simulated social environment. During subsequent sessions they are permitted to self-administer the drug they like the best. Some studies require that the subjects perform a task (e.g., riding a stationary bicycle) to earn doses. The abuse liability of different drugs is assessed by how often they are chosen for self-administration or by how much work a subject does to earn a dose. Scales measuring drug effect are also administered. The paradigm has the advantage of directly observing the behavior involved with ingesting the drug, albeit under somewhat artificial circumstances. It works best for former sedative-hypnotic abusers without psychiatric illness. It is probably safe to infer that those subjects are administering the drug to get high. For other subjects the reason for self-administration may not be clear. Do patients with anxiety disorder self-administer the drugs because they are effective anxiolytics or because they induce euphoria? Similarly, if subjects are in withdrawal from sedative-hypnotic drugs or ethanol, do they choose the agent that alleviates their withdrawal symptoms most effectively or the drug that produces the greatest euphoria? An additional problem with this design is that it exposes subjects to multiple doses of potentially addictive drugs.

An alternative strategy is to administer only a single dose of the test drugs and then compare subjective responses associated with abuse liability. A set of scales, which differs slightly among laboratories, usually consists of the Morphine Benzedrine Group subscale of the Addiction Research Center Inventory (ARCI-MBG), self-reports of sedation, liking, and intensity of drug effect; monetary street value of the drug; and similarity to reference drugs of abuse. Studies demonstrate that estimates of abuse liability using this paradigm are consistent with assessments based on the self-administration model. One disadvantage of the single-dose paradigm is that it measures only subjective effects, not behavior. It also has some of the same limitations as the self-administration paradigm. Does the subject like the drug because it has a therapeutic effect or because it is intoxicating? Both designs attempt to circumvent the problem by including an adequate battery of scales that measure several different dimensions of drug effect. Dosage equivalency and homogeneity of the subjects (especially with respect to a personal or family history of psychoactive substance abuse and psychiatric illness) are critical factors in the study design and in the interpretation of data from both models.

The predictive models in humans clearly establish that benzodiazepines occupy an intermediate position on the spectrum of abuse liability of sedative-hypnotic drugs. Methaqualone and barbiturates generally produce higher ARCI-MBG and drug-liking scores than do benzodiazepines. Buspirone (BuSpar), a nonbenzodiazepine anxiolytic agent (i.e., it is essentially devoid of benzodiazepine agonist activities), has little or no abuse liability in those models. With respect to differences among the benzodiazepines, the weight of the evidence suggests that diazepam has greater abuse liability than halazepam (Paxipam), oxazepam (Serax), chlordiazepoxide, or clorazepate (Tranxene). Diazepam, lorazepam, alprazolam, and triazolam exhibit similar profiles of abuse potential using those paradigms. The clinical relevance of the findings has not been adequately studied.

Flunitrazepam (Rohypnol), a benzodiazepine agonist, is not marketed in the United States but has entered the country through sources in Central and South America. Reports of abuse have appeared in both the clinical literature and public media. The drug has been implicated in date rape, in which flunitrazepam is added to a woman's alcoholic beverage to reduce her judgment, inhibition, and physical ability to resist sexual activity. Memory for the event may also be impaired by the combination of alcohol and flunitrazepam. A comprehensive review of the abuse liability of flunetazepam published in 1997 concluded that little evidence suggested that the drug had higher abuse liability than other benzodiazepines, except for its preference among opioid abusers. Nonetheless, the manufacturer has reformulated the drug, making it more difficult to disguise when added to ethanol. Also requiring further study is the relative roles of pharmacokinetic and pharmacodynamic facts in determining the abuse liability of various benzodiazepines. Some drugs (e.g., diazepam) may appear to have high abuse liability because of rapid absorption from the gastrointestinal tract after oral doses. Little is known about differences in abuse liability between full and partial agonists or among drugs that have preferential effects on specific subtypes of the benzodiazepine receptor. Zolpidem (Ambien), for example, is an imidazopyridine hypnotic agent with a rapid onset of action and a short elimination half-life. Although some evidence suggests that it is selective for the central benzodiazepine type 1 receptor (BZ 1), other studies suggest that zolpidem and triazolam depress energy metabolism in the same areas of the brain. With respect to subjective, psychomotor, and memory effects, there are no significant differences between a single 10-mg dose of zolpidem and a single 0.25-mg dose of triazolam. High doses of triazolam (0.75 mg) are identified more often as similar in effect to barbiturates, benzodiazepine, or alcohol than are high doses of zolpidem (45 mg). Zolpidem abuse and dependence have been reported.

Research in the 1990s investigating patient characteristics that influence abuse liability shows that when alcoholic persons and their adult children are given a single dose of alprazolam or diazepam, they have greater increases on abuse potential scales than do nonalcoholic controls without a family history of alcoholism. The differences in reinforcing effects are not attributable to pharmacokinetic differences as measured by peripheral plasma concentrations; however, pharmacodynamic differences have been noted using functional magnetic resonance imaging and electroencephalographic measures. A survey of 5000 male college students found that 23 percent of those with a positive family history of alcohol abuse reported using benzodiazepines (versus 0.9 percent of those without such a family history). Findings from another study indicate that moderate drinkers self-administer higher doses of diazepam than do light drinkers. Whether these results are drug specific or apply to the class of benzodiazepines as a whole is not known.

When using a self-administration model, subjects with anxiety do not choose diazepam more frequently than they do placebo, but when anxious subjects seeking treatment are tested, they show a high rate of diazepam selection. As no evidence from survey data or clinical experience suggests that patients with uncomplicated anxiety disorders have high rates of benzodiazepine abuse, these seemingly contradictory findings point out the limitations of self-administration in nondependent subjects (i.e., whether subjects with psychic distress take the drug for its therapeutic or euphoric effects).

EPIDEMIOLOGY

Several surveys have been conducted to determine the extent of benzodiazepine use by prescription and by illicit means. Drug sales to retail pharmacies provide one measure of benzodiazepine use. Sales of benzodiazepines are monitored by IMS Global Services, Ltd. The data indicate that benzodiazepine tranquilizer sales in the United States peaked in 1973 to 1975, when annual sales were approximately 87 million prescriptions. Between 1980 and 1983 sales of benzodiazepines to retail pharmacies in the United States declined from an average maintenance dose for the major indication per 1000 inhabitants per day of 17.5 to 15.8, but by 1985 it was back up to 17.1. Sales of drugs with long half-lives such as diazepam and flurazepam decreased, whereas sales of drugs with shorter half-lives such as alprazolam, triazolam, and temazepam (Restoril) increased. From 1986 to 1989 benzodiazepine tranquilizer sales declined to about 56 million prescriptions.

The prevalence of benzodiazepine use is presented in Table 11.12-1 Alprazolam accounted for 33 percent of the U.S. market share in 1989, diazepam for 25 percent and lorazepam for 19 percent. Of the benzodiazepine hypnotics, triazolam had a 49 percent market share in 1989, temazepam 30 percent, and flurazepam 21 percent. In 1989 the United States showed greatest volume of retail sales of benzodiazepines, but per capita exposure was at the median of the nine countries with the largest number of sales (United States, France, Japan, Italy, United Kingdom, Germany, Spain, Brazil, and Canada). The United States had a per capita exposure of 16.9 dosage units per year for benzodiazepines used as tranquilizers; France had the highest (55 dosage units per year), and Brazil had the lowest of the nine countries (7.3 dosage units per year). Despite having the lowest total sales volume, Canada had a per capita exposure of 30.9 dosage units per year. Rates of per capita exposure to benzodiazepine tranquilizers were three to five times higher than were rates of exposure to benzodiazepine hypnotic agents, except in the United Kingdom, where hypnotic use exceeded tranquilizer use (12.4 versus 8.9 per capita exposure). In 31 countries surveyed, benzodiazepine tranquilizer sales increased by 13 percent and benzodiazepine hypnotic sales increased by 47 percent from 1981 to 1989. Notable exceptions were the United Kingdom, where sales of both tranquilizers and hypnotics declined, and Germany, where a decline in tranquilizer sales was almost offset by an increase in hypnotic sales. In 1989, lorazepam had 20.7 percent of the world market share, diazepam had 17.1 percent, and alprazolam, 10.5 percent.

- Retail sales of benzodiazepines reached their highest level in 1973–1975 at 87 million a year but have declined gradually since then
- The United States has the highest volume of sales in the world, but per capita sales are at the median of the nine countries with the largest sales
- Sales of drugs with short elimination half-lives (e.g., alprazolam) have increased compared with drugs with long half-lives (e.g., diazepam)
- The National Institute on Drug Abuse Household Survey found that the percent of the general population reported nonmedical use of tranquilizers
- A survey of the United States population showed that self-reported medical use of a tranquilizer declined from 10.9 percent to 8.3 percent from 1970 to 1990; hypnotic use declined from 3.5 to 2.6 percent during the same period
- Persons who abuse alcohol and drugs use and abuse benzodiazepines at higher rates than do anxiety disorder patients without substance abuse histories

Table 11.12-1 Prevalence of Benzodiazepine Use

In 1990 over half of the patients surveyed in the United States who were taking tranquilizers took them for a month or less, and 25 percent took them for a year. Seventy percent of hypnotic users took them for less than a month, and 14 percent for a year or longer. Benzodiazepine sales worldwide continued to fluctuate between 1990 and 1996. In 1996 the United States accounted for the greatest volume of retail sales measured in U.S. dollars, followed by Japan, Italy, France, Germany, Brazil, Argentina, Spain, and Belgium. In 1996 alprazolam accounted for 13.2 percent of world market share in U.S. dollars; followed by clonazepam (12 percent) and lorazepam (11.4 percent), diazepam accounted for about 7.7 percent. In the United States clonazepam accounted for 28.2 percent of benzodiazepine market share in U.S. dollars followed by midazolam (20.1 percent) and alprazolam (15.6 percent).

Interview data are important supplements to prescription monitoring. Despite problems with validity and reliability, self-report data offer insight into the appropriateness of benzodiazepine use. In surveys of the U.S. population, self-reported tranquilizer use declined slightly from a 1970–1971 survey in which 10.9 percent of the adult population reported use of anxiolytics during the previous year to 8.3 percent in a 1990 survey. Hypnotic use declined from 3.5 to 2.6 percent during the same time period, with little change since 1979. Long-term users were more likely to be older and to be women, and they had high levels of emotional distress and chronic health problems. Over half of patients surveyed in 1990 took benzodiazepines for a month or less, and 25 percent took them for longer than 12 months, an increase from the 15 percent who were long-term users in 1979. The reasons for the increase are not clear, but they may include chronic benzodiazepine treatment for panic disorder, an aging population that is more likely to take benzodiazepines, or a decrease in the number of short-term users.

Seventy percent of hypnotic users took the drug for less than a month in 1990, and 14 percent used them for 12 months or longer, a slight increase from 1979, when 11 percent of users took the drug for 12 months or longer.

A survey of unsupervised changes in dosage indicated that 12 percent of patients had decreased their anxiolytic dosage, and 6 percent had increased it; 9 percent of patients taking hypnotics decreased their dosage, and 8 percent increased it. To put these unauthorized increases in perspective, the same survey indicated that 13 percent of patients have unauthorized increases in antidepressant dosages, and those drugs have low abuse liability. A prospective study found that patients were more likely to use antidepressants than benzodiazepines on a long-term basis, suggesting that long-term use should not, in itself, be used to measure abuse liability.

The National Institute on Drug Abuse's National Household Survey indicated that nonmedical use of tranquilizers was not a major public health problem. In 1994, the total percentage of the general population reporting nonmedical use of tranquilizers in their lifetime was 4 percent; 1.9 percent of those 12 to 17 years old, 4.5 percent of those 18 to 25 years old, 8.2 percent of those 26 to 34 years old, and 3 percent of those over 35 years of age reported nonmedical use. A total of 0.5 percent of the population reported nonmedical use of tranquilizers in the month prior to the survey, ranging from 0.2 to 0.6 percent among the different age groups.

Surveys of psychiatric patients (except those diagnosed as substance abusers) have demonstrated high rates of benzodiazepine prescription but almost uniformly low abuse. In one study of 2719 outpatients none of the 178 patients who had received benzodiazepines were diagnosed with abuse or dependence on the basis of criteria in the revised third edition of DSM (DSM-III-R). Studies of inpatient psychiatric patients suggest that the rate of benzodiazepine abuse or dependence ranges from 0.4 to 13 percent of admissions. A study from the University of Munich found that 6.7 percent of 9408 admissions had a diagnosis of benzodiazepine abuse or dependence, approximately half of whom were dependent on benzodiazepines alone. Lorazepam was the most commonly abused benzodiazepine, and oxazepam was the least, even though the latter drug was the most commonly prescribed benzodiazepine in the country.

Substantial evidence indicates that benzodiazepines are frequently used by patients who abuse other drugs. A survey of drug abuse treatment centers across the United States in 1979–1981 found that 22.6 percent of patients used minor tranquilizers (primarily benzodiazepines) weekly or more frequently. In a survey of opioid abusers in Sheffield, England, 90 percent reported benzodiazepine use daily or almostly daily. Use began with a prescription in one third of the sample. The most commonly used benzodiazepine was diazepam and the primary goal was relief from such symptoms as insomnia, withdrawal, and anxiety rather than a high. Lower rates of benzodiazepine use were reported in French (50 percent) and German (30 percent) studies. In the last two studies heroin addicts underreported benzodiazepine use, requiring toxicological studies to detect use.

Reports from Scotland since the mid-1980s indicated that intravenous drug abusers were using temazepam, often in combination with buprenorphine (Buprenex). One study reported that 92 percent of intravenous drug abusers had used temazepam in the year preceding the survey, and most of them had injected the drug intravenously. Marketed as a liquid-filled capsule, the fluid was extracted by a syringe and injected. That formulation was changed to a gel-filled capsule, which drug abusers liquefy by boiling with water or heating in a microwave prior to injection. Several cases of ischemia secondary to vasculitis and venous thrombosis were reported as a consequence of intravenous or intraarterial injection of the new formulation. In recent studies in Australia 37 percent of intravenous drug abusers reported benzodiazepine use in a typical drug-using month, paralleling the situation in the United States and Europe. A study in Denmark examined drugs in blood samples from unconscious drug addicts after the intake of an heroin overdose and found one or more benzodiazepines (usually diazepam) in 75 percent of patients. In a study from Canada of inpatients admitted for treatment of severe benzodiazepine dependence, patients had an extensive history of other lifetime and concurrent psychoactive substance use disorders. All patients had a prior history of other psychoactive drug use: 77 percent reported past opioid dependence and 53 percent past alcohol dependence. At admission, 83 percent of the patients were opioid dependent and 67 percent were cocaine dependent. In addition, patients in this study

had a high frequency of lifetime psychiatric disorders (major depression [33 percent] and panic disorder [30 percent]), and current psychiatric diagnoses (antisocial personality disorder [42 percent], avoidant personality disorder [25 percent], generalized anxiety disorder [20 percent], borderline personality disorder [17 percent], and panic disorder [13 percent]).

Several studies examined rates of benzodiazepine use among patients at methadone clinics. Three different U.S. clinics reported 22, 40, and 44 percent of their patients had benzodiazepines in their urine. European clinics report comparable rates. Flunitrazepam (where available) appears to be the preferred benzodiazepine. Usually taken orally, it may also be snorted. In other countries, diazepam, alprazolam, and lorazepam are most commonly abused. In a study from Austria, patients in a methadone clinic rated their preference for the effects of a variety of drugs. Benzodiazepines were rated behind heroin, cocaine, all opiates, cannabis, barbiturates, and stimulants. Flunitrazepam and diazepam were the highest-rated benzodiazepines, but alprazolam was not available in Austria when the survey began. In a study in three U.S. cities, methadone (Dolophine)-maintenance patients rated diazepam as producing the best high, with lorazepam and alprazolam also valued for their effects and considered all three significantly different from clorazepate, oxazepam, and chlordiazepoxide. Concern has been raised about abuse of alprazolam in methadone clinics, and at least one clinic reported that alprazolam use has surpassed diazepam use. Patients taking methadone presumably use benzodiazepines to boost the effects of methadone, but some studies have suggested that self-medication is also an important motivation. Opioid abusers who abuse benzodiazepines are more likely to engage in such other high-risk behaviors as needle sharing.

Cocaine abusers appear less likely to use benzodiazepines than are patients in methadone clinics, with alcohol and opioids the preferred secondary drugs of abuse. Benzodiazepines are used to attenuate the cocaine crash or to alleviate anxiety during cocaine use. These patients generally use therapeutic doses of benzodiazepines on an intermittent basis.

Surveys indicate that many alcoholic persons have taken or are currently taking benzodiazepines. They receive benzodiazepines for treatment of the alcohol withdrawal syndrome or coexisting anxiety or sleep disorders and often present for such treatment without revealing the extent of their alcohol use to the prescribing physician. Physicians must be cautious because evidence suggests an increased risk of benzodiazepine abuse in alcoholics; however, case reports document the efficacy of benzodiazepines in selected alcoholic persons with anxiety disorders.

Experimental studies have shown that moderate drinkers self-administer diazepam and that alcoholic persons have greater euphoric responses to a single dose of alprazolam than do control subjects. Both diazepam and alprazolam increase euphoria and liking scores in alcoholic persons and increase desire for ethanol as measured by self reports on visual analog scales. The changes in euphoria and liking are minimal with halazepam (compared with diazepam), suggesting a lower abuse liability in such patients.

Most survey data indicate that between 12 and 33 percent of alcoholic persons who enter treatment use benzodiazepines concurrently. Alcoholic women may have higher rates of concurrent use than alcoholic men. How many alcoholic patients misuse benzodiazepines is not entirely clear, but one study found that 15 percent of alcoholic outpatients who also used sedatives (mostly benzodiazepines) used them as prescribed, 24 percent had both used them appropriately and abused them, and 61 percent abused them. Another study reported that a little more than half of alcoholic outpatients with positive urine drug screens for benzodiazepines were abusing them. These data should be regarded cautiously because treatment population surveys are biased to select only patients for whom previous therapy has failed.

In Finland drug usage was evaluated in 1993 in drivers suspected of driving under the influence. Benzodiazepines were the most frequent drugs found in body fluid samples. Their usage went up from 6 percent in 1979 to 22.9 percent in 1993. Similarly, in Oslo, the drugs found most frequently in blood and urine samples of suspected drunken drivers were alcohol, tetrahydrocannabinol, benzodiazepines, and amphetamines.

If 33 percent of patients with alcoholism use benzodiazepines, and between 50 and 60 percent of those patients are abusing them, then approximately 15 to 20 percent of all alcoholic persons presenting for treatment may be abusing benzodiazepines. Benzodiazepines are used to self-medicate withdrawal symptoms or anxiety disorders, to produce euphoria, and to enhance the effects of ethanol. Other groups may also be at high risk for benzodiazepine abuse. In England and Wales, a 1995 pilot study in the prisons showed an increase in the number of urine samples that tested positive for opioids or benzodiazepines, from 4.1 percent in 1993–1994 to 7.4 percent in 1995. People with disabilities appear to abuse tranquilizers at up to twice the rate of people without disabilities.

DIAGNOSIS AND CLINICAL FEATURES

Diagnosis DSM-IV lists a number of sedative-, hypnotic-, or anxiolytic-related disorders (Table 11.12-2) but contains specific diagnostic criteria only for sedative, hypnotic, or anxiolytic intoxication (Table 11.12-3) and sedative, hypnotic, or anxiolytic withdrawal (Table 11.12-4). Other sedative-, hypnotic-, or anxiolytic-related disorders have their diagnostic criteria outlined in the DSM-IV sections that are specific for the major symptom (e.g., sedative-, hypnotic-, or anxiolytic-induced psychotic disorder.

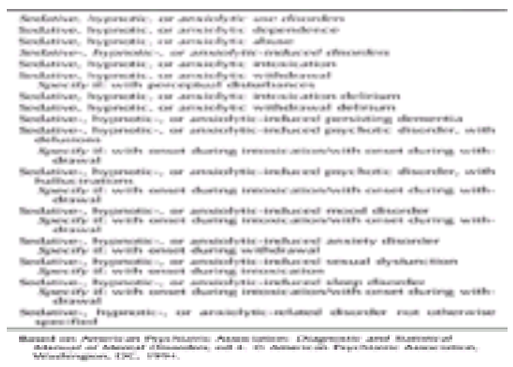

Table 11.12-2 DSM-IV Sedative-, Hypnotic-, or Anxiolytic-Related Disorders

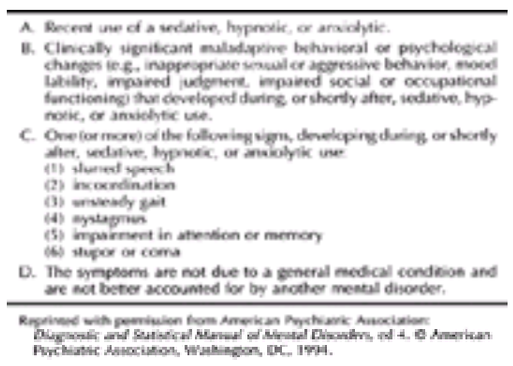

Table 11.12-3 DSM-IV Diagnostic Criteria for Sedative, Hypnotic, or Anxiolytic Intoxication

A. Cessation of (or reduction in) sedative, hypnotic, or anxiolytic use that has been heavy and prolonged.
B. Two (or more) of the following, developing within several hours to a few days after criterion A:
(1) autonomic hyperactivity (e.g., sweating or pulse rate greater than 100)
(2) increased hand tremor
(3) insomnia
(4) nausea or vomiting
(5) transient visual, tactile, or auditory hallucinations or illusions
(6) psychomotor agitation
(7) anxiety
(8) grand mal seizures
C. The symptoms in criterion B cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

Specify if:
With perceptual disturbances

Table 11.12-4 DSM-IV Diagnostic Criteria for Sedative, Hypnotic, or Anxiolytic Withdrawal

Dependence and Abuse Sedative, hypnotic, or anxiolytic dependence and sedative, hypnotic, or anxiolytic abuse are diagnosed according to the general criteria in DSM-IV for substance dependence and substance abuse (see Table 11.1-3, Table 11.1-4, and Table 11.1-8).

Intoxication DSM-IV contains a single set of diagnostic criteria for intoxication by any sedative, hypnotic, or anxiolytic substance (Table 11.12-3). Although the intoxication syndromes induced by all those drugs are similar, subtle clinical differences are observable, especially with intoxications that involve low doses. The diagnosis of intoxication by one of that class of substances is best confirmed by obtaining a blood sample for substance screening.

Withdrawal DSM-IV contains a single set of diagnostic criteria for withdrawal from any sedative, hypnotic, or anxiolytic substance (Table 13.11-4). The clinician can specify “with perceptual disturbances” if illusions, altered perceptions, or hallucinations are present but are accompanied by intact reality testing. Benzodiazepines are associated with a withdrawal syndrome, and withdrawal from barbiturates can be life threatening. Withdrawal from benzodiazepines can also result in serious medical complications, such as seizures.

Delirium DSM-IV allows diagnosis of sedative, hypnotic, or anxiolytic intoxication delirium and sedative, hypnotic, or anxiolytic withdrawal delirium (see Table 10-22 and Table 10-23). Delirium that is indistinguishable from delirium tremens associated with alcohol withdrawal is more commonly seen with barbiturate withdrawal than with benzodiazepine withdrawal. Delirium associated with intoxication can be seen with either barbiturates or benzodiazepines if the dosages are high enough.

Persisting Dementia DSM-IV allows diagnosis of sedative-, hypnotic-, or anxiolytic-induced persisting dementia (see Table 10-31). The existence of the disorder is controversial, since whether a persisting dementia is due to the substance use itself or to associated features of the substance use is uncertain. The diagnosis will need further validation by DSM-IV criteria.

Persisting Amnestic Disorder DSM-IV allows diagnosis of sedative-, hypnotic-, or anxiolytic-induced persisting amnestic disorder (Table 10-39). Amnestic disorders associated with sedatives, hypnotics, and anxiolytics may have been underdiagnosed. One exception is the increased number of reports of amnestic episodes associated with short-term use of benzodiazepines with short half-lives (e.g., triazolam).

Psychotic Disorders The psychotic symptoms of barbiturate withdrawal can be indistinguishable from those of alcohol-associated delirium tremens. Agitation, delusions, and hallucinations are usually visual, but sometimes tactile or auditory features develop after about 1 week of abstinence. Psychotic symptoms associated with intoxication or withdrawal are much more common with barbiturates than with benzodiazepines and are diagnosed as sedative-, hypnotic-, or anxiolytic-induced psychotic disorders (see Table 13.3-4). The clinician can further specify whether delusions or hallucinations are the predominant symptoms.

Other Disorders Sedative, hypnotic, and anxiolytic use has also been associated with mood disorders (see Table 14.6-18), anxiety disorders (see Table 15.6-18), sleep disorders (see Table 21-18), and sexual dysfunctions (see Table 19.1a-20). When none of those diagnostic categories are appropriate for a person with a sedative, hypnotic, or anxiolytic use disorder, the appropriate diagnosis is sedative-, hypnotic-, or anxiolytic-related disorder not otherwise specified (Table 11.12-5).

The sedative-, hypnotic-, or anxiolytic-related disorder not otherwise specified category is for disorders associated with the use of sedatives, hypnotics, or anxiolytics that are not classifiable as sedative, hypnotic, or anxiolytic dependence; sedative, hypnotic, or anxiolytic abuse; sedative, hypnotic, or anxiolytic intoxication; sedative, hypnotic, or anxiolytic withdrawal; sedative, hypnotic, or anxiolytic intoxication delirium; sedative, hypnotic, or anxiolytic withdrawal delirium; sedative-, hypnotic-, or anxiolytic-induced persisting dementia; sedative-, hypnotic-, or anxiolytic-induced persisting amnestic disorder, sedative-, hypnotic-, or anxiolytic-induced psychotic disorder; sedative-, hypnotic-, or anxiolytic-induced mood disorder; sedative-, hypnotic-, or anxiolytic-induced sexual dysfunction; or sedative-, hypnotic-, or anxiolytic-induced sleep disorder.

Table 11.12-5 DSM-IV Diagnostic Criteria for Sedative-, Hypnotic-, or Anxiolytic-Related Disorder Not Otherwise Specified

Clinical Features and Patterns of Abuse

Oral Use Sedative, hypnotic, and anxiolytic drugs can all be taken orally, either occasionally to achieve a time-limited specific effect or regularly to obtain a constant, usually mild, intoxication. The occasional-use pattern is associated with young persons who take the substance to achieve specific effects—relaxation for an evening, intensification of sexual activities, and a short-lived mild euphoria. The user's personality and expectations about the substance's effects and the setting in which the substance is taken also affect the substance-induced experience. The regular-use pattern is associated with middle-aged, middle-class people who usually obtain the substance from the family physician as a prescription for insomnia or anxiety. Abusers of this type may have prescriptions from several physicians, and the pattern of abuse may go undetected until obvious signs of abuse or dependence are noticed by the person's family, coworkers, or physicians.

Intravenous Use A severe form of abuse involves the intravenous use of these substances. The users are mainly young adults intimately involved with illegal substances. Intravenous barbiturate use is associated with a pleasant, warm, drowsy feeling, and users may be inclined to use barbiturates more than opiates or opioids because of the low cost of barbiturates. The physical dangers of injection include transmission of the human immunodeficiency virus (HIV), cellulitis, vascular complications from accidental injection into an artery, infections, and allergic reactions to contaminants. Intravenous use is associated with rapid and profound tolerance, dependence, and a severe withdrawal syndrome. One survey reported that 28 percent of heroin addicts injected benzodiazepines, and these patients had higher rates of polydrug use, HIV risk-taking behavior, criminal activity, psychological distress, health problems, and overdose than addicts who did not inject benzodiazepines.

Benzodiazepines Since the introduction of chlordiazepoxide in 1960, benzodiazepines have become the primary drugs used to treat anxiety and insomnia, largely replacing barbiturates and other sedative-hypnotic agents. Zolpidem, an imidazopyridine hypnotic drug, is chemically distinct from the benzodiazepines but has similar clinical effects and acts at the $GABA_A$-benzodiazepine receptor complex. The benzodiazepines have lower abuse liability than most barbiturates, pose a much lower risk when taken in overdose, and have fewer interactions with other drugs. The advantages of the benzodiazepines must be weighed against the risk for abuse and physiological dependence.

Intoxication Benzodiazepine intoxication can be associated with behavioral disinhibition, potentially resulting in hostile or aggressive behavior. The effect is perhaps most common when benzodiazepines are taken in combination with alcohol. Benzodiazepine intoxication is associated with less respiratory depression than

barbiturate intoxication.

Withdrawal Syndrome

SIGNS AND SYMPTOMS Studies in the early 1960s by Leo Hollister established that abrupt discontinuation of high doses of chlordiazepoxide or diazepam could lead to a withdrawal syndrome. More-recent studies show that therapeutic doses given for weeks to months may also be associated with withdrawal syndrome.

The American Psychiatric Association's "Task Force Report on Benzodiazepine Dependence, Toxicity, and Abuse" defined withdrawal as a true abstinence syndrome consisting of "new signs and symptoms and worsening of preexisting symptoms following drug discontinuance that were not part of the disorder for which the drugs were originally prescribed." Many authorities have taken issue with that definition of withdrawal and prefer to distinguish withdrawal only from recurrence, not from rebound symptoms, viewing the true abstinence syndrome as consisting of rebound symptoms plus new signs and symptoms.

The signs and symptoms of the benzodiazepine discontinuation syndrome (Table 11.12-6) have been classified as major or minor, like those of the alcohol withdrawal syndrome. According to that classification, minor symptoms include anxiety, insomnia, and nightmares. Major symptoms (which are extremely rare) include grand mal seizures, psychosis, hyperpyrexia, and death.

The following signs and symptoms may be seen when benzodiazepine therapy is discontinued; they reflect the return of the original anxiety symptoms (recurrence), worsening of the original anxiety symptoms (rebound), or emergence of new symptoms (true withdrawal)

Disturbances of mood and cognition:
- Anxiety, apprehension, dysphoria, pessimism, irritability, obsessive rumination, paranoid ideation

Disturbances of sleep:
- Insomnia, altered sleep-wake cycle, daytime drowsiness

Physical signs and symptoms:
- Tachycardia, elevated blood pressure, hyperreflexia, muscle tension, agitation–motor restlessness, tremor, myoclonus, muscle and joint pain, nausea, coryza, diaphoresis, ataxia, tinnitus, grand mal seizures

Perceptual disturbances:
- Hyperacusis, depersonalization, blurred vision, illusions, hallucinations

Table 11.12-6 Signs and Symptoms of the Benzodiazepine Discontinuation Syndrome

The discontinuance syndrome may also be divided into symptoms of rebound, recurrence, and withdrawal. *Rebound symptoms* are symptoms for which the benzodiazepine was originally prescribed that return in a more severe form than they had before treatment. They have a rapid onset following termination of therapy and a brief duration. *Recurrence* refers to return of the original symptoms at or below their original intensity. The pattern and course of these symptoms will reflect the anxiety disorder for which treatment was originally instituted.

Withdrawal symptoms (Table 11.12-6) are loosely categorized into four types: (1) disturbances of mood and cognition, (2) disturbances of sleep, (3) physical signs and symptoms, and (4) perceptual disturbances. Mood and cognitive symptoms are anxiety, apprehension, dysphoria, irritability, obsessive ruminations, and paranoia. Sleep disturbances include insomnia, altered sleep-wake cycle, and daytime drowsiness. Somatic symptoms are agitation, tachycardia, palpitations, motor restlessness, muscle tension, tremor myoclonus, nausea, coryza, diaphoresis, lethargy, muscle and joint pain, hyperreflexia, ataxia, tinnitus, and seizures. Perceptual disturbances include hyperacusis, depersonalization, blurred vision, illusions, and hallucinations.

The temporal sequence of symptom development is not well established, but upon the abrupt cessation of benzodiazepines with short elimination-half-lives, symptoms may appear within 24 hours and peak at 48 hours. Symptoms arising from abrupt discontinuance of benzodiazepines with long half-lives may not peak until 2 weeks later. Although some investigators suggest that a subgroup of patients has withdrawal syndromes that last for many months, no medical or scientific evidence validates the existence of such a syndrome. Prolonged symptoms are almost certainly attributable to recurrence of the original anxiety or progression of the anxiety disorder itself.

RISK FACTORS Factors influencing the development of the discontinuance or withdrawal syndrome are listed in Table 11.12-7. Studies on both humans and animals have attempted to identify risk factors for the development of physiological dependence. Animal studies demonstrate that the severity of withdrawal is greater with higher dosages and longer periods of drug administration, but that has not been as consistently demonstrated in clinical populations. When patients are stratified into high- and low-dose groups, the withdrawal syndrome is seen to be more severe in the high-dose group. However, two recent studies, one using a daily 21-mg dosage of diazepam equivalent as the cutoff separating high- and low-dosage groups and the other using three groups based on diazepam daily dosage (less than 6 mg, between 6 and 10 mg, and more than 10 mg), indicate no significant differences in withdrawal symptoms between groups. One possible explanation for the failure to demonstrate a consistent relation between dose and withdrawal symptoms is that subjects in clinical studies are being treated for an anxiety disorder, and when the benzodiazepine is discontinued, the reemergence of the original anxiety symptoms may be confused with withdrawal symptoms. Furthermore, the drug dosage is probably higher in patients with the most severe disease, complicating any relation between dosage and the intensity of the discontinuance syndrome.

- Dosage of benzodiazepine
- Duration of benzodiazepine treatment
- Rate of drug taper
- Psychopathology

Table 11.12-7 Factors Influencing the Development of the Benzodiazepine Discontinuation Syndrome

According to one study withdrawal symptoms are related to treatment duration when the length of the treatment is less than 8 months but not when it is a year or longer. The findings of another group indicate that patients taking benzodiazepines for more than 5 years have more withdrawal symptoms than those taking them for less than 5 years.

Mild withdrawal symptoms may occur with abrupt discontinuation of therapeutic doses after 4 weeks of benzodiazepine treatment. There is a risk of rebound insomnia after a few days to 1 week of treatment with benzodiazepine hypnotic drugs with short elimination half-lives. Benzodiazepine hypnotics with longer elimination half-lives are less likely to induce rebound insomnia upon abrupt discontinuation. The likelihood of a serious withdrawal syndrome increases as treatment continues, and many authorities see 4 months of treatment at therapeutic doses as a critical point in the development of clinically significant physiological dependence. That does not imply, however, that 4 months is an upper limit for treatment duration.

The risk of withdrawal is also influenced by the rate at which the drugs are discontinued. Gradual tapering of the benzodiazepines with short elimination half-lives is associated with fewer withdrawal symptoms than is their abrupt discontinuation. Clinical research shows less distinct differences between gradual and abrupt discontinuation of benzodiazepines with long half-lives, either because these drugs have a self-tapering action or because the period of tapering and observation in

many studies is insufficient.

If benzodiazepines are abruptly discontinued, the withdrawal syndrome related to short half-life agents appears earlier and may be more intense than that with long half-life drugs. Differences in intensity have not been proved because most studies do not monitor withdrawal symptoms for 2 weeks, which may be the time of peak symptoms with some drugs with long half-lives. Furthermore, any difference in withdrawal severity between short and long half-life agents is not entirely supported by animal studies. There is no difference in symptom severity of the withdrawal syndrome after animals are treated with either midazolam or chlordiazepoxide, for example, because essentially all benzodiazepines, regardless of their pharmacokinetic properties in humans, are eliminated very rapidly in small-animal species.

The development of physiological dependence differs depending on whether it results from benzodiazepine partial agonists or full agonists. In animal models the partial agonists bretazenil and abecarnil are associated with fewer withdrawal symptoms than are such classic agonists as diazepam or clorazepate (the prodrug for desmethyldiazepam). Clinical studies in anxious patients, however, indicate that abrupt termination of abecarnil is associated with withdrawal symptoms in some patients.

Some studies in animals indicate that periodic administration of the benzodiazepine antagonist flumazenil (Romazicon) during the chronic administration of lorazepam, diazepam, triazolam, or clobazam may attenuate the withdrawal syndrome.

Personality traits may be a risk factor for development of the benzodiazepine withdrawal syndrome. Withdrawal severity is greater in patients with higher scores on the dependence scale of the Minnesota Multiphasic Personality Inventory–2 (MMPI-2), high prewithdrawal levels of anxiety and depression, lower educational level, and passive-dependent personality disorder.

Overdose The benzodiazepines, in contrast to the barbiturates and the barbiturate-like substances, have a large margin of safety when taken in overdoses, a feature that contributed significantly to their rapid acceptance. The ratio of lethal to effective dose is about 200 to 1 or higher because of the minimal respiratory depression associated with the benzodiazepines. Even when grossly excessive amounts (more than 2 grams) are taken in suicide attempts, the symptoms include only drowsiness, lethargy, ataxia, some confusion, and mild depression of the user's vital signs. A much more serious condition prevails when benzodiazepines are taken in overdose in combination with other sedative-hypnotic substances, such as alcohol. In such cases small doses of benzodiazepines can cause death. The availability of flumazenil, a specific benzodiazepine antagonist, has reduced the lethality of the benzodiazepines, since flumazenil can be used in emergency rooms to reverse the effects of the benzodiazepines.

Barbiturates Since the advent of the benzodiazepines, barbiturates use has been limited in modern medicine. Phenobarbital (Solfoton) is still prescribed as an anticonvulsant and as a sedative, especially for children. It is also a common component of many combination products and reduces the stimulating effects of sympathomimetic agents. Butalbital is an intermediate-acting barbiturate found in a widely used combination product that also contains acetaminophen and caffeine (Fiornal) and is approved for the treatment of muscle contraction headaches. Given the limited availability of barbiturates, it is uncommon, at least in the United States, for addiction units to treat patients dependent on barbiturates other than butalbital and phenobarbital. The barbiturates marketed currently in the United States are listed in Table 11.12-8.

The substitution technique for sedative-hypnotic withdrawal requires calculation of equivalent doses of phenobarbital to replace the sedative-hypnotic agent that the patient is taking. The following are doses of various sedative-hypnotic agents for which a 30-mg dose of phenobarbital should provide adequate coverage of a withdrawal syndrome. Daily doses of phenobarbital should rarely exceed 600 mg using this protocol.

Generic Name	Trade Name	Dose (mg)
Amobarbital	Amytal	100
Aprobarbital	Alurate	40
Butabarbital	Butisol	100
Butalbital	Many combination products (e.g., Fiorinal)	100
Pentobarbital	Nembutal	100
Secobarbital	Seconal	100
Chloral hydrate	Generic	500
Ethchlorvynol	Placidyl	500
Glutethimide	Generic	250
Meprobamate	Miltown	400

Table 11.12-8 Barbiturates and Other Sedative-Hypnotic Agents

A major disadvantage of the use of the barbiturates is the development of pharmacokinetic and pharmacodynamic tolerance. *Tolerance* is defined as reduced drug response as a result of either decreased drug concentration at the site of action, usually the result of increased drug metabolism (pharmacokinetic) or of cellular adaptive changes with unchanged or higher drug concentrations at the site of action (pharmacodynamic). Pharmacodynamic tolerance begins after acute doses and continues to develop over weeks to months. Tolerance to the mood-altering and sedative effects develops to a greater extent than does tolerance to the lethal effects, increasing the risk of accidental overdose.

Intoxication When barbiturates and barbiturate-like substances are taken in relatively low doses, the clinical syndrome of intoxication is indistinguishable from that associated with alcohol intoxication. The symptoms include sluggishness, incoordination, difficulty in thinking, poor memory, slowness of speech and comprehension, faulty judgment, disinhibition of sexual and aggressive impulses, a narrowed range of attention, emotional lability, and exaggeration of basic personality traits. The sluggishness usually resolves after a few hours, but the impaired judgment, distorted mood, and impaired motor skills may remain for 12 to 24 hours, depending primarily on the half-life of the abused substance. Other potential symptoms are hostility, argumentativeness, moroseness, and (occasionally) paranoid and suicidal ideation. The neurological effects include nystagmus, diplopia, strabismus, ataxic gait, positive Romberg's sign, hypotonia, and decreased superficial reflexes.

Dependence and Withdrawal Physiological dependence may develop after a daily dose of 400 mg of pentobarbital for 3 months; abrupt discontinuation results in paroxysmal abnormalities on the electroencephalogram (EEG) in about 30 percent of patients. At a daily dosage of 600 mg of pentobarbital for 1 to 2 months, a withdrawal syndrome characterized by anxiety, insomnia, anorexia, tremor, and EEG changes occurs in about half of the patients, and 10 percent may have a single seizure. At higher dosages of 800 to 2200 mg a day for several weeks to months, abrupt discontinuation leads to minor symptoms within 24 hours of the last dose, which include apprehension and uneasiness, insomnia, muscular weakness, twitches, coarse tremors, myoclonic jerks, postural faintness and orthostatic hypotension, anorexia, vomiting, and EEG changes. Minor symptoms may persist up to 2 weeks. At high doses major symptoms develop. As many as 75 percent of patients may have grand mal seizures on the second or third day after withdrawal, and two thirds have more than one seizures. The interictal EEG shows four spike-wave discharges per-second. Two thirds of these patients develop delirium between the third and eighth day of withdrawal, which is sometimes accompanied by hypothermia, which may be fatal. Disorientation, visual hallucinations, and frightening dreams may precede the onset of full delirium. Delirium may be exceedingly difficult to reverse, even with large doses of a barbiturate; thus clinicians should never wait for the appearance of withdrawal symptoms before instituting therapy. The duration of the withdrawal syndrome is between 3 and 14 days; most end by the eighth day.

Overdose Barbiturates are lethal when taken in overdose, because they induce respiratory depression. In addition to intentional suicide attempts, accidental or unintentional overdoses are common. Barbiturates in home medicine cabinets are a common cause of fatal drug overdoses in children. As with benzodiazepines the lethal effects of barbiturates are additive to those of other sedative-hypnotic drugs, including alcohol and benzodiazepines. Barbiturate overdose is characterized by induction of coma, respiratory arrest, cardiovascular failure, and death.

The lethal dose varies with the route of administration and the degree of tolerance for the substance after a history of long-term abuse. For the most commonly abused barbiturates, the ratio of lethal to effective dose ranges between 3 to 1 and 30 to 1. Dependent users often take an average daily dose of 1.5 grams of a short-acting barbiturate, and some have been reported to take as much as 2.5 grams a day for months. The lethal dose is not much greater for the long-term abuser than it is for the neophyte. Tolerance develops quickly to the point at which withdrawal in a hospital becomes necessary to prevent accidental death from overdose.

Miscellaneous Sedative-Hypnotic Drugs The drugs discussed below have little or no role in modern therapeutics. Unfortunately, prescriptions for some have been increasing, especially in New York, where a 1989 triplicate prescription program has led to a 44 percent decline in benzodiazepine prescribing in retail pharmacies, 60 percent in the Medicaid program, and 30 percent in Blue Cross–Blue Shield programs. Corresponding prescription increases of 125 percent for meprobamate, 29

percent for ethychlorvynol, and 136 percent for chloral hydrate have been reported.

The older sedative-hypnotics drugs are similar in effect to the barbiturates, and they lead to tolerance and physiological dependence. The withdrawal syndrome is similar to the barbiturate withdrawal syndrome, and the protocols described for barbiturates should be used for safe withdrawal of patients dependent on those drugs.

Meprobamate Meprobamate, a carbamate derivative, has weak efficacy as an antianxiety agent. At clinical doses in humans, it has minimal muscle-relaxant effects, but it may have a mild analgesic effect in musculoskeletal pain and may potentiate analgesics. Typical daily doses are between 1200 and 1600 mg, with a maximum of 2400 mg, in three or four divided daily doses. A discontinuance syndrome occurs after several weeks of treatment with a daily dosage of 2400 mg and mild symptoms may be seen with long-term therapy at doses of 1600 mg daily. Onset of the discontinuance syndrome occurs within 12 to 48 hours after abrupt discontinuation and lasts for an additional 12 to 48 hours. Seizures may be common in withdrawal from meprobamate and reports published in the 1970s suggest that serious withdrawal symptoms are more common with meprobamate than with barbiturates. Fatalities from overdose have been reported after doses as low as 12 grams. The manufacturer offers the following guidelines for blood concentration: 5 to 20 µg/mL is the normal range with recommended doses; 30 to 100 µg/mL is associated with mild-to-moderate overdosage, with patients in stupor or light coma; 100 to 200 µg/mL is associated with serious overdose, deeper coma, and fatalities; concentrations above 200 µg/mL are associated with more fatalities than survivals. Meprobamate induces microsomal enzymes and may exacerbate intermittent porphyria.

Chloral Hydrate Chloral hydrate is used as a hypnotic in doses of 0.5 to 2.0 grams. After oral administration it is rapidly transformed to trichloroethanol, the metabolite responsible for its pharmacological activity. It is also effective in blocking experimentally induced seizures; however, anticonvulsive and hypnotic doses are similar in humans, making the benzodiazepines and barbiturates better choices for anticonvulsive medications.

At high doses chloral hydrate may produce respiratory depression, hypotension, gastric necrosis, depressed cardiac contractility, and a shortened refractory period. Even at therapeutic doses it is associated with gastric distress and flatulence. Somnambulism, disorientation, and paranoid ideation may occur. Tolerance and physiological dependence develop with long-term use, and the withdrawal syndrome is similar to the barbiturate abstinence syndrome. Several drug interactions occur with chloral hydrate, including displacement of ral anticoagulants and acidic drugs from protein binding sites by the metabolite trichloroacetic acid. When combined with furosemide, flushing, tachycardia, hypotension or hypertension, and diaphoresis have been reported. It potentiates the effects of ethanol, and it should not be used in patients with intermittent porphyria. Fatalities from overdose may occur with as little as 4 grams, although patients have survived after taking 30 grams.

Ethchlorvynol Ethchlorvynol is a rapidly acting sedative-hypnotic agent with anticonvulsant and muscle-relaxant properties. Recommended doses are 500 to 1000 mg. Initial effects (which may include euphoria) occur 15 to 30 minutes after an oral dose and plasma levels peak at 1 to 1.5 hours. The elimination half-life of the parent compound is 10 to 20 hours. The duration of the hypnotic effect is about 5 hours. Long-term use of ethchlorvynol has been associated with toxic amblyopia, scotoma, nystagmus, and peripheral neuropathy, which are usually reversible upon drug discontinuation. Intravenous self-administration may cause pulmonary edema.

Idiosyncratic reactions of excitement and stimulation have been described. Hypersensitivity reactions with urticaria and rare fatal thrombocytopenia may also arise. It should not be used in patients with intermittent porphyria. Tolerance, physiological dependence, and a withdrawal syndrome are seen with long-term administration. Lethal doses are typically between 10 and 25 grams; one person was reported to have died after taking 2.5 grams with ethanol, and one patient survived but was in a coma for 7 days after taking 50 grams.

Glutethimide and Methyprylon Glutethimide and methyprylon (no longer marketed in the United States) are piperidinedione sedative-hypnotic drugs that have high liability for abuse. Glutethimide resembles the barbiturates in most respects, but differs from them in having significant anticholinergic activity. An overdose can cause ileus, bladder atony, mydriasis, hyperpyrexia, myoclonic jerks, and convulsions. A lethal dose is between 10 and 20 grams; intoxication may be seen at a dose of 5 grams. An unusual characteristic of glutethimide is that a withdrawal syndrome can occur in patients taking therapeutic doses (0.5 to 3.0 grams daily) even when they have not stopped taking the drug. The abstinence syndrome includes tremulousness, nausea, tachycardia, fever, tonic muscle spasms, and grand mal seizures. Withdrawal from a combination of glutethimide and antihistamine has caused catatonia and dyskinesia. When glutethimide is taken with codeine (the street name is a “load”) a euphoria similar to that with heroin results. In these patients, detoxification may require both opioid withdrawal and sedative withdrawal.

Methaqualone Methaqualone is no longer available in the United States, and much of what is sold on the street as methaqualone is actually diazepam. Methaqualone is a quinazoline with sedative, anticonvulsive, local anesthetic, and antispasmodic activity. It has antitussive effects comparable to those of codeine and weak antihistaminic activity. During the 1960s and 1970s, those in the drug culture considered it to provide the ultimate high of all sedative-hypnotic agents, producing euphoria comparable to that from heroin. Chronic users may take daily dosages between 75 mg and 2 grams, with an average daily dosage of 775 mg. Adverse effects include peripheral neuropathy, nightmares, somnambulism, gastric discomfort, and urticaria. Death has been reported after 8 grams, but one report attributed most deaths under the influence of methaqualone to accidents due to impairment produced by the drug. Tolerance and physiological dependence are seen with chronic dosing.

An overdose of methaqualone may result in restlessness, delirium, hypertonia, muscle spasms, convulsions, and (in very high doses) death. Unlike barbiturates, methaqualone rarely causes severe cardiovascular or respiratory depression, and most fatalities result from combining methaqualone with alcohol.

TREATMENT

Withdrawal

Benzodiazepines Guidelines for the treatment of benzodiazepine discontinuance syndrome and the clinical management of withdrawal are presented in Table 11.12-9. The most common clinical situations that require medically supervised withdrawal from the benzodiazepines involve patients with anxiety disorders or chronic insomnia who have been maintained on therapeutic doses of benzodiazepines for several months or years, patients taking supratherapeutic doses of benzodiazepines for treatment-resistant types of anxiety or because of inappropriate dosage escalation, and patients who abuse benzodiazepines as part of a mixed abuse pattern (e.g., those who use benzodiazepines to self-medicate alcohol withdrawal or to end a cocaine run).

1. Evaluate and treat concomitant medical and psychiatric conditions
2. Obtain drug history and urine and blood sample for drug and ethanol assay
3. Determine required dose of benzodiazepine or barbiturate for stabilization, guided by history, clinical presentation, drug-ethanol assay, and in some cases challenge dose
4. Detoxification from supratherapeutic dosages:
   a. Hospitalize if there are medical or psychiatric indications, poor social supports, or polysubstance dependence or the patient is unreliable
   b. Some clinicians recommend switching to longer-acting benzodiazepine for withdrawal (e.g., diazepam, clonazepam); others recommend stabilizing on the drug that patient was taking or on phenobarbital
   c. After stabilization reduce dosage by 10 percent on the second or third day and evaluate the response, keeping in mind that symptoms that occur after decreases in benzodiazepines with short elimination half-lives (e.g., lorazepam) appear sooner than with those with longer elimination half-lives (e.g., diazepam)
   d. Reduce dosage further by 10 to 25 percent every few days if tolerated
   e. Use adjunctive medications if necessary (e.g., carbamazepine, β-adrenergic receptor antagonists, valproate, clonidine, and sedative antidepressants have been used but their efficacy in the treatment of the benzodiazepine abstinence syndrome has not been established)
5. Detoxification from therapeutic dosages:
   a. Initiate 10 to 25 percent dose reduction and evaluate response
   b. Dose, duration of therapy, and severity of anxiety influence the rate of taper and need for adjunctive medications
   c. Most patients taking therapeutic doses have uncomplicated discontinuation
6. Psychological interventions may assist patients in detoxification from benzodiazepines and in the long-term management of anxiety

Table 11.12-9 Guidelines for Treatment of Benzodiazepine Discontinuance Syndrome

In planning a rational withdrawal clinicians should remember the factors that influence the development of physiological dependence. The risk of withdrawal is greatest in patients taking high doses over long periods. The onset of withdrawal and its peak severity are earlier with agents with short half-lives, and if they are not tapered, withdrawal from them may be more severe than that from agents with long elimination half-lives, although the last point has not been definitively established. Concurrent use of other sedative-hypnotic agents (e.g., barbiturates or ethanol) may alter both the time course and severity of the benzodiazepine withdrawal syndrome.

TAPERING The basic principle underlying safe withdrawal is gradual tapering of the benzodiazepine dosage. In cases of detoxification from therapeutic doses, the

daily dosage is known, and the tapering protocol is easily calculated. Anyone taking a benzodiazepine for 2 weeks or longer should be tapered from the drug. Initially, the dosage is reduced by approximately 10 to 25 percent, and the patient is observed for any signs and symptoms of withdrawal. Withdrawal signs appear earlier for drugs with short half-lives than for drugs with long half-lives. Subsequent reductions depend on how the patient responds to initial changes and require individualization based on careful observation of the patient's condition following each dosage change.

In some cases patients taking high therapeutic doses of a benzodiazepine for a year or more may require several months or longer to stop the medication completely, not primarily for pharmacological reasons, but so they can learn alternative strategies for coping with anxiety. Most patients taking midrange therapeutic doses for a shorter time tolerate weekly reductions ranging from 10 to 25 percent. Most authorities agree that the last phases of drug discontinuation are the most difficult for the patient, and it may be necessary to slow the taper rate or to stop the taper entirely. The adjunctive use of nonbenzodiazepine medications may be useful in these circumstances.

Detoxification from supratherapeutic dosages of benzodiazepines may require a slightly different approach. Most clinicians hospitalize such patients because of the greater medical risks associated with supratherapeutic dosage withdrawal. Patients may be tapered using the benzodiazepine they have been taking or switched to a drug with a long elimination half-life, such as diazepam or clonazepam (Klonopin), using the dose equivalencies listed in Table 11.12-10 to determine the initial daily dosage. The estimated equivalent dosage is then administered in divided doses on day 1 to ensure that an accurate history and appropriate equivalency are established. Some clinicians stabilize patients on that dosage for 2 to 3 days; others prefer to reduce the dose by 30 percent on the second day, followed by 5 to 10 percent daily reductions. The use of carbamazepine (Tegretol) or valproate (Depakote) in high-dosage withdrawal often permits even larger daily reductions in the benzodiazepine dose. Most high-dose detoxification can be completed in 2 weeks or less using this protocol. For some patients the dose cannot be reduced that rapidly, however, and slower, longer tapers are sometimes necessary. The efficacy of anticonvulsants for the treatment of the benzodiazepine discontinuance syndrome has not been established, although clinical experience to date is encouraging.

Generic Name	Trade Name	Dose (mg)
Alprazolam	Xanax	1
Chlordiazepoxide	Librium	25
Clonazepam	Klonopin	0.5–1
Clorazepate	Tranxene	15
Diazepam	Valium	10
Estazolam	ProSom	1
Flurazepam	Dalmane	30
Lorazepam	Ativan	2
Oxazepam	Serax	30
Prazepam	Paxipam	80
Temazepam	Restoril	20
Triazolam	Halcion	0.25
Quazepam	Doral	15
Zolpidem*	Ambien	10

* An imidazopyridine benzodiazepine agonist.

Table 11.12-10 Approximate Therapeutic Equivalent Doses of Benzodiazepines

P>When the physician knows the patient has been taking supratherapeutic dosages but cannot determine the exact dosage, 20 mg of diazepam may be given to estimate tolerance. The dose should be repeated every 2 hours until mild sedation occurs. The total dose required to induce mild sedation is then considered the initial dose, and the detoxification proceeds as described above.

Some concerns have been raised regarding a lack of cross-tolerance between triazolobenzodiazepines and other benzodiazepines. Those concerns are based entirely on anecdotal reports and are not supported by controlled trials or experimental data. Case reports suggest that diazepam does not adequately treat the withdrawal syndrome from alprazolam and that the combination of chlordiazepoxide and diazepam fails to attentuate withdrawal symptoms from trialozam, although questions have been raised concerning the adequacy of the diazepam doses in those cases. Others report that lorazepam can successfully treat triazolam withdrawal and that clonazepam can be substituted for alprazolam in patients with panic disorder. If the primary drug that the patient is taking is not going to be used in the withdrawal protocol, clonazepam or lorazepam may be the best drugs to use when detoxifying patients who have been taking supratherapeutic dosages of triazolobenzodiazepines. It is not clear whether higher doses of diazepam would have alleviated the alprazolam withdrawal syndrome in the published case reports. Some authorities recommend the use of phenobarbital in such cases.

DETOXIFICATION FROM MULTIPLE DRUGS OF ABUSE Polysubstance abuse may present special problems for safe withdrawal. The most common polysubstance abuse pattern influencing medical management of detoxification from benzodiazepines is the concurrent use of alcohol, opioids, and cocaine. Combination with alcohol alters the time course and increases the severity of the sedative withdrawal syndrome. Adequate dosages of a benzodiazepine usually suffice for safe withdrawal; however, in rare instances even large dosages of diazepam can be ineffective, and switching to a barbiturate becomes necessary.

When supratherapeutic doses of benzodiazepines are abused with large amounts of opioids, it is best to discontinue the former drug first and then stabilize the patient on methadone or some oral opioid. When the period of risk for major symptoms of sedative-hypnotic withdrawal passes, opioid withdrawal may begin. Addiction to low or moderate dosages of benzodiazepines or opioids often permits simultaneous withdrawal from both classes of drugs.

Benzodiazepines are often used to terminate a cocaine or other psychostimulant run or to decrease anxiety induced by cocaine. Benzodiazepines used intermittently in that manner usually do not require detoxification. The chronic use of high dosages of benzodiazepines with cocaine is less common but does require medically supervised benzodiazepine taper. The cocaine abstinence syndrome is characterized by depression, irritability, lethargy, amotivation, hypersomnolence, confusion, and drug craving. The clinical presentation of the sedative-hypnotic withdrawal syndrome may be altered by recent cocaine use and is best monitored by carefully measuring vital signs (e.g., increases in pulse, temperature, and blood pressure).

Some clinicians prefer to use phenobarbital for detoxification of patients with mixed-drug abuse. A dose of phenobarbital equivalent to the benzodiazepine and other sedatives the patient is taking is calculated (Table 11.12-8 and Table 11.12-10) or, preferably, the dose is determined from a challenge test, and the patient is stabilized on that amount in divided daily doses for the period of peak risk of withdrawal. The maximum daily dosage of phenobarbital is 600 mg. After stabilization, phenobarbital dosage is reduced by 30 to 60 mg every 2 or 3 days.

ADJUNCTIVE MEDICATIONS Several adjunctive medications are used to treat the benzodiazepine withdrawal syndrome, but in no case has their efficacy been consistently supported in controlled trials nor is there evidence that any specific adjunctive medication is superior to another.

Carbamazepine, given in doses that achieve the therapeutic concentrations for treatment of seizures, may partially attenuate the withdrawal syndrome from benzodiazepines. Initial doses are 200 mg twice a day, although some clinicians recommend a single dose of 400 mg at bedtime to take advantage of the sedative effect. If initial doses are well tolerated, carbamazepine is increased to 600 mg on the second or third day. Typical total daily doses range from 400 to 800 mg. After several days of treatment benzodiazepine dosage is tapered. Despite reports that tapering can be completed within a week, even from supratherapeutic dosages, some patients require a slow taper that lasts several weeks. Carbamazepine can be tapered quickly 2 to 4 weeks after the last benzodiazepine dose. Carbamazepine may not be successful in withdrawing patients with panic disorder because it is ineffective in blocking panic attacks, but has shown some success even in these patients, as long as a slow benzodiazepine taper is used. The efficacy of other anticonvulsants is undetermined, but clinical experience suggests that valproate may reduce withdrawal symptoms as well. Enteric-coated tablets of divalproex (Depakene) are used in starting dosages of 500 to 1000 mg divided in two or three daily doses. Dosages are increased to achieve serum concentrations of 50 to 120 µg/mL. Some clinicians prefer to use daily loading doses of 20 mg/kg. For patients who abuse alcohol and benzodiazepines, valproate should be avoided when liver enzyme activities are three times their normal values. Gabapentin (Neurontin) may also reduce benzodiazepine withdrawal symptoms, but experience is limited.

The b-adrenergic receptor antagonists may also attenuate withdrawal symptoms. Propranolol (Inderal) in doses of 60 to 120 mg may reduce the symptoms of benzodiazepine withdrawal, although tachycardia and elevated blood pressure are the primary symptoms affected, while the subjective sense of discomfort and dysphoria persists. The b-adrenergic receptor antagonists do not have prophylactic effects against seizures and should not be used in monotherapy for withdrawal. Nevertheless, in some cases propranolol or atenolol (Tenormin), 50 to 100 mg, may be helpful adjuncts to withdrawal treatment.

Clonidine (Catapres), 0.1 mg administered twice a day to 0.2 mg three times a day or as a patch, has been used in the treatment of low-dose benzodiazepine

withdrawal with variable results. Clonidine does not provide protection against withdrawal seizures. It may be effective only when used before withdrawal symptoms develop.

Although antidepressants have not been rigorously studied in the treatment of benzodiazepine withdrawal, many experienced clinicians prescribe them. Agents with well-established antipanic and sedative effects may be useful adjunctive medications for patients whose anxiety recurs during taper or after drug discontinuation. Imipramine (Tofranil), amitriptyline (Elavil), doxepin (Adapin, Sinequan), nefazodone (Serzone), trazodone (Desyrel), selective serotonin reuptake inhibitors, and monoamine oxidase inhibitors may all be useful in that role. Melatonin is a useful treatment for insomnia during withdrawal.

PSYCHOLOGICAL TREATMENTS Specific psychological treatments for withdrawal have not been widely studied. Cognitive behavioral strategies for anxiety management have been applied to patients withdrawing from benzodiazepines with mixed results. Patients who meet the criteria for generalized anxiety disorder are poor candidates for relaxation training.

Many practitioners believe that successful withdrawal requires transmitting to the patient a sense of control over the withdrawal symptoms. In support of this belief, placebo substitution is associated with fewer withdrawal symptoms after drug discontinuation than is withdrawal without placebo. Apparently the belief that one is taking an effective medication is enough to reduce symptoms.

One way to foster a sense of control over withdrawal symptoms is to link the symptoms of anxiety to environmental intrapsychic stressors. Cognitive restructuring teaches patients about the withdrawal syndrome and helps them identify and relabel withdrawal symptoms as anxiety, thus permitting the implementation of adaptive coping strategies, which include systematic desensitization, in vivo graded exposure, and group problem solving. Using a diary to record mood states and their precipitants sometimes helps cognitive restructuring. A diary may also alert the clinician to maladaptive responses to benzodiazepine withdrawal, such as increased alcohol consumption.

The concept of “cognitive coping” should be introduced to patients, and examples of self-statements (“talking to yourself”) that are applicable to withdrawal and anxiety management should be discussed and provided as flash cards. They include such statements as “I feel nervous now but it won't last,” “I feel bad but it's not worse than when I had the flu,” or “I feel uncomfortable, but nothing bad is going to happen to me.” Self-statements should be short, simple, and relevant to the patient.

Patients are encouraged to be active participants in developing their withdrawal schedule. Clinicians should be flexible about the rate of taper and should encourage the patient to join in the withdrawal process, especially those who are withdrawing from therapeutic doses. It is often useful to request that patients choose which doses should be decreased or eliminated according to their perceived need. For some patients, setting a maximum permissible daily dose may be necessary.

LONG-TERM OUTCOME Few adequately designed follow-up studies have been carried out on patients who terminated benzodiazepine treatment. Many studies suffer from sample selection bias, diagnostic heterogeneity of the sample, and failure to assess environmental factors or to control for concurrent psychotherapy or psychoactive medication; but despite those shortcomings, several interacting findings have emerged.

In one study of patients who had discontinued benzodiazepines from 10 months to 3.5 years earlier, 70 percent were no longer taking benzodiazepines and had few or no symptoms, 22 percent were not taking benzodiazepines but required other psychotropic medications, and 8 percent had returned to benzodiazepine use. Another study assessed patients who were evaluated for a discontinuation program 3 to 6 years earlier and found that 45 percent were not using benzodiazepines, although some were using other psychoactive medication. Of those who successfully completed the tapering program, 73 percent were benzodiazepine free at follow-up, compared with 39 percent of patients who entered but did not complete the program, and 14 percent of patients who did not participate in the program. Another study of patients treated for benzodiazepine dependence found that 56 percent of benzodiazepine-free (no use during the preceding month) patients had moderate-to-severe anxiety, and 38 percent had moderate-to-severe depression at 1 to 5 years follow-up. A different study found that even though 66 percent of patients were not taking benzodiazepines at follow-up, 75 percent had taken them at some time during the 5 years after entering a discontinuation program.

The follow-up studies suggest that most patients can successfully discontinue taking benzodiazepines. They also indicate that some patients experience recurrent anxiety that requires alternative psychoactive medication or reinstitution of benzodiazepine therapy. However, a subgroup of patients who discontinue benzodiazepines actually show improvement in anxiety over pretapering levels, which suggests that those who continue to have significant symptoms of anxiety or depression while taking a benzodiazepine should probably undergo a drug-free trial period. The value of a structured program for discontinuation and the substitution of medications with low abuse liability are supported in several studies. There appears to be no relation between long-term outcome (i.e., not using benzodiazepines at follow-up) and the dosage or duration of treatment or the specific benzodiazepine that was discontinued.

Barbiturates There are three common methods of establishing the barbiturate dosage required for safe withdrawal: (1) administration of a test dose of pentobarbital (Nembutal) to determine tolerance, (2) calculation of required doses based on estimated equivalencies, and (3) administration of phenobarbital loading doses.

In the first method the initial step is to determine tolerance. Once intoxication has subsided but before withdrawal symptoms have developed, an oral dose of 200 mg of pentobarbital is administered on an empty stomach and the effects are observed after 1 hour to determine the stabilization dose (Table 11.12-11). If no changes are observed, the test is repeated 3 hours later using 300 mg. If there is still no response, the total requirement may exceed 1600 mg a day. The calculated daily dose is divided and given every 4 to 6 hours for a 2- to 3-day stabilization period. Daily dose reductions are usually 10 percent of the stabilization dose, but withdrawal regimens must be individualized. Phenobarbital may be substituted for pentobarbital for stabilization and withdrawal at one third the dose.

Symptoms after Test Dose of 200 mg Oral Pentobarbital	Estimated 24-Hour Oral Pentobarbital Dose (mg)	Estimated 24-Hour Oral Phenobarbital Dose (mg)
Level I: Asleep but arousable; withdrawal symptoms not likely	0	0
Level II: Mild sedation; patient may have slurred speech, ataxia, nystagmus	500–600	150–200
Level III: Patient is comfortable; no evidence of sedation; may have nystagmus	800	250
Level IV: No drug effect	1000–1200	300–600

Modified from Cicaulo DA, Shader RI, editors: *Clinical Manual of Chemical Dependence*. American Psychiatric Press, Washington, DC, 1991. From data in Ewing JA, Rakerwell WT: Diagnosis and management of depressant drug dependence. Am J Psychiatry 125:1808, 1967.

Table 11.12-11 Pentobarbital Test Dose Procedure for Barbiturate Withdrawal

The second method of barbiturate detoxification requires calculating the equivalent hypnotic dose of phenobarbital on the basis of the dosage of barbiturate or other sedatives the patient reports taking, also taking into consideration any alcohol consumed. A dose of 30 mg of phenobarbital is substituted for an equivalent hypnotic dose of the sedative. The patient is stabilized for the period of peak vulnerability to withdrawal—2 to 3 days for sedative-hypnotic agents with short half-lives—and reductions of 30 to 60 mg of phenobarbital are made every 2 or 3 days. Clinicians using this method report that only rarely are doses of phenobarbital greater than 600 mg required. The procedure is not recommended, however, because published equivalencies are only approximations, and patients vary greatly in their metabolism and pharmacodynamic response to the same dose of the sedative. Furthermore, animal studies indicate that cross-tolerance among the various anxiolytic and sedative-hypnotic agents is not complete. Further, the method relies on the patient's history of drug use, which is often unreliable. Plasma concentrations can establish which sedatives have been ingested and may indicate the degree of tolerance when clinical correlations are made. Estimation of tolerance (and thus determination of dosage requirements) is best made after either a test dose or a loading dose is administered. Table 11.12-8 and Table 11.12-10 list approximate equivalencies of selected barbiturates, benzodiazepines, and sedatives.

The final method for medical withdrawal from barbiturates involves using loading doses of phenobarbital. According to the original protocol, 120-mg doses are administered every 1 to 2 hours until three of five signs are present—nystagmus, drowsiness, ataxia, dysarthria, emotional lability—or if patients are in withdrawal, until abstinence symptoms abate. No additional drug is administered, and because of its long half-life, the drug self-tapers. Patients are assessed before each dose.

Some clinicians have modified the protocol to use doses of 60 mg every 1 to 2 hours and to use a gradual taper rather than abrupt discontinuation. The originators of the protocol reported a mean loading dose of 1440 mg, with hourly doses sometimes required for 15 to 20 hours. They have also administered phenobarbital intravenously at 0.3 mg/kg per minute, with close medical supervision, for medically ill patients.

Overdose The treatment of overdose of the general class of substances involves gastric lavage, activated charcoal, and careful monitoring of vital signs and central nervous system activity. Overdose patients who come to attention while awake should be kept from slipping into unconsciousness. Vomiting should be induced, and activated charcoal should be administered to delay gastric absorption. If the patient is comatose, the clinician must establish an intravenous fluid line, monitor the patient's vital signs, insert an endotracheal tube to maintain a patent airway, and provide mechanical ventilation if necessary. Hospitalization of a comatose patient in an intensive care unit is usually required during the early stages of recovery from such overdoses.

SUGGESTED CROSS-REFERENCES

Substance-related disorders are discussed throughout Chapter 11 with an introduction and overview and relevant general tables in Section 11. Biological therapies are the focus of Chapter 31; benzodiazepines in Section 31.10 , monoamine oxidase inhibitors in Section 31.20 , and serotonin-specific reuptake inhibitors in Section 31.25.

11.13 ANABOLIC-ANDROGENIC STEROID ABUSE

HARRISON G. POPE, JR., M.D., AND KIRK J. BROWER, M.D.

The anabolic steroids are a family of drugs comprising the natural male hormone testosterone and a group of many synthetic analogues of testosterone synthesized since the 1940s (Table 11.13-1). All these drugs possess various degrees of *anabolic* (muscle-building) and *androgenic* (masculinizing) effects. Thus they should more correctly be called anabolic-androgenic steroids: however, the terms anabolic steroids and simply steroids are used for brevity. Steroids have a number of legitimate medical applications, such as in the treatment of hypogonadal men, and in the treatment of certain diseases, such as muscular dystrophy, various anemias, and the wasting syndrome associated with acquired immune deficiency syndrome (AIDS). However, steroids are widely used illicitly by individuals seeking to gain increased muscle mass and strength, either for athletic purposes or simply to improve personal appearance.

Compounds usually administered orally
Fluoxymesterone (Halotestin, Android-F, Ultandren)
Methandienone (formerly called methandrostenolone) (Dianabol)
Methyltestosterone (Android, Testred, Virilon)
Mibolerone (Cheque Drops*)
Oxandrolone (Anavar)
Oxymetholone (Anadrol, Hemogenin)
Mesterolone (Mesteranon, Proviron)
Stanozolol (Winstrol)
Compounds usually administered intramuscularly
Nandrolone decanoate (Deca-Durabolin)
Nandrolone phenpropionate (Durabolin)
Methenolone enanthate (Primobolan depot)
Boldenone undecylenate (Equipoise*)
Stanozolol (Winstrol-V*)
Testosterone esters blends (Sustanon, Sten)
Testosterone cypionate
Testosterone enanthate (Delatestryl)
Testosterone propionate (Testoviron, Andriolan)
Testosterone undecanoate (Andriol, Restandol)
Trenbolone acetate (Finaject, Finaplix*)
Trenbolone hexahydrobenzylcarbonate (Parabolan)

* Veterinary compound.
† Many of the brand names listed above are foreign, but are included because of the widespread illicit use of foreign steroid preparations in the United States.

Table 11.13-1 Examples of Commonly Used Anabolic Steroids†

HISTORY

Testosterone was first synthesized in 1935, and by the 1940s various synthetic derivatives of testosterone had appeared. Both the anabolic and androgenic actions of these drugs were quickly recognized; they were reportedly first used by Hitler's troops in World War II to increase aggressiveness, although this claim has been difficult to verify. Also in the late 1930s and early 1940s a number of psychiatric investigations suggested that testosterone possessed antidepressant properties. The hormone was believed to be especially effective for the “male climacteric” and was frequently prescribed in Europe and in the United States for depressed middle-aged men. With the advent of electroconvulsive therapy (ECT) and standard antidepressant medications, however, the use of anabolic steroids for psychiatric purposes rapidly waned.

By the 1950s athletes had recognized the value of anabolic steroids. The first reported use of these drugs in athletics was apparently by the Russians in 1954, followed within a few years by elite athletes from many other countries. Over the next three decades the use of steroids rapidly expanded among athletes at all levels, especially in sports requiring muscle mass and strength, such as bodybuilding, powerlifting, football, and field events such as the shot put. During the 1960s and 1970s many placebo-controlled studies tested whether anabolic steroids were truly effective for gaining muscle mass. The results of these studies were frequently equivocal, usually because the studies employed dosages and durations of steroid administration far below those used by actual athletes in the field. On the basis of these studies many reputable textbooks and reviews in pharmacology and endocrinology concluded that steroids were ineffective for athletic purposes. Athletes who had actually used these drugs and who were aware of the enormous muscle gains that they could produce tended to hold the medical profession in great contempt for its ignorance; consequently, these athletes often discounted medical warnings about the possible physical and psychiatric dangers of these agents.

By the late 1980s and early 1990s medical professionals increasingly acknowledged that anabolic steroids were indeed highly effective for achieving muscle gains and that use of these agents had approached epidemic proportions in the United States. Early reports also began to document psychiatric morbidity from steroids as well. These trends led to increasing concern about the public health consequences of anabolic steroid use, and in 1991 the United States Congress passed the Steroid Trafficking Act, adding anabolic steroids to the list of Schedule III controlled substances and placing jurisdiction over these substances in the hands of the Drug Enforcement Administration (DEA). Based on widespread anecdotal experience with anabolic steroids users it seems as if this legislative change has had a marked effect in that it has led to a diminished supply of genuine steroids on the black market and a greatly increased number of counterfeit steroids with no pharmacological effects. However, unlike many of the other drugs of abuse, anabolic steroids may be purchased legally without a prescription in many countries, and can be sent illicitly by mail to the United States (e.g., to post office boxes). This pattern makes interdiction difficult, and ensures that a substantial supply of genuine steroids will be available to illicit users in the United States for the foreseeable future.

COMPARATIVE NOSOLOGY

Psychiatric syndromes associated with use of anabolic steroids are cited in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorder* (DSM-IV) under the general category of other substance-related disorders. The 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) classifies steroid-related disorders under abuse of non-dependence-producing substances, along with agents such as antacids and laxatives. A rapidly growing body of literature, however, now supports a syndrome of anabolic steroid dependence and withdrawal, together with several anabolic steroid-induced psychiatric disorders. The best established among the latter are a syndrome of hypomanic or manic symptoms associated with steroid use and a depressive syndrome associated with steroid withdrawal. This chapter will parallel the standard terminology of DSM-IV for other drugs of abuse, discussing anabolic steroid dependence and abuse, anabolic steroid-induced mood disorder, anabolic steroid-induced psychotic disorder, and anabolic steroid-induced disorder not otherwise specified.

EPIDEMIOLOGY

Anabolic steroid use is widespread among men in the United States but is much less frequent in women. Among the most reliable data regarding the prevalence of steroid use are those from the National Household Survey on Drug Abuse (NHSDA). This survey, which has been conducted regularly since 1971, first included questions about anabolic steroids in 1991. Findings from this survey indicated that approximately 900,000 American males and approximately 150,000 American females reported having used anabolic steroids at some time during their lives. Approximately 250,000 males and 50,000 females were estimated to have used steroids within the past year. Among individuals who had used these drugs during the past year, nearly one quarter or 64,000 were between 12 and 17 years old. Various studies of high school students in the United States have produced even higher estimates of the prevalence of anabolic steroid use among adolescents. For example, one study of 3403 twelfth-grade boys in 46 public and private hospitals in the United States found that 6.6 percent of students reported current or past use of anabolic steroids, with two thirds of the users reporting that they had first tried these drugs when they were 16 years of age or less. Similarly high estimates have emerged from other studies of high school and college students in the United States; the prevalence of steroid use among male students has generally been many

times greater than that among female students in these studies. One possible criticism of these results, however, is that some students may have misunderstood the survey questions and claimed that they had used anabolic steroids when in fact they had used only corticosteroids, prescribed to them for conditions such as asthma or dermatological problems. Even allowing for this possible source of error, however, it is evident that rates of anabolic steroid use among American adolescents are high.

The current high rates of steroid use among younger individuals appears to represent an important shift in the epidemiology of steroid use. As recently as the mid-1970s use of these drugs was largely confined to competition bodybuilders, other elite weight-training athletes, and elite athletes in other sports. Currently, however, it appears that an increasing number of young men, and occasionally even young women, may be using these drugs purely to enhance personal appearance rather than for any athletic purpose.

Individuals with one form of substance abuse are often found to abuse other substances as well, and some studies document polysubstance use among steroid users. However, other anabolic steroid users report that they carefully abstain from using drugs such as alcohol and cocaine, because they are concerned with maximizing their muscularity or athletic ability. Anabolic steroid users, especially those involved in competition bodybuilding, may use a wide variety of other *ergogenic* (performance-enhancing) drugs to gain muscle, lose fat, or lose water for bodybuilding competitions. Other drugs commonly used by competitive bodybuilders are thyroid hormones, such as liothyronine (Cytomel) and lerothyroxine (Synthroid); human growth hormone and its daughter compound, somatomedin-C (insulin-like growth factor-1 [IGF-1]); insulin; dehydroepiandrosterone (DHEA); androstenedione; sympathomimetic agents such as amphetamines, ephedrine and pseudoephedrine (Sudafed); b-adrenergic receptor agonists such as clenbuterol; the amino acid derivative gamma hydroxybutyrate (GHB); various laxatives and diuretics; the opioid agonist-antagonist nalbuphine (Nubain), and others.

PHARMACOLOGY

Chemistry All steroid drugs—including anabolic-androgenic steroids, estrogens, and corticosteroids—are synthesized in vivo from cholesterol and resemble cholesterol in their chemical structure (Fig. 11.13-1). Testosterone has a four-ring chemical structure containing 19 carbon atoms (Fig. 11.13-2). Most synthetic derivatives of testosterone are produced by one or more of the following modifications: (1) forming an ester at the 17-b-hydroxyl group, (2) adding an alkyl group to the 17-a position, or (3) altering the structure at a different carbon site.

FIGURE 11.13-1 Physical effects of anabolic steroid use. These photographs compare a “natural” bodybuilder who has never used anabolic steroids (left), with a man who has used large doses of anabolic steroids over several years (right). Both men are 67 inches tall and have 7 percent body fat. The man on the left weighs 170 pounds and represents approximately the maximum degree of muscularity obtainable without drugs. His fat-free mass index is 25.4 kg/m $_2$ by the formula of Elena Kouri et al. (see references). The man on the right weighs 213 pounds and has a fat-free mass index of 31.7 kg/m $_2$. Note that the muscle hypertrophy from steroid use is particularly marked in the upper body in the pectoralis, deltoid, trapezius, and biceps muscles. Any man significantly more muscular than the man on the left has almost certainly abused anabolic steroids.

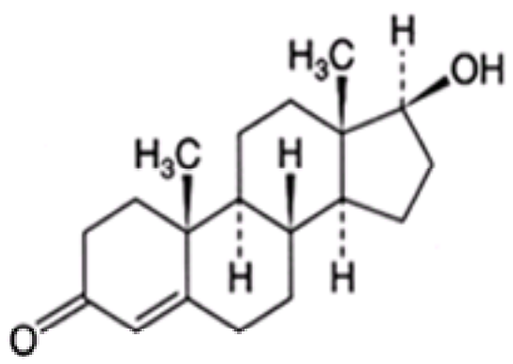

FIGURE 11.13-2 Molecular structure of testosterone.

Aqueous testosterone suspension is essentially inactive when ingested by the oral route because of first-pass metabolism in the liver, and is only briefly active when injected because it is rapidly absorbed and metabolized. Synthetic steroids overcome these problems. Testosterone esters (such as testosterone cypionate (Depo-Testosterone) and testosterone enanthate) confer the advantage of slower absorption than testosterone when injected, and their effects last from 2 to 4 weeks. Testosterone esters are hydrolyzed to testosterone after they are absorbed, so these agents can be monitored by blood concentrations. Testosterone is metabolized in part to dihydrotestosterone, which is up to 10 times more potent than testosterone as an androgen, and in part to the estrogen estradiol, which accounts for some of the adverse effects seen in men, such as gynecomastia. The effects of testosterone depend both on the balance of metabolic enzymes and on the concentration of androgen receptors in a particular tissue. The C-17-alkylated synthetic steroids make oral administration possible, but once-daily use is generally required.

Pharmacodynamics Steroids bind androgen receptors in the cytoplasm of cells. The androgen-receptor complex is then translocated to the cell nucleus where it augments gene transcription and ultimately new protein synthesis. The anabolic steroid effects desired by illicit users result especially from new protein synthesis in muscle tissue. The mechanism of action for psychoactive effects is poorly understood, but may include enzymatic conversion to estrogen in certain brain regions.

Normal testosterone plasma concentrations for men range from 300 to 1000 ng/dL. Generally, 200 mg of testosterone cypionate taken every 2 weeks will restore physiological testosterone concentrations in a hypogonadal male. A eugonadal male who initiates physiological dosages of testosterone will have no net gain in testosterone concentrations, because exogenously administered steroids shut down endogenous testosterone production via feedback inhibition of the hypothalamic-pituitary-gonadal axis. Consequently, illicit users take higher-than-therapeutic dosages in order to achieve supraphysiological effects. The dose-response curve for anabolic effects may be logarithmic, which could explain why illicit users generally take 10 to 100 times the therapeutic dosages.

Effects on Specific Organs and Systems The first effects of endogenous androgens are to induce male sexual differentiation in the fetus. Accumulating evidence suggests that fetal and perinatal androgens cause sexual dimorphism of the brain (at least in nonhuman mammals) as well as differentiation of the sexual organs. During puberty, testosterone levels increase in boys to produce male secondary sex characteristics. The phallus, prostate, and seminal vesicles all grow and develop, and testosterone and gonadotropins are involved in sperm production. Androgens cause the larynx to enlarge, the vocal cords to lengthen and thicken, and the voice to deepen. A male pattern of body hair develops, including hair on the face and chest. Sebaceous glands grow and increase their secretions, predisposing the adolescent to acne. Bones and muscles also grow during puberty as a result of androgen stimulation. Exogenous administration of anabolic-androgenic steroids to a prepubertal male will also induce all these effects.

In adults, physiological levels of testosterone continue to be important for spermatogenesis, although abnormally high levels will suppress spermatogenesis by

inhibiting release of luteinizing hormone, which is also required for spermatogenesis. Exogenous steroids increase muscle growth, promote mineralization of bones, and stimulate erythropoiesis by increasing erythropoietin levels and by direct action on the bone marrow.

Therapeutic Indications Anabolic steroids are primarily indicated for testosterone deficiency (male hypogonadism), hereditary angioedema (a congenital skin disorder), and some uncommon forms of anemia. In women they are given, although not as first-choice agents, for metastatic breast cancer, osteoporosis, endometriosis, and adjunctive treatment of menopausal symptoms. In men they have been used experimentally as a male contraceptive and for treating major depressive disorder and sexual disorders in eugonadal men. Recently, they have been used to treat wasting syndromes associated with AIDS.

Adverse Reactions The most common adverse medical effects of anabolic steroids involve the cardiovascular, hepatic, reproductive, and dermatological systems. In general, the more common adverse effects tend to be cosmetic and are reversible upon cessation of the steroid agent. Serious, life-threatening effects occur rarely but the long-term consequences of nonmedical steroid use have not been studied. A recent report revealed a shortened life span in mice exposed to high-dose anabolic steroids, but the generalizability to humans is unknown. It is established that the orally active C-17-alkylated steroids are generally more toxic to the liver and more likely to adversely affect cholesterol levels than the injectable testosterone esters.

Anabolic steroids produce an adverse cholesterol profile by increasing levels of low-density lipoprotein cholesterol and decreasing levels of high-density lipoprotein cholesterol. High-dose steroid use may also activate hemostasis. Steroids are widely reported to increase blood pressure, although most controlled studies fail to confirm this. Nevertheless, the adverse effects on cholesterol and hemostasis have led to concerns of increased coronary artery disease and atherosclerosis among steroid users. Isolated case reports of myocardial infarction, cardiomyopathy, left ventricular hypertrophy, and stroke among steroid users do exist, but there are no epidemiological studies that assess the risk to the cardiovascular and cerebrovascular systems from using high-dose, illicit steroids; fortunately, changes in cholesterol levels are reversible when steroids are discontinued.

Liver effects include cholestatic jaundice, benign and malignant liver tumors, and peliosis hepatis (blood-filled cysts that may rupture and cause death), although all these effects are rare. At least one case of prostatic cancer has been reported, and benign prostatic hypertrophy is also possible. Steroid-induced effects in males include testicular atrophy and sterility, both reversible after discontinuing steroids, and gynecomastia, which may persist until surgical removal. In females, shrinkage of breast tissue, irregular menses (diminution or cessation), and masculinization (clitoral hypertrophy, hirsutism, and deepened voice) can occur. Masculinizing effects in women may be irreversible, although this issue has not been well studied. Androgens taken during pregnancy could cause masculinization of a female fetus. Dermatological effects include acne and male pattern baldness. Anabolic steroid abuse by children has led to concerns that steroid-induced premature closure of bony epiphyses could cause shortened stature. Other uncommon adverse effects include edema of the extremities due to water retention, exacerbation of tic disorders, sleep apnea, and polycythemia.

Laboratory Findings The use of anabolic steroids can be associated with elevations in liver function tests such as bilirubin, lactate dehydrogenase (LDH), alkaline phosphatase, aspartate amino transferase (AST or SGOT), and alanine amino transferase (ALT). However, elevations in LDH, ALT, and AST, as well as the muscle enzyme creatine phosphokinase (CPK), are common in weight-training athletes, even in the absence of steroid use, as a result of muscle trauma from intensive weightlifting. The enzyme g-glutamyltransaminase (GGT), which is present exclusively in liver and not in muscle, may be more useful to distinguish frank liver toxicity from mere muscle trauma in steroid users.

An altered cholesterol profile—decreased levels of high-density lipoprotein cholesterol and increased levels of low-density lipoprotein cholesterol—is seen especially with oral administration of the C-17-alkylated anabolic steroids. Total cholesterol and triglycerides concentrations may also be elevated. Increases in the hematocrit and hemoglobin levels may occur relative to a patient's baseline values, although the hematocrit is rarely abnormally elevated unless steroids are combined with erythropoietin, as some endurance athletes have done.

Endocrine Tests Steroids inhibit the release of luteinizing hormone (LH) and follicular-stimulating hormone (FSH), resulting in lower serum levels. Serum testosterone and estradiol levels vary with the particular agent and timing of the sample. For example, the use of supraphysiological doses of testosterone esters will increase both testosterone and estradiol levels whereas the exclusive use of most other anabolic steroids will decrease these hormonal levels. Similarly, testosterone and estradiol levels are decreased during steroid withdrawal because of the lingering inhibition of the hypothalamic-pituitary-gonadal axis.

Other Tests Semen analysis may reveal decreased sperm count and motility as well as abnormal sperm morphology. Left ventricular hypertrophy (LVH) can be found on the electrocardiogram (ECG), although steroid non-users can have LVH on the basis on intensive strength training alone. An echocardiogram can rule out impaired diastolic function, which has been reported in some steroid users with LVH.

ETIOLOGY

The major reason for taking illicit steroids is to enhance either athletic performance or physical appearance. Steroid-taking is reinforced because steroids can produce the athletic and physical effects that users desire, especially when combined with proper diet and training. Further reinforcement derives from winning competitions and from social admiration for physical appearance. Steroid users also perceive that they can train more intensively for longer durations with less fatigue and with decreased recovery times between workouts.

The dramatic effects of anabolic steroids on muscle growth are illustrated in Figure 11.13-1, which compares a “natural” bodybuilder who has never used these drugs with a bodybuilder of identical height and body fat who has used steroids extensively.

While the anabolic or muscle-building properties of steroids are clearly important to those seeking to enhance athletic performance and physical appearance, psychoactive effects may also be important in the persistent and dependent use of anabolic steroids. Anecdotally, some steroid users report feelings of power, aggressiveness, and euphoria, which become associated with and can reinforce steroid-taking.

Cross-sectional studies have delineated a number of demographic and psychosocial differences between steroid users and nonusers. In general males are more likely to take steroids than females, and athletes are more likely to take steroids than non-athletes. Among weight lifters, one study found that both steroid users and individuals thinking about using steroids (high-risk group) were more likely than those not thinking about using steroids (low-risk group) to spend increased time each week lifting weights, to be training specifically for a bodybuilding competition, to use nonsteroidal substances for training enhancement (such as vitamins, amino acids, protein supplements, stimulants, and so-called natural testosterone releasers), and to know other steroid users. The study highlights the importance of training characteristics, other substance use, and peer influences as risk factors for initiating steroid use.

Interestingly, the high-risk nonuser group was more likely than either the low-risk group or the steroid users to “feel not big enough.” Indeed, recent investigations have suggested that some male and female weightlifters may suffer from muscle dysmorphia—a form of body dysmorphic disorder in which the individual feels that he is not sufficiently muscular and lean. Individuals with muscle dysmorphia may perceive themselves to be much smaller and weaker than they actually are, causing this disorder to formerly be called reverse anorexia nervosa. Such individuals appear to be particularly likely to experiment with anabolic steroids and other ergogenic drugs as compared to individuals who do not display comparable disorders of body image. By extension, the risk factors for dependent use may overlap with those for initial use. One study found higher steroid doses and more dissatisfaction with body image among dependent users than nondependent users, suggesting that both pharmacological factors and self-perceptions were risk factors for steroid dependence.

ANABOLIC STEROID DEPENDENCE AND ABUSE

The possibility of anabolic steroid dependence was mentioned in the scientific literature as early as 1980. Three case reports appeared in the medical literature between 1988 and 1990, which described young men who initially took steroids to enhance their weight-lifting and bodybuilding activity, and later used the drugs to combat depression when they tried to stop using them. The men reported feeling addicted and sought professional help to stop using illicitly obtained steroids because they were unable to accomplish discontinuation on their own.

Several research groups have utilized the revised third edition of DSM (DSM-III-R) criteria for substance dependence to diagnose steroid dependence in samples of weightlifters taking illicit steroids. One group made presumptive DSM-III-R diagnoses using an anonymous, self-administered questionnaire and found responses suggestive of steroid dependence in 57 percent of 49 men. Self-reported diagnostic symptoms and their frequencies included taking more steroids than intended (51 percent), difficulty cutting down or controlling use (16 percent), continuing to use despite adverse consequences (37 percent), tolerance (18 percent), and withdrawal (84 percent). In addition to a desire to take more steroids (52 percent), and headaches (20 percent), the most frequently reported withdrawal symptoms were

depressive in nature and included fatigue (43 percent), depressed mood (41 percent), restlessness (29 percent), anorexia (24 percent), insomnia (20 percent), and decreased libido (20 percent).

Another research group, using a face-to-face interview and the Structured Clinical Interview for DSM-III-R (SCID), found that 14.3 percent of 77 steroid users met criteria for steroid dependence. A third group reported that approximately 25 percent of 88 steroid users undergoing extensive clinical research interviews and assessment for psychiatric and medical effects appeared to manifest dependence on steroids. Finally, a study of 91 inpatient substance abuse treatment programs identified 68 steroid users of whom 69 percent were judged to meet DSM-III-R criteria for steroid dependence. The wide range of prevalence rates across the four studies (14 to 69 percent) probably reflects differences in sampling and differences in diagnostic methods, so the true prevalence of steroid dependence in steroid users and in the general population is unknown.

Unpublished observations suggest that women may also manifest steroid dependence, but female dependence on male hormones appears to be relatively rare when compared to men. Also, there appear to be no reported cases of anabolic steroid dependence in patients who were prescribed steroids for legitimate medical indications such as hypogonadism or anemia. Thus, physicians need not be concerned about dependence when legitimately prescribing steroids at therapeutic doses.

Etiology The mechanism of steroid dependence is not firmly established. For example, some authors have argued that steroid dependence represents a compulsive attachment to athletic activities—accompanied by feeling high when actively participating in those activities—rather than to any psychoactive properties of the steroids themselves. According to this view, steroids are taken more for their “muscle-active” than for their psychoactive properties. Indeed, steroids do not produce immediate sensations of euphoria following short-term administration, nor do animals self-administer steroids, as happens with drugs like cocaine and heroin. Although users do report euphoria following long-term administration (days to weeks) of steroids, such feelings could result from satisfying workouts or from the social rewards for having a big and muscular body.

Nevertheless, steroids do bind to specific receptors in the brain and alter neurotransmitter functioning, albeit in ways that are poorly elucidated to date. Steroids have also been used effectively to treat major depressive disorder and several controlled studies document the mood-altering properties of steroids. Finally, steroids mimic the electroencephalographic patterns produced by dopaminergic stimulants and they appear to sensitize the brain to the rewarding properties of amphetamine. One recent study demonstrated a steroid-induced increase in endogenous opioid concentrations in the ventral tegmental area, a portion of the brain postulated to be involved in the reinforcing action of other abused drugs such as cocaine. However, direct stimulation of brain reward pathways by anabolic steroids has not been proven.

In addition to positive reinforcement mechanisms, the negative reinforcement mechanisms of avoiding withdrawal symptoms, particularly depression, and avoiding the feeling of being too small may contribute to steroid dependence.

Course and Prognosis No longitudinal studies of dependent steroid users have been published to date. Based on two case reports it appears that steroid dependence can develop within 9 to 12 months after initiating use. In these cases users took supratherapeutic doses, and combined multiple steroid drugs, including both oral and injectable forms. However, dependence has also been described in a male weightlifter who used a single, oral agent at three times the therapeutic dose for nearly 9 years. Severity of dependence is also variable. In one study, 8.2 percent of 49 steroid users reported six or more DSM-III-R dependency symptoms, which is consistent with severe dependence.

Some authors have speculated that steroid withdrawal has two phases, with phase 1 lasting a week or less and consisting of opioid-like withdrawal symptoms. Phase 2 begins within the first week, consists of depressive symptoms, and may last for several months. Other than one case report, however, there is no published evidence of opioid-like withdrawal symptoms following the discontinuation of anabolic steroids.

Few steroid users seek substance abuse treatment. One study estimated that steroid users accounted for less than 0.1 percent of patients entering treatment programs for substance abuse. The low number of documented treatment cases stands in contrast to the large number of Americans estimated to use steroids illicitly (300,000 per year) and to be at risk for developing dependence (14 to 69 percent of users). However, it is not clear that most individuals fulfilling research criteria for steroid dependence require treatment in order to discontinue use.

Treatment Few descriptions and no controlled trials have been published of treatment for steroid-related disorders. Treatment is based on a comprehensive assessment including history, mental status and physical examinations, and laboratory tests. As in the case of other psychiatric disorders, treatment should address both the primary disorder and associated biological, psychological, and social factors. As in the case of other substance use disorders, treatment must motivate steroid users to discontinue use, ameliorate withdrawal-related symptoms, target associated psychiatric disorders, and address psychosocial triggers to relapse.

Abstinence is the treatment goal of choice for patients manifesting steroid abuse or dependence. To the extent that steroid users abuse other addictive substances (including alcohol), traditional treatment approaches for substance-related disorders may be utilized. Nevertheless, steroid users may differ from other addicted patients in several ways that have implications for treatment. First, the euphorigenic and reinforcing effects of steroids may only become apparent after weeks or months of use in conjunction with intensive exercising. When compared to immediately and passively reinforcing drugs such as cocaine, heroin, and alcohol, steroid use may entail more delayed gratification. Second, steroid users may manifest greater commitment to culturally endorsed values of physical fitness, success, victory, and goal directness than users of other illicit drugs. Finally, steroid users are often preoccupied with their physical attributes, and may rely excessively on these attributes for self-esteem. Treatment therefore depends on a therapeutic alliance that is based on a thorough and nonjudgmental understanding of the patient's values and motivations for using steroids.

Steroid Withdrawal Supportive therapy and monitoring are essential for treating steroid withdrawal because suicidal depressions can occur. Hospitalization may be required when suicidal ideation is severe. Patients should be educated about the possible course of withdrawal, and reassured that symptoms are time-limited and manageable. Antidepressant agents are best reserved for patients whose depressive symptomatology persists for several weeks after steroid discontinuation and who meet criteria for major depressive disorder. Selective serotonin reuptake inhibitors (SSRIs) are the preferred agents because of their favorable adverse effect profile and their effectiveness in the only reported case series of treated steroid users with major depressive disorder. Physical withdrawal symptoms are not life-threatening and do not ordinarily require pharmacotherapy. Nonsteroidal anti-inflammatory drugs (NSAIDs) may be useful to treat musculoskeletal pain and headaches.

Endocrine Pharmacotherapies Various endocrine pharmacotherapies for steroid withdrawal have been proposed on theoretical grounds, including testosterone substitution and taper, human chorionic gonadotropin, and estrogen blockers. Endocrine pharmacotherapies have as their goal the restoration of hypothalamic pituitary gonadal axis function. Hypothalamic pituitary gonadal activity can remain depressed for 12 or more weeks following cessation of prolonged, high-dose steroid use and resembles hypogonadotropic hypogonadism. However, there are no studies demonstrating the efficacy of endocrine pharmacotherapies for treating illicit steroid users during withdrawal, so their use remains experimental and cannot be routinely recommended.

ANABOLIC STEROID-INDUCED MOOD DISORDERS

Irritability, aggressiveness, hypomania, and frank mania associated with anabolic steroid use probably represent one of the most important public health issues associated with these drugs. Although athletes using these drugs have long recognized that syndromes of anger and irritability (sometimes called “roid rage”) could be associated with steroid use, these syndromes were little recognized in the scientific literature until the late 1980s and 1990s. Since then a series of observational field studies of athletes has suggested that some steroid users develop prominent hypomanic or even manic symptoms during steroid use. Of the 12 such studies that have appeared to date, 11 have found at least some such effects in association with anabolic steroid use, with an apparent association between the dosage of steroids used and the frequency of psychiatric effects. Specifically, in individuals using the equivalent of 300 mg of testosterone a week or less, psychiatric effects appear rare; in individuals taking intermediate dosages, between 300 and 1000 mg of testosterone equivalent per week, mood syndromes appear more common; and in individuals taking the equivalent of more than 1000 mg a week mood syndromes become quite common and are occasionally severe.

The association of steroid dose with psychiatric effects is illustrated by examining individual studies. At the low end of the dosage range, for example, one study of 53 men examined individuals who were using a mean dose of only 318 mg of testosterone or equivalent a week. The men in this study exhibited essentially no psychiatric changes during steroid use. By comparison, another study examined 71 men and 6 women who were using a mean dose estimated as somewhat more than 500 mg a week. The authors of this study noted that 1 (1.3 percent) of the subjects developed mania and 6 (7.8 percent) developed hypomania. One subject (1.3 percent) described major depressive disorder during steroid use, and 5 (6.5 percent) subjects reported major depressive disorder in association with steroid withdrawal. Three of the five users reported a suicide attempt during a period of withdrawal from steroid use. At the high end of the dosage range, a third study

examined 39 men and 2 women who had used a mean of 750 mg per week. In this study, five (12 percent) of the subjects reported a manic syndrome, and five (12 percent) reported psychotic symptoms at some time in association with steroid use. Interestingly, among the 8 subjects reporting manic or psychotic symptoms or both in this study, the average weekly dose was about 900 mg. A further illustration of the relationship between steroid dose and the prevalence of psychiatric syndromes is provided in Table 11.13-2, which provides the frequency of hypomanic, manic, and major depressive syndromes reported among 88 steroid users in one study where the users are grouped on the basis of the maximum dosage of steroids used. Psychiatric syndromes are almost absent at the lowest dosages, but affected nearly half of the individuals using dosages equivalent to 1000 mg or more of testosterone a week.

Weekly Steroid Dose[a] (No. of Users)	No. (%) of Subjects Displaying Mood Disorders[a]			
	Manic Episode	Hypomanic Episode	Major Depressive Disorder	Total[b]
Low (N = 12)	0	1 (8)	0	1 (8)
Medium (N = 51)	0	5 (10)	3 (6)	7 (14)
High (N = 25)	4 (16)	3 (12)	7 (28)	11 (44)

[a] Significance of relationship between increasing doses of steroids and prevalence of mood disorders by two-sided trend test: manic episode, P = .01, major depressive disorder, P = .003, total, P = .004.
[b] Total is less than sum of individual categories because some individuals displayed both a manic or hypomanic episode and a major depressive episode in association with steroids.
[c] Low represents less than 300 mg/wk of testosterone or equivalent; medium, 300 to 1000 mg/wk; and high, more than 1000 mg/wk.

Table 11.13-2 Relationship of Weekly Steroid Dosage to Prevalence of Mood Disorders

Observational field studies, however, are subject to a number of methodological limitations common to retrospective studies of this nature. First, subjects are being asked to describe psychiatric symptoms that may have occurred well in the past and that therefore may be colored by recall bias. Second, these subjects were generally taking drugs obtained on the black market that were of unknown potency or authenticity. Thus, assumptions regarding the nature and dosage of the drugs are necessarily crude at best. Third, selection bias may influence which subjects present for interviews in observational studies: subjects who have experienced prominent psychopathology in association with steroid use might be either more likely or less likely to participate. Fourth, expectational effects and influences from the subculture of the gymnasium may greatly influence subjects' reactions to steroids. For example, an individual lifting weights regularly in a “hard core” gymnasium might be primed to expect increases in his irritability and aggression with steroid use, even if such changes do not actually occur.

Laboratory studies using anabolic steroids in normal volunteers avoid most of these limitations, but are subject to problems of their own. Specifically, most laboratory studies, including endocrinological investigations, physiological studies, and studies using anabolic steroids to treat various medical conditions, have used very modest doses of testosterone or other anabolic steroids, rarely exceeding the equivalent of 300 mg of testosterone a week. Furthermore, such studies have rarely attempted to measure psychiatric effects systematically. Not surprisingly, these studies have generally failed to note prominent psychiatric changes in their subjects. As a result, some such studies have erroneously concluded that anabolic steroids lack psychiatric effects. This error is similar to that of many earlier negative studies of the effects of steroids on muscle growth, again because the studies typically used doses far lower than those actually used by athletes in the field.

Recently, four newer laboratory studies have appeared in which normal male volunteers were given dosages of 500 mg a week or more of testosterone or equivalent under placebo-controlled, double-blind conditions. These studies represent the first available controlled investigations that have used doses of steroids more closely approximating those used by actual steroid abusers. Of 109 men receiving such dosages in these four studies combined, 5 exhibited prominent hypomanic or manic syndromes during steroid exposure. These subjects displayed levels of symptomatology that might be expected to seriously impair normal social or occupational functioning; one subject study even requested that he be placed in seclusion on the ward where the study was conducted. By contrast, however, the great majority of the men in these four studies exhibited very few behavioral changes with high dosages of anabolic steroids. Thus, it appears that most individuals taking anabolic steroids, even at fairly high dosages, will experience few psychiatric effects although an occasional individual may develop a severe manic or hypomanic reaction. At present the mechanism of these reactions is unknown; they may represent an idiosyncratic phenomenon unrelated to premorbid psychiatric function.

Figure 11.13-3 shows changes in ratings of manic symptoms in three subjects who received testosterone cypionate in dosages up to 600 mg a week versus inert placebo, each for periods of 6 weeks in a double-blind, crossover design. Subjects varied widely in their response to testosterone. The subject on the left side of the figure exhibited virtually no change in manic ratings during either the testosterone or placebo periods; the subject in the middle displayed a modest rise in manic symptoms in association with testosterone, but not sufficient to significantly affect his social or occupational functioning. By contrast, the subject on the right displayed a marked manic reaction, approaching the range of patients hospitalized for treatment of manic episodes, requiring the investigators to discontinue testosterone administration 1 week earlier than planned. The symptoms of mania resolved promptly within 2 weeks following discontinuation of testosterone.

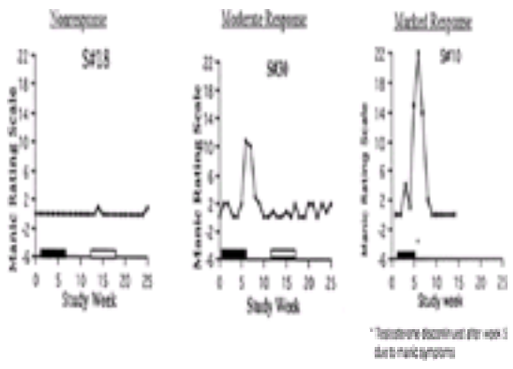

FIGURE 11.13-3 Examples of marked response, moderate response, and nonresponse to testosterone versus placebo on the Young Manic Rating Scale. The black bar represents the period of testosterone cypionate administration in each subject. Testosterone was administered in gradually increasing doses (150 mg/wk for the first 2 weeks, 300 mg/wk for the next 2 weeks, and 600 mg/wk for the final 2 weeks of the period). The white bar represents the period of placebo administration. A 6-week washout period was interposed between the two treatment periods to minimize carryover effects.

It is difficult to extrapolate from these findings to estimate the frequency of prominent hypomanic or manic reactions among steroid users in the field. Illicit users may employ higher dosages than could ethically be administered in the laboratory; such users may take several different steroids together (“stacking”); they may use alcohol or other drugs while taking steroids; and of course they do not screen themselves with the same care as would be the case in a laboratory study. Finally, some users may become more sensitized to the psychiatric effects of steroids after using them for multiple courses over time; since most of the subjects in available laboratory studies were steroid-naive prior to treatment they may not be representative of actual steroid users in the field. For all these reasons the crude rate of approximately 5 percent previously estimated may represent a lower bound for the true prevalence of steroid-induced hypomanic and manic syndromes in the overall population of users.

A possible serious consequence of steroid-induced mood disorders may be violent or even homicidal behavior. Several published reports have anecdotally described individuals with no apparent history of psychiatric disorder, no criminal record, and no history of violence who committed violent crimes, including murder, while under the influence of anabolic steroids. In a number of cases steroid use has been cited in criminal trials as a possible mitigating factor in the defense of such individuals. Although a causal link is difficult to establish in these cases, evidence of steroid use has frequently been presented in forensic settings as a possible mitigating factor in criminal behavior. One recent study of 133 sequential, newly incarcerated male felons found that 3 (2.3 percent) reported committing violent crimes while under the influence of anabolic steroids.

At least one published study, together with anecdotal experience, suggests that violence associated with anabolic steroids is frequently directed at women. In one

study that specifically examined this issue 23 male steroid users were compared with 14 male non-users, using the Conflict Tactics Scales to assess users' relationships with their girlfriends or spouses. Significant differences emerged on several of these scales between users on drugs and nonusers and between users on drugs and the same users when off drugs.

Anabolic steroid-induced depressive syndromes have generally not been reported in laboratory studies, but have been documented in field studies. Case reports of completed suicides associated with steroid withdrawal have also appeared. In some instances it appears that a brief and self-limited syndrome of depression occurs upon steroid withdrawal, probably as a result of the depression of the hypothalamic-pituitary-gonadal axis following exogenous steroid administration. Such syndromes might be expected to occur more often in the field than in laboratory settings because athletes typically take steroids for longer intervals than would occur in the laboratory, resulting in more pronounced neuroendocrine depression and shrinkage of the testes.

Not all depressive syndromes of this nature, however, are self-limited. Some reports have described episodes of depression that continued for months after discontinuing steroids, and which required treatment with fluoxetine (Prozac), tricyclic antidepressant agents, or electroconvulsive therapy (ECT). Again, however, given the uncontrolled and retrospective nature of these observations, it is difficult to judge the true frequency of such syndromes in the field.

ANABOLIC STEROID-INDUCED PSYCHOTIC DISORDER

Psychotic symptoms are rare in association with anabolic steroid use but have been described in a few cases, primarily in individuals who were using the equivalent of more than 1000 mg of testosterone a week. Usually these symptoms have consisted of grandiose or paranoid delusions, generally occurring in the context of a manic episode, although occasionally occurring in the absence of a frank manic syndrome. In most cases reported psychotic symptoms have disappeared promptly (within a few weeks) after the discontinuation of the offending agent, although temporary treatment with antipsychotic agents was sometimes required. As with manic reactions to steroids, the mechanism for these seemingly idiosyncratic psychotic reactions is unknown. It is interesting to note, however, that the chemically related family of hormones, corticosteroids, also produce idiosyncratic manic and psychotic symptoms in occasional individuals while creating few psychiatric effects in the great majority of patients. The mechanism of action of these idiosyncratic effects with corticosteroids is also unknown.

ANABOLIC STEROID-RELATED DISORDER NOT OTHERWISE SPECIFIED

Occasional anecdotal reports have described decreases in symptoms of anxiety disorders, such as panic disorder and social phobia, during steroid use, and exacerbations of these disorders during steroid withdrawal. Conversely, some individuals report increases in anxiety symptoms while taking steroids. However, no systematic data are available on these entities.

Anabolic steroid use may frequently be associated with use of other licit and illicit ergogenic drugs. Thus, athletes may exhibit both physical and psychiatric morbidity associated with the use of these other drugs, and also may develop apparent abuse and dependence of multiple ergogenic drugs, although this syndrome has been poorly characterized in the literature to date. For example, use of ephedrine and other central nervous system stimulants to promote fat loss may lead to insomnia, anxiety, and other features of stimulant abuse and dependence syndromes. Use of large doses of adrenal hormones, such as DHEA and androstenedione, may lead to masculinizing effects in female athletes. DHEA may also possess antidepressant properties, although data in this area remain limited. Use of excessive dosages of thyroid hormones may produce psychiatric effects similar to those seen in thyrotoxicosis. Use of the opioid agonist/antagonist nalbuphine, a drug increasingly popular among anabolic steroid users, may lead to features of opioid dependence, and may even require detoxification.

Mr. A. is a 26-year-old, single white man. He is 69 inches tall and presently weighs 204 pounds with a body fat of 11 percent. He reports that he began lifting weights at age 17, at which time he weighed 155 pounds. Within a year of beginning his weightlifting he began taking anabolic steroids after obtaining them through a friend at his gymnasium. His first cycle of steroids, lasting for 9 weeks, involved methandienone, 30 mg orally a day, and testosterone cypionate, 600 mg intramuscularly a week. During these 9 weeks he gained 20 pounds of muscle mass. He was so pleased with these results that he took five further cycles of anabolic steroids over the course of the next 6 years. During his most ambitious cycle, approximately 1 year ago, he used testosterone cypionate, 600 mg per week; nandrolone decanoate (Deca-Durabolin), 400 mg a week; stanozolol (Winstrol), 12 mg a day; and oxandrolone (Anavar), 10 mg a day.

During each of the cycles Mr. A. has noted euphoria, irritability, and grandiose feelings. These symptoms were most prominent during his most recent cycle, when he felt invincible. During this cycle he also noted a decreased need for sleep, racing thoughts, and a tendency to spend excessive amounts of money. For example, he impulsively purchased a $2700 stereo system when he realistically could not afford to spend more than $500. He also became uncharacteristically irritable with his girlfriend, and on one occasion put his fist through the side window of her car during an argument—an act inconsistent with his normally mild-mannered personality. After this cycle of steroids ended, he became moderately depressed for about 2 months, with hypersomnia, anorexia, markedly decreased libido, and occasional suicidal ideation.

Mr. A. smoked marijuana almost daily during his last 2 years of high school and continues to smoke at least twice a week. He has experimented briefly with hallucinogens, cocaine, opiates, and stimulants, but has rarely used them in the last 5 years. However, he has used a number of drugs to lose weight in preparation for bodybuilding contests. These include ephedrine, amphetamine, triiodothyronine, and thyroxin. Recently, he has also begun to use the opioid agonist-antagonist nalbuphine (Nubain) intravenously to treat muscle aches from weight lifting. He reports that intravenous nalbuphine use is widespread among other anabolic steroid users of his acquaintance.

Mr. A. exhibits characteristic features of muscle dysmorphia. He checks his appearance dozens of times a day in mirrors, or when he sees his reflection in a store window or even in the back of a spoon. He becomes anxious if he misses even one day of working out at the gym, and acknowledges that his preoccupation with weightlifting has cost him both social and occupational opportunities. Although he has a 48-inch chest and 19-inch biceps, he has frequently declined invitations to go to the beach or a swimming pool for fear that he would look too small when seen in a bathing suit. He is anxious because he has lost some weight since the end of his previous cycle of steroids and is eager to resume another cycle of anabolic steroids in the near future.

SUGGESTED CROSS-REFERENCES

An overview of substance-related disorders is given in Chapter 11; mood disorders are discussed in Chapter 14 and psychotic disorders in Chapter 13. Body dysmorphic disorder is covered in Chapter 16.

CHAPTER 12. SCHIZOPHRENIA

12.1 SCHIZOPHRENIA: INTRODUCTION AND OVERVIEW

ROBERT W. BUCHANAN, M.D. AND WILLIAM T. CARPENTER, JR., M.D.

Schizophrenia is the paradigmatic illness of psychiatry. It is a clinical syndrome of variable but profoundly disruptive psychopathology, which involves thought, perception, emotion, movement, and behavior. The expression of these symptoms varies across patients and over time, but the cumulative effect of the illness is always severe and usually long lasting.

HISTORY

Written descriptions of symptoms commonly observed today in patients with schizophrenia are found throughout recorded history. Early Greek physicians described delusions of grandeur, paranoia, and deterioration in cognitive functions and personality. These behaviors were generally considered to merit social sanction. However, since these symptoms are not necessarily unique to schizophrenia, one cannot be certain whether these behaviors were actually associated with what today would be called schizophrenia. Indeed, several scholars have argued that schizophrenia is of relatively recent origin.

Schizophrenia did not emerge as a medical condition worthy of study and treatment until the eighteenth century. By the nineteenth century the various psychotic disorders were generally viewed as insanity or madness, and the movement to conceptualize the condition as a regrettable affliction replaced the view of insanity as a reprehensible behavior. During the middle to late nineteenth century many clinical categories were described, but a general approach capable of integrating the widely diverse manifestations of mental illness into distinguishable clinical syndromes was lacking.

A major impediment to distinguishing schizophrenia from other forms of psychoses was the existence of another common type of insanity, *general paresis*. The symptom manifestations of general paresis were quite diverse and overlapped extensively with those of schizophrenia. The cause of syphilitic insanity was subsequently traced to a spirochetal infestation, and antibiotics were eventually found to be effective in treatment and prevention. The identification of syphilitic insanity enabled Emil Kraepelin to delineate the two other major patterns of insanity: *manic-depressive psychosis* and *dementia praecox* (or dementia of the young), and to group together under the diagnostic category of dementia precox the previously disparate categories of insanity, such as hebephrenia, paranoia, and catatonia. In differentiating dementia precox from manic-depressive disorder, Kraepelin emphasized what he believed to be the characteristic poor long-term prognosis of dementia precox, as compared to the relatively nondeteriorating course of manic-depressive illness. In *Dementia Praecox and Pathophysiology* (1919) Kraepelin went on to describe what he believed to be the two principal pathophysiological or disease processes occurring in dementia precox:

> On the one hand we observe a weakening of those emotional activities which permanently form the mainsprings of volition. In connection with this, mental activity and instinct for occupation become mute. The result of this part of the process is emotional dullness, failure of mental activities, loss of mastery over volition, of endeavor, and of ability for independent action. The essence of personality is thereby destroyed, the best and most precious part of its being, as Griesinger once expressed it, torn from her . . . The second group of disorders, which gives dementia praecox its peculiar stamp . . . consists in the loss of the inner unity of the activities of intellect, emotion, and volition in themselves and among one another. Stransky speaks of an annihilation of the "intrapsychic co-ordination" . . . [T]his annihilation presents itself to us in the disorders of association described by Bleuler, in incoherence of the train of thought, in the sharp change of moods as well as in desultoriness and derailments in practical work. But further, the near connections between thinking and feeling, between deliberation and emotional activity on the one hand, and practical work on the other is more or less lost. Emotions do not correspond to ideas.

The description of the former process provides the conceptual framework for the avolitional or negative symptom component of the illness, and the description of the latter process provides the conceptual framework for the positive symptoms of schizophrenia.

In 1911 Eugen Bleuler, recognizing that dementia was not a usual characteristic of dementia precox, suggested the term *schizophrenia* (splitting of the mind) for the disorder. Bleuler introduced the concept of primary and secondary schizophrenic symptoms; his four primary symptoms (the four As) were abnormal associations, autistic behavior and thinking, abnormal affect, and ambivalence. Of these four symptoms Bleuler viewed as central to the illness the loss of association between thought processes and among thought, emotion, and behavior. Typical examples of these losses of associations are silly giggling on receiving news of the death of a loved one, the introduction of magical thinking and peculiar concepts into an ordinary discussion, and the sudden display of angry behavior without experiencing anger (or an understandable provocation).

Bleuler's view that a dissociative process is fundamental to schizophrenia and that this process underlies a wide variety of the symptom manifestations of schizophrenia has supported a major paradigm for conceptualizing the illness, namely, that in spite of its various manifestations, schizophrenia is a single disease entity in which there is extensive similarity in cause (etiology) and mechanism (pathophysiology) across all patients with the disorder. In this view, a neurophysiological disturbance of indeterminate origin and nature occurs that is manifest as dissociative processes adversely influencing the development of mental capacities in the areas of thought, emotion, and behavior. Depending on the individual's adaptive capacity and environmental circumstances, this fundamental process could lead to secondary disease manifestations such as hallucinations, delusions, social withdrawal, and diminished drive.

There are many parallels in medicine for this single-disease model. Diabetic patients share an impairment in glucose metabolism, but the secondary manifestations vary considerably depending on which organ systems are involved. Similarly, seizure disorders may share a common pathophysiological mechanism, but different lesion locations lead to marked variability in signs and symptoms. One patient may have full-body convulsions, while another may experience strange sexual sensations and excessive religiosity. The diverse manifestations of syphilitic insanity best illustrate the utility of this disease-entity approach for schizophrenia.

The major alternative etiopathophysiological model conceptualizes schizophrenia as a clinical syndrome rather than a single disease entity. This view holds that although patients with schizophrenia share a sufficient commonality of signs and symptoms to validly differentiate them from patients with other forms of psychosis (e.g., mood disorder with psychotic features, substance-induced psychotic disorder), more than one disease entity will eventually be found within this syndrome. This view is supported by the existence of multiple risk factors and heterogeneity in clinical presentation, treatment response, and clinical course. The emergence over the past 50 years of proof that mental retardation is a clinical syndrome comprised of multiple disease entities rather than a single disease entity best illustrates this construct. Schizophrenia currently maintains the status of a clinical syndrome in the absence of evidence for the existence of a single disease entity.

There are other competing models for conceptualizing schizophrenia, which, although seriously debated in the past, are presently dismissed as demonstrably invalid or so seriously reductionistic as to not account for major observations associated with the illness. Nondisease models, such as the societal reaction theory ("a sane reaction to an insane world") or Thomas Szasz's theory that schizophrenia is a myth enabling society to manage deviant behavior, cannot adequately account for the distribution of schizophrenia among biological relatives, the myriad of associated brain abnormalities, the normalizing effects of drug treatment, and the extensive similarity and lifetime prevalence and clinical manifestations of schizophrenia across widely divergent cultures. Narrow framework disease models that attempt to account for the illness solely at the level of psychological mechanisms are also demonstrably inadequate in accommodating the known facts of the illness. Genetic or immunovirological causal factors cannot be addressed by reductionistic theories operating at the psychological or social levels. The many biological, psychological, and social factors relevant to the understanding and treatment of the person with schizophrenia require a broad medical model and eschew reduction to any single level of the functioning organism.

In summary, schizophrenia is appropriately and accurately conceptualized as a disease process. Although it is possible that a unifying etiology or pathophysiology will eventually be uncovered that will account for all or almost all cases, it seems more likely that more than one disease entity exists within the clinical syndrome of schizophrenia, with each having a distinguishable etiology and pathophysiology. Any reductionistic approach to the description or explanation of the disorder cannot adequately account for the range of relevant information and facts. A broad medical model that integrates factors ranging from the molecular to the psychosocial level of organization is necessary to describe schizophrenia, to account for the range of pathogenic influences, and to provide for treatment and rehabilitation.

EPIDEMIOLOGY

Schizophrenia is a leading public health problem that exacts enormous personal and economic costs worldwide. Schizophrenia affects just under 1 percent of the world's population (approximately 0.85 percent). The number of affected individuals increases if schizophrenia spectrum disorders are included in prevalence estimates. The concept of schizophrenia spectrum disorders is derived from observations of psychopathological manifestations in the biological relatives of patients with schizophrenia. Diagnoses and approximate lifetime prevalence rates (percentage of population) for spectrum disorders are: schizoid personality disorder (fractional), schizotypal personality disorder (1 to 4 percent), schizoaffective psychosis (0.7 percent), and atypical psychoses and delusional disorder (0.7 percent). The relation of these disorders to schizophrenia in the general population is unclear, but in family pedigree studies the presence of a proband with schizophrenia significantly increases the prevalence of these disorders among biological relatives.

Schizophrenia is found in all societies and geographical areas. Although comparable data are difficult to obtain, incidence and lifetime prevalence rates are roughly equal worldwide. The positive symptom component of the disorder usually becomes manifest during late adolescence and early adulthood, although there is a difference in onset associated with gender. In males, the incidence of the onset of positive symptoms peaks during years 17 to 27, whereas in females the peak incidence is a lengthy plateau between the years 17 to 37. Rural and urban incidence figures are probably similar, but there is a greater prevalence of schizophrenia among urban and lower socioeconomic populations. This is generally attributed to the “social drift” phenomenon in which afflicted or vulnerable individuals tend to lose their occupation and social niche and drift toward pockets of poverty and inner-city areas. Occasional geographical areas of increased prevalence of schizophrenia are interesting in terms of illness etiology. For example, a Northern Scandinavian isolated population appears to have a gene pool enriched for schizophrenia vulnerability, probably brought to the region generations ago by two immigrating families.

Because schizophrenia begins early in life; causes significant and long-lasting impairments; makes heavy demands for hospital care; and requires ongoing clinical care, rehabilitation, and support services, the financial cost of the illness in the United States is estimated to exceed that of all cancers combined. In 1990 the direct and indirect costs of schizophrenia were estimated at $33 billion. The locus of care has shifted dramatically over the last 40 years from long-term hospital-based care to acute hospital care and community-based services. In 1955 about 500,000 hospital beds in the United States were occupied by the mentally ill, the majority of whom had a diagnosis of schizophrenia; that figure is now under 250,000.

Deinstitutionalization has dramatically reduced the number of beds in custodial facilities, but an overall evaluation of the consequences of deinstitutionalization is disheartening. Many patients have simply been transferred to alternative forms of custodial care (instead of to treatment or rehabilitative services), including nursing home care and poorly supervised shelter arrangements. Others have been released to communities often unable or unwilling to provide the minimal requirements for clinical care or humane support. For the more fortunate patients the burden of care has shifted to the family, creating an extreme hardship for large numbers of families in this country. The estimated overall financial burden to these families ranges from $2 to 2.5 billion. The less fortunate patient may either have no place to live, be forced to live in circumstances of isolation and hopelessness, or end up in jail. Patients with a diagnosis of schizophrenia are reported to account for 33 to 50 percent of homeless Americans. Managed care places further pressure to reduce bed utilization while communities remain marginally prepared and a relative dearth of alternative care systems exists. Continuity-of-care systems, which include assertive outreach programs and supervised housing and emergency care, provide an effective alternative to hospital-based care for many patients, but costs are substantial, and simply shifting cost from impoverished public hospital sectors has not proved feasible.

ETIOLOGY

The etiological process or processes by which a causal agent creates the pathophysiology of schizophrenia is not yet known. However, a good deal is known about risk factors for developing schizophrenia, which leads to direct inferences regarding possible etiopathophysiologies. Family, twin, and adoptive studies have long since documented a robust contribution of genetic factors to the etiology of schizophrenia, with genetic factors established as relevant to some, perhaps all, cases. However, it is not yet known which genes are involved or how the proteins they produce contribute to the pathophysiology of schizophrenia. Recent linkage analyses have made substantial progress towards identifying a potential location on chromosome 6, and have also provided preliminary indications of additional genetic contributions associated with chromosomes 4, 8, 15, and 22. Other markers of early influences, including gestational and birth complications, exposure to influenza epidemics, Rhesus (Rh) incompatibility, starvation, and an excess of winter births, further suggest a neurodevelopmental pathological process in schizophrenia; however, here, too, the exact pathophysiological mechanisms associated with these risk factors are not known. There are interesting reports that a subgroup of patients with the avolitional component of the illness, as assessed by the deficit syndrome, do not share in the winter birth excess, but rather show a summer birth excess, suggesting the possibility of a separate disease entity within the schizophrenia syndrome. A number of speculations regarding viral and immune mechanisms, sometimes posited as an explanation of the season of birth risk factor, are plausible, but no virus or immune mechanism has yet been established as an etiological factor in schizophrenia. Finally, substance abuse has been identified as a risk factor for developing schizophrenia.

A central conceptual issue in the investigation of the etiology of schizophrenia is whether schizophrenia is a neurodevelopmental or a neurodegenerative disorder. Is the cause of schizophrenia to be found in the failure of the normal development of the brain, or is it to be found in a disease process that alters a normally developed brain? Both these options, or a combination of these options, may be true because the schizophrenia syndrome probably represents more than one disease process, or a developmental abnormality may increase the risk for the subsequent occurrence of the disorder. Although Kraepelin believed that schizophrenia had an early onset and was a chronic deteriorating disorder, the examination of the clinical course of the illness has not been helpful in clarifying this issue. Subtle neurological manifestations, cognitive dysfunction, and disturbances in affect are often present early in the course of illness, usually prior to the onset of hallucinations and delusions, and perhaps from birth. However, it is not clear whether these abnormalities reflect abnormal brain development or are the consequences of an early lesion to a normal brain. Nor is it clear whether the early morbid picture progresses into the full manifestation of psychosis or whether early morbidity represents a vulnerability state susceptible to expressing psychosis in the context of a later lesion, or stressful new demands on cognition and interpersonal skills later in adolescence and early adulthood. It is clear that the illness process usually plateaus within the first 5 to 10 years of psychosis and does not manifest progressive deterioration throughout its course. Late-life improvement, perhaps based on a decrease in the intensity of the psychotic component of the illness, is more typical than continued progression.

An alternative perspective, which has produced somewhat less ambiguous results, is the neuropathological investigation of schizophrenia. Although there are sporadic reports of gliosis in schizophrenic brains, which may indicate the presence of a neurodegenerative disease process and subsequent neuropathological response, the preponderance of current evidence is consistent with the hypothesis that schizophrenia is a neurodevelopmental disorder. Of particular relevance in this regard are the neuropsychological, cognitive psychological, and neuroimaging findings in first-episode cases, which tend to be similar to findings in more chronic cases and, in the few longitudinal studies, tend not to progress. Perhaps even more decisive are abnormalities in morphological features, which are believed to be developmental in nature and are associated with at least some forms of schizophrenia. Such findings range from abnormalities in peripheral development such as finger ridge formation to abnormal cell migration to landmarks of abnormal brain development such as asymmetry of the planum temporale. The consistency with which the known data point to early deviations in the development of the central nervous system has been useful in focusing theory and investigative work.

The explosion of information on the neurobiology of brain development has led to considerable new knowledge on the potential mechanisms of pathogenic influences. It is now clear that subtle deviations in the development of the brain could create dysfunctions associated with specific behaviors. Postmortem findings of abnormalities in neural plate formation, which suggest a deviation in programmed cell migration or reduced cell density, provide intriguing support for the proposition that the developmental process that establishes normal brain cytoarchitecture may have gone awry in schizophrenia. Another view is that the brain has established extensive redundancy during the developing years, and that the fine-tuning necessary for efficient functioning involves eliminating certain nerve cells and many of the synapses connecting cells. A failure to adequately prune nerve cells and synapses, or to err in selection for pruning could, in theory, underlie dysfunctions that later lead to schizophrenia symptoms. Altered nerve cell migration or pruning are speculative, but illustrate plausible mechanisms by which risk factors could alter normal brain development in schizophrenia.

Principal hypotheses regarding causation include altered expression of genes, neuroimmunovirology factors, and birth and pregnancy complications such as hypoxic

or neurotoxic damage.

Altered Expression of Genes Schizophrenia and schizophrenia-related disorders (i.e., schizotypal, schizoid, and paranoid personality disorders; schizophreniform disorder; and other nonaffective psychotic disorders) occur at an increased rate among the biological relatives of patients with schizophrenia. This increased rate is most dramatically illustrated in the case of monozygotic twins, who have an identical genetic endowment and a concordance rate for schizophrenia between 40 to 50 percent. This rate is four to five times the concordance rate in dizygotic twins or the rate of occurrence found in other first-degree relatives (i.e., siblings, parents, or offspring). The role of genetic factors is further reflected in the drop off in occurrence of schizophrenia among second- and third-degree relatives, in whom one would hypothesize a decreased genetic loading. The finding of a higher rate of schizophrenia among the biological relatives of an adopted-away person who develops schizophrenia, as compared to the adoptive, nonbiological relatives who rear the patient has added further support to the overwhelming pedigree and twin study evidence suggesting a significant genetic contribution to the etiology of schizophrenia. However, the data on monozygotic twins clearly demonstrate the fact that individuals who are genetically vulnerable to schizophrenia do not inevitably become schizophrenic; environmental factors must be involved in determining a schizophrenia outcome. If a vulnerability and liability model of schizophrenia is correct in its postulation of an environmental influence, then other biological or psychosocial environmental factors may prevent or cause schizophrenia in the genetically vulnerable individual. Possible environmental factors include the risk factors described, as well as psychosocial factors.

A major obstacle to delineating which genes are involved in schizophrenia is the fact that the mode of genetic transmission in schizophrenia is unknown. No current model (e.g., single gene dominant or recessive, polygenetic, multifactorial, or latent trait) satisfactorily accounts for the data. Determining the mode of transmission in a putative genetic disorder requires a known phenotype and genetic homogeneity across the pedigrees. Neither of these conditions is met in schizophrenia. To understand the etiology of schizophrenia, it will eventually be necessary to identify the actual genes and their products, and to evaluate their expression in the brain. The delineation of the different phenotypic manifestations of the schizophrenic genes or markers of the phenotypes is crucial, both for case ascertainment and in moving genetic inquiry closer to the neuronal effects of schizophrenia-related genes. Measures of smooth pursuit eye movements (SPEM), information processing (e.g., the continuous performance task and forced span of attention test), and sensory gating are the most prominent candidate markers. These measures have been found to distinguish schizophrenic probands and their biological relatives from control groups. Similarly, patients and their biological relatives are more likely than comparison groups to fail to inhibit neuronal response to a repeated stimuli (measured by a peak amplitude in electrical signal at about 50 milliseconds). The P50 sensory gating phenomena marker is of particular interest because it captures a basic neuronal property whose dysfunction could explain schizophrenic pathophysiology. In a recent application a defect in a neuronal mechanism that regulates response to auditory stimuli was used to define a schizophrenia phenotype, and positive linkage was found on an area of chromosome 15 with markers near the site of the a 7 nicotinic receptor. This receptor is thought to mediate normal inhibition of the auditory evoked response to the second of paired stimuli.

It has proven exceedingly difficult to progress from evidence confirming a genetic contribution to the etiology of schizophrenia to evidence implicating specific genes in the disease. Nonetheless, the area of genetic investigation is highly promising because there is unequivocal evidence for a genetic contribution to some, perhaps all, forms of the illness. There is presently an explosion of knowledge and techniques relevant to discovering the genetic basis for human disease. Linkage analysis has quickly moved from a few marker probes to banks of hundreds, and the entire genome will soon be examined with probes spaced along all chromosomes. Analytic techniques have been developed to evaluate polygenetic disorders, and gene substructure techniques now enable investigators to focus on candidate genes found to distinguish schizophrenic brains.

Neuroimmunovirology Immune and viral hypotheses of schizophrenia are as old as scientific knowledge in these areas. That a virus could cause a neuropsychiatric disease was confirmed when Pasteur isolated the rabies virus in 1881. But schizophrenia is not an acute encephalitis or a fulminating infection; it involves more subtle pathophysiological mechanisms, which make it more difficult to establish etiology. Furthermore, the epidemiological data supporting an infectious theory, although interesting, is weak. Schizophrenia may have a north to south prevalence gradient in the Northern hemisphere (south to north in the Southern hemisphere), may be endemic to a few areas (e.g., northern Sweden), has a winter birth excess, and, similar to multiple sclerosis, has monozygotic twin discordance. However, it has been difficult to conduct definitive studies of immunovirological hypotheses because any potential marker of an immune or viral process associated with schizophrenia is applicable to only some cases of schizophrenia and is subject to interpretation as being due to conditions associated with the disease (e.g., crowding of chronically hospitalized patients, exposure of chronic patients living in low socioeconomic circumstances, and poor health habits).

Viral theories remain popular despite the difficulty of validating any particular version. Their popularity stems from the fact that several specific viral theories have the power to explain the particular localization of pathology necessary to account for a range of manifestations in schizophrenia without overt febrile encephalitis. The six general pathogenic models of viral and immune pathophysiology relevant to schizophrenia are described next.

Retroviral Infection A retrovirus can insert itself into the genome and thereby alter it which could initiate a genetic contribution to schizophrenia. It is postulated that the retrovirus inserts itself into the genome and alters the expression of the host's own genes and the genes of the host's offspring toward the development of schizophrenia (the virogene hypothesis). There is no evidence at present to support the retrovirus theory of schizophrenia, and at least one study has failed to find retrovirus-associated enzymes that would be present in an active infection but not in a virogene scenario.

Current or Active Viral Infection Many researchers postulate that viruses with an affinity for the central nervous system are involved in the etiology of schizophrenia. It is hypothesized that either a neurotropic virus infects nerve cells in discrete parts of the brain and causes sustained alterations in the functioning of the involved neural systems, or that byproducts of a viral infection have direct toxic effects on nerve cell functioning. Abnormal immune indices have been reported in schizophrenia and could be indicative of an active infectious process; however, most investigators consider the viral factor to be an early event that results in ensuing brain damage, which in twins has a long-lasting effect.

An alternative formulation of this hypothesis is based on the observation that viruses can infect the brain, with substantive disease manifestations only showing up many years later. In theory, this could account for the subtle early manifestations frequently observed in schizophrenic patients, which are followed by more intense symptom manifestations 10 to 30 years later.

A substantial challenge to either formulation of the current or active viral infection hypothesis is the absence of direct evidence substantiating a viral etiology, including the lack of physical signs of encephalitis (e.g., lymphocytic infiltrate) in postmortem tissue and the failure to recover or isolate a putative agent.

Past Viral Infection This hypothesis posits a virus infecting certain brain tissues either early in life to create a vulnerability to schizophrenia or as a causal mechanism for the initial illness processes that later lead to the picture of classic schizophrenia. The resulting tissue damage produces long-lasting alterations in neural systems, leading to schizophrenia manifestations without persistent viral infection. Gliosis, sometimes observed in postmortem tissue, would support the proposition of an earlier viral infection, and would also help account for the fact that signs of encephalitis are not ordinarily observed in the postmortem brain tissue of schizophrenia patients. A limited number of experiments have been unsuccessful in using brain material from schizophrenic patients as a source for transmitting central nervous system (CNS) viral infection into the brain tissue of other species. Although many viruses do not easily cross species, these studies lend some support to the proposition that even if a virus is relevant to the etiology of schizophrenia, it is not causing an active infection at the time of patient death.

Virally Activated Immunopathology One of two general mechanisms is proposed in this category. The first is based on the observation that viruses are normally endogenous to the human brain and are discontinuously or focally distributed in the brain. Periodic viral reactivation of these foci normally does not result in psychotic symptoms. However, in an individual with a genetically or environmentally determined abnormal immune response to viruses, it is hypothesized that viral reactivation could result in an induction of schizophrenic psychopathology. This theory regards the products of immunoreactivity, such as alpha interferon, as the mediators of the pathogenic influence. There is little direct evidence to support this hypothesis, but it receives indirect support from findings of abnormalities in alpha interferon responsiveness in schizophrenic patients as compared to normal controls.

The second mechanism in this category is that the virus may induce the host to fail to recognize its own tissues as “self” and, as a consequence, mount a destructive immune response against them. The virus may do this by altering some cellular component, such as normally cryptic neural cell surface proteins, causing it to stimulate a host response. A cytotoxic or antibody response would cause direct interference of nerve-cell function by either destruction of the cells or, in the case of receptor proteins, altered neurotransmission.

Autoimmune Pathology The aforementioned viral induction of an autoimmune pathology is an example of this pathogenic model. Schizophrenia has also been hypothesized to be an idiopathic autoimmune disease, such as rheumatoid arthritis or systemic lupus erythematosus; wherein, for reasons that are not entirely clear but probably involve genetics, some tissues are not recognized as self and become the target of immune response.

Secondary Influences: In Utero Exposure to Maternal Infection A number of epidemiological studies have reported that women who are exposed to influenza epidemics during the second trimester of pregnancy are more likely to give birth to offspring who are at increased risk for schizophrenia. This observation raises the possibility that some attribute of maternal infection such as fever or cytokine activation perturbates normal brain development during the period of active neural cell migration. This interesting etiological angle has recently been challenged by studies attempting to assess whether the mother was actually infected, rather than simply being exposed to an epidemic. Such case ascertainment might strengthen the finding, but at present this type of study can only be validly conducted using a prospective design and contemporaneous serological and molecular diagnostic techniques.

Birth and Pregnancy Complications Infants born with a history of pregnancy or birth complications are at increased risk for developing schizophrenia as adults. The reason for this has not been established. The following plausible explanations, which are not mutually exclusive, guide present-day research.

1. The genes that create vulnerability for schizophrenia may also alter early embryonic development in a manner that leads to increased likelihood of gestational and birth complications.
2. Adverse influences on the developing brain during early gestation create a risk for both birth complications and schizophrenia. The potential role of Rh incompatibility as a risk factor for schizophrenia is an interesting example of this proposition.
3. Gestational or birth complications may cause hypoxic damage. Brain regions most frequently implicated as deviant in schizophrenia (e.g., hippocampus) are among the areas in the developing brain that are most sensitive to hypoxia.

PATHOPHYSIOLOGY

Schizophrenia is a disease of the brain. However, it is easier to make this assertion than to document any actual deviations in brain physiology. Since the illness represents a disturbance in some, but not all, brain functions, it is reasonable to suppose that specific areas or neural circuits of the brain are involved and that the manifestations of schizophrenia must necessarily involve altered processing of physiological information; this altered processing would, in turn, be dependent on disturbances of cytoarchitectural, biochemical, or electrophysiological properties of the neural systems.

Throughout most of this century examination of postmortem brain tissue has been the principal source of data with relevance to the neuroanatomy of schizophrenia. Early reference to schizophrenia as “the graveyard of neuropathology” was not because of a lack of neuropathological findings, but rather because of the lack of a discernible pattern in the frequently observed pathological findings and the possibility that deviations were either artifactual in nature or were a consequence, rather than a cause, of the disease. For example, head trauma and viral infections affecting the brain would be more common in crowded custodial hospitals than in typical comparison groups. Moreover, the widespread use of neuroleptic drugs in the treatment of schizophrenia introduced additional artifacts in the investigation of brain pathophysiology. Finally, knowledge of brain-behavioral relations was not sufficiently detailed to guide neuropathological inquiry during much of this century.

Scientists have long been keenly aware of the necessity for the development of noninvasive techniques to study the functioning brain of living patients. This is particularly important in the absence of valid animal models. During the middle third of this century, pneumoencephalography (PEG) provided substantial evidence for enlarged brain ventricles, suggesting diminished tissue in schizophrenia compared to controls. Electroencephalography (EEG) provided nformation on cortical surface electrical activity, but neither PEG nor EEG techniques could provide a comprehensive evaluation of the functioning human brain.

The development of structural (e.g., computerized axial tomography [CT] and magnetic resonance imaging [MRI]) and functional (e.g., positron emission tomography [PET], single photon emission computerized tomography [SPECT], functional MRI, magnetoencephalography, and MR spectroscopy) in vivo imaging techniques have made a more detailed view of brain structure and physiology possible. These techniques have become available at a time when a better understanding of the interconnections between cortical and subcortical structures and their implications for brain-behavior relations is emerging from preclinical studies of the brain. CT studies have replicated the PEG observation of enlarged ventricles and have further shown that a substantial proportion of schizophrenic patients, in comparison to normal controls, exhibit increased sulcal widening. These results suggest that schizophrenic patients may have relatively less brain tissue, a condition that could represent either a failure to develop or a subsequent loss of tissue. With its enhanced gray and white matter resolution, MRI is able to provide a far more detailed assessment of specific brain structures. Studies employing MRI have found evidence in schizophrenic patients for decreased cortical gray matter, especially in the temporal cortex, decreased volume of limbic system structures, (e.g., the amygdala, hippocampus, and parahippocampus), and increased volume of basal ganglia nuclei. These findings are consistent with the findings of neuropathological examinations of postmortem tissue, including ultrastructural examination, which in some cases indicates cell loss, misalignment of cells, altered intracellular structure and protein expression, or gliosis.

Structural findings may help clarify the meaning of altered patterns of function. Functional imaging studies have documented abnormal patterns of glucose metabolism or blood flow during the performance of specific cognitive tasks. These techniques are also able to provide insights into the functional neuroanatomy of the various symptom complexes that characterize patients with schizophrenia, with preliminary evidence suggesting a differential association of functional indexes with the positive psychotic symptoms and primary, enduring negative symptoms (Fig. 12.1-1 and Fig. 12.1-2).

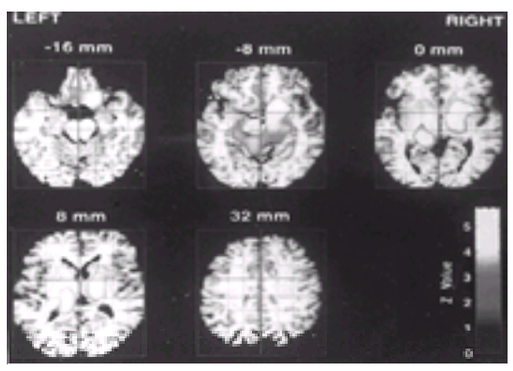

FIGURE 12.1-1 Axial sections demonstrating brain areas with significantly increased activity during auditory verbal hallucinations in the group study. Functional PET results (threshold at $Z > 3.09$, $P < 0.001$, by reference to the unit normal distribution) are displayed in color, superimposed upon a single structural T1-weighted magnetic resonance imaging (MRI) scan that has been transformed into the Talairach space for anatomical reference. Section numbers refer to the distance from the anterior commissure-posterior commissure line, with positive numbers being superior to the line. The areas of activation extend into the amygdala bilaterally, and into the right orbitofrontal cortex. Although these regions of extension are consistent with the limbic paralimbic component of activity during hallucinations, and may contribute to drive and affect in this context, definitive statements cannot be made in the absence of discrete maxima. Present-day knowledge of the pathophysiology of schizophrenia is acquired from the study of living subjects by using structural and functional imaging, and anatomically relevant symptom assessment and neuropsychological techniques. These technologies are supplemented by advances in postmortem biochemical, molecular, and structural evaluations to test increasingly sophisticated neuroanatomical and biochemical theories of schizophrenia.

Major Neuroanatomical Theories Over the last 20 years there has been a gradual evolution from conceptualizing schizophrenia as a disorder that involves discrete areas of the brain to a perspective that views schizophrenia as a disorder of brain neural circuits. These neural circuit models of the pathophysiology of schizophrenia posit that either a structural or a functional lesion disrupts the functional integrity of the entire circuit. There are several factors that have contributed to this change in perspective. First, the delineation of the neuroanatomy of the different neurotransmitter pathways has led to an increased appreciation of how different brain regions are connected with each other and how cortical and subcortical structures are able to reciprocally regulate the function of each other. For example, the identification of the mesolimbic and mesocortical dopaminergic pathways contributed to the development of neuroanatomical hypotheses implicating the prefrontal cortex and limbic system in the pathophysiology of schizophrenia. The further delineation of the reciprocal regulatory pathways between the prefrontal cortex and the limbic system, particularly the hippocampus, led to more recent formulations of these hypotheses, in which limbic and prefrontal neuroanatomical models of schizophrenia have been integrated into a single unifying neurodevelopmental theory of schizophrenia. These hypotheses propose that an early developmental lesion of the dopaminergic tracts to the prefrontal cortex results in the disturbance of both prefrontal and limbic system function, and leads to the positive and negative symptoms and cognitive impairments observed in patients with schizophrenia.

Prefrontal cortex and limbic system hypotheses are the predominant neuroanatomical hypotheses of schizophrenia. The demonstration of decreased volumes of prefrontal gray or white matter, prefrontal cortical interneuron abnormalities, disturbed prefrontal metabolism and blood flow, decreased volumes of hippocampal and entorhinal cortex, and disarray or abnormal migration of hippocampal and entorhinal neurons provide strong support for the involvement of these brain regions in the pathophysiology of schizophrenia. In the context of neural circuit hypotheses linking the prefrontal cortex and limbic system, studies demonstrating a relation between hippocampal morphological abnormalities and disturbances in prefrontal cortex metabolism or function are particularly interesting.

A second contributing factor to the adoption of a neural circuit conceptual framework has been the increased understanding of how the brain is organized into local microcircuits, which consist of the connections among afferent and efferent neurons and interneurons, and macrocircuits. An example of the latter are the segregated parallel basal ganglia-thalamocortical neural circuits, which connect the cerebral cortex with the thalamus through the basal ganglia. Each of these circuits is hypothesized to subserve a discrete range of functions. Several investigators have used these circuits as a starting point for their hypotheses of schizophrenic pathophysiology. These hypotheses differ from each other primarily on their point of emphasis. For example, integrating data from animal studies, and neurobehavioral, functional, and structural imaging studies in humans, it has been hypothesized that dysfunction of the anterior cingulate basal ganglia-thalamocortical circuit underlies the production of psychotic symptoms (Fig. 12.1-1) and dysfunction of the dorsolateral prefrontal circuit underlies the production of primary enduring negative or deficit symptoms (Fig. 12.1-2). Dysfunction in one of these circuits may be independent from dysfunction in the other.

P>A third factor has been the elucidation of the neural basis of cognitive functions observed to be impaired in patients with schizophrenia. The observation of the relationship among impaired Wisconsin Card Sort Test (WCST) performance and diminished prefrontal cortex blood flow and diminished hippocampal volume provides strong support for the validity of prefrontal cortex or limbic system neuroanatomical models. Similarly, the delineation of the neural circuits for language and attention or information processing have influenced the conceptualization of schizophrenia pathophysiology. The classic language circuit, which includes Wernicke's and Broca's areas and associated cortical and subcortical structures, has been hypothesized to be involved in the production of hallucinations, delusions, and positive formal thought disorder. This hypothesis is the most important alternative to the anterior cingulate hypothesis for positive symptoms. The involvement of this circuit, at least for auditory hallucinations, has been documented in a number of functional imaging studies contrasting hallucinating versus nonhallucinating patients.

Attention and information processing abnormalities are routinely observed in patients with schizophrenia. The type of abnormalities range from disturbances in sensory gating to disturbances in visual information processing. The latter impairments have been argued to be selectively related to negative symptoms. The overlap between brain regions that have been implicated in the production of negative symptoms and the visual information processing neural circuit, which includes inferior and superior parietal and prefrontal cortices, caudate and thalamic nuclei, and the reticular activating system, provides a neuroanatomical rationale for the relationship between these two dimensions of schizophrenia and a conceptual framework for future studies of the neuroanatomy of negative symptoms.

The development of neural circuit hypotheses offers tremendous advantages to the investigation of the neuroanatomy of schizophrenia. First, these hypotheses more accurately reflect the actual organization of the brain. Second, models of neural circuit hypotheses can be developed to investigate how perturbations of circuit function can lead to schizophrenia signs and symptoms. Neural circuit models have been created for both the cognitive and symptom manifestations of schizophrenia. Third, neural circuit hypotheses provide a conceptual framework for hypothesis-testing studies and optimize the interpretation of information derived from current brain imaging and postmortem studies. Finally, the use of neural circuit models implicates brain regions, such as the thalamus and the cerebellum, that are not typically conceptualized as being central to the neuroanatomy of schizophrenia.

Major Biochemical Theories Information is processed in neuronal networks through the transmission of an electrical signal from a nerve cell through its axon and across synapses to postsynaptic receptors on other nerve cell components. Nerve cells generally receive, process, and send signals to and from thousands of other cells. The transmission of the signal across the synapse and the processing of the signal within a cell involve a complex series of biochemical events that require large amounts of energy and include gene expression and the synthesis and degradation of protein. It is evident that physiological function in any brain system involves the chemistry of that system, and that dysfunction can emanate from these biochemical processes. It is therefore natural to assume that the biochemistry of the brain plays a fundamental role in the disruptions of brain function involved in schizophrenia. The move from a general concept of the biochemistry of schizophrenia to specific theories is based on two principal sources of knowledge. The first is an ever-increasing understanding of intracellular communication from the cell membrane to the nucleus and the cell's genetic material and of intercellular communication through the various neurotransmitter systems of the brain. The second source is knowledge of the mechanism of action of drugs that can induce schizophrenia-like behaviors or that alter symptom expression in patients with schizophrenia. Our knowledge of cellular communication and the pharmacological actions of antipsychotic drugs have led to biochemical hypotheses involving dopamine, noradrenalin, serotonin, acetylcholine, glutamate, and several neuromodulatory peptides and their receptors. Because there are many possibilities, it is important to understand the general development of a biochemical hypothesis of schizophrenia, of which the dopamine hypothesis is the most prominent and enduring.

Dopamine and Schizophrenia The hyperdopamineric hypothesis of schizophrenia arose from two sets of observations of drug action relating to the dopaminergic system. Drugs that increase dopamine system activity, such as d-amphetamine, cocaine, levodopa (Larodopa), and methylphenidate (Ritalin), can induce a paranoid psychosis that is similar to some aspects of schizophrenia. When administered to schizophrenic patients, these compounds may produce a transitory worsening of symptoms, especially in the area of hallucinations, delusions, and thought disturbance. In contrast, drugs that share the capacity to block postsynaptic dopamine receptors reduce the symptoms of schizophrenia. Substantial evidence supports the role of postsynaptic dopamine blockade as an initiating factor in a cascade of events responsible for the mode of therapeutic action of antipsychotic drugs. Other mechanisms, such as depolarization blockade, have been implicated as plausible explanations for long-term antipsychotic effects. That these actions are actually corrective for the pathophysiological disturbance in schizophrenia is suggested by the fact that dopamine-stimulating drugs can worsen schizophrenic symptoms or induce psychosis. This rationale for the role of dopamine excess, particularly for the cognitive and positive symptom aspects of schizophrenia, is compelling.

However, despite the compelling evidence for the role of dopamine in schizophrenia, testing the hypothesis has proven problematic. Clinical studies across a broad range of indices of dopamine metabolism have been characterized by marked variability in results. The most decisive clinical testing of the hypothesis has been at the level of observed drug action and symptom manipulation. Studies aimed at measuring abnormal concentrations of dopamine or its metabolites in blood, urine, and spinal fluid are confronted by problems that are almost insurmountable. In large fluid compartments, alterations in dopamine metabolism associated with schizophrenia will represent only a minor contribution to the particular index of dopamine metabolism; spinal fluid necessarily provides a summation of total brain activity, most of which is not considered germane to schizophrenia, and blood and urine provide even more indirect indices.

Functional imaging studies provide indirect evidence of dopamine involvement through the examination of metabolic rates in brain regions where dopamine is an important neurotransmitter. For example, data confirming metabolic alterations in limbic anatomy are consistent with a disturbance in dopamine metabolism, but it is not possible to determine the extent to which this reflects an alteration of dopamine biochemistry versus an alteration of any one of a number of interacting neurotransmitter and neuromodulatory systems. A more informative approach for assessing abnormal dopamine metabolism in patients with schizophrenia is to infuse

subjects with an indirect dopamine agonist and then determine the extent to which radioligand occupancy of postsynaptic dopamine receptors is reduced by competition with the increased endogenous dopamine. The comparison of preinfusion and postinfusion radioligand occupancy provides an index of dopamine release and reuptake rates. PET studies of dopamine receptor distribution and the density of receptor expression may offer an alternative approach for documenting the dopamine hypothesis. The observation of an increased quantity of dopamine type 2 (D_2) receptors in the caudate nucleus of drug-free schizophrenic patients is an example of this approach, but replication has been difficult. The extension of this approach to other dopamine receptor types is an important new direction of research.

Finally, there is the potential for the relatively precise biochemical study of dopamine in postmortem tissue, but here, as with the use of body fluids, sources of artifact and imprecision have been difficult to manage. The concentration of a neurotransmitter in any tissue will be altered as cellular components break down following death and as small differences in dissection from brain to brain take place. The administration of neuroleptic drugs during life almost always confounds the biochemistry of postmortem tissue, and one can rarely be sure of the extent to which any biochemical finding is secondary, rather than primary, to the schizophrenic disease process. In addition, there are a large number of candidate areas for brain dysfunction, so that one may easily examine the wrong location. It is also quite possible that areas of biochemical dysfunction earlier in life are no longer dysfunctional at the time of death or that the biochemistry of death may obscure the biochemistry of life.

Despite these methodological limitations, postmortem studies have reported differences between schizophrenic and control brains. For example, increased concentration of dopamine has been found in the left amygdala (a limbic system structure) in the postmortem brains of patients with schizophrenia. This finding has been replicated and, since it is lateralized, is not likely to be an artifact. There has also been a report of an increase in D_2 postsynaptic receptors in postmortem tissue of schizophrenic patients whose medical records provided a diagnosis of schizophrenia but did not reveal neuroleptic drug use. These results suggest that the increase in binding (receptor) number is not secondary to neuroleptic drugs. The investigation of receptor abnormalities has been extended to other dopamine receptor types, and an increase of D_4 receptors in entorhinal cortex, independent of antipsychotic use, has been reported.

Although conclusive evidence for the dopamine excess theory has been elusive, the hypothesis remains a viable explanation for the positive symptoms of schizophrenia. It is a particularly robust proposition for explaining the antipsychotic effect of neuroleptic drugs. Interestingly, recent studies have suggested the possibility that a dopamine deficiency may also occur in schizophrenic patients. For example, an inverse correlation between cerebrospinal fluid (CSF) and homovanillic acid (HVA) concentrations and negative symptoms has been reported. Also, patients with influenza encephalitis, who were mistaken for being schizophrenic, tended to have emotional dullness and low drive. Similarities in these cases with aspects of Parkinson's disease (which is known to involve loss of dopamine neurons) and the fact that some of these postencephalitic patients developed Parkinson's disease, lends support to a dopamine deficiency hypothesis for the negative symptom aspect of schizophrenia. In addition, neuroleptic drugs, which are dopamine-blocking agents, produce behaviors suggestive of the negative symptoms of schizophrenia in animals and humans free of mental illness. A modification of the dopamine hypothesis, incorporating the possibility of concomitant dopamine excess and deficiency, would restrict dopamine excess to the dopaminergic pathways projecting to the basal ganglia and limbic system and dopamine deficiency to the mesocortical pathways. Hypofunction of the mesocortical neurons would account for the negative symptoms of schizophrenia.

Glutamate and Schizophrenia Glutamate is the major excitatory neurotransmitter in the brain. Interest in the possible role of glutamate in the pathophysiology of schizophrenia has emerged from an increased understanding of the N-methyl- D-aspartate (NMDA) receptor complex, a major glutamate system receptor; an increased understanding of the interactions between glutamatergic and dopaminergic and GABAergic systems; and observations of the acute and chronic effects of phencyclidine (PCP). The consequences of PCP use provide a compelling model of schizophrenia symptomatology. Short-term administration of PCP produces symptoms that have been argued to mimic both the positive and negative symptoms of schizophrenia. Chronic administration produces a hypodopaminergic state in the prefrontal cortex, a state that has been argued to result in negative symptoms. PCP occupies receptors within the open calcium channels of the NMDA receptor complex, thereby blocking ion flow. PCP and the analogue ketamine (Ketalar) interfere with glutamatergic transmission. In addition to the observation of schizophrenia-like symptomatology in humans abusing PCP or ketamine has been used in the laboratory and has been observed to produce transitory mild manifestations of positive and negative symptoms in normal volunteers and a transitory and mild worsening of positive symptoms in patients with schizophrenia. Activation of dopamine receptors inhibiting glutamatergic neurons or decreased NMDA-mediated inhibition of dopamine neurons, either directly or through the actions of GABAergic interneurons, could be associated with a dopamine-excess psychosis (Fig. 12.1-3). These considerations support a hypoglutamatergic hypothesis for schizophrenia pathophysiology and predict a therapeutic effect for compounds activating the NMDA receptor complex. This is a difficult strategy to implement because excessive glutamatergic activity is neurotoxic; however, activation of the NMDA receptor complex via the glycine site with either glycine or d-cycloserine has been reported to alleviate negative symptoms in patients with schizophrenia.

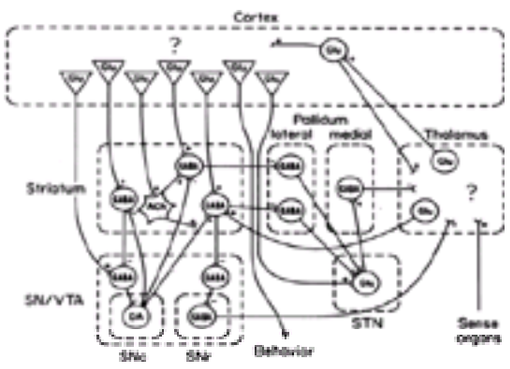

FIGURE 12.1-3 A tentative scheme of interactions between glutamate and dopamine in the basal ganglia. The cholinergic interneurone in the striatum is a large, aspiny cell with a rich collateral network that can be assumed to make synaptic contacts with a large number of other striatal cells. The cholinergic interneurone receives a cortical glutamatergic input on its soma, while its axon terminals are in synaptic contact with medium-sized, spiny GABAergic output neurones. Only two such GABA neurons are shown but in reality it is reasonable to assume that one cholinergic neurone innervates many GABAergic neurones. The cholinergic interneurone also makes contact (although maybe not forming a real synapse) with dopaminergic nerve terminals. From the way the synapses are drawn here, the cortex would be able to control the activity in the GABAergic output neurones projecting to the thalamus via the medial segment of the globus pallidus (partly via the subthalamic nucleus and substantia nigra pars reticulata. In this manner the cortex can selectively suppress impulse flow in one subpopulation of GABAergic projection neurones while facilitating impulse flow in another, thus presumably enabling a meaningful behavior by suppressing irrelevant locomotor programs. The importance of glutamatergic pathways for maintaining a purposeful behavior is revealed by the primitive locomotor pattern that results from treatment with the NMDA antagonist MK-801.
For the sake of simplification, the different thalamic nuclei are not shown. Conceivably, striatopallido-thalamic neurones can influence the entire thalamus via, for example, the reticular nucleus, which communicates with all other thalamic nuclei. Apart from the corticostriatal glutamatergic pathway, there are at least three other corticifugal systems that the cortex can use to protect itself from overstimulation: (1) the corticonigral projection; (2) the corticothalamic projection, which terminates in the thalamic intralaminar nuclei, from which a thalamostriatal projection originates; and (3) the corticosubthalamic projection.

Abbreviations: DA, dopamine; Glu, glutamate; Snc, Substantia nigra pars compacta; Snr, substantia nigra pars reticulata; STN, subthalamic nucleus; VTA, ventral tegmental area. Trends Neurosci *13:*896, 1990.)

The glutamatergic hypothesis exemplifies a major transition that has occurred recently in the biochemistry of schizophrenia. Prior to this transition, observations of drug actions in schizophrenia first led to clinical treatment and then to the advancement of the pathophysiological theory of schizophrenia. With the ever-increasing knowledge of the neural organization of the brain and of the various properties and receptor sites of neurotransmitters, it is now possible to postulate pathophysiological theory first and then attempt to derive new clinical treatment from theory. New treatment approaches will be developed more rapidly in the future, based on a broader range of pathophysiological hypotheses and the availability of animal models for aspects of the illness that are not therapeutically responsive to dopamine blockade-based medications.

Other Neurotransmitters and Neuromodulators Any neurotransmitter involved in neural systems subserving behaviors whose disruption could result in symptoms

of schizophrenia is naturally of interest in schizophrenia theory and research. The rich innervation of the frontal cortex and limbic system with serotonergic neurons, the modulatory effect of these neurons on dopaminergic neurons, and the involvement of these pathways in the regulation of a broad range of complex functions has led several investigators to posit a pathophysiological role for serotonin in schizophrenia. These hypotheses have taken various forms over the course of the last four decades. In the early 1950s a serotonergic deficiency hypothesis was proposed for schizophrenia. Observations of hallucinations in subjects who had ingested lysergic acid diethylamide (LSD), a compound that is chemically similar to serotonin and blocks serotonin receptor sites, furthered the hyposerotonin hypothesis. However, drugs that decrease serotonin activity tend to reduce schizophrenic symptoms (e.g., reserpine [Serpasil], some antipsychotics, clozapine [Clozaril]), and have diminished interest in the deficiency hypothesis.

Of greater current interest are hypotheses positing that a serotonin excess causes positive and negative symptomatology. The robust serotonergic antagonist activity of clozapine and other new-generation antipsychotics, coupled with clozapine's demonstrated effectiveness for positive symptoms in chronic, treatment-resistant patients have contributed to the current emphasis on this proposition. However, several studies have raised questions about the efficacy of serotonin antagonists for either negative symptoms broadly defined or deficit symptoms. Moreover, pharmacological modification of serotonin systems with specific serotonergic agents has not produced impressive clinical results.

As with the dopamine hypothesis, the strength of the support for the serotonin hypothesis is derived from reasoning based on knowledge of brain and behavior relationships, the anatomy of neural transmitter systems, and drug mechanism of actions, and the same weaknesses in the clinical and postmortem studies on dopamine apply to serotonin also.

A similar rationale can be applied to construct hypotheses implicating norepinephrine in the psychopathology of schizophrenia. Anhedonia, (i.e., the impaired capacity for emotional gratification and the decreased ability to experience pleasure), has long been noted to be a prominent feature of schizophrenia. A selective neuronal degeneration within the norepinephrine reward neural system could account for this symptom. However, biochemical and pharmacological data bearing on this proposal are inconclusive. As with dopamine and serotonin, there have been both noradrenergic excess and deficiency pathophysiological hypotheses.

Neuromodulatory hypotheses focus on the fact that neuropeptides, such as substance P and neurotensin, are co-localized with the catecholamine and indolamine neurotransmitters, and influence the action of these neurotransmitters. Alterations in neuromodulatory mechanisms could facilitate, inhibit, or otherwise alter the pattern of firing in these neuronal systems. Explorations of neuromodulator hypotheses are preliminary and inconclusive at this time.

Integrative Hypotheses The natural evolution of pathophysiological hypotheses of schizophrenia is the development of comprehensive models that integrate both neuroanatomical and biochemical hypotheses. The superimposition of the neurotransmitters involved in the connections among cortical, basal ganglia, and thalamic structures that comprise the basal ganglia-thalamocortical neural circuits is a prime example of this approach. Through glutamate projections from the cortex to the basal ganglia, the cerebral cortex facilitates the performance of selected behaviors while inhibiting others. The excitatory glutamatergic neurons terminate on GABAergic and cholinergic neurons, which in turn suppress or excite dopaminergic and other neurons. This regulatory activity can enable the cortex to protect itself from overstimulation from thalamocortical neurons. The elucidation of the neuroanatomy and biochemistry of cortical microcircuits has also served as a starting point for the articulation of pathophysiological hypotheses of schizophrenia. These integrative models provide a framework for identifying potential neurotransmitter targets for drug development, as well as providing explanatory models for the observed effects of pharmacological agents in patients with schizophrenia (e.g., PCP-induced psychotic symptoms mediated through the interactions of glutamate and other neurotransmitter systems in the neocortex, basal ganglia, or limbic system structures).

DIAGNOSIS

The history of the diagnosis of schizophrenia is often misunderstood, which has led to erroneous conclusions about the validity of the diagnostic process. Throughout most of the twentieth century there has been substantial agreement among diagnosticians throughout the world, using seemingly divergent diagnostic approaches, in the recognition of typical cases of schizophrenia. There has also been no difficulty in distinguishing schizophrenia from normality. Although useful refinements have evolved, diagnostic systems in place when effective drug treatment was introduced in 1952 were capable of identifying suitable subjects for therapy.

The major areas of disagreement among diagnostic approaches were how broad the definition of schizophrenia should be; whether positive symptoms, including hallucinations, delusions, and positive formal thought disorder, were required; and whether positive symptoms in the absence of known organic causes always signified schizophrenia. In general, the broader the definition the greater the likelihood that more subtle cases would be included and the greater the likelihood that disagreement would arise regarding the diagnosis of such cases. Even in such cases, there was little disagreement regarding the presence of psychopathology; rather, when present, the disagreement focused on whether the psychopathology observed was part of schizophrenia. This difference in viewpoint did create problems, which became important as different types of drugs were found to be effective for different classes of illness.

The success of the scientific search for more effective drugs for specific disease classes created the urgency to establish an agreed-upon diagnostic approach to schizophrenia and the major affective disorders in order to maximize appropriateness of treatment. The need for such agreement was also highlighted by the results of an influential study comparing diagnostic approaches in the United Kingdom with those in New York City, in which it was convincingly demonstrated that American diagnosticians employed a much broader and less defined construct of schizophrenia than their British counterparts. For a time in North America, especially in the northeastern United States, a broad definition of schizophrenia tended to include two categories of patients ill suited for the standard pharmacological treatment of schizophrenia. The first category was patients with bipolar or major depressive disorders with psychotic features, who, if erroneously considered to have schizophrenia, were administered antipsychotic medication rather than the more specific and effective treatments available for patients with these disorders (i.e., antidepressants, lithium, and electroconvulsive therapy). The second category included patients with schizophrenia spectrum personality disorders, (i.e., schizoid, schizotypal, and borderline personality disorders). These patients were sometimes misdiagnosed as having schizophrenia and were thus likely to be administered drugs designed for the positive symptoms of schizophrenia, which provided them little benefit and subjected them to substantial risk.

A considerable body of research during the 1960s and 1970s clarified many diagnostic issues and set the stage for the development of a diagnostic system implemented in the third edition of the American Psychiatric Association's *Diagnostic and Statistical Manual of the Mental Disorders* (DSM-III). The DSM-III approach, with specified symptom-based diagnostic criteria and demonstrated reliability, is now the accepted diagnostic system in North America and throughout the international research community. The use of this approach has led to the reliable and consistent differential diagnosis of schizophrenia, which has enhanced scientific and clinical communication and substantially increased the likelihood of the effective use of diagnostically specific treatments. The DSM-III approach has been retained in the revised third edition of DSM (DSM-III-R) and the fourth edition of DSM (DSM-IV) and has been incorporated in the International Classification of Diseases (ICD) diagnostic system. The ultimate goal is to standardize the diagnosis of schizophrenia across all diagnostic systems. Substantial progress has been made in this area, with extensive integration between DSM-IV and the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10).

Beyond Diagnosis A valid diagnostic system for schizophrenia has considerable utility for clinical and epidemiological purposes. It is now possible to estimate the occurrence of schizophrenia accurately, to identify individuals suffering from the illness process, to guide treatment and rehabilitation considerations, and to differentiate schizophrenia from other illnesses with similar manifestations but with importantly different treatment requirements. However, diagnosis at the syndrome level has not been an adequate guide to the scientific study of either the etiology or pathophysiology of schizophrenia nor to the development of treatments for all key features of the illness.

The traditional approach to reducing the heterogeneity of the schizophrenia syndrome has been to delineate subtypes and attempt to confirm or disprove their validity. The classic subtypes, disorganized (DSM-IV) or hebephrenic (ICD-10), paranoid (DSM-IV and ICD-10), catatonic (DSM-IV and ICD-10) and simple schizophrenia (ICD-10) or simple deteriorative disorder (DSM-IV) represent the most frequently used subtype approach for reducing heterogeneity. Although important differences such as age of onset and pattern of symptom development validate these subtypes, the classical subtypes have not provided a strong heuristic framework for the study of differential etiology and pathophysiology.

In light of the limitations of the classic subtypes, alternative approaches have been sought to reduce syndromal heterogeneity. One approach that has received considerable attention is the proposition that specific symptom complexes define pathological entities that differ from one another in neuroanatomical pathophysiology, in course and onset, in treatment requirements, and possibly in etiology. Interest in the proposition that symptom complexes, or domains of psychopathology, represent unique disease processes has emerged from the extensive study of the longitudinal patterns of symptom manifestations in patients with schizophrenia. A large number of studies have documented that the symptoms of schizophrenia usually segregate into three semi-independent symptom complexes: (1) hallucinations and delusions; (2) disorganized behavior, including positive formal thought disorder, bizarre behavior, and inappropriate affect; and (3) primary, enduring negative or deficit symptoms, including restricted affective experience and expression, diminished drive, and poverty of thought. Longitudinal studies provide

support for the long-term independence and stability of these domains. These results suggest a modification of the central paradigm for the study of the etiopathophysiology and neuroanatomy of schizophrenia: the study of the etiopathophysiology and neuroanatomy of schizophrenia becomes the study of the etiopathophysiology and neuroanatomy of hallucinations and delusions, of disorganized behavior, and of negative symptoms. This approach is also germane for treatment and rehabilitation studies.

The domains approach has been extensively applied to the investigation of deficit symptoms. These symptoms differ from the other symptom complexes in their familial heritability, neuroanatomy as evidenced in both structural and functional neuroimaging studies, and response to antipsychotic treatment. Long-term outcome, season of birth, and age of onset are also distinctive. These results provide strong support for the heuristic value of this approach and raise the hope that this approach to heterogeneity reduction will yield more decisive data in studies of etiopathophysiology and neuroanatomy and will provide explicit information regarding the efficacy profile of pharmacological treatments.

Cognitive Impairment In addition to the three symptom complexes, patients with schizophrenia also manifest a broad array of cognitive impairments, including impaired performance on measures reflecting attention, information processing, executive function, memory, and language capabilities. These manifestations are not used in the diagnosis of schizophrenia, but are a critical component of the disorder. On a theoretical level, attentional and verbal memory impairments are conceptualized as vulnerability markers, which may be useful in defining schizophrenia phenotypes, may be applicable to early detection, and may provide a basis for creating new models for treatment development. Cognitive impairments are also hypothesized to meaningfully determine many aspects of quality of life and functional capacity and adjustment. Moreover, the neuropsychological assessment of cognitive impairments permits probablistic anatomical inferences, and the use of cognitive tasks that assess these impairments has become increasingly important in guiding functional neuroimaging studies.

The relations among cognitive impairments and the symptoms of schizophrenia are unclear. For many years, cognitive impairments were conceptualized as the psychological foundations of symptom manifestations. However, there is a large body of evidence that has documented the relative independence of cognitive impairments and symptoms. For example, clinical trials have repeatedly demonstrated that large changes in symptom status can occur without a corresponding improvement in cognitive function as reflected in cognitive or neuropsychological test performance. Parenthetically, these trials have also revealed the lack of effective pharmacological treatment for these fundamental manifestations of the illness. The use of the three-symptom complex model and less complex cognitive paradigms may lead to the elucidation of possible relationships between the various cognitive impairments and the symptom complexes.

In summary, the manifestations of schizophrenia have been consistently described since the turn of the century. The conceptualization of schizophrenia as a clinical syndrome, importantly distinguished from manic-depressive and other psychoses, has been validated. Research on diagnostic systems has produced modest modifications in classification and has demonstrated the adequacy of the reliability and validity of current approaches. It has also produced a reasonable degree of uniformity in international usage that serves both clinical and scientific purposes. Because the clinical syndrome of schizophrenia probably represents more than one pathological process, specifically addressing the etiology, pathophysiology, and treatment of specific symptom complexes offers important new power to research designs.

COURSE, PROGNOSIS, AND OUTCOME

In his pioneering description of schizophrenia Emil Kraepelin argued that schizophrenia was characterized by an early onset, which was followed by a chronic deteriorating course. Eugen Bleueler suggested that a chronic deteriorating course was a frequent but not a necessary outcome. However, neither of these early workers took into account the extent to which their observations were based on chronic, institutionalized populations. Extensive longitudinal-outcome data on patients who were treated prior to and after the introduction of antipsychotics support a more optimistic prognostic picture. Whereas schizophrenia is always a serious disease, it is now clear that patients suffering from it may follow a variety of courses over the long term, including some that are relatively benign. It remains true that although schizophrenia does not always progress to a deteriorated end state, there are substantial and enduring adverse consequences for most patients.

The course of the illness can be divided into four major epochs: premorbid adjustment, onset of illness, middle course, and late course.

Premorbid Adjustment Premorbid adjustment refers to symptoms that appear prior to the onset of positive symptoms. Twenty-five to fifty percent of patients with schizophrenia have abnormal premorbid adjustment, which may be manifested as poor social and scholastic adjustment or diminished social drive; decreased emotional responsivity; withdrawn, introverted, suspicious, or impulsive behavior; idiosyncratic responses to ordinary events or circumstances; short attention span; and delayed developmental milestones or poor motor and sensorimotor coordination. Childhood asociality, a trait that has been referred to in the past as a poor prognostic indicator, is probably more appropriately conceptualized as the early morbid manifestation of deficit symptomatology. Disturbances in social behavior have been picked up as early as infancy by workers who have noticed a lack of responsiveness and emotional expression in infants who later developed schizophrenia. It is also evident, however, that deficit symptoms may have their onset following psychosis and become part of the progression of the illness during the initial years of psychosis. Subtle forms of positive formal thought disorder may also be manifest before overt hallucinations and delusions occur. Studies that have evaluated the development of the offspring of mothers with schizophrenia have observed cognitive difficulties during the pre-teen and teenage years in these high-risk children.

Onset of Illness The second epoch, onset of illness, typically refers to the onset of positive symptoms (i.e., hallucinations, delusions, and positive formal thought disorder). The onset of positive symptoms is insidious in about half of the patients, with the earliest signs of involvement occurring many years before the appearance of the more blatant manifestations of psychosis. In other cases, onset is relatively sudden or acute, with the onset of positive symptoms marking a sharp deviation in development. Patients with the insidious type of onset are very likely to have a poor intermediate course and a poor long-term outcome. In contrast, patients with normal development and ordinary personality attributes who experience a relatively sudden appearance of hallucinations, delusions, and disorganized thought vary widely in their intermediate and long-term outcomes.

Although the rate of schizophrenia is relatively similar in women and men, there are gender differences in age of onset. In males, the peak age of onset ranges from 17 to 27, whereas females tend to have a wider and flatter window of vulnerability, with age of onset generally between ages 17 and 37.

Middle Course The middle epoch or course of illness may be subdivided into two subepochs. The first 5 to 10 years of illness are frequently characterized by multiple exacerbations of positive symptoms, during which a patient may return to an asymptomatic baseline between episodes, or remain actively psychotic without achieving full recovery. This subepoch is followed by a plateau phase, in which patients experience a stabilization of their symptoms and a decrease in the number of exacerbations. Recent studies have made it evident that the underlying deterioration associated with schizophrenia principally occurs during the onset of illness and the first half of the middle phase, rather than over the remaining course of illness. However, complications caused by the illness lead to ever-increasing impediments to normal existence, so that secondary effects may be progressive even though the primary pathology has plateaued. For example, patients who live in understimulating environments will lose social skills and work capabilities even if their symptoms improve. Effective treatment late in the course of a chronic disease will diminish morbidity, but it will not restore lost experience and opportunity—nor will it overcome stigma. A history of disabling schizophrenia is a serious social and occupational burden regardless of the degree of recovery.

Late Course In the late epoch there is a tendency for the intensity of positive symptoms to diminish, and many patients with long-term impairments regain some degree of social and occupational competence. Although the illness becomes less disruptive and easier to manage, the effects of years of dysfunction are rarely overcome. It would be highly unusual for an individual with a chronic form of the illness to gain the niche in society and the quality of personal life that would have been possible had the illness not been present. More typically, patients continue to manifest direct signs of the illness process throughout their lives. Twenty- to forty-year follow-up studies provide a basis for estimating that approximately 55 percent of patients with schizophrenia have moderately good outcomes and 45 percent have more severe outcomes. These figures are more optimistic than earlier views for at least two reasons. First, sample selection was broader and more representative. Second, effective treatments, which make a considerable difference in the short-term course, also have a modest impact on the long-term course of the illness.

Although no present treatment approach can prevent or cure schizophrenia, some approaches have had remarkable remedial effects on course. Despite not being scientifically verified, there is considerable evidence from a large body of clinical experience that a form of schizophrenia referred to as *devastating schizophrenia*, which represented about 15 percent of the cases before the introduction of antipsychotic medication, now represents only about 5 percent of the cases. This form of the illness had an acute rather than insidious onset, but, paradoxically, had an unrelenting deteriorating course. Another line of evidence suggests that outcome may be related to the time interval between the initial detection of schizophrenia and the initiation of antipsychotic treatment. The more rapidly patients are treated, the more benign is the course of illness. This observation has led to an increased interest in establishing a methodology for early detection and the development of intensive therapeutic interventions, which combine pharmacological and psychosocial treatments, in order to ascertain whether future course can be substantially affected by treatment. There is also considerable evidence suggesting that the prophylactic use of antipsychotic medication reduces the relapse rate by more than

one-half. This fact is largely responsible for making it possible to substantially reduce inpatient care in favor of brief hospital stay, crisis intervention, and community-based treatment. The level of success associated with this major shift in primary treatment setting as well as the serious shortcomings associated with shifting care to unprepared communities are noted in the discussion on treatment and rehabilitation.

Predictors of outcome have been principally found to be related to the already-established pattern of illness, the early developmental pattern, and the emotional qualities of the patient. Patients with limited emotional expression, who demonstrate a lack of social drive and social affiliation during childhood, and who display poor social and occupational functioning in recent years, are quite likely to run a chronic course of the illness. On the other hand, patients who have a normal developmental history with an abrupt onset of psychosis, and who have not established a pattern of social and occupational failure, have a much better prognosis. There is also evidence that prognosis is better in females than males. However, some patients in the good prognosis group will progress to a devastating form of the illness. In general, there are more reliable predictors of poor than good prognosis, with prognosis uncertain until the pattern of illness has been established.

There are interesting results from the World Health Organization study of the social determinants of outcome in different cultures. This work has documented that the course of schizophrenia tends to be more benign in developing countries than in developed countries. This difference in course is generally understood as representing a psychosocial influence on course rather than cultural differences in the causes of schizophrenia. The incidence and lifetime prevalence of the disease appear to be relatively comparable across cultures and societies. One compelling explanation for the observed difference is that the sociocentric structures of developing countries place less demand on individual performance and provide a more broadly supportive interpersonal environment than do the egocentric cultures of more developed nations. With their marked emphasis on individual accomplishment and productivity, the latter nations are more demanding and stressful for those with impaired drive or impaired mental functioning. Rather than finding an appropriate, usually reduced level of functioning, the patient with schizophrenia in Western industrialized societies tends to be isolated, with greatly reduced opportunities for work and meaningful social contacts. Indicative of this lack of involvement, unemployment rates for patients with schizophrenia are over 70 percent in the United States.

TREATMENT AND REHABILITATION

The history of the care and treatment of patients with schizophrenia is replete with instances of both humane and inhumane approaches. From a practical and moral standpoint, the value of humane care is intrinsic and does not rest on scientific evaluation of efficacy. There is a large body of literature and scientific data regarding the pharmacological and psychosocial interventions and the rehabilitation of patients with schizophrenia. The general conclusions of this accumulated information are presented below.

Pharmacological Interventions Prior to 1952, there were no generally applicable, effective pharmacological treatments of schizophrenia. Reserpine had been used with some limited success, and electroconvulsive treatment (ECT) was important in reducing symptoms in the most acutely disturbed cases. This situation changed abruptly with the introduction of chlorpromazine (Thorazine) in France in 1952 and in North America in 1954, which ushered in the modern era of effective pharmacological therapy for schizophrenia.

The antipsychotic drugs used to treat schizophrenia have a wide variety of mechanisms of action, but all share the capacity to occupy postsynaptic dopamine receptors in the brain. Conventional antipsychotics or dopamine-receptor antagonists are often referred to as *neuroleptics* because of their neurological adverse effects. The new antipsychotics are less likely to exhibit these effects and have been referred to as atypical antipsychotics or serotonin-dopamine antagonists. The generally recognized clinical effect of antipsychotic drugs is to diminish symptom expression and reduce relapse rates. Although sedation may be a side effect and diminished anxiety a clinical effect, the primary value of these drugs is their remedial effect on positive symptoms, and not their sedating or tranquilizing properties. In contrast to positive symptoms, conventional antipsychotics have not been shown to be effective for either primary, enduring negative or deficit symptoms or the cognitive impairments observed in patients with schizophrenia.

Antipsychotic drugs are used throughout the world for four primary clinical purposes: (1) to manage acute positive symptomatic disturbances; (2) to induce remission from positive symptom exacerbations; (3) to maintain the achieved clinical effect over prolonged periods of time (maintenance therapy); and (4) to prevent relapses or new episodes of positive symptom expression (prophylactic therapy). A recent emphasis with regard to the use of conventional antipsychotic drugs has been on dose reduction, in the hope of diminishing adverse effects without losing clinical benefit. The intent is to administer the drugs in a manner that will increase patient compliance and avoid illness exacerbations caused by patients' discontinuing their medication.

The first atypical antipsychotic to be available for clinical use was clozapine. Clozapine has a unique mechanism of action, and was shown in the 1970s to have a superior effect on patients resistant to the therapeutic effects of conventional antipsychotics. However, patients on clozapine run an approximately 1 percent risk of agranulocytosis. This potentially lethal cessation in the production of white blood cells was associated with a series of deaths in Finland during the mid-1970s and led to a decreased use of clozapine in Europe and a failure to market the drug in the United States. Interest in clozapine in the United States was rekindled by the results of a large-scale multicenter study in chronic, treatment-resistant patients with schizophrenia. The study yielded convincing evidence of clozapine's effectiveness in ameliorating positive symptoms in approximately one-third of these patients. In addition, the study also showed that clozapine could be used with relative safety within the context of careful monitoring for agranulocytosis. Clozapine represents the first incremental gain in the effectiveness of the pharmacological agents used to treat schizophrenia since the original introduction of chlorpromazine.

The demonstration of clozapine's efficacy for treatment-resistant patients has spawned considerable interest in the development of new pharmacological treatments for schizophrenia. Risperidone (Risperdal), olanzapine (Zyprexa), quetiapine (Serlect), ziprasidone and other compounds have quickly followed. Since the specific mode of clozapine's superior therapeutic efficacy is not known, it is not possible to design new compounds with confidence that they will have superior efficacy. However, each of the new medications appears to be as effective an antipsychotic drug as the conventional antipsychotics, but with a substantially decreased adverse effect burden. This decreased adverse effect burden may result in greater effectiveness based on better patient compliance, and may reduce the incidence of long-lasting adverse effects (e.g., tardive dyskinesia). As each new drug is introduced, it will be important to examine whether the drug shares with clozapine a superior efficacy for positive symptoms. In addition, it will be important to examine if there are any meaningful advantages to using atypical antipsychotic medications in first-episode patients. Finally, future drug development must also recognize the absence of significant therapeutic efficacy of currently available medications for the primary avolitional component of the disease and the fundamental cognitive impairments detected by various psychological performance tasks. The rapidly advancing knowledge of brain biochemistry and brain-behavior relationships has set the stage for the development of new models for psychopathological processes other than positive symptoms. These new models may prove useful for screening potential novel treatments, which would enable a more comprehensive treatment of the varied manifestations of schizophrenia.

Lithium and antiepileptic, antidepressant, and antianxiety drugs have also been used to treat the positive symptoms of schizophrenia. However, these drugs have not proved to be effective alternatives to antipsychotic therapy, nor has there been a consistent demonstration of substantially enhanced benefits when they are used in combination with antipsychotics. A small subgroup of patients may be differentially responsive to a class of drugs other than antipsychotics, but in the absence of the capacity to identify in advance which patients will respond favorably, it is difficult to prove or disprove this proposition. In contrast, these drugs and a series of medications that counteract the side effects of conventional antipsychotics have been effective for co-occurring anxiety and depressive, manic, and aggressive symptoms.

Augmentation strategies have also been used for persistent negative symptoms, including deficit symptoms. These strategies have included the use of dopamine and serotonergic and noradrenergic agents. Perhaps the most promising development is the attempt to treat these symptoms by activating the NMDA receptor at the glycine site. Glycine and d-cycloserine have produced encouraging results in preliminary controlled clinical trials.

ECT was frequently used to treat patients with schizophrenia prior to the introduction of antipsychotic drugs. ECT is particularly effective in the treatment of catatonic stupor and excitement, but generally produces results similar to those obtained with antipsychotics, (i.e., a reduction of positive symptoms rather than a reversal of long-term functional impairments). Although ECT is safe and painless, its use is restricted, in part by litigation and societal attitudes, but also because any therapeutic advantage gained in an initial series of treatments is not easily maintained. Also, there is no indication that ECT is effective in patients who are resistant to conventional antipsychotics. For all of these reasons, drug treatment approaches are generally preferred.

Psychosocial Interventions The debate over whether patients should be administered pharmacological agents or psychosocial treatments has given way to the search for how these treatments should be optimally integrated. Controlled clinical trials have conclusively demonstrated that intensive psychotherapy is less effective than drug treatment; that it is not superior to less expensive, less ambitious psychosocial forms of psychotherapy; and that it should no longer be considered an alternative to the use of antipsychotic drugs. In addition, studies have repeatedly demonstrated that supportive forms of psychosocial treatment are entirely compatible with drug treatment and can increase the effectiveness of overall treatment, reduce the amount of medication necessary, enhance patient participation in

the full range of treatment, and optimize social and occupational functioning. Especially impressive are studies documenting the considerable additional benefit achieved in reducing relapse and hospitalization rates when family therapy and education programs are added to maintenance pharmacological treatment. These studies make it clear that psychosocial and rehabilitative interventions have become essential components of the comprehensive treatment of patients with schizophrenia.

Psychosocial and rehabilitation interventions include supportive, problem-solving, educationally oriented psychotherapy; family therapy and education programs aimed at helping patients and their families understand the patient's illness, reduce stress, and enhance coping capabilities; social and living skills training; vocational training, including job coaching; and the provision of supervised residential living arrangements. The development and increased utilization of psychosocial services have been complemented by the evolution of services designed to decrease the utilization of inpatient hospital services and to maintain the patient in the community. Assertive community treatment teams are designed to provide intensive outreach services to patients who are unable to be maintained in the community with traditional outpatient clinical treatment. Crisis management services, including 24-hour crisis beds and partial hospitalization programs, represent alternatives to hospitalization during periods of symptom exacerbation.

The development of these services reflects the ongoing shift in the treatment of the patient with schizophrenia from a hospital-based to a community-based system of care. When optimal treatment with these services is provided, the rewards of therapeutic accomplishment, reduction in morbidity, and economic cost benefits are profound and rival therapeutic accomplishments found anywhere in medicine. The demonstrated benefits of these services challenge the field to establish an adequate community-based treatment approach prepared to meet the challenge and demands of broad-based integrated treatment.

FUTURE DIRECTIONS

The care and study of the person afflicted with schizophrenia are extraordinarily interesting and promising. Basic brain science has matured, and technological advances permit increasingly sophisticated questions to be addressed regarding the anatomy, ultrastructure, and function of the brain. The field is closer to understanding risk factors at the level of causal mechanism, and new treatments are being developed at an increasing rate. The cadre of schizophrenologists capable of integrating basic and clinical sciences has grown substantially, and new paradigms providing heuristic advantage in the classification of psychopathological phenomena provide and address the problem of heterogeneity, which has undermined so much of the investigative work in schizophrenia. Physiological markers have been validated, and investigators are able to articulate, with ever-increasing specificity, the what and where of brain dysfunction in patients with schizophrenia.

The twenty-first century promises to be a time of fundamental discovery regarding the etiology and pathophysiology of what may be the world's most vexing public health problem. These developments have emerged at a time of decreasing stigma, increasing partnership in clinical care and research with citizen advocacy groups, and the initiation of nationwide private fundraising for research on this disease.

SUGGESTED CROSS-REFERENCES

More detailed discussions of etiology, brain structure and function, clinical features, and somatic and psychosocial treatments are presented in the other sections of Chapter 12. A detailed introduction to areas of neuroscience and cognitive science relevant to schizophrenia is provided in Section 1.2 on functional neuroanatomy, Section 1.3 on neuronal development and plasticity, Section 1.15 and Section 1.16 on brain imaging, and Section 3.1 on perception and cognition.

12.2 SCHIZOPHRENIA: EPIDEMIOLOGY

GRAYSON S. NORQUIST, M.D., M.S.P.H., AND WILLIAM E. NARROW, M.D., M.P.H.

An etiologically puzzling and clinically severe disorder, schizophrenia has long held the attention of psychiatric epidemiologists. Until fairly recently, however, efforts to elucidate the epidemiology of schizophrenia were hindered by two critical deficiencies: the lack of reliable case definition and limited generalizability of findings because of reliance on treated samples. Two lines of scientific development have converged since the late 1970s to help resolve these issues and advance epidemiological studies of schizophrenia. First was the development of *Diagnostic and Statistical Manual of Mental Disorders* (DSM), culminating in the publication of operationalized criteria for schizophrenia in the third edition of DSM (DSM-III). Second, modern epidemiological methods, particularly those of chronic disease and genetic epidemiology, have been applied to the study of schizophrenia. These methods have increased the robustness of epidemiological research findings because of their emphasis on precise study designs, representative sampling, and sophisticated techniques of data analysis.

Psychiatric epidemiology is traditionally concerned with patterns of psychopathology in human population groups and the factors that influence these patterns. It examines the occurrence of pathology in terms of time, place, and individual characteristics, in order to elucidate the etiology of illness and its population burden. In terms of schizophrenia, such research includes studies of prevalence and incidence, natural history of illness including risk and protective factors for onset, remission, and relapse; longitudinal followup of populations at high risk for schizophrenia, including children of parents with schizophrenia or relatives of a proband with schizophrenia; and genetic epidemiology, including twin, family, association, and linkage studies in samples that are representative of the persons with schizophrenia, an associated marker of interest, or a population isolate with a high prevalence of the disorder.

In epidemiology, a *population* is a collection of individuals defined by time, place, and characteristics such as age, sex, and race. Although general community populations are often studied, epidemiological study populations may be defined in other ways, including treatment status or exposure to a risk factor. For rare disorders such as schizophrenia, it is often easier to sample study cases from treated populations. However, by excluding untreated cases, the findings are not generalizable to all individuals with schizophrenia. *Point prevalence* is defined as the number of persons in a population who are affected with a disorder at a given point in time. *Incidence* is defined as the number of persons without a disorder at the beginning of a given time period who subsequently develop the disorder in that time period. A “first” or “true” incident case has never had a previous episode of disorder; a *recurrent* case has had a previous episode. *Period prevalence* includes existing cases at the beginning of a given time period (point prevalence), plus all incident cases developing in the time period, both first incidence and recurrence. An important concept in epidemiology is that prevalence is proportional to incidence and duration ($P \sim I \times d$). Thus, in a chronic condition such as schizophrenia, a steady prevalence is maintained by a long duration of illness despite a relatively low incidence rate; cutting short the duration of illness would decrease the prevalence of the condition if incidence remained unchanged.

EVOLUTION OF NOMENCLATURE AND DIAGNOSTIC CRITERIA

The value of operationalized diagnostic criteria as a commonly accepted language for clinicians and researchers cannot be overemphasized. In the United States the DSM system of classification has become the diagnostic standard for both clinical and research purposes.

DSM In 1952 the first edition of DSM (DSM-I) was published by the Mental Hospital Service of the American Psychiatric Association. DSM-I was derived largely from the section on mental disorders in the Standard Classified Nomenclature of Disease developed by the National Conference on Nomenclature of Disease in 1933. In DSM-I, “Schizophrenic Reactions” were classified under “Disorders of Psychogenic Origin or without Clearly Defined Physical Cause or Structural Change in the Brain.” and were described as “synonymous with formerly used term dementia praecox.”

It represents a group of psychotic reactions characterized by fundamental disturbances in reality relationships and concept formations, with affective, behavioral, and intellectual disturbances in varying degrees and mixtures. The disorders are marked by strong tendency to retreat from reality, by emotional disharmony, unpredictable disturbances in stream of thought, regressive behavior, and in some, by a tendency to “deterioration.” The predominant symptomatology will be the determining factor in classifying such patients into types.

The types of schizophrenic reactions were simple, hebephrenic, catatonic, paranoid, acute undifferentiated, chronic undifferentiated, schizo-affective, childhood, and residual.

DSM-II The second edition of DSM (DSM-II) was published in 1968 and was an attempt to achieve uniformity of diagnostic classification at an international level. The nomenclature used in DSM-II was based, with a few exceptions, on the terms used in the eighth revision of the World Health Organization's (WHO's) *International Statistical Classification of Diseases, Injuries, and Causes of Death* (ICD-8). DSM-II had initial attempts to remove from the diagnostic nomenclature implications about the nature or cause of a disorder. Thus, the “schizophrenic reaction” of DSM-I became “schizophrenia” in DSM-II. Attempts were also made to distinguish schizophrenia from the psychotic mood disorders. The term *schizophrenia* was defined as:

> . . . a group of disorders manifested by characteristic disturbances in thinking, mood, and behavior. Disturbances in thinking are marked by alterations of concept formation which may lead to misinterpretation of reality and sometimes to delusions and hallucinations, which frequently appear psychologically self-protective. Corollary mood changes include ambivalent, constricted, and inappropriate emotional responsiveness and loss of empathy with others. Behavior may be withdrawn, regressive and bizarre. The schizophrenias, in which the mental status is attributable primarily to a thought disorder, are to be distinguished from the Major affective illnesses which are dominated by a mood disorder. The paranoid states are distinguished from schizophrenia by the narrowness of their distortions of reality and by the absence of other psychotic symptoms.

Several subtypes remained unchanged in DSM-II: simple, hebephrenic, paranoid, childhood, and residual. Catatonic type was divided into excited and withdrawn subtypes, and schizoaffective type was divided into excited and depressed subtypes. Acute undifferentiated type was renamed acute schizophrenic episode. Latent type was distinguished from the DSM-I chronic undifferentiated type in order to cover patients unofficially diagnosed as having incipient, prepsychotic, pseudoneurotic, pseudopsychopathic, or borderline schizophrenia.

DSM-III and DSM-III-R The publication of the third edition of DSM (DSM-III) in 1980 represented a revolutionary advance in the development of a common diagnostic language for clinicians and researchers. It offered explicit criteria for diagnosing disorders based on observable signs and symptoms, rather than the earlier prose definitions that had a rather wide latitude of clinical interpretation. Beginning with DSM-III and continuing through the revised third edition of DSM (DSM-III-R) and the fourth edition (DSM-IV), the criteria for schizophrenia have followed a general pattern. These are: (1) a listing of the psychotic symptoms, of which one or two are required to be present; (2) a requirement for decline in social functioning and self-care; (3) “exclusion criteria” in which other disorders must be ruled out before assigning a diagnosis of schizophrenia; and (4) a duration and course criterion. Thus, in DSM-III, *schizophrenic disorder* was defined by the presence of six criteria: Criterion A required the presence of one of a list of six psychotic symptoms: three having to do with delusions; two with auditory hallucinations; and one with thought disorder associated with affective disturbance, delusions, hallucinations, or catatonic or grossly disorganized behavior. Criterion B required a deterioration in functioning from a previous level. Criterion C required a 6-month duration of illness with an active phase that included criterion A, and additional prodromal and residual symptoms, which were listed. Criterion D excluded persons for whom psychotic symptoms were preceded by a manic or depressive syndrome or for whom the mood syndrome was not “brief” in relation to the duration of the psychotic syndrome. Criterion E restricted age of onset to under 45 years. Criterion F ruled out syndromes that were “due to” any organic mental disorder or mental retardation. In DSM-III, catatonic, paranoid, and residual types were maintained. Hebephrenic

type was renamed *disorganized type*. The term *chronic* was removed from *chronic undifferentiated type*. Schizoaffective type was removed from the schizophrenic disorders, renamed *schizoaffective disorder* and placed in the “Psychotic Disorders not Elsewhere Classified” category; unlike schizophrenia, no criteria were provided for the diagnosis of schizoaffective disorder in DSM-III. Another innovation in DSM-III was its classification of course of illness into categories of subchronic, chronic, subchronic with acute exacerbation, chronic with acute exacerbation, and in remission.

DSM-III-R, published in 1987, contained several changes in criteria for schizophrenia (no longer “schizophrenic disorder”). The various types of delusions specified in DSM-III criterion A were simplified—DSM-III-R distinguished only bizarre and nonbizarre delusions. In addition criterion A symptoms were expanded to allow nonauditory hallucinations. A minimum duration requirement of 1 week for criterion A symptoms was set. Criterion B was clarified, with a comparison point of the person's highest-ever level of functioning. Criterion C in DSM-III became criterion D in DSM-III-R; little was changed in this criterion except for the addition of “marked lack of initiative, interests, or energy” as a prodromal or residual symptom. Criterion D, the mood disorder exclusion, became criterion C in DSM-III-R; now if a mood syndrome was ever present during an active phase of the illness, schizophrenia was not diagnosed. Significantly, criterion E, the age requirement, was dropped in DSM-III-R. The organic mental disorder exclusion remained in DSM-III-R, and a new criterion was added that dealt with the comorbidity of autistic disorder and schizophrenia.

DSM-IV Few changes were made to the diagnosis of schizophrenia in DSM-IV. Most significantly for case identification, the duration requirement for criterion A symptoms was increased to 1 month. In Criterion A, the concept of negative symptoms was added and the concept of loosening of associations was dropped and replaced with “disorganized speech.” Specific criteria for prodromal and residual phases were dropped. Modifications were made to the organic disorder exclusion to include direct physiological effects of a substance, and the autistic disorder relationship was expanded to include all pervasive developmental disorders. No additional schizophrenia types were added in DSM-IV.

DIAGNOSTIC ASSESSMENT INSTRUMENTS

Identification of persons with mental disorders in the community, regardless of treatment status or severity of disorder, is the ultimate test of a diagnostic classification system. In order to be useful for service planning and research needs, a credible diagnostic classification system must be able to detect and correctly classify untreated cases and cases on the threshold of diagnosis. Unfortunately, for many years the lack of reliably operationalized diagnostic criteria hindered the ability of epidemiologists to identify cases in the community, and prevalence rates were usually based on treated cases only.

Diagnostic Interview Schedule In the 1970s several psychiatric interviews were developed: the Schedule for Affective Disorders and Schizophrenia (SADS), a clinical interview based on Research Diagnostic Criteria (RDC); the Present State Examination (PSE), a nondiagnostic clinical interview that covered present symptoms only; the Psychiatric Epidemiological Research Interview (PERI), another nondiagnostic interview; and the Renard Diagnostic Interview, a diagnostic interview based on Feighner diagnostic criteria. The development of DSM-III in 1980 spurred renewed interest in gathering community epidemiological data based on the new criteria, but none of these interviews were entirely suitable for the purpose. To respond to this need, the Diagnostic Interview Schedule (DIS) was developed for use in the National Institute of Mental Health (NIMH) Epidemiologic Catchment Area (ECA) Program. The DIS covered DSM-III criteria for schizophrenia and schizophreniform disorder; Research Diagnostic Criteria for schizophrenia and schizoaffective disorder, manic and depressed types; and Feighner criteria for schizophrenia. It was a highly structured interview, based on respondent self-report only, which did not allow interviewer discretion in the administration of questions or recording of responses and did not rely on other clinical information to make diagnoses. Diagnoses were generated by computer algorithm, not by the interviewer. Because of these factors, the DIS was suitable for administration by nonclinician interviewers and could be administered in large surveys for relatively low cost. The DIS has undergone subsequent revisions to incorporate DSM-III-R and DSM-IV diagnostic criteria and it has been translated into over twenty other languages. Various reliability and validity studies performed on the DIS have demonstrated inconsistent results for schizophrenia; in such studies, results are often within an acceptable range if corrected for the low prevalence of schizophrenia in the population.

CIDI With the evolution of the DSM and the International Classification of Diseases (ICD) diagnostic systems, the need for a comprehensive diagnostic instrument for use in cross-cultural and comparative studies worldwide became apparent. To address this need, the Composite International Diagnostic Instrument (CIDI) was developed as a joint venture of WHO and the U.S. Alcohol, Drug Abuse, and Mental Health Administration. The structured question-and-probe structure of the DIS served as the template for the construction of the CIDI. Questions from the PSE, an interview widely used in epidemiological studies outside the United States were then added. Updates of the CIDI added criteria from the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10), and then DSM-III-R and DSM-IV criteria. The CIDI, like the DIS, remains a highly structured diagnostic interview with diagnoses made via computer algorithm. Throughout its development, efforts were made to ensure its cross-cultural appropriateness.

COMMUNITY SURVEYS

Three community surveys are most frequently cited for data on the prevalence and incidence of schizophrenia.

ECA NIMH Epidemiologic Catchment Area Program The ECA NIMH Program is the largest community survey of mental disorders ever undertaken in the United States. A total of 18,571 household residents and 2290 institutional residents (of nursing homes, jails, psychiatric hospitals) age 18 and over were sampled and interviewed in five areas: New Haven, Baltimore, Durham, St. Louis, and Los Angeles. Two face-to-face interviews were done 12 months apart (Wave I and Wave II). A telephone interview (face-to-face in New Haven) of the household respondents was conducted 6 months after Wave I. The institutional residents were interviewed in Waves I and II only; no telephone interview was conducted for these respondents. DSM-III diagnostic data were obtained at Waves I and II using the DIS. Respondents were asked about their use of health services at each wave. Questions to ECA respondents pertaining to use of mental health services covered use of ambulatory specialty mental and addictive, general medical, and human services, and admissions to hospitals and residential treatment centers for reasons related to mental health or addictions.

National Comorbidity Survey Following the success of the ECA Program, the National Comorbidity Survey (NCS) was conducted in the early 1990s to obtain more detailed information about mental disorders in the community, particularly the relation between co-occurring mental disorders and co-occurring mental and substance use disorders. Conducted by the Institute for Social Research at the University of Michigan, the study used a nationally representative household sample of 15- to 54-year-olds. A modified version of the CIDI (the UM CIDI) for DSM-III-R was used in the NCS. For psychotic disorders, in addition to a CIDI computerized diagnosis, a clinical reinterview was conducted with individuals who screened positive for psychosis on the CIDI. Results pertaining to the schizophrenia and related disorders are usually presented in a summary category called *nonaffective psychosis*, which is made up of schizophrenia, schizophreniform disorder, schizoaffective disorder, delusional disorder, and atypical psychosis. Comparisons of the results of the ECA to the NCS are not straightforward because of the differences in the diagnostic instrument, differences in age range of respondents, and temporal differences, among other factors.

WHO Collaborative Study on the Determinants of Outcome of Severe Mental Disorders (DOS) This study was conducted at 12 field centers in 10 countries across the world. At each of the 12 centers, all persons in a catchment area making first contact with a psychiatric, medical, or other agency for symptoms of possible schizophrenia were identified, assessed, and followed for 2 years. Like the NCS, the study selected only individuals between the ages of 15 and 54. The assessment instrument was the PSE. The final cohort size was 1379. Incidence of schizophrenia was obtained in 7 sites and clinical information on diagnosis and course was obtained at all 12 sites.

PREVALENCE

A 1987 review of over 70 prevalence studies of schizophrenia published since 1948 identified point prevalence in various population groups ranging from 0.06 percent to 1.7 percent, with lower rates in developing countries. It was suggested that this difference was not entirely caused by differences in diagnostic procedures and study methods. Rather, it was posited that higher recovery rates in developing countries and etiological heterogeneity, among other factors, could account for at least a tenfold difference in prevalence.

The prevalence of schizophrenia in the ECA is presented in Table 12.2-1. According to convention in the presentation of ECA results, these figures represent the combined prevalence of schizophrenia and schizophreniform disorders. One-month prevalence is conventionally viewed as “current” prevalence, so based on the ECA results, 0.7 percent of the adult population currently has a diagnosis of schizophrenia. The 1-year prevalence is similar, whether measured retrospectively or prospectively. The prospective period prevalence illustrates the chronicity of schizophrenia: more than twice as many persons had the disorder at the start of the year (0.7 percent) as developed the disorder or had a relapse during the following year (0.3 percent).

Length of Time	Prevalence (%) (SE)
1-month	0.7 (0.1)
1-year	1.0 (0.1)
Lifetime	1.5 (0.1)
Prospective	
1-month	0.7 (0.1)
1-year new	0.3 (0.1)
1-year total	1.1 (0.1)

SE, standard error

Table 12.2-1 Prevalence of Schizophrenia Disorders in the NIMH Epidemiologic Catchment Area Program

Based on the UM CIDI DSM-III-R computer diagnosis, the lifetime prevalence of “narrowly defined psychotic illness” (schizophrenia or schizophreniform disorder) in the National Comorbidity Survey was 1.3 ± 0.2 percent, very close to the ECA lifetime prevalence. Based on clinician diagnoses, the lifetime prevalence of narrowly defined psychotic illness in the NCS dropped to 0.16 ± 0.06 percent.

In examining the sociodemographic correlates in Table 12.2-2, it is helpful to keep in mind that an unadjusted prevalence represents the prevalence of schizophrenia as it actually appears in the community. The odds ratio tells us whether this rate is different when corrected for differences in age, sex, race, marital status, and socioeconomic status among the groups. For example, the prevalence of schizophrenia among blacks is 1.2 ± 0.2 percent, twice as high as for non-black, non-Hispanic persons. However, when correcting for differences in age, sex, race, and socioeconomic status between the ethnic groups, the odds of having schizophrenia among blacks (0.86) is actually no different than the odds for non-black, non-Hispanic persons (whose odds ratio as the comparison for this group is set at 1.00). It should also be noted that despite the size of the ECA survey, relatively few cases of schizophrenia were detected so there is limited power to detect significant differences in prevalence.

Correlates	Unadjusted Rate, % (SE)	Odds Ratio*
Age		
18–24	0.8 (0.2)	—
25–44	1.1 (0.2)	2.31
45–64	0.5 (0.1)	0.76
≥65	0.1 (0.1)	0.10†
Sex		
Male	0.7 (0.1)	—
Female	0.7 (0.1)	0.80
Race or ethnicity		
Black	1.2 (0.2)	0.86
Hispanic	0.4 (0.2)	0.57
Non-Black and non-Hispanic	0.6 (0.1)	—
Marital status		
Married	0.5 (0.1)	—
Single	1.1 (0.2)	2.55
Separated or divorced	1.5 (0.3)	2.61†
Widowed	0.4 (0.2)	2.27
Socioeconomic status		
1 (high)	0.3 (0.1)	—
2	0.6 (0.2)	2.28
3	0.9 (0.1)	3.96
4 (low)	1.2 (0.2)	8.14†

* Odds ratios adjust for age, sex, race or ethnicity, marital status, socioeconomic status, and ECA site.
† $P = 0.0011$ Bonferroni-corrected P value of $= 0.055$
SE, standard error

Table 12.2-2 Sociodemographic Correlates of 1-Month Prevalence of Schizophrenia in the NIMH ECA Program

Persons over age 65 were significantly less likely than persons between 18 to 24 years of age to have a diagnosis of schizophrenia. Persons aged 25 to 44 were twice as likely to have the diagnosis, although this difference did not reach statistical significance. The sex ratio was relatively even. Although blacks had twice the rate of schizophrenia in the community compared to other ethnic groups, when adjusted for socioeconomic status, age, and other factors, this difference disappeared. Being unmarried, particularly separated or divorced, was associated with a diagnosis of schizophrenia. There was an eightfold increase in odds of having schizophrenia in the lowest socioeconomic quartile compared to the highest quartile.

Comorbidity of schizophrenic disorders with substance use disorders in the ECA Program is shown in Table 12.2-3. Both the ECA and the NCS have demonstrated extremely high lifetime comorbidity of the psychotic disorders and substance use disorders; 50 to 60 percent of persons with schizophrenia or nonaffective psychosis had a comorbid alcohol or drug use diagnosis. Comorbidity in the NCS was higher, which may be due to methodological differences as well as secular changes in drug and alcohol use in the United States.

Comorbid Disorder	Rate (%) (SE)
Alcohol dependence	24.0
Any alcohol use disorder	33.7
Drug dependence	12.9
Any drug use disorder	27.5
Any drug or alcohol use disorder	47.0

SE, standard error

Table 12.2-3 Comorbidity of Schizophrenia With Substance Use Disorders in the ECA Program

INCIDENCE

In the WHO DOS, incidence (based on service contacts) ranged between 0.016 and 0.042 percent per year across the sites for broadly defined schizophrenia. For narrowly defined schizophrenia, incidence showed less variation, ranging from 0.007 to 0.014 percent, which was not a statistically significant difference. Age- and sex-specific incidence showed a tendency toward earlier onset in males, a consistent finding in both developing and developed countries. Overall disease expectancy was virtually the same for males and females across the overall age range of 15 to 54 years. Because the DOS minimized methods variance through standardized case ascertainment and assessment methods, the consistency in the incidence of narrowly defined schizophrenia across several international sites is a noteworthy finding. The study's investigators raised fundamental questions in the study of risk factors for schizophrenia such as the possibility of a widely distributed genetic liability, the roles of ubiquitous and culturally specific environmental factors in interacting with that liability, and alternatively, the possibility of multiple genetic liabilities with remarkably similar phenotypic expression in various population groups.

Several studies report that the incidence of schizophrenia is on the decline. Interpretation of these findings is not easy, requiring as it does an accounting of the rapid changes in psychiatry that have occurred in the past 30 years, as well as in social policy and in population demographics. For example, incidence based on inpatient admissions, once widely accepted, is no longer a valid indicator of illness onset because of the shift of treatment away from institutionalization. Diagnostic systems have changed dramatically and these changes are likely to be reflected in different estimates. As the populations of developed countries continue to get older, fewer citizens will be at risk for developing schizophrenia. The issue of declining incidence has not yet been satisfactorily resolved and controversy remains as to what degree the findings represent a true decline in new cases versus a methodological artifact.

USE OF SERVICES

In the ECA Program about 64 percent of persons with a current diagnosis of schizophrenia used some form of mental health service in a 1-year period, a relatively high treated percentage compared to the other disorders surveyed and similar to bipolar I and II disorder and somatization disorder. About 17 percent received inpatient treatment at some point in the year. Consistent with the clinical picture of schizophrenia, most treated individuals had contact in a specialty or general medical setting. Among all ECA disorders, individuals with schizophrenia had the highest proportion (46 percent) treated in the specialty sector, and the bulk of treatment visits were made to this sector as well. Despite the large number of people who had visited the general medical sector, relatively few visits were made there. About 14 percent of persons with schizophrenia were seen only in the general medical sector.

RISK FACTORS

The term *risk* refers to the likelihood that a person who does not currently have schizophrenia will develop the disorder after exposure to certain factors. Thus, a *risk factor* for schizophrenia is an inherent or acquired characteristic or an external condition associated with an increased probability of developing schizophrenia. Epidemiological studies in schizophrenia seek to determine the most important risk factors for this disorder.

The concept of risk can be expressed in several ways. The most common is a report of the absolute number of new schizophrenia cases detected in a population exposed to a postulated risk factor. The terms *relative risk (risk ratio)* and *risk difference (attributable risk)*—expressions of the relationship of the incidence in those exposed to the risk factor to that of those not exposed—are also often used. In case control studies, if the disorder is rare, the risk ratio is approximated by an odds ratio.

Significant risk factors are identified through the use of several different study designs. One type, cross-sectional studies, reports descriptive data at a defined point in time, such as the increased presence of a particular factor in a population with a higher prevalence of schizophrenia. Case control studies compare schizophrenia cases with unaffected controls and determine whether those who express the disease were exposed to a given risk factor. The most informative (and expensive) study design is the prospective cohort study, which follows a group over time to determine whether those exposed to certain risk factors have a higher incidence of schizophrenia.

Risk factors are categorized in several different ways: demographic and concomitant factors (such as age, sex, race, social class), precipitating factors that operate immediately before the onset of schizophrenia (such as life events, migration), and predisposing factors that act for a long period of time or during an earlier part of life (such as genes, perinatal complications, infections). Another schema describes risk factors as either familial influences or sociodemographic factors. The latter can be further subdivided into mutable factors (such as social class, marital status, immigration) and immutable ones (such as ethnic group, sex, birthplace); mutable sociodemographic factors could be a result and not a cause of the disease. This latter distinction is particularly difficult to disentangle in cross-sectional studies.

Several cautions are necessary before reports from studies of risk factors for schizophrenia are evaluated. First, a high prevalence of schizophrenia in a particular area may be the result of protracted illness rather than an increased incidence of schizophrenia (i.e., prevalence is roughly equal to incidence × duration). Second, studies that report only the prevalence of schizophrenia may have failed to control other confounding factors, such as socioeconomic status, that might increase prevalence. Third, designating something as a risk factor does not imply that everyone exposed to it is at personal risk of developing schizophrenia. It means that the group of people exposed to the risk factor at some time are likely to show a higher incidence of schizophrenia than a similar group who were not exposed. Risk does not prove causation but rather an association between that risk factor and the development of schizophrenia. Fourth, schizophrenia may be an etiologically heterogeneous disorder involving many risk factors and many protective factors. Earlier studies or risk factors have many methodological problems, the most important being the failure to standardize diagnostic criteria for selection of schizophrenia cases. However, those studies have helped in the continued search to understand this complicated disorder.

Genetic Factors Identification of a genetic influence is a major challenge in the understanding of schizophrenia. The search for a genetic risk factor has been examined through studies of twins, of families, and of adopted-away children of parents with schizophrenia. Twin studies have shown a concordance of 33 to 78 percent among monozygotic twins, but of only 8 to 28 percent in dizygotic twins. Those results may be affected by selection bias if monozygotic twins are more likely to come to the attention of researchers than are dizygotic twins. Also, monozygotic twins may have greater environmental similarity. Family studies reveal that first-degree relatives of a person with schizophrenia have approximately a fivefold to tenfold chance of developing schizophrenia than nonrelatives. Children have about a 35 percent greater chance of schizophrenia if both parents have schizophrenia compared with about a 1 percent lifetime risk if neither parent has schizophrenia. Although the results from family studies are thought to indicate genetic influences, similar environmental factors among relatives cannot be discounted. Adoption studies are conducted in an effort to control environmental influences. Those studies show that the adopted-away offspring of persons with schizophrenia are at increased risk for schizophrenia and schizophrenia-spectrum disorders. More recent studies using narrower, criterion-based definitions of schizophrenia have reported risk figures that are lower than those reported in earlier studies.

Although there are methodological problems with all three study approaches, findings from them suggest some type of genetic influence in schizophrenia, the significance of which has yet to be delineated. Likewise, the mode of transmission has not been found. Recent efforts have focused on linkage analyses and attempts to locate specific genes. Genetic and environmental factors play a role in the development of schizophrenia, and further refinement in methodology should help to identify the environmental and genetic components of schizophrenia.

Ethnicity and Racial Factors Several studies have discovered differences in the prevalence and number of new cases of schizophrenia among various ethnic and racial groups. The findings are not consistent and may result from failure to control for confounding factors such as social class, age, sex, and immigration status. Data from the NIMH ECA study confirm that if potential confounding factors such as socioeconomic status are controlled, the difference in prevalence across races disappears.

Previous studies of different geographical areas have found a higher prevalence and a larger number of new cases in different countries (e.g., Ireland) and within countries (e.g., the Istrian peninsula of Yugoslavia). Most studies comparing geographical areas are usually flawed because they fail to validate diagnostic methods in different ethnic groups and localities. The WHO Determinants of Outcome study reported that the incidence of schizophrenia is similar in various cultures, especially when a restricted definition is used. If true differences in incidence can be shown, perhaps differences in environmental characteristics, genetic characteristics, or both, can be found in these areas.

Age Early studies showed mean ages of onset for schizophrenia well below 45 in men and women. However, recent data indicate that onset after age 45 is not as rare as was previously assumed. Data from the ECA study reveal that schizophrenia may remain undiagnosed in the elderly because the disease has a different presentation in this age group. When compared with younger persons, most elderly people with delusions or hallucinations may not have the typical pattern of chronic progressive schizophrenia and are less likely to be significantly impaired or to be under the care of a mental health specialist.

Sex Studies that do not separate groups by age of onset show a male-to-female ratio of close to 1, but this changes when various age cohorts are examined. Men are most likely to have the onset of symptoms between ages 15 and 25; women are at highest risk at ages 25 to 35; the reasons for this difference are not clear. The disease may manifest differently in the two sexes, hormonal factors may be involved or sociocultural factors may predispose men to earlier case findings.

As data from the WHO DOS show, when different cultures are examined the findings (earlier date for first treatment and first hospitalizations for men) are the same. More asocial premorbid characteristics, birth complications, and cerebral structural changes (especially in the left or dominant hemisphere) have been reported in men than in women, and schizophrenia in men may have a more chronic and disabling course. The findings are not conclusive and are limited by methodological problems such as failure to control for sociocultural factors.

Season and Birth Order Studies have shown that a disproportionate number of persons with schizophrenia are born during winter months (seasonal excess of approximately 10 percent); which, together with a birth pattern in their nonschizophrenic siblings that is similar to that seen in the general population, suggests the presence of a seasonal factor. Proposed explanations for this seasonal effect include deleterious environmental factors in the winter (such as temperature, nutritional deficiencies, infectious agents); a genetic factor in those with a propensity for schizophrenia that protects against infection and other insults and thus increases the likelihood of survival; and more frequent conception in the spring and summer by the parents of persons with schizophrenia.

Although no experimental testing has been conducted, studies appear to favor the harmful-effects hypothesis that schizophrenia involves infectious agents, but the

other hypotheses have not been ruled out conclusively. Although some studies in the southern hemisphere confirm a higher birth rate for schizophrenic persons in winter than in other seasons, further study of that hypothesis is needed. There are a number of methodological problems with previous studies. If there are statistically significant increases of schizophrenic births during the southern hemisphere winter, environmental factors should be favored over sociocultural ones. Whether winter- and summer-born persons with schizophrenia differ is not clear, but that would not necessarily be expected if the causative agent is active all year but more active in the colder months.

Early studies also reported a characteristic birth order pattern for persons with schizophrenia, but the results have not been consistent and family size can affect the findings. For example, some have found schizophrenia to be unusually common in the youngest children of large families and in the first-born sons of small families. Again, methodological problems limit the value of the studies.

Birth and Fetal Complications When compared with controls, persons with schizophrenia as a group, and especially male infants, experience a greater number of birth complications. Some studies have also reported a relationship between perinatal complications and early onset of disease, negative symptoms, and poorer prognosis. The crucial factor appears to be transient perinatal hypoxia, although not all infants so affected later develop a psychiatric disorder. There is, however, a general trend toward psychopathology in persons who have suffered obstetrical complications; such events appear to increase the vulnerability to development of schizophrenia and probably are not a specific cause. Some have proposed that complications at birth may be the result of preexisting fetal neurodevelopmental abnormalities or a vulnerability to such abnormalities. No prospective studies have been done, and retrospective case control studies may be biased if informants interviewed about a relative with schizophrenia try harder to remember birth complications than do informants reporting on healthy controls. Obstetrical records often refer only to severe complications.

Social Class Social class can be specified in various ways using some combinations of income, occupation, education, and place of residence. In previous studies the prevalence and number of newly identified cases of schizophrenia have been reported to be higher among members of the lower than the upper social classes. Two different explanations have been proposed. One explanation is that socioenvironmental factors found at lower socioeconomic levels are a cause of schizophrenia (social causation theory). Those factors include more life event stressors, increased exposure to environmental and occupational hazards and infectious agents, poorer prenatal care, and fewer support resources if stress does occur.

The other explanation is that lower socioeconomic status is a consequence of the disorder (social selection or drift theory). The insidious onset of inherited schizophrenia is believed to preclude elevating one's status or to cause a downward drift in status. Prospective studies have shown that persons with schizophrenia have less upward mobility from generation to generation than do the general population and that there is downward drift after the onset of symptoms. Many continue to argue this unsettled question, but a recent study strongly suggests that social drift processes are more important than social causation.

Marital Status Reports based on first hospital admissions have shown higher rates of schizophrenia for unmarried than for married patients, and some have inferred that single status contributes to the development of schizophrenia. However, the phenomenon may be similar to that described under social class; that is, the disease lessens the chance of marriage and increases the chance of divorce. Studies have not shown marriage to have a protective effect against schizophrenia and have not shown an excess of schizophrenia in widowed persons. Previous research using subjects hospitalized for the first time may have been flawed because unmarried and married men appear to have different hospital utilization patterns.

Immigration A higher risk for schizophrenia among recent immigrants than in native populations has been reported, but no study to date has confirmed that immigration stress leads to schizophrenia. Indeed, the ECA study found a low prevalence of schizophrenia among Mexican-Americans studied in Los Angeles, most of whom were immigrants. The generally reported increased prevalence of schizophrenia among immigrants could result from selection (i.e., persons with schizophrenia may be more likely to leave their families); from the failure to control for such other factors as social class, age, and sex; or from the failure to compare immigrant patients to nonimmigrant controls from the same homeland. These methodological issues limit any conclusions that can be drawn from existing reports.

Urbanization and Industrialization The prevalence of schizophrenia has been reported to be higher in urban environments than in rural areas. This is consistent with widely held beliefs that cities are places of rapid change and social disorganization, whereas rural areas are more socially stable and the inhabitants more integrated. However, data from the ECA study show no difference in the prevalence of schizophrenia between urban and rural areas when such factors as race, sex, and age are controlled.

The assertion that the prevalence and incidence of schizophrenia have increased in the twentieth century has been tested by comparing developing countries with industrialized nations, but such studies are fraught with methodological problems. For example, because infant mortality is lower in industrialized countries, those likely to develop schizophrenia may survive more frequently. Families are smaller and more insular, and ill members may be more obvious. The question of whether schizophrenia is more prevalent in modern times has also been studied by analyzing the reported number of new cases over time. However, it is difficult to control for probable diagnostic or recognition bias across centuries, especially for a disease that was first defined only in the late 1800s.

Life Stressors The association between stressful life events (such as loss of job, divorce) and the etiology and course of schizophrenia has been much studied. Schizophrenia or relapse of a preexisting disorder often follows extraordinary stress, so it has been suggested that such stress might provoke acute schizophrenia in a healthy person. Others argue that stress plays only a marginal role in the pathogenesis of the disorder or simply triggers schizophrenia in vulnerable persons. The few studies that have considered the issue have suffered the usual methodological problems of retrospective case-control studies and have had difficulty in outlining predispositional factors in schizophrenia. The stressor might have triggered the onset of a disorder that would have occurred without the stressor. The issue is not settled and will require further studies, especially prospective ones in which the role and severity of stressors in individual cases can be considered.

Infections Anatomical changes suggestive of viral infection of the central nervous system have been reported in some people with schizophrenia. A viral hypothesis is consistent with seasonal excesses and geographical differences. Viruses could also interact with a genetic predisposition, familial transmission, or both, in complex ways in the development of the disease. Recent studies have reported that exposure to viral infections during the second trimester may increase the risk for development of schizophrenia. As yet no study has conclusively shown an association between viral infection and the onset of schizophrenia. Further studies, especially those that can show evidence of viral transmission, are needed.

Suicide Risk Suicide is a leading cause of mortality in people suffering from schizophrenia. Estimates vary, but as many as 10 percent of people with schizophrenia may die because of a suicide attempt. Although the risk for suicide is greater in people with schizophrenia than in the general population, some risk factors—such as being male, white, and socially isolated—are similar in both groups. Factors such as depressive illness, a history of suicide attempts, unemployment, and recent rejection also increase the risk for suicide in both populations. Previous studies have revealed other risk factors that are unique to this disorder. Among these are being young and male and having a chronic illness with numerous exacerbations. A postdischarge course involving high levels of psychopathology and functional impairment increases the risk for suicide. In addition, people who have a realistic awareness of the deteriorative effects of the illness and a nondelusional assessment of their future are at increased risk for suicide. Other factors such as fear of further mental deterioration, hopelessness, excessive dependence on treatment, or loss of faith in treatment increase the risk of suicide in people with schizophrenia. The risk of mortality is especially high in the young, during the early postdischarge period, and early in the course of illness, although the risk persists across the person's life span. Risk factors identified in previous studies may be helpful in assessing acute suicidal risk in a specific individual. Further research is needed to better understand what risk factors are most predictive of future suicide in people with schizophrenia and what interventions are most helpful in preventing suicide.

Childhood Schizophrenia As with adult-onset schizophrenia, different diagnostic criteria can affect the interpretation of results from studies of childhood-onset schizophrenia. Early definitions of childhood-onset schizophrenia tended to be broad and often included patients with autistic disorder. Recent diagnostic systems have departed from these earlier definitions by using the more restrictive criteria applied to adults that emphasize hallucinations and formal thought disorder. This restrictive definition, however, fails to consider developmental issues, such as the nature of delusions in childhood, and how a formal thought disorder can be diagnosed in a child under 8 years of age whose formal cognitive processes are not fully developed. Others have considered developmental stages in diagnosing childhood-onset schizophrenia, but no consensus has been reached. The accuracy of any reported epidemiological data on childhood-onset schizophrenia is compromised by differences in diagnostic criteria. Therefore, the prevalence of childhood-onset schizophrenia is not clear, but it is probably less than that of early infantile autism and is estimated to be less than that of adult-onset schizophrenia. There does not appear to be a greater incidence in boys than girls, as there is in infantile autism.

The risk factors of childhood-onset schizophrenia are not well known, and many investigators have simply extrapolated from adult findings. However, environmental stressors, perinatal complications, and central nervous system dysfunction have all been reported to occur more frequently in children who are diagnosed with

schizophrenia.

FUTURE DIRECTIONS

Future epidemiological work in schizophrenia should use multisite, prospective, long-term studies. The WHO studies provide some of the foundations for such proposed efforts. However, longitudinal prospective studies of people at risk should be carried out, from near birth, and extending through the ages of major risk (early adult years). Such studies, with appropriate controls, should incorporate opportunities for genetic mapping of families at risk; chromosomal studies; and current laboratory measures of potential psychophysiological vulnerability such as continuous performance and sensory discrimination testing, neuroimaging, and other measures evolving with methodological advances. The expense of such studies would not be greater than that of comparable multisite, long-term studies of risk factors for cardiovascular and other diseases and would be small compared to the extraordinary direct and indirect costs of this most devastating of mental disorders.

SUGGESTED CROSS-REFERENCES

Some of the methods and concepts applicable to this section are discussed in Section 5.2 on statistics and experimental design. The genetics of schizophrenia is discussed in Section 12.5. Other aspects of schizophrenia are presented throughout the other sections of Chapter 12. Other psychotic disorders are reviewed in Chapter 13. Section 11.3 discusses amphetamine-related disorders, Section 11.7 discusses hallucinogen-related disorders, and Section 11.11 discusses phencyclidine-related disorders.

12.3 SCHIZOPHRENIA: BRAIN STRUCTURE AND FUNCTION

RAQUEL E. GUR, M.D., FH.D. AND RUBEN C. GUR, FH.D.

The past decade has seen a transformation in psychiatric thinking about schizophrenia. Its conception as a complex behavioral disorder that reflects an interplay between biological and psychosocial factors has been changing as developments in the neurosciences have yielded tools for probing neural substrates of behavior. In particular, advances in neuroimaging methods have enabled translational research in which schizophrenia can be studied from the molecular to the behavioral levels using complementary top-down and bottom-up strategies. Such work has identified some consistent aberration in brain structure and function that may help formulate our new conception of schizophrenia as a brain disorder. This is not to dismiss environmental stressors, but rather to put these in the perspective of a brain disorder in evolution.

Two major aspects of brain integrity can be assessed through neuroimaging: structural anatomy and functional activity. In view of the complexity and course of schizophrenia, these measures need to be taken across the life span and longitudinally to document the association between brain changes and behavior. Furthermore, the disorder-related effects are superimposed on healthy individual differences—for example, sex differences and maturational changes—that have to be established in healthy people before we can understand pathological changes. However, despite the complexity of such an approach, its implementation can yield new opportunities for elucidating the neural substrate of schizophrenia in a way that will lead to improved diagnosis and treatment.

Accordingly, the section first describes studies of structural imaging in schizophrenia, which have been linked to neuropathological findings in postmortem research. This is followed by findings obtained by functional imaging studies.

NEUROANATOMICAL STUDIES IN SCHIZOPHRENIA

Neuroanatomical correlates of dysfunctional performance have provided the foundation for current thinking about brain regulation of behavior. The behavioral aberrations manifested in schizophrenia implicate a diffuse abnormality likely to involve several brain systems. Defining the neuroanatomical differences and possible changes associated with schizophrenia is arguably a prerequisite for understanding its neural substrates and for interpreting functional studies of brain physiology and neurochemistry. Structural studies have progressed from reliance on ratings to planimetric measures and, more recently, reliable computerized segmentation methods for obtaining volumetric measures. The improvement in precision of neuroanatomical parameters has yielded some consistency in effects and correlations with clinical and neurobehavioral measures.

Structural Neuroimaging Earlier neuroimaging studies with computerized tomography (CT) applied nonvolumetric measures and suggested enlarged ventricles, implying reduced brain parenchyma. Magnetic resonance imaging (MRI) has advanced the study of the neuroanatomy of schizophrenia. It offers improved sensitivity for examining sulcal changes, better contrast resolution, direct multiplanar imaging, lack of bone artifacts, and no ionizing radiation. The field has progressed from initial studies of small samples, examining multiple regions with low-field scanners, using linear and area measurements, to the application of computerized image analysis in large samples. This has enabled linking neuroanatomical measures to two behavioral dimensions: clinical features of the disorder and neurocognitive deficits.

Whole Brain and CSF Volumes Studies with MRI have replicated earlier findings with CT indicating smaller brain volume and more cerebrospinal fluid in patients with schizophrenia than in healthy people. As can be seen in Figure 12.3-1, a person with schizophrenia shows evidence for widening of CSF spaces in both the ventricles and the sulci. Image segmentation methods have permitted increasingly precise quantitation of brain and CSF volume, and although these studies generally support the notion of increased CSF relative to brain volume in schizophrenia, they also indicate considerable overlap with healthy people (Fig. 12.3-2). This suggests that abnormalities at the level of whole brain may characterize only subtypes of patients with schizophrenia. Some patients exhibit a concomitant decrease in brain and increase in CSF volume, consistent with atrophy, whereas other patients show concomitant decreases in brain and CSF volume (hence cranial volume) which is more consistent with dystrophy. A third group shows neither abnormality.

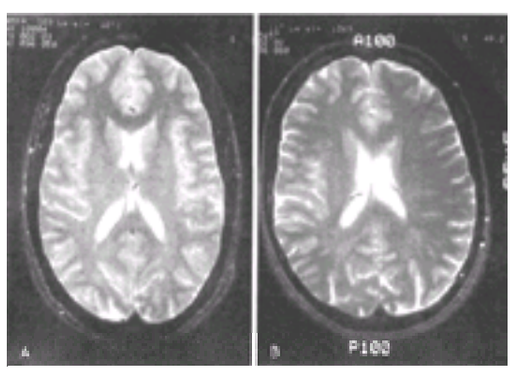

FIGURE 12.3-1 MRI of a young healthy adult **(A)** and a same-aged adult with schizophrenia **(B)**. Radiological examination showed evidence of the patient's increased cerebrospinal fluid in ventricles and sulci.

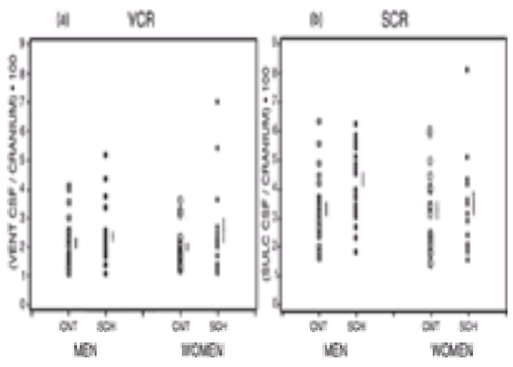

FIGURE 12.3-2 Scatterplot of brain volume of adults with schizophrenia relative to that of healthy adults matched sociodemographically.

These measures have been related to phenomenological and other clinical variables such as premorbid functioning, symptom severity, and outcome. The results

suggest that whole brain measures are related to clinical features. Abnormalities in these measures are likely to be more pronounced in patients with poorer premorbid functioning, more severe symptoms, and worse outcome. The concept of brain reserve that has been suggested in other disorders, such as Alzheimer's disease, may apply to schizophrenia as well. Thus, normal brain and CSF volumes are preliminary indicators of protective capacity. As our understanding of how brain systems regulate behavior in health and disease improves, we can take advantage of neuroimaging to examine specific brain regions implicated in the pathophysiology of schizophrenia.

Regional Volumes Examination of brain regions implicated in schizophrenia has required methodological developments to enable testing specific hypotheses regarding the neuroanatomical basis of the aberrant behavior. Studies have evolved beyond comparing patients with controls, and current work linking regional measures to specific symptoms and subtypes requires large samples and systematic data acquisition. Furthermore, given the subtle changes evident in schizophrenia, findings must be evaluated relative to well-characterized healthy people. For example, the effects of normal aging appear to be sexually dimorphic. Cross-sectional studies reported age-related reduction in frontal and temporal lobe volumes in healthy men but not women (Fig. 12.3-3).

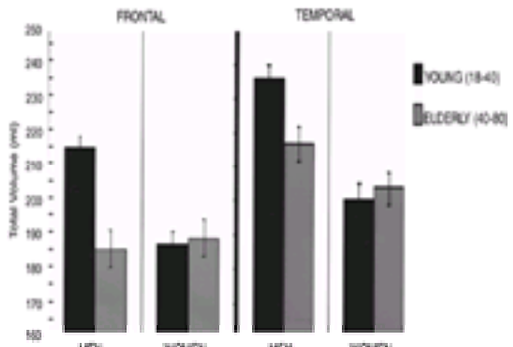

FIGURE 12.3-3 Frontal and temporal lobe volume in younger and older healthy adult men and women. (Reprinted with permission from Cowell PE, Turetsky BT, Gur RC, Grossman RI, Shtasel DL, Gur RE: Sex differences in aging of the human frontal and temporal lobe. J Neurosci *14:*4748, 1994.)

The main regions showing consistent abnormalities in schizophrenia have been frontal and temporal lobe structures. Lower frontal and temporal lobe volume has been observed in patients than in healthy controls matched demographically (Fig. 12.3-4). Reduced temporal lobe volume correlated with both memory impairment and severity of negative symptoms. These findings were observed in first-episode patients, indicating that structural changes are evident at the first clinical presentation, which supports a neurodevelopmental origin. The differences are more pronounced in men than in women with schizophrenia.

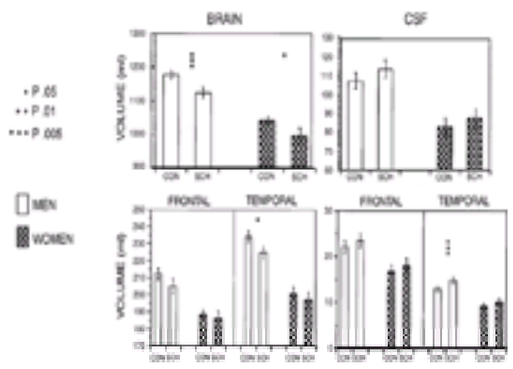

FIGURE 12.3-4 Frontal and temporal lobe volume in adults with schizophrenia compared with that of healthy adults matched sociodemographically.

Reduced volume was reported in multiple regions including the superior temporal gyrus, hippocampus, and thalamus. These structures are critical for maintaining the integrity of the complex behaviors that are impaired in schizophrenia. Figure 12.3-5 illustrates some of the regions that show abnormal volume in schizophrenia, as well as an example of an image that has been segmented into gray and white matter and CSF. Most regions show volume decrease; the exception is basal ganglia regions reported to show increased volume in schizophrenia. This increase seems to be related to the effects of dopamine receptor antagonists.

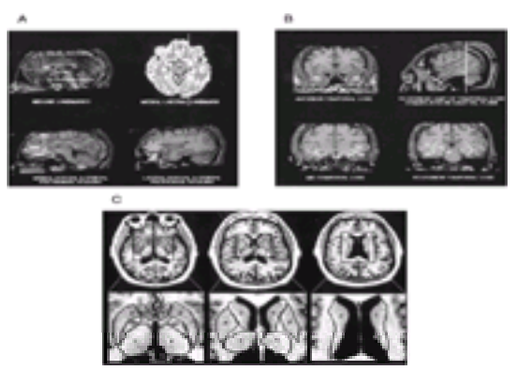

FIGURE 12.3-5 Illustration of regions that have shown volume abnormalities in schizophrenia: **A**, frontal lobe; **B**, temporal lobe; **C**, basal ganglia.

Gray Matter and White Matter Segmentation MRI can yield detailed anatomical information apart from the demarcation of brain and CSF. With sequences that are T1-weighted it is possible to segment gray from white matter (Fig. 12.3-5A, upper right image). Several lines of investigation have demonstrated advantages of applying such methods. Gray matter changes have been found during adolescence and in the course of the normal aging process. Gray-white segmentation is critical in developmental studies in which age-related decreases in gray matter may be obscured by simultaneous increases in total brain and cranial volumes. These improvements in image processing methodology have helped determine whether tissue loss and disorganization in schizophrenia is primarily a gray matter deficit or whether abnormalities in white matter are also involved.

Reduced cortical gray matter was noted in a number of studies that evaluated chronic patients with schizophrenia. More recently, one study of first-episode patients also reported a gray matter deficit in individuals with a recent onset of illness.

Longitudinal Studies Efforts to elucidate the pathophysiology of schizophrenia have focused on the role of the neurodevelopmental relative to progressive neurodegenerative processes. Documenting neuroanatomical aberrations with structural neuroimaging and evaluating their course in relation to clinical and neurobehavioral manifestations can help test such hypotheses. CT and MRI studies have been primarily cross-sectional, and a longitudinal design is necessary to examine the possibility of progressive deterioration suggested by the neurodegenerative hypothesis. The few longitudinal evaluations of structural abnormalities have not been integrated with clinical and neurobehavioral measures.

Results from CT follow-up studies, with planimetric methods and ratings of sulcal enlargement, have varied. Some studies found no significant changes in

ventricle-brain ratio (VBR) in relatively small samples rescanned after a number of years, commonly ranging from 2 to 5. Other studies reported that some patients do show an increased VBR over similar time spans. The investigators noted that these initial studies have limitations related to sample size, patient characteristics, and scanning and measurement procedures.

While most follow-up CT studies evaluated chronic patients with schizophrenia, MRI longitudinal studies have examined first-episode patients. This is an informative population because the design enables prospective follow-up starting early in the course of illness. One group of investigators found no ventricular changes in a follow-up (1–2 years) study of 13 patients and 8 controls. Lyn DeLisi and her colleagues initially evaluated 16 patients and 5 controls, studied 2 years after a first psychotic episode. Patients showed no consistent change in ventricular size with time, although there were individual increases or decreases. With a larger group of 24 patients and 6 controls no significant changes were observed in ventricular or temporal lobe volume at follow-up. Recently, a report on 20 of these patients and 5 controls rescanned over 4 years noted greater decreases in whole-brain volume and enlargement in left ventricular volume in patients and concluded that subtle cortical changes may occur after the onset of illness.

These authors have described a reliable and validated method for obtaining MRI measures of brain volume. In healthy adults, these parameters have been related to sex differences and the effects of aging, and in schizophrenia, they were related to clinical features. This method was applied in a longitudinal study of 40 patients (20 first-episode, 20 previously treated) and 17 healthy controls, rescanned an average of 2.5 years later. Volumes of whole brain, CSF, and frontal and temporal lobes were measured. Severity of negative and positive symptoms was assessed, medications were monitored, and neurobehavioral functioning in eight domains was evaluated. First-episode and previously treated patients had smaller whole-brain and frontal and temporal lobe volumes than controls at intake. Longitudinally, reduced frontal lobe volume was found only in patients, whereas temporal lobe reduction was also seen in controls. The association between volume reduction and symptom change differed between patient groups, but in both first-episode and previously treated patients, volume reduction was associated with decline in some neurobehavioral functions. The existence of neuroanatomical and neurobehavioral abnormalities in first-episode patients indicates that brain dysfunction occurred before clinical presentation. However, the longitudinal studies suggest progression in which anatomical changes may affect some clinical and neurobehavioral features of the illness in some patients.

The limited number of longitudinal MRI studies and small sample sizes leaves the question of progression unresolved and precludes confident distinction of disease-related changes from those associated with normal aging. Furthermore, standard therapeutic interventions need to be included in such longitudinal studies.

FUNCTIONAL NEUROIMAGING

Application of Functional Brain Imaging Methods Evolving technology provides an increasing array of measures of brain function. Some of these measures overlap and others are complementary. For example, the functional integrity of the brain can be examined through measures related to energy metabolism, such as rates of glucose and oxygen utilization and cerebral blood flow. Neuroreceptor function can be assessed through methods for measuring receptor density and affinity at presynaptic and postsynaptic sites. Methods that have been applied in schizophrenia included the Xenon-133 (^{133}Xe) clearance technique for measuring cortical cerebral blood flow; positron emission tomography (PET) for assessing glucose metabolism, cerebral blood flow, and neuroreceptor functioning; single photon emission computerized tomography (SPECT) for studying cerebral blood flow and neuroreceptors; and, more recently, functional MRI (fMRI) for measuring changes attributable to cerebral blood flow. Figure 12.3-6 illustrates the application of such methods in healthy people.

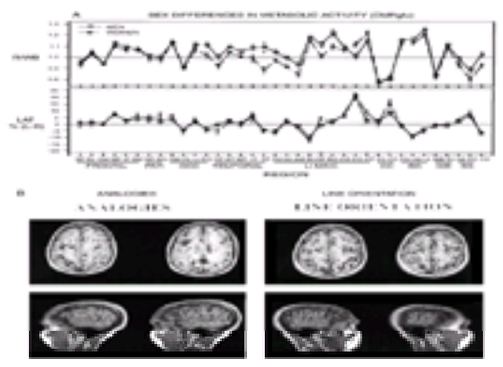

FIGURE 12.3-6 Illustration of functional imaging data obtained in healthy people: **A**, sex differences in local glucose metabolism; **B**, activation with verbal and spatial tasks as seen by functional MRI. Abbreviations: SF, superior frontal; DL, dorsal prefrontal-lateral; DM, dorsal prefrontal-medial; MF, midfrontal; IF, inferior frontal; SM, sensorimotor; SP, superior parietal; SG, supramarginal gyrus; OL, occipital cortex, lateral; OM, occipital cortex, medial; LI, lingual gyrus; FG, fusiform gyrus; OT, occipital temporal; ST, superior temporal; MT, midtemporal; IT, inferior temporal; TP, temporal pole; PH, parahippocampal gyrus; HI, hippocampus; AM, amygdala; IN, insula; OF, orbital frontal; RG, rectal gyrus; CA, cingulate gyrus-anterior; CG, cingulate gyrus; CP, cingulate gyrus-posterior; C1, corpus callosum-anterior; C2, corpus callosum-posterior; CN, caudate nucleus; LM, lenticular-medial (globus pallidus); LL, lenticular-lateral (putamen); MB, mammillary body; TH, thalamus; MI, midbrain; PO, pons; CE, cerebellum. Cortical regions are grouped by lobe in a rostral-caudal order, followed by corpus callosum and subcortical regions. This order heuristically also reflects ontogenic and evolutionary development. Top graph shows means + SEM of region to whole brain (R/WB) ratios, and bottom graph shows laterality differences in percentage, i.e., 100*(LR)/mean(L,R). (See Color Plate 7.)

Links between clinical features of schizophrenia and brain function have been guided by hypotheses relating behavior to specific brain regions and systems implicated in schizophrenia. These links are based on preclinical research and the emergence of symptoms commonly seen in schizophrenia that also occur following brain lesions. Persistent negative symptoms have been observed as a eurobehavioral sequela of frontal lobe damage. Other frontal lobe functions such as abstraction, attention, verbal fluency, mental flexibility, and concept formation are also impaired. Productive positive symptoms of hallucinations and delusions have been related to the temporolimbic system, and this region is also implicated by evidence of impaired learning and memory. The greater impairment in verbal functions, the similarity of some symptoms to those observed in patients with left temporal lobe epilepsy, and the increased frequency of left-handedness (or, rather, “left-sidedness” as measured by a combined index of strength of right-handedness, footedness, and sighting dominance) in schizophrenia have led to the laterality hypothesis stipulating left hemispheric dysfunction. Thus the laterality gradient has been examined in several studies. Subcortical regions have been studied with special emphasis on the basal ganglia (implicated by the dopamine hypothesis) and the thalamus (related to sensory gating).

These early efforts, focusing on brain systems that are likely to modulate normal and pathological psychotic behavior, have generated hypotheses that can be examined with functional brain imaging. In addition to obtaining baseline measures of the resting topography of glucose metabolism and cerebral blood flow, functional imaging is an especially powerful methodology for the probe paradigm. There are two complementary approaches: neurobehavioral probes and neuropharmacological probes. The application of neurobehavioral probes has enhanced our ability to evaluate brain systems that regulate specific processes in healthy people and in those affected by schizophrenia, including attention, learning, memory, and executive functions. Neuropharmacological probe paradigms include examination of neuroreceptor function as well as the effects of pharmacological intervention on cerebral blood flow and metabolism.

CEREBRAL METABOLISM AND BLOOD FLOW STUDIES

Semour Kety and his colleagues have pioneered the measurements of whole-brain metabolism and blood flow in healthy people and reported normal values for patients with schizophrenia. Subsequent studies of regional cerebral metabolism and blood flow can be divided into those that measure the physiological parameters at a resting state and those that introduce a perturbation, or challenge, in the form of a neurobehavioral probe or a pharmacological intervention. Initially, investigators have aimed at assessing whether resting cerebral blood flow and glucose metabolism differ between patients with schizophrenia and healthy controls. The topography of physiological activity was examined along the anterior-posterior, subcortical-cortical, and lateral dimensions.

Resting Baseline The frontal lobes were implicated when early physiological studies of cerebral blood flow, reported that patients did not show the normal pattern of more anterior than posterior flow. This “hypofrontal” disturbance in the anterior-posterior gradient has been supported by some, but not all, studies of resting cerebral blood flow (by ^{133}Xe and SPECT) and glucose metabolism (with PET). The relation between this pattern of metabolic activity and clinical variables has also been examined. Decreased frontal metabolic activity has been associated with duration of illness and negative symptoms. Longer duration of illness and more severe

negative symptoms are related to a relative decrease in frontal lobe metabolism.

Differences in resting values between patients and controls were also found in laterality indexes, suggesting relatively higher left hemispheric values in more severely ill patients. Furthermore, improvement in clinical status correlated with a shift toward lower left hemispheric metabolism relative to that in the right hemisphere. This supports hypotheses derived from behavioral data concerning lateralized abnormalities in schizophrenia.

After assessing global, anterior-posterior, and lateral dimensions, investigators have begun the study of functional changes in brain systems linked to other impaired behavior in schizophrenia. Dysfunction in temporolimbic structures, including the hippocampus as well as temporal cortex, is supported by neuroanatomical and neuropsychological studies. Lateralized abnormalities in these regions, with greater left than right hemispheric dysfunction, are implicated by characteristic clinical features of schizophrenia, such as thought disorder, auditory hallucinations, and language disturbances. PET studies of temporal lobe metabolism show both increased and decreased glucose utilization. Decreased metabolism was also noted in hippocampus and anterior cingulate cortex. Studies in this region have been limited in part by instrument resolution.

Metabolism and flow pattern in temporolimbic regions have also been related to symptoms. An oxygen-15 (^{15}O)-labeled water study with PET described abnormal cerebral blood flow in the parahippocampal gyrus, associated with positive symptoms. Hallucinations were associated with SPECT blood flow changes in the hippocampus, parahippocampus, and amygdala. There are conflicting reports of superior temporal gyrus functional changes in schizophrenia during active auditory hallucinations. While one study suggested that patients with hallucinations have lower relative metabolism in Wernicke's region, another study showed asymmetrical temporal lobe perfusion (lower in the left than the right) in patients with auditory hallucinations. In one PET study the rate of glucose metabolism was greater in the left anterior temporal lobe and was related to the severity of symptoms. This is consistent with another reported association between severity of symptoms and a relative increase in left hemispheric metabolism.

These reports varied in the method used and definition of regional parameters. Most studies used ratios such as region to whole brain or anterior to posterior rather than absolute values of activity. Inconsistencies in findings could also be related to sample size, heterogeneity, analytical approaches, and individual techniques. Most studies included relatively small samples of patients, which varied in important clinical factors such as chronicity, symptom subtypes and severity, level of functioning, and history of treatment. Furthermore, inclusion criteria varied, and some laboratories applied more stringent criteria (e.g., related to history of comorbidity of substance abuse or head trauma with loss of consciousness). Another potential source of variability in results is the definition of resting state. Investigators have been reluctant to include an unstructured resting state because of concern that such measures will be uncontrolled and therefore produce unreliable results. Some studies used reduced sensory input, and others used sensory stimulation to standardize this condition. However, several studies examined the reproducibility of resting baseline measures with relatively unstructured conditions (i.e., eyes open and ears unoccluded, with ambient noise kept to a minimum). These studies found high reproducibility among healthy subjects and patients with schizophrenia.

Given the demonstrated reliability of the standardized resting baseline condition, these authors believe such a condition should be included in physiological neuroimaging studies. This will serve three main purposes. First, it will permit comparison across studies within a center as technology evolves and patient characteristics change. Without a common resting baseline condition it would be impossible to interpret differences in results. Second, it will enable comparability across centers. Imagine the need to explain why two centers using the same or similar tasks find evidence for different regional abnormalities in schizophrenia. If resting baseline values are available and are comparable in the two samples, different task effects could be legitimately attributed to theoretically meaningful sources such as task condition or symptomatic variability. Third, a standardized resting baseline provides a reference point for determining whether a given task or condition has increased neural activity. In studies that have included such a condition, cognitive activation was consistently shown to increase cortical activity in both patients and controls. Using a resting baseline condition enables the investigator to make much stronger statements in interpreting regional effects. Rather than being restricted to statements that a given region has changed in its activation relative to the remainder of the brain, resting baseline data can be used to determine whether the task has induced increased neural activity.

Functional changes in the basal ganglia have been examined with PET and SPECT. Several PET studies implicate basal ganglia dysfunction in schizophrenia. The withdrawal-retardation factor (emotional withdrawal, blunted affect, and motor retardation) of the Brief Psychiatric Rating Scale has been negatively correlated with PET basal ganglia metabolic activity. Neuroleptic-naive patients with schizophrenia were reported to have relatively increased blood flow in the left globus pallidus. Other PET studies report decreased basal ganglia metabolism in schizophrenia, while yet others found increased basal ganglia metabolic rates following administration of neuroleptic medication.

Thus, while the contribution of PET metabolic and blood flow studies so far has been to add to the growing evidence implicating basal ganglia involvement in schizophrenia, the exact nature of the dysfunction remains unclear. In particular, the relation between basal ganglia and frontal lobe activity in schizophrenia needs further scrutiny. Emerging evidence from structural and functional imaging indicates a dynamic interrelationship between the various key regions. One study showed that patients with schizophrenia not only fail to activate dorsolateral prefrontal cortex in response to the Wisconsin Card Sorting Test, but they also fail to inhibit caudate activation. Hence, in schizophrenia, basal ganglia continue to show relatively increased flow in the caudate during performance of the task, while healthy controls seem to demonstrate a reciprocal relationship in which relative blood flow decrease in the basal ganglia is associated with increased perfusion to the frontal region.

Activation Studies Regardless of the debate over the value of obtaining resting baseline measures, measures of cerebral blood flow and metabolism during the performance of cognitive tasks clearly tend to accentuate differences between patients and controls. Perhaps even more importantly, such measures are critical for establishing the link between behavioral deficits and the ability of brain regions to become activated in response to task demands. This expectation has been supported in studies that used neurobehavioral probes.

The general approach in the field has been to work from hypotheses, derived from neurobehavioral data, which associate behavioral measures with regional brain function. Task selection can be made to include a target task (for which patients are expected to have a differential deficit) and control tasks. Patients are then compared with healthy controls in the pattern of task-induced changes in regional brain activity. This has now become the established research paradigm and significant progress has been made since the early studies with ^{133}Xe.

The authors, Daniel Weinberger, and their colleagues applied the ^{133}Xe method during resting measures and while subjects were performing specific tasks. Both groups found no differences in overall or hemispheric cerebral blood flow between patients and controls at resting baseline. However, distinct abnormalities were seen when physiological activity was measured in response to cognitive probes. Pursuing the laterality hypothesis, the first author of this section and coworkers administered tasks with a demonstrated link to left (verbal analogies) and right (spatial line orientation) hemispheric functioning. Healthy controls showed the expected greater left hemispheric increase for the verbal task and greater right hemispheric increase for the spatial task. However, patients with schizophrenia had a bilaterally symmetrical activation for the verbal task and greater left hemispheric activation for the spatial task. Thus, patients failed to show the normal left hemispheric dominance for the verbal task and instead showed left hemispheric overactivation for the spatial task.

Similarly, Weinberger and coworkers found no regional abnormalities in the resting cerebral blood flow of patients with schizophrenia. However, distinct abnormalities were reported in the dorsolateral prefrontal region during activation with the Wisconsin Card Sorting Test of abstraction and mental flexibility, which is sensitive to frontal lobe damage. Application of this paradigm to the study of monozygotic twins discordant for schizophrenia revealed that all affected twins had lower dorsolateral prefrontal cortex cerebral blood flow response than discordant cotwins. Furthermore, negative symptoms, which have been related to frontal lobe dysfunction, showed a negative correlation with frontal blood flow during performance of executive tasks but not control tasks. Probing brain systems with specific tasks has also been advanced in SPECT and in cerebral blood flow studies with PET. These methods have also indicated abnormalities in patients with schizophrenia with a range of tasks including memory, executive, and attentional measures. The consistent finding is a lack of normal regional activation in response to task, and activation in some regions not seen in healthy subjects.

These results suggest that brain systems recruited for the performance of specific tasks in healthy people are not similarly engaged in patients with schizophrenia. What may account for such aberrations? Genetic liability, neurodevelopmental abnormalities in which brain systems fail to achieve maturity, or the impact of a psychotic process that interrupts normally developed structures and processes? Does therapeutic intervention ameliorate the abnormal signature? How specific are the results to schizophrenia? These are some of the questions yet to be answered that can certainly be addressed with neuroimaging.

Functional MRI The introduction of MRI is an exciting, more recent development in functional imaging research. Functional MRI methods offer several potential advantages over PET for imaging brain function, including higher spatial resolution, higher temporal resolution, noninvasiveness, lack of ionizing radiation, direct correlation with anatomical imaging, greater reproducibility, and economy. Disadvantages include the loud background noise generated by the gradients, difficulties in

presenting stimuli and performing tasks in the magnet bore, claustrophobia, low signal-to-noise ratio for most methods, and lack of quantitation in physiological units for most methods. Many of these disadvantages can be overcome by using specialized equipment compatible with the MRI environment. These methods are described briefly because they are recent and hold potential for functional imaging in schizophrenia.

Currently, three main techniques exist for MRI of the brain. Gadolinium bolus-tracking was the first technique to be applied to mapping task-specific regional brain function in animals and humans by use of MRI. In normal brain, gadolinium diethylenetriaminepentaacetic acid (DPTA) is an intravascular tracer, allowing semiquantitative transit time and blood volume images to be calculated with rapid imaging techniques. Because of the accumulation of the intravascular tracer, the number of determinations is limited to two to three per day. Because gadolinium DPTA is an intravascular tracer, dynamic measurements of its passage through brain yield measurements of cerebral blood volume and mean transit time rather than cerebral blood flow, but changes in cerebral blood flow are generally reflected by changes in these other indexes.

Blood oxygenation–sensitive imaging has been most widely applied to fMRI, replicating previous PET studies. The technique relies on magnetic susceptibility effects of deoxyhemoglobin that cause regional signal decreases in imaging sequences that are sensitive to susceptibility (e.g., echoplanar or routine gradient echo sequences). With regional brain activation studies a net increase in signal intensity is observed in regions known to be activated by the task. The increase in image intensity corresponds to a local decrease in deoxyhemoglobin. This finding is attributed to a greater increase in regional blood flow than in regional oxygen consumption, a notion supported by PET measurements of blood flow and oxygen consumption with regional brain activation. A wide variety of pulse sequences can be used to obtain blood oxygenation–sensitive imaging measures. Many simple activation paradigms have been tested, and activation has been observed with both fast and slow imaging. A typical response is a 1 to 25 percent change in regional image intensity, which develops over 3 to 8 seconds following task initiation. Susceptibility effects of deoxyhemoglobin are field dependent. Thus, a scanner with 1.5 tesla field strength would typically record signal changes with functional activation of about 0.25 to 5 percent, while at 4 telsa changes up to 25 percent have been observed. The main advantage of ultrafast imaging is that the time course of signal change can be observed and multislice imaging can be carried out in a reasonable time period.

The third technique, arterial spin tagging (quantitative perfusion imaging) uses magnetization tagging of endogenous arterial water to determine the perfusion of brain parenchyma by comparing images obtained with and without a labeled arterial supply. The method is analogous to steady-state techniques used in PET, since the regional signal intensity depends upon the arterial blood flow (which delivers labeled spins) and the T1 relaxation rate (which causes the labeling to decay). This technique has the important advantage of providing quantitative cerebral blood flow parameters. Furthermore, perfusion is measured in brain parenchyma directly and is thus better localized than measurements obtained by use of an intravascular tracer, which is most sensitive to venous outflow effects. There may also be less motion sensitivity than with blood oxygenation–sensitive imaging.

Application of this technology to the study of schizophrenia is quite new. Perry Renshaw and colleagues measured the relative change in image signal intensity caused by photic stimulation in eight patients and nine controls. The mean signal intensity change in the primary visual cortex was significantly greater in patients than in controls. A subsequent study examined a sample of 12 subjects with schizophrenia and 11 healthy controls performing a word fluency task, associated with left frontal lobe function. Patients showed less left frontal activation and greater left temporal activation than controls. Sensorimotor cortex and supplementary motor area activation were examined in right-handed patients (8) and controls (9) during finger-to-thumb opposition. All subjects showed a significant activation of the supplementary motor area and both ipsilateral and contralateral sensorimotor cortices. Compared with controls, patients showed a decreased activation of both sensorimotor cortices and supplementary motor area as well as a reversed lateralization effect. Increased understanding of the technology and elucidation of neural systems involved in the processing of tasks in healthy people should enhance our ability to apply this methodology to schizophrenia.

Effects of Medication The pharmacological status of patients undergoing metabolic and blood flow studies has varied. Research has ranged from investigations in which antipsychotic agents were considered a variable that needed to be controlled to those in which pharmacological intervention was introduced in a standardized fashion to examine treatment effects on the regional metabolic landscape. The washout period in studies that attempted to control the effects of antipsychotic drugs on cerebral blood flow and metabolism has commonly been short, ranging from 2 to 4 weeks. This period is a compromise between what is feasible and desirable. Monte Buchsbaum and colleagues examined cerebral glucose metabolism in cortical-striatal-thalamic circuits in a large sample of unmedicated men with schizophrenia. They found that patients had low metabolic activity in the medial frontal cortical regions and the basal ganglia, as well as an impaired lateralization pattern in the frontal and temporal regions. More recently in schizophrenia research, antipsychotic drug-naive first-episode patients have been studied. This population is particularly informative when the study is focused on the effects of pharmacological intervention. The study of neuroleptic-naive patients before pharmacological intervention separates the disease state from its treatment. The pattern of abnormalities summarized above is evident in first-episode patients across studies that examined differences between their first episode and episodes of previously treated patients. This suggests that disruption in normal brain processes is apparent at the presentation of illness and cannot be attributed to treatment or chronicity. While this is an informative approach, further progress can be made in metabolic studies using complementary methods to integrate pharmacological probes with metabolic studies.

A repeated-measures longitudinal design has been applied in a limited number of PET studies. In addition to examining symptom severity over time, this paradigm is singularly useful when pharmacological intervention is standardized. One study compared the effects of thiothixene (Navane) and haloperidol (Haldol) in chronic patients who were scanned off medication and after 4 to 6 weeks on medication. A different pattern of global and regional glucose metabolism was seen in the two groups. In another study PET scans were obtained at weeks 5 and 10 of a double-blind crossover trial of haloperidol and placebo in 25 patients with schizophrenia. Low relative metabolism in the striatum on placebo was associated with improved symptomatology. Responders to treatment had increased metabolism in the striatum after treatment. Nonresponders failed to show such a change and had more marked hypofrontality on medication. In a subsequent study, 12 patients were scanned before and 4 to 6 weeks after treatment with clozapine (Clozaril) or thiothixene. The drugs had a differential effect, with clozapine increasing and thiothixene decreasing metabolism in the basal ganglia, right more than left. Henry Holcomb and coworkers used a repeated-measures design to study glucose metabolism in 12 patients on a fixed dose of haloperidol and 5 and 30 days after drug withdrawal. No differences were observed between metabolism on medication and after 5 days of discontinuation. However, at 30 days, metabolism decreased in the caudate, putamen, and anterior thalamus and increased in the frontal cortex and anterior cingulate. The authors concluded that the basal ganglia are the site of the primary antidopaminergic action of haloperidol and that other changes observed are mediated through the cortical-striatal-thalamic pathways. The integration of pharmacological and neurobehavioral probes is a potentially powerful approach. For example, patients exhibited enhanced activation of the anterior cingulate after administration of apomorphine, suggesting a modulating role for dopamine.

Methodological Considerations and Potential Limitations Anxiety has complex effects on regional cerebral blood flow and metabolism, which investigators in a few laboratories have reported. It would seem desirable to measure anxiety carefully by use of complementary behavioral and psychophysiological procedures and to examine the relation of these measures to the regional metabolic and cerebral blood flow values and performance.

Motivation is an important factor in cognitive studies of schizophrenia. Whether poor performance can be improved by providing instructions and monetary reinforcement has been addressed in studies with the Wisconsin Card Sorting Test. One approach to this issue is the calculation of “mental effort” scores by subtracting basal cognitive abilities (e.g., I.Q. measures) from current performance. This difference between current and basal performance provides a measure of how well subjects perform in relation to their inherent ability, which may provide a parameter of motivation that can be related to cognitive and physiological data. This approach has been taken in ^{133}Xe and PET cerebral blood flow studies.

Task selection and choice of stimuli raise several questions. There are reasons to prefer elemental tasks that have been used extensively in cognitive psychology and are applicable across physiological measurements. A continuous presentation format of the tasks provides flexibility and ensures that subjects receive continuous stimulation during the measurement epoch. The importance of examining the issue of epoch has been recently demonstrated in a study by the Iowa group.

In many studies, self-paced task presentation was used with the hope of engaging the subject's utmost mental resources and efforts. This was considered essential for the ^{133}Xe and the PET flurodeoxyglucose studies, which integrate data across long periods of clearance (15 and 40 minutes, respectively). The disadvantage of self-paced administration for the PET cerebral blood flow and functional MRI measurements may, however, outweigh their advantage because of the brief measurement epoch. For brief duration, there could be considerable variability in the number of stimuli processed by subjects, and because patients with schizophrenia have slower initiation and response times, the differences in cerebral blood flow activation between patients and controls could be hard to interpret.

Central to the goal of relating regional cerebral blood flow change to task performance and clinical state variables is the problem of correlating behavioral data with physiologic data that are themselves intercorrelated. Innovative statistical approaches (e.g., Statistical Probability Mapping [SPM]) are used to address the global scaling factors inherent in this area of investigation.

NEURORECEPTOR STUDIES

Study of Neuroreceptors Another critical window for assessing brain function, the study of neuroreceptors, can give insight into the nature of neurochemical abnormalities in schizophrenia. Because advances in elucidating the pathophysiology of schizophrenia require understanding neurotransmitter function, the application of PET and SPECT to the study of receptor occupancy is likely to have an impact in the near future. These efforts are guided both by an extensive psychopharmacological literature and by advances in basic neuroscience on neuroreceptor subtyping. Functional neuroimaging is the meeting ground of preclinical and clinical neuropharmacology. Human neuroreceptor PET studies have built on progress with in vitro binding measurements of receptor density and affinity and neuroreceptor autoradiography. Psychotic symptoms seen in schizophrenia have been associated with dysfunction of dopamine, and the dopamine hypothesis has undergone revisions on the basis of these data.

PET Studies of D_2 Ligands The development of radioligands for PET studies first focused on the dopamine type 2 (D_2) receptor because of its clinical significance in relation to treatment with a neuroleptic agent. The study of antipsychotic drug-naive patients could potentially differentiate effects of the psychotic state before antipsychotic-drug intervention. Two major methodologies for quantitative measurement were developed and applied in the study of schizophrenia. Investigators at Johns Hopkins University applied [^{11}C]*N*-methylspiperone and reported that patients have higher D_2 Bmax values than controls. Studies at the Karolinska Institute, using [^{11}C]raclopride, reported similar B_{max} and K_d values in patients and controls.

These apparent differences have been discussed and summarized extensively and are likely related to multiple factors including patient variables, ligand properties, and PET modeling methods. Because the ligands differ in binding properties and sensitivity to endogenous dopamine, studies permitting a more direct comparison will be particularly helpful. In such an effort, Anna-Lena Nordstrom and coworkers evaluated the reproducibility of the [^{11}C]*N*-methylspiperone finding in a study of seven neuroleptic-naive patients and seven controls, before and after administration of 7.5 mg of haloperidol. Consistent with previous quantitative PET study of [^{11}C]raclopride binding, there were no differences between patients and controls pretreatment, and after haloperidol the specific binding of [^{11}C]*N*-methylspiperone was reduced by 80 to 90 percent. More recently, investigators at Johns Hopkins replicated the initial report in a new sample of drug-naive patients with schizophrenia. Other data reveal D_2 receptor density increases in psychotic, but not in nonpsychotic, patients with bipolar I disorder. The increase is comparable to that reported in schizophrenia. This raises questions regarding the specificity of the dopamine hypothesis to schizophrenia versus other psychotic syndromes.

Jean-Luc Martinot and coworkers measured D_2 striatal dopamine receptors using [^{76}Br]-bromospiperone in a PET study of 12 untreated patients with schizophrenia and found no increase in receptors in patients relative to controls. In a subsequent study, [^{76}Br]bromolisuride was applied to the measurement of striatal D_2 receptors in 19 untreated patients and 14 controls. Again, no differences in striatum-to-cerebellum ratios emerged, and no relation to symptoms or subtypes was evident in either study.

Receptor Function and Clinical Response The study of neuroreceptors can also address issues related to the relationship between receptor function and signs such as akathisia, commonly seen in patients treated with neuroleptic agents. Farde and colleagues determined in four control subjects the activity of [^{11}C]SCH 23390, a selective D_1 receptor antagonist. Two PET studies, at low and high doses of the radioligand, were conducted per subject. Transient akathisia occurred only when binding in the basal ganglia was at a high level with 45 to 59 percent occupancy. The D_2 receptor antagonist [^{11}C]raclopride was measured in 20 controls and 13 patients. Akathisia was associated with maximal ligand binding in the basal ganglia in patients and controls. Adam Wolkin and colleagues found that neuroleptic-resistant patients with schizophrenia did not differ from neuroleptic responders in degree of D_2 receptor occupancy by the antipsychotic agents. The regional distribution and kinetics of haloperidol binding were studied with [^{18}F]haloperidol in a PET study of five patients with schizophrenia examined while on haloperidol and after a drug washout and nine controls. Wide regional distribution of the ligand was evident in the cerebellum, basal ganglia, and thalamus, in contrast to the specific binding to the basal ganglia of [^{18}F]*N*-methylspiroperidol. Thus, small structural differences among butyrophenones are associated with changes in kinetics and distribution.

Typical and Atypical Antipsychotics PET neuroreceptor methods have also been applied in studies comparing atypical (serotonin–dopamine antagonists) and typical (dopamine receptor antagonists) antipsychotic drugs. The properties of clozapine binding to D_1 and D_2 receptors were examined in an open study of 5 patients, relative to 22 patients treated with dopamine receptor antagonists. Clozapine induced lower D_2 occupancy (38 to 63 percent), whereas D_2 receptor occupancy with dopamine receptor antagonists at conventional doses was 70 to 89 percent. Neuroleptic-induced extrapyramidal syndromes were associated with higher D_2 occupancy. In a follow-up study, Nordstrom and coworkers examined the relation between D_2 receptor occupancy and antipsychotic drug effect in a double-blind PET study using [^{11}C]raclopride. Seventeen patients with schizophrenia were randomly assigned to three groups treated with varied dosages of raclopride. A PET study was conducted at steady-state on 13 patients during the third to fourth week of treatment. A curvilinear relation between plasma concentration of raclopride and D_2 receptor occupancy was obtained. A significant relationship was noted between D_2 receptor occupancy and Brief Psychiatric Rating Scale percentage change as a measure of outcome. The D_2 receptor occupancy in patients who had extrapyramidal adverse effects was higher than in patients without. Nordstrom and coworkers examined D_1, D_2, and 5-hydroxytryptamine type 2 (5-HT_2) receptor occupancy in 17 patients treated with clozapine (125 to 600 mg a day) applying [^{11}C]SCH23390, [^{11}C]raclopride, and [^{11}C]*N*-methylspiperone. D_2 receptor occupancy (20 to 67 percent) was lower than for dopamine receptor antagonists (70 to 90 percent); D_1 receptor occupancy (36 to 59 percent) was higher than that reported for dopamine receptor antagonists (0 to 44 percent); and 5-HT_2 receptor occupancy was high (84 to 94 percent). Thus clozapine shows a combination of relatively high D_1, low D_2, and quite high 5-HT_2 receptor occupancy values, and serum concentrations are not predictive of receptor occupancy. In a PET study of [^{11}C]raclopride, Shitis Kapur and coworkers determined D_2 receptor occupancy induced by 2 mg a day of haloperidol for 2 weeks in seven patients. High levels of D_2 occupancy (53 to 74 percent) were noted with substantial clinical improvement. A similar investigation in nine patients receiving 2 to 6 mg a day of risperidone (Risperdal) showed receptor occupancy (66 to 79 percent) similar to that of dopamine receptor antagonists and higher than that of clozapine. When 10 patients with psychoses treated with loxapine were evaluated for D_2 and 5-HT_2 receptor occupancy, the agent differed from serotonin-dopamine antagonists. It has high 5-HT_2 receptor occupancy, which is not higher than D_2 occupancy. These research paradigms illustrate the integration of functional neuroimaging with pharmacological research. Incorporation of these strategies to psychopharmacological studies of schizophrenia with available therapeutic agents can advance the field and guide treatment intervention.

SPECT Studies The D_2 receptor SPECT ligand iodine-benzamide ^{123}I-iodobenzamide (IBZM) has been applied in studying dopamine D_2 receptors in patients with schizophrenia. Fifty-six patients were evaluated and a semiquantitative analysis of D_2 receptor binding was calculated (basal ganglia to frontal cortex ratio of activity). These ratios in patients taking typical neuroleptic agents were significantly lower than those in the neuroleptic-free subjects but not lower than those in the patients taking serotonin-dopamine antagonists (clozapine, remoxipride). No overall elevation of D_2 receptor binding was observed comparing 20 patients off medications and 20 controls, but a left lateralized asymmetry was found in male patients.

METABOLITE STUDIES: MAGNETIC RESONANCE SPECTROSCOPY (MRS)

MRS provides analytical qualitative and quantitative data on cellular metabolism and molecular structure. It has been used to study metabolism in vitro and in vivo in animals and humans. Spectral localization methods permit the measurement of ^{1}H and ^{31}P nuclear magnetic resonance (NMR) spectra from precisely localized volumes of interest, and this provides the basis for applying these techniques to study brain diseases. Because the technology is fundamentally similar to that used in MRI, several groups have begun to develop an approach that integrates these two modalities into a single examination. There are few reports that use this approach to investigate the underlying metabolism of neuropsychiatric disorders. Jay Pettegrew and colleagues pioneered applying phosphorus-31 (^{31}P) methods to the study of several neuropsychiatric diseases, including schizophrenia. They reported hypofunction in the dorsolateral prefrontal cortex in a sample of antipsychotic drug-naive patients with schizophrenia. The patients had significantly lower levels of phosphorus monoesters (PME) and higher levels of phosphorus diesters (PDE) than normal controls. Inorganic phosphate concentration was decreased and ATP concentration was increased in the patients. These latter results were interpreted as reflecting hypofunction of the dorsal prefrontal cortex in the patients. This interpretation is consistent with reports of decreased blood flow and decreased utilization of glucose in this region, as summarized above. A follow-up case report described a patient who exhibited in the ^{31}P MRS spectra PME and PDE levels similar to those reported for schizophrenia, well before the onset of psychotic symptoms. This finding led the authors to suggest that MRS may be of value in examining high-risk subjects such as family members of patients with schizophrenia for the presence of spectral abnormalities. Another group reported ^{31}P MRS results on patients with schizophrenia that support the findings of Jay Pettegrew and coworkers. Thus, a growing body of evidence from several laboratories shows converging findings.

This suggests the possibility of dysfunction in the normal process of programed synaptic pruning. Abnormal pruning could result in neuronal loss as well as upregulation of the postsynaptic dopaminergic receptors. These changes observed with ^{31}P clearly suggest that there should be alterations in the levels of the

compounds routinely detectable by localized proton MRS.

Considerable interest exists in obtaining solvent-suppressed proton spectra in humans. As the technical issues involved in obtaining spectra are being solved, it is important to begin to relate MRS measurements to the underlying biochemistry in the tissue being sampled. The role of *N*-acetylaspartate was reviewed by D.L. Birken and W.H. Oldendorf. This compound was found by NMR in glia and neurons but not on astrocytes. For this reason *N*-acetylaspartate concentration has been proposed as an index of neuronal integrity. The roles of the amino acids present in the brain have been examined. There is about 12 mM glutamate present in the brain, making it by far the most abundant amino acid. The rates of glutamate synthesis and oxidation differ in astrocytes and neurons. Two important products of glutamate are glutamine which is formed from glutamate by glutamate synthetase located in astrocytes and g-aminobutyric acid (GABA), an inhibitory neurotransmitter. Aspects of the metabolism of these compounds and the influence of this metabolism on MRS spectral appearance has received increased attention. Glutamate is largely confined to the tissue in which it is formed by barriers in permeability. Glutamine can be converted to glutamate at the site of neurotransmitter activity by glutaminase, which is present in neurons. The combination of two enzymes, glutamine synthetase (which converts glutamate to glutamine) and glutaminase, acts as a sort of cycle to maintain the concentrations of glutamate and glutamine. GABA and glutamate concentrations were determined by MRS in cultured preparations of cortical neurons and cerebellar granule cells, and colleagues granule cells contained large amounts of glutamate, while the neuronal cells contained large amounts of GABA.

Detection of these compounds in vivo in clinical studies showed increased glutamine concentrations in patients with chronic hepatic encephalopathy. Douglas Rothman and coworkers showed that it is possible to determine the glutamine concentration in human brain by spectral editing methods. The glutamine concentrations reported were in excellent agreement with literature values. These workers referenced their measurement of glutamate to the concentration of total creatine present (9.6 mM) in the brain. The key feature in their methodology was the use of short echo delays (12 milliseconds) to estimate the glutamate present. It seems therefore that MRS can be used to measure the concentrations of these amino acids, which may provide some insights into the activity of the excitatory glutamate and inhibitory (GABA) neurotransmitters present in the tissue being sampled. The studies so far are preliminary, since larger samples and a comprehensive and systematic approach to behavioral assessment are needed to link behavioral dimensions to both neuroanatomy and metabolism.

FUTURE DIRECTIONS

Structural and functional neuroimaging research in schizophrenia has made progress in advancing the understanding of neuroanatomical and neurophysiological substrates of this disorder. Structural imaging studies have identified subtypes of patients with reduced brain volume, and lower regional volumes have also been reported in structures that are key to healthy processing of complex behavior. While it is too early to outline with any precision the network of regions most affected, some consistent evidence has emerged implicating frontotemporal and corticostriatal thalamic regions. By and large, these structural abnormalities are present early in the course of illness and are related to disease features. These research methods can be applied to informative populations such as high-risk individuals and in genetic paradigms. Furthermore, recent evidence for progressive changes in some patients encourages longitudinal studies.

Two areas have been examined in functional imaging studies: energy metabolism and neuroreceptor studies. In a review of this field Goran Sedvall concluded that the major future contribution for understanding the pathophysiology of schizophrenia will be achieved through advanced resolution and development of new ligands for neurotransmitter systems. While the authors agree on the potential of these developments, they believe that metabolic studies can make unique contributions that will prove essential for finding the neural basis of schizophrenia and ultimately for improved treatment. In the context of the overall effort in neurobiological research in schizophrenia, functional neuroimaging studies have advanced the understanding of brain dysfunction related to neurobehavior and neuropharmacology. The field has reached some maturity in developing appropriate paradigms, and there is now a need for adequate sample size in patient and healthy populations, with attention to clinical heterogeneity and variability in brain function in relation to gender and age.

One of the major challenges in this research is the integration of neuroimaging data across anatomical and functional measures with clinical and neurobehavioral variables. A potential strength of functional neuroimaging is the integration of data on neuroreceptor function, metabolites, and metabolic activity. Ultimately, dysfunctional neurotransmitter systems translate to aberrant metabolism. Since cerebral blood flow and metabolism reflect neuronal activity, relating these domains is prerequisite to understanding the neurobiology of schizophrenia. As new receptor subtypes are cloned and radioligands are developed and available for human studies, it will be necessary to know which neuroreceptor measures result in increased neuronal activity and in turn how regional activation relates to behavior.

Thus, while new receptor ligands and improved resolution are welcome and exciting, as is the development of methods for MRS and flow measures, it is unlikely that the neural basis of schizophrenia will simply result from applying the right method with sufficient resolution. Rather, the harder and longer route of understanding the interaction among the brain's structural integrity, regional activity, and neuroreceptors as they affect the clinical and neurobehavioral manifestations of schizophrenia will probably be needed. On the positive side, this examination may yield partial answers of immediate benefit for treatment, and the evolution of this work will systematically improve our ability to articulate a neuropsychiatric perspective of this devastating disorder.

SUGGESTED CROSS-REFERENCES

The neural basis of schizophrenia psychopathology is further discussed in Section 1.1 an introduction and overview of neural sciences, in Section 1.2 on functional neuroanatomy, in Section 1.4 on monoamine neurotransmitters, in Section 1.10 on basic molecular neurobiology, and in Section 3.5 on brain models of mind. Neuroimaging is presented in Section 1.15 and Section 1.16. Typical antipsychotics drugs are presented in Section 31.17 on dopamine receptor antagonists. Atypical antipsychotics are covered in Section 31.26 on serotonin-dopamine antagonists. Other aspects of schizophrenia are discussed throughout Chapter 12.

12.4 SCHIZOPHRENIA: NEUROBIOLOGY

MICHAEL F. EGAN, M.D., AND THOMAS M. HYDE, M.D., Ih.D.

Schizophrenia is a chronic mental illness affecting approximately 1 percent of the population. Beginning in early adulthood, schizophrenia typically causes a dramatic, lifelong impairment in social and occupational functioning. From a public health standpoint, the costs of treatment and lost productivity make this illness one of the most expensive disorders in medicine. Despite the tremendous economic and emotional costs, research on schizophrenia lags far behind that on other major medical disorders. A primary impediment to developing more effective treatment is the limited understanding of the etiology and neurobiology of this disorder. New technologies, such as neuroimaging and molecular genetics, are removing the obstacles that once blocked major progress in the field. Although the stigma associated with the illness has not yet been eliminated, these new techniques have markedly altered the conception of the nature of schizophrenia.

One of the most rapidly changing fields is genetics. Family, twin, and adoption studies have clearly shown that genes play a prominent role in the development of schizophrenia. Estimates of heritability typically range from 50 to 85 percent. Initial attempts to isolate major genes using linkage studies were unsuccessful, but more recent approaches using increasingly sophisticated methods have uncovered several chromosomal regions that may harbor genes of minor effect. It seems likely that schizophrenia is the result of the interaction of many genes, some of which also interact with environmental factors. Investigations of environmental factors have looked at the role of stress, viruses, obstetrical complications, and in utero insults, among others. None of these have been definitively shown to be causative. It is possible that different combinations of genetic and environmental factors affect specific neurobiological systems, leading to a final common pathway of neural dysfunction.

Several neurobiological abnormalities have been found to have major implications for understanding the pathophysiology of schizophrenia. The first are structural brain abnormalities. Initially seen decades ago using pneumoencephalography, structural changes have been more clearly delineated using computerized tomography (CT) and magnetic resonance imaging (MRI). The most commonly reported alterations include enlarged lateral ventricles, enlarged third ventricle, and reduced volume of a number of structures, including hippocampus, amygdala, and frontal and temporal cortices. These abnormalities may predate the onset of illness. Second, functional cortical deficits have been seen with a variety of techniques, such as neuroimaging and neuropsychological testing. Prefrontal and temporal lobe dysfunction is most prominent, and is possibly related to structural abnormalities. Third, neuropathological studies have consistently failed to find any evidence of gliosis to account for the structural deficits. If anything, they tend to find subtle cytoarchitectural alterations. The recurring theme of this research suggests some type of failure in neuronal migration, orientation, or connectivity. Finally, several neurotransmitter systems appear to play a role, particularly in the expression of positive as well as negative psychotic symptoms. Evidence for alterations in the dopamine system is the most compelling. Other neurotransmitters have also been implicated, including glutamate, serotonin, and g-aminobutyric acid (GABA).

Neurochemical, structural, and functional imaging abnormalities can be understood in the context of the neural circuits involved and models of the illness. Cortico-striato-thalamic, limbic, and dopamine systems all appear to play a role. These three interconnected pathways mediate different aspects of higher-level information processing, such as judgment, memory, planning, and motivation. Their involvement could arise in several ways. One model suggests that neurodevelopmental abnormalities occur in utero. The clinical manifestations of schizophrenia appear only after brain development is largely completed, in late adolescence. Although this hypothesis has come to dominate thinking about schizophrenia, the neurodevelopmental model has several weaknesses.

ROLE OF GENES AND ENVIRONMENT

Genetic Factors Family, twin, and adoption studies indicate that there is a major heritable component to schizophrenia. Whereas the incidence in the normal population is approximately 0.5 to 1 percent, the lifetime risk in first-degree relatives is roughly 10 percent, indicating that the risk to first-degree relatives is 10 times that of the general population. This strongly implicates a familial factor in the etiology of the illness. Twin and adoption studies have shown that this is mostly, if not entirely, due to genetic factors. For example, the concordance rate in monozygotic twins is approximately 50 percent, as compared to 10 to 14 percent for dizygotic twins, suggesting that heritability may be as high as 80 percent. Of seven adoption studies, all found an increased incidence of schizophrenia in biological relatives, but not in adoptive relatives. This data convincingly demonstrates that genetic factors rather than shared, familial environmental factors are at work.

Although such epidemiological data implicate a major heritable component, the genetic architecture appears complex. Early attempts at modeling genetic transmission in families (using segregation analysis) suggested that heritability could not be explained by a single, dominant gene. In the early 1990s, increasingly sophisticated modeling indicated that at least several genes were involved, each with incomplete penetrance. One very real possibility is that there are many genes of minor effect. Such genes are difficult to detect using traditional linkage approaches. A triggering role for the environment in those with a genetic predisposition has also been hypothesized. While genetic modeling has been heuristically useful, the lack of a clear genetic mechanism complicates attempts to find the causative genes.

Early linkage studies were based on traditional assumptions that a single dominant gene produced the illness. These were, in general, unsuccessful. The first published study to use restriction fragment length polymorphisms (RFLP) reported linkage between two markers on the long arm of chromosome 5 (5q11-13) and schizophrenia. Subsequently, a number of other groups using separate cohorts were unable to replicate this, and several were able to clearly reject linkage to loci from 5q. While this failure dampened enthusiasm for genetic studies of schizophrenia, the relentless advances in statistical genetics and the molecular biology of the human genome have provided powerful new tools for detecting genes of minor effect. For example, some of the problems with specifying the unknown parameters needed for linkage analysis can be circumvented by using nonparametric approaches. These approaches use large collections of sibling pairs, both affected with the illness. As investigators have begun to use such tools, positive linkage reports for schizophrenia susceptibility genes of minor effect have been reported. Recent examples of putative schizophrenia susceptibility loci yielding some evidence of confirmation include loci on chromosomes 6, 8, and 22.

Despite real advances, several statistical issues continue to complicate interpretation of linkage studies. First, ambiguities persist about what diagnoses should be included. Family and adoption studies have suggested that diagnoses such as schizoaffective disorder, schizotypal personality disorder, and atypical psychosis are genetically related. To hedge their bets, investigators looking for linkage typically test several definitions of “schizophrenia spectrum,” ranging from narrow to very broad inclusion criteria. This means that more family members are included in the analysis as diagnostic criteria broaden. Second, the issue of which genetic model to use continues to plague parametric approaches. Typically, linkage studies include dominant, recessive, and mixed models. Here again, investigators hedge their bets by testing three or four genetic models. Since both problems lead to multiple testing, correction for multiple comparisons is indicated. Unfortunately, it is not entirely clear how to correct for this multiple testing. Currently, the commonly accepted significance level (*p* values) for initial linkage reports is ~10_{-4} to 10_{-5} or a logarithm of the odds (LOD) score of 3.3 and 0.01 for confirmation. Several groups have published putative replications of linkage findings based on these statistical criteria.

The first linkage study with some independent confirmation came from a study of a large Irish cohort. Using microsatellite markers and 186 multiplex schizophrenia families, evidence was found for linkage to the short arm of chromosome 6 (6p22). However, when adjusting for multiple comparisons, a genome-wide significance was estimated at .05 to .08 percent. When the original cohort was extended to 265 pedigrees, an LOD score of 3.51 was obtained, again using a moderately broad definition of illness. The LOD score was highest with a model of intermediate penetrance; of note, only 15 to 30 percent of pedigrees were linked. Supportive evidence for linkage to 6p22 was found in three independent studies. Interestingly, the three replications were different from the original in several ways; one used a recessive model and a narrow definition. In contrast to the original findings, a dominant model and broad disease definition yielded an LOD score of 0.06. A second replication study found suggestive linkage at a marker very close to the one in the original report. Not unexpectedly, a number of studies have failed to replicate the D6p22 linkage. These results illustrate some of the complexities of linkage studies of schizophrenia, but also provide some hope that these methods will uncover the genes involved in schizophrenia.

In addition to 6p22-24, at least two other regions have yielded evidence of linkage to schizophrenia. Ann Pulver and colleagues first described evidence for suggestive linkage to chromosome 8 at 8p22-p21 using 57 multiplex families. Soon after, another group, using a very broad definition of illness, reported confirmatory evidence for linkage using the Irish cohort; again, only 10 to 25 percent appeared to be affected by this putative susceptibility gene. A second attempt at replication by a multicenter collaborative group also found support for linkage. Suggestive evidence for a third potential vulnerability locus was reported for chromosome 22 at q12-q13.1.

Although the evidence for susceptibility loci in these reports does not overlap completely, the differences in location are not large. In other heritable complex diseases, for example, susceptibility genes have been cloned that are 20 centimorgans (about 20 million base pairs) away from the sites initially linked to the illness. As with 6p22-24, the strength of evidence for linkage to both 8p22-p21 and 22q12-q13.1 depends in part on what is acceptable as a significant replication. This in turn is related to how multiple tests are corrected for using a variety of phenotypes and model parameters. It is possible that there are schizophrenia susceptibility genes in a roughly 10 to 20 cM area in these regions that may each affect a small percentage of families. Several other regions have received attention but the evidence is less compelling. These regions include, at present, 5q, 6q, 9p, 18p, and 22q.

Using the candidate gene approach, weak support for involvement of the dopamine type 3 (D_3) receptor gene has emerged. In 1992, an excess of homozygosity was noted in schizophrenia patients compared to controls for a polymorphism in the first exon of the D_3 receptor gene. A few subsequent studies have supported a modest association between schizophrenia and homozygosity of the Ser-9-Gly polymorphism, but a large number of other studies failed to replicate this association. Linkage studies with D_3 receptor gene polymorphisms have not found significant LOD scores. As more functional variants in candidate genes are discovered, focused association studies of these genes will become increasingly common.

It is crucial to determine exactly what is inherited. One possibility is that genes determine susceptibility to certain environmental factors. Another possibility is that specific neurobiological abnormalities are produced by specific genes. Family studies have shown that relatives have an increased incidence of several neurobiological traits associated with schizophrenia. These include structural brain abnormalities, changes in evoked potentials, eye-tracking dysfunction, negative symptoms, and subtle cognitive deficts. These parameters could be more basic phenotypes that are closer to the molecular manifestations of the genes that cause schizophrenia. If so, they may improve the ability to detect these genes.

Environmental Factors Family-based epidemiological studies clearly demonstrate that environmental factors play a role in the pathophysiology of schizophrenia. The contributions of environmental factors have been estimated to be as much as 30 to 50 percent. Genetic modeling indicates that genes could set the threshold for liability to environmental factors. It is sobering to realize that environment can play a crucial role even in disorders that appear to be autosomal dominant. For example, phenylketonuria is an autosomal-dominant disorder that causes mental retardation. The illness is expressed, however, only if individuals with the abnormal gene ingest phenylalanine. Without this critical environmental exposure, the illness does not develop. Environmental factors hypothesized to play a role in schizophrenia range from problems with maternal bonding and early rearing to poverty, immigration status, stress, and viruses. The neurodevelopmental hypothesis has shifted the research focus somewhat from psychosocial variables to those that affect brain development. Several specific insults have been implicated, including pregnancy and birth complications, in utero viral infections (such as influenza), season of birth, and prenatal starvation.

Research into pregnancy, obstetric, and neonatal complications has had a particularly significant impact on the field. These complications include events such as prolonged labor, prematurity, preeclampsia, toxemia, fetal distress, and hypoxia. The majority of studies examining the incidence of such complications find increases in patients with schizophrenia. Positive studies include those that compare patients with matched controls, with their own well siblings, and even with a monozygotic twin discordant for schizophrenia. On the other hand, several impressive negative reports, including prospective, epidemiological surveys have failed to find a significant increase in such complications. However, these studies have been criticized on methodological grounds, thereby leaving the issue in doubt. Some authors have suggested that perinatal complications may increase risk only in persons with a genetic predisposition whereas others assert just the opposite. Although these conflicting findings make definite conclusions tentative, the bulk of the data suggests that perinatal complications are increased somewhat in patients with schizophrenia.

One possibility for how such complications lead to schizophrenia is that they produce some type of brain damage. The hippocampus, for example, is particularly susceptible to perinatal hypoxia and this limbic structure is thought to play an important role in schizophrenia. A number of studies have found that patients with a history of obstetric complications have increased likelihood of structural brain abnormalities, such as enlarged ventricles. A similar relationship has been seen in nonschizophrenic controls with a history of obstetric complications. However, many studies have failed to find any relationship between structural abnormalities and obstetric complications. Some authors have suggested that only nongenetic forms of the illness (sporadic cases) are more likely to have structural problems and obstetric complications, but data on this are very mixed. More problematic, obstetric complications are thought to mediate increased risk by transient hypoxia but hypoxia typically produces gliosis, a finding notably absent from the postmortem literature on schizophrenia. An alternative explanation is that obstetric complications are themselves secondary to abnormal fetal brain development. In any event, if obstetric complications increase the risk of schizophrenia, they are likely to be a minor factor; most persons with these complications do not develop schizophrenia and most patients with schizophrenia do not have an obvious history of obstetric complications.

A second risk factor that has been extensively studied is season of birth. There appears to be an increased incidence of schizophrenia associated with winter and spring birth dates. This finding is controversial, and has been attributed by detractors to a statistical artifact. If there is such a relationship, it could implicate an infectious process, such as a virus; viral infections are more common during winter months. Viral hypotheses have taken several forms, and candidates include slow viruses, retroviruses, or virally activated autoimmune reactions. In a related vein, several large-scale epidemiological studies have reported that the frequency of schizophrenia is increased following exposure to influenza during the second trimester. The effect is slight, however, and some studies have not observed this relationship. Another intriguing risk factor is starvation or poor nutrition. In studies of the effects of starvation during World War II in Holland, researchers found that starvation at the time of conception and in the first trimester increased the risk of developing schizophrenia by a factor of 2. Other factors recently reported to increase the risk of schizophrenia include Rh incompatibility and low intelligence quotient (I.Q.).

At this point, no single major factor has been unambiguously identified as an environmental cause of schizophrenia, and it is likely that none exists. As with genetic loci, environmental effects probably consist of a variety of factors, each having a minor effect at best. These will be difficult to detect, as will their hypothesized interaction with genes of minor effect, without large-scale studies.

STRUCTURAL AND FUNCTIONAL NEUROIMAGING

Neuroimaging studies of schizophrenia have demonstrated alterations in both structural and functional measures. Structural abnormalities include increased volume of the third and lateral ventricles, sulcal widening, and reduced volume of gray matter regions. Functional abnormalities include alterations in blood flow and measures of chemical moieties using MRI spectroscopy. Neuroimaging has also been used to assay receptor density and dynamic parameters related to dopamine release. Neurochemical studies are discussed separately in sections on specific neurotransmitters.

Neuroimaging has had a major impact on the conceptualization of schizophrenia. The notion that patients with schizophrenia have an actual deficit in the volume of brain tissue clearly established that this was a brain disease rather than a purely psychological or biochemical disorder. Functional neuroimaging has implicated the prefrontal and temporal lobes in particular, and has begun to relate activity in these regions to the clinical manifestation of schizophrenia. As critical as these findings have been, important controversies remain.

Structural Abnormalities One of the most widely replicated neurobiological findings in schizophrenia research is that of altered volume of cerebral structures. Increased size of the cerebral ventricles and reduced brain volume were observed early in the twentieth century using pneumoencephalography and postmortem material. These early findings, however, had little enduring impact on the field. The advent of CT technology renewed interest in cerebral volumetric parameters. The earliest CT studies found enlargement of the lateral and third ventricles and cortical sulci. Although these findings were initially viewed with skepticism, over 100 subsequent studies have been published with lateral ventricular enlargement reported in 75 percent, third ventricular enlargement in 83 percent, and cortical changes in 67 percent. Concerns that ventricular enlargement could be secondary to factors such as antipsychotic medications, institutionalization, and diet have generally been ruled out. Furthermore, studies using MRI, with its markedly enhanced resolution, have confirmed the presence of lateral and third ventricular enlargement and provided estimates of tissue loss to be roughly 3 to 10 percent.

The finding of ventricular enlargement dramatically shifted the focus of research on schizophrenia. Subsequently, several critical questions have dominated this landscape. First, is ventricular enlargement caused by focal areas of tissue loss or a more generalized process? Second, do the structural abnormalities predate the

onset of the illness, implicating a neurodevelopmental process, or do they arise concomitantly with the illness, suggesting a neurodegenerative process? Third, are all patients affected or only a subgroup? Finally, what are the functional implications of these abnormalities?

To localize brain abnormalities, researchers have looked at a variety of measures, including cortical sulcal enlargement, ventricular enlargement, and quantitative measures of individual brain structures. Regarding cortical sulcal enlargement the data are split, with some reporting sulcal enlargement in the frontal and temporal lobes whereas others have found more diffuse enlargement. More specific measures of cortical volume typically show reductions of temporal and, less consistently, frontal lobe volume. These reductions involve gray rather than white matter, although some studies have found reductions in white matter as well. Regional volumetric studies of specific brain structures have generally focused on the temporal lobes. Bilateral volume reductions in amygdala-hippocampus, parahippocampal gyrus, entorhinal cortex, and superior temporal gyrus have been reported. In the ventricular system, increased volume in the temporal poles of the lateral ventricles has been found most often; increased volume of the frontal horns and third ventricle is also commonly found. In quantitative studies of subcortical regions, findings have been mixed. Some researchers find no changes in areas such as caudate, putamen, nucleus accumbens, and external segment of the globus pallidus; others have reported increased striatal volume and reduced globus pallidus (internal segment) volume. Increased striatal volume is thought to be an effect of treatment with antipsychotic medications. Reduced volume of the thalamus has also been observed.

The notion that the temporal and frontal lobes may play a particularly important role in schizophrenia has been supported by findings from other areas. For example, neurological damage to the temporal lobes sometimes produces positive psychotic symptoms, such as hallucinations, while damage to the frontal lobes is associated with negative symptoms such as apathy, social withdrawal, and blunted affect. On neuropsychological testing, patients with schizophrenia typically show impaired frontal and temporal lobe function. More recently, magnetic resonance spectroscopy has been used to examine these regions. This new technology can measure in vivo concentrations of a variety of neurochemical moieties. These include *N*-acetyl aspartate (NAA), an intraneuronal amino acid sensitive to mitochondrial energy metabolism and to pathological processes affecting neuronal integrity, choline-containing compounds, creatine plus phosphocreatine, glutamate, glutamine, and high-energy phosphate-containing compounds. Several intriguing findings have emerged. First, specific reductions of NAA have been observed in the dorsolateral prefrontal cortex and hippocampal area, probably reflecting neuronal pathology in these locations. Other areas are, for the most part, unaffected. Second, an imbalance between phosphomonoesters and phosphodiesters has been described in the frontal cortex. These studies, combined with volumetric data, lend support to the theory that there may be selective deficits in frontal and temporal regions.

Attempts to pinpoint when volumetric alterations occur have led to studies of patients at the onset of their illness. This issue is crucial to understanding what neurobiological processes could possibly account for structural abnormalities. In general, first-break studies have found the same alterations seen in prior studies of patients with chronic schizophrenia. These results are supported by the lack of relation between volumetric alterations and duration of illness or age of onset seen in studies of such patients. If an active process produced tissue loss, the loss would be correlated with illness duration, which it is not in most studies. On the other hand, cognitive deficits associated with schizophrenia do not progress but probably develop very early in the illness. Although portions of these deficits may be present even in childhood, a significant component probably develops sometime around the onset of the illness. It is not inconceivable that structural abnormalities could develop at the same time. Such changes would not necessarily be detected by first-break studies. Another approach has been to scan first-break patients when they initially present for treatment and then again several years later. The results have been mixed: some find no changes whereas others have suggested that a subgroup of patients do show slight, but progressive tissue loss. The latter approach has been criticized on methodological grounds and certainly more studies are needed. At present, it seems fairly certain that structural abnormalities are present from very early on in the illness.

A third issue is whether structural alterations are present in all patients or only a subgroup. Several early studies had found associations between ventricular enlargement and a variety of clinical characteristics, including poor premorbid adjustment, age of onset, cognitive impairment, negative symptoms, poor response to antipsychotic medications, and greater incidence of tardive dyskinesia. Such observations have led to suggestions that there are two forms of schizophrenia, one involving a hyperdopaminergic state and the other involving structural abnormalities. Since then, many CT and MRI studies have examined this issue but have generally failed to confirm this schema. Structural abnormalities do appear to be correlated to some degree with cognitive impairment and negative symptoms, but these correlations are not particularly robust. Another approach to subtyping has been to look at the distribution of these deficits. In a meta-analysis of studies that have used CT scans to evaluate ventricular enlargement, the lack of a bimodal distribution in over 1000 patients suggests that a clear subgroup with these abnormalities does not exist.

An elegant attempt to assess the frequency of structural abnormalities was provided by a study of discordant monozygotic twin pairs. Unaffected monozygotic twins serve as an ideal control for assessing illness-related changes. In an MRI study of 15 such pairs, the ill twin had more pronounced deficits for most structural measures in over 85 percent of cases. These findings are similar to those of a prior twin study using CT scans. The data suggest that volumetric abnormalities in schizophrenia are very common, if not ubiquitous; detecting the abnormality may depend on having a perfectly matched genetic control (Fig. 12.4-1) because patients with normal ventricular volume were often seen to have significantly larger ventricles than their unaffected twin. However, when this MRI study of twins was expanded to 27 discordant pairs, lateral ventricular enlargement was only seen in about 63 percent of the affected twins relative to the unaffected twins. This is only somewhat higher than 50 percent, which is what would be expected by chance. In this expanded sample, it appears that ventricular enlargement may not be universal. In contrast, hippocampal measures continued to predict the affected twin in roughly 80 percent of cases, which is significantly higher than the 50 percent chance level; this suggests that hippocampal pathology is common. Although the exact percent of patients having structural abnormalities is not known, it is probably fairly high. An alternative view is that structural abnormalities represent a quantitative trait that is commonly associated with schizophrenia but neither necessary nor sufficient to produce the illness.

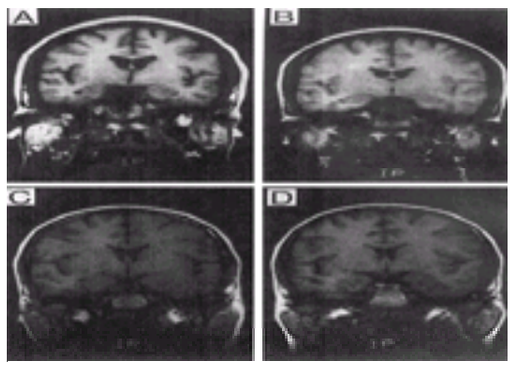

FIGURE 12.4-1 MRI scans (coronal sections) of two sets of discordant monozygotic twins (**A** and **B** = set 1; **C** and **D** = set 2). For each pair, one has schizophrenia (**A** and **C**) while the other does not (**B** and **D**). For both pairs, the affected twin has larger ventricles than the unaffected twin, even though ventricular size appears to be within the normal range for the affected twin (C). (Courtesy of D. Weinberger and E. F. Torrey.)

In summary, structural abnormalities, such as enlarged ventricles and reduced cortical volume, are a prominent feature of schizophrenia. It is unclear whether cortical involvement is multifocal or diffuse. Temporal and frontal lobe regions are certainly involved. These abnormalities are present very early in the illness. It is too early to say, however, whether they are present from birth or develop at a later stage. Structural abnormalities may be present in a majority of patients, although the exact percentage is unknown. The prevalence is most apparent when compared to ideally matched genetic controls. Structural abnormalities are correlated to some degree with clinical aspects of the illness, such as cognitive deficits. A key issue remains unresolved: what neurobiological processes account for these enigmatic changes?

Functional Neuroimaging Functional neuroimaging refers to a group of methods that look at changes in regional neural activity by measuring regional cerebral blood flow (rCBF) or glucose utilization. These two parameters can be measured with several techniques, including positron emission tomography (PET),* (SPECT), and more recently functional MRI (fMRI), each having its own particular advantages and disadvantages. These techniques have been used to explore brain regions that may be dysfunctional in schizophrenia. Several designs have been employed: (1) patients and controls are compared at rest; (2) they are compared during cognitive testing that normally increases activity in a particular brain region; and (3) brain activity is correlated with psychiatric symptoms, either cross-sectionally among patients or within a patient over time. The most consistent finding is reduced activation of the prefrontal cortex (hypofrontality), but other regions, such as the temporal lobes, have also been implicated. Also, correlations have been found between specific symptom clusters and regional activity in both frontal and temporal areas (Fig. 12.4-2).

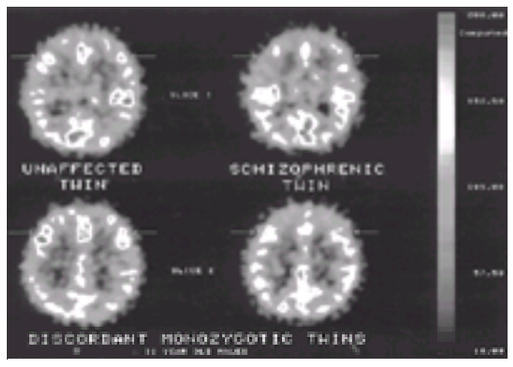

FIGURE 12.4-2 PET scans using H_2O_{15} of two monozygotic twins, one with (right) and one without (left) schizophrenia. Top and bottom scans show two levels through the dorsolateral prefrontal cortex. At the time of scanning, subjects are performing a cognitive task that typically requires prefrontal cortical function. The affected twin blood flow to the dorsolateral prefrontal cortex is markedly reduced compared to the unaffected twin. (Courtesy of R. Berman and D. Weinberger.) (See Color Plate 8.)

Frontal lobe function has been studied most intensively. Initially reported in 1974, the finding of reduced frontal blood flow has been controversial. Many studies, particularly those looking at the resting state, have not found evidence of hypofrontality. Such studies have been criticized, however, because the resting state is an uncontrolled feature and may introduce unnecessary variability. Using cognitive tasks that appear to require prefrontal activation in controls, a number of studies have consistently found that patients with schizophrenia fail to increase blood flow to this region. Although many resting studies have reported hypofrontality, most, if not all, studies using activation tasks have found hypofrontality; this suggests that the use of activation tasks can increase the sensitivity of these procedures to detecting abnormalities by assessing function of regions involved in the illness (Fig. 12.4-2).

The finding of hypofrontality in schizophrenia has often been interpreted as an artifact of poor performance, motivation, clinical state, medications, or other factors. However, studies have not shown that these factors account for differences between patients and controls. For example, poor performance on working memory tasks is not necessarily associated with reduced prefrontal blood flow. Patients with Huntington's disease and groups with low I.Q. who do equally poorly on prefrontal cognitive tasks, are able to activate the dorsolateral prefrontal cortex. Interestingly, hypofrontality appears to be correlated with several structural and neurochemical indices. Prefrontal activation is highly correlated with homovanillic acid (HVA) concentrations in cerebrospinal fluid, possibly reflecting prefrontal dopamine activity. Hypofrontality has also been correlated with hippocampal volume in one study of discordant monozygotic twins, suggesting a dysfunctional circuit. Finally, preliminary reports suggest that reduced prefrontal NAA concentrations, markers of neuronal integrity, are correlated with reduced frontal activation. These data imply that hypofrontality could result from a process that affects neuronal viability in both frontal and hippocampal regions and that these have downstream effects on the regulation of prefrontal dopamine.

The temporal lobe has also been examined with functional neuroimaging techniques. Both elevated and reduced blood flow has been reported. The most common finding is an association between resting blood flow and positive psychotic symptoms. For example, one report found a correlation between increased psychopathology and blood flow to the left parahippocampal gyrus; a second found a similar correlation between positive symptoms and left temporal lobe blood flow. More specific correlations have been seen for auditory hallucinations and activation of Broca's area and medial temporal regions. A potential criticism of this finding is that patients may have simply been responding to auditory hallucinations with their own vocalizations. Activation of Broca's area, in this case, would be expected and trivial. Research into the relation between symptom clusters and blood flow revealed that positive symptoms were associated with increased medial temporal flow, negative symptoms with decreased prefrontal (dorsolateral) blood flow, and disorganization with increased cingulate flow. This parcelation of symptoms with neuroanatomy suggests that separate but related neurophysiological processes may underlie specific types of symptoms. The few studies that examine several regions simultaneously tend to find changes in the coordinated activity between regions, particularly between prefrontal and temporal areas. Typically, increased activation in temporal areas is found in functional connectivity of the two regions.

One report on other brain regions found increased left globus pallidus activity at rest; others have reported both decreased and increased glucose utilization in the striatum (Fig. 12.4-3). Antipsychotic medications appear to increase striatal metabolism, suggesting that medications are an important confound. Reduced cingulate activation has also been described. As newer techniques that do not depend on radioactivity, such as fMRI, are more commonly used, further characterization of these and other brain regions can be expected.

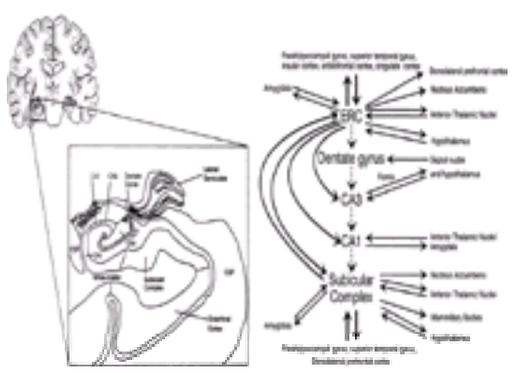

FIGURE 12.4-3 A, Schematic diagram of the mesial temporal lobe at the level of the body of the hippocampus and posterior entorhinal cortex, in coronal section. **B**, The illustrated connections of the coronal section are described in this table. (Drawn by Kyle Christensen.)

In summary, blood flow to several brain regions, including prefrontal and temporal areas, is altered in schizophrenia. These changes may be related to or may underlie positive and negative symptoms as well as some cognitive deficits. Regional abnormalities may also be related to each other, indicating a more global problem with the function of the larger systems or neural networks. Many questions remain. How closely are the changes in temporal and prefrontal activity associated with the clinical features of schizophrenia? Is the activation of other brain regions affected? Can functional brain imaging pinpoint which brain areas cause specific symptoms? What neurobiological processes account for differences in brain function? Correlations with structural abnormalities, dopamine metabolites, and regional NAA levels suggest that these variables could play a role.

NEUROPATHOLOGY

The neuropathological basis of schizophrenia remains obscure despite an increased number of techniques applied to the investigation of this subject. The future appears bright, however, as more laboratories across the world become engaged in this research. Regions that have become the focus of postmortem studies include temporal and limbic structures (hippocampus, amygdala, hypothalamus, nucleus accumbens, and cingulate cortex), and prefrontal and orbitofrontal cortices. Other paralimbic structures recently have been added to the neural network thought to be dysfunctional in schizophrenia, including the ventral tegmental area, substantia nigra, anterior thalamic nuclei, and entorhinal cortex. With this focused approach a number of intriguing findings have emerged; almost all still need independent replication, and the confounds of antemortem exposure to antipsychotic drugs must be considered when reviewing these studies.

Temporal Lobes

Mesial Structures Perhaps the one region that has received the greatest attention in postmortem schizophrenia research is the mesial temporal lobe, which contains the entorhinal cortex, amygdala, and hippocampal formation (Fig. 12.4-3). These structures have been examined in both morphological and neurochemical studies. The entorhinal cortex, which relays cortical input into the hippocampus and distributes output from the hippocampus to a diverse group of brain structures, has been carefully scrutinized. The laminar distribution of neurons in the superficial layers of the rostral entorhinal cortex has been reported to be abnormal and disorganized by

several independent groups of investigators. One study in particular has suggested that the subtle changes in neuronal aggregation may be restricted to layers II and III. Taken together, these data suggest a mild disruption of normal cytoarchitectural features. Although it may not be impossible for this to occur later in life, the findings would strongly support the notion that abnormal neuronal migration may occur during brain development in patients with schizophrenia.

The finding that cytoarchitectural abnormalities are present in the entorhinal cortex have recently been contested by two carefully controlled, anatomically precise studies. Both studies failed to find the abnormal cytoarchitectural features described previously and suggested that earlier reports may have been confounded by incomplete matching of sections from normal controls and individuals with schizophrenia. The normal cytoarchitecture of the entorhinal cortex markedly changes along its rostrocaudal extent, making the issue of appropriate matching critical. However, the entorhinal cortex may not be entirely normal in schizophrenia; one study found a limited reduction in neuronal number and density. This is consistent with other reports of smaller volume, a reduction in the number of neurons, and volumetric measures using MRI.

Neurochemical elements that subserve the anatomic integrity of a given brain region have also been measured, as an indirect assessment of the cytoarchitecture. Microtubule-associated proteins (MAPs) are important elements of the neuronal cytoskeleton. One recent study found a marked loss of MAPS immunoreactivity in the subiculum and the entorhinal cortex in schizophrenia. This finding was interpreted as support for and evidence of cytoarchitectural abnormalities in this mesial temporal lobe. However, given the qualitative nature of most immunostaining techniques, direct replication and additional investigations with more quantifiable strategies are needed.

Synaptophysin is a synaptic vesicle protein, and as such is widely distributed throughout the central nervous system. Levels of synaptophysin or its mRNA on both can be used as indices of synaptic density. Decreased synapsin I, but not synapsin IIb or synaptophysin, has been found in the hippocampus of patients with schizophrenia. A more recent report noted a reduction in synaptophysin messenger ribonuclei acid (mRNA) in CA4, CA3, subiculum, and the parahippocampal gyrus. There were no changes in synaptophysin in these regions, however, suggesting that the loss of synapses may occur at extra-hippocampal sites. Alternatively, local circuits within the hippocampus may be compromised but the ability to detect these changes is limited by the volume of extra-hippocampal input to this brain region. In any event, this finding is another element in the emerging picture of structural alterations in the mesial temporal lobe.

Hippocampus The hippocampus, the predominant structure within the mesial temporal lobe, also may have anatomic abnormalities. Postmortem studies of the hippocampus have proliferated since the mid-1980s. One group found a volume reduction in the whole hippocampal formation in schizophrenia. Others, however, have reported that decreased volume is restricted to the white matter of the left hippocampus, or in the volume of the CA4 subfield. A number of other postmortem studies have found subtle structural abnormalities in the hippocampal formation in schizophrenia, providing a relatively robust body of evidence implicating alterations of the hippocampal formation in schizophrenia.

Within the pyramidal cell layer of the hippocampus, the most recognizable microscopic feature is the orientation of pyramidal cells. While cellular disarray in the CA1-prosubiculum and CA1-CA2 interface has been observed by one group, at least three other groups were unable to replicate this finding. Decreased numbers of pyramidal cells in hippocampal subfields and reduced neuronal size (in left CA1 and CA2, and right CA3) have also been found. These are both consistent with prior MRI findings. Alteration in the density of staining of the mossy fibers in the hilus of the dentate gyrus, and several hippocampal subfields have been seen as well. However, this finding is surprising because cell loss in the adjacent entorhinal complex should lead to an increase in the staining density of the mossy fibers. Finally, decreased polysialic acid-neural cell adhesion molecule (PSA-NCAM) immunoreactivity has been reported in the CA4 subfield of the hippocampus in schizophrenia. PSA-NCAM, a cell adhesion molecule, is thought to be important in synaptic rearrangements in adulthood. Although no clear consensus has emerged on the nature of pathological change within the hippocampus proper, there is abundant evidence of structural abnormalities.

Amgydala The amygdala, located within the mesial temporal lobe, has major interconnections with the entorhinal cortex and hippocampus, as well as many other structures. The amygdala appears to have a smaller volume in schizophrenia patients; this finding is in accordance with postmortem reports.

Prefrontal Cortex Postmortem studies of the prefrontal cortex have been stimulated by the deficits observed with in vivo neuroimaging. One recent study found increased neuronal density in prefrontal area 9; a change of similar magnitude was observed in occipital area 17 as well, suggesting a widespread pathological process. This finding was interpreted as representing a loss of neuropil throughout the cortex in schizophrenia without accompanying gliosis. Area 9 has also been shown to have a smaller average neuronal size and an increased density of smaller neurons, with unchanged glial size and density. The absence of gliosis again suggests that the pathological change in schizophrenia is probably not an active inflammatory process. Area 17, visual cortex, did not show any of these abnormalities, suggesting some anatomic specificity of this finding. In addition to smaller neuronal size, layer 3 pyramidal cells may have diminished dendritic spine density, which in part may explain the abnormalities in neuropil noted by others. Finally, area 46, prefrontal cortex adjacent to area 9, also has increased neuronal density in layers 2, 3, 4, and 6, and a thinning of layer 2. Taken together, these studies suggest a loss of neuropil in the prefrontal cortex, and abnormalities in the cellular constituency of this region.

A somewhat murky picture has emerged from studies of the distribution of neurons in the subcortical white matter underlying the prefrontal cortex. Such neurons are thought to represent a vestige of neuronal migration during early brain development. One group found an increased density of nicotinamide-adenine dinucleotide phosphate diaphorase-positive neurons in the deep white matter and a lower density in the superficial white matter underlying the superior and middle frontal gyri. This is consistent with a developmental arrest in the migration of cortical neurons from deeper white matter areas to superficial cortical layers. A second, similar study looked at MAP2-immunoreactive neuron distribution in the subcortical white matter underlying area 46 and the transition zone between areas 46 and 9 in the prefrontal region. Patients with schizophrenia had a greater density of MAP2-immunoreactive neurons in the superficial white matter compared to controls. In contrast to the first study, no differences are seen in deeper white matter. This was interpreted as either abnormal expression of MAP2, a defect in neuronal migration, a failure of programmed cell death, or a decrease in white matter volume in schizophrenia patients. Although these two studies looked at different neuronal subpopulations, the different findings are contradictory and must be interpreted with caution.

Orbitofrontal Cortex The orbitofrontal cortex has also come under scrutiny, at least in part because of interconnections with a variety of limbic system structures and the efficacy of leukotomy in the treatment of some clinical aspects of schizophrenia. In area 10, orbitofrontal cortex, a decrease in neuronal number, maximal in layers 4 and 5, and in cortical thickness has been observed in a small sample of schizophrenia subjects. A similar reduction in areas 4 (frontal), 24 (cingulate), and 17 (occipital), has also been seen, suggesting a pancortical process. A more recent study found a significant reduction in neuronal density in layer 6 of area 10, but also in layer 5 of area 24 (cingulate cortex) and layer 3 of area 4 (primary motor cortex). The meaning of changes in such disparate layers cannot be easily explained, especially in light of the findings in areas 9 and 17.

Neurochemical analyses also have been performed on the prefrontal cortex as an index of structural integrity. One group examined the concentrations of synaptic vesicle associated protein-25 (SNAP-25) a synaptosomal associated protein involved in neurotransmitter release. Using quantitative Western blots, they found an elevation in SNAP-25 concentrations in area 9, reductions in areas 10 and 20 (temporal cortex), and no change in area 17. Such findings could be due to either a change in synaptic density or to an abnormality in neurotransmitter release; the former interpretation may account at least in part for the decreased neuropil in area 9.

Cingulate Cortex The anterior cingulate cortex (area 24) is part of the neural network subserving the cortical regulation of emotion and attention, both of which appear to be deficient in schizophrenia. In a series of postmortem studies, one group demonstrated an increase in vertical axon number in the cingulate cortex of schizophrenia patients. These researchers have also reported abnormalities in neuronal aggregation in layer 2 of area 24 and a decrease in the number of interneurons in layers 2-6 of this region. Others have seen an abnormality in the usual asymmetry of weight and surface area for the anterior cingulate cortex; independent replication of these findings will be important.

Other Regions Subcortical structures also may have an abnormal anatomy in schizophrenia. Consistent with MRI studies, the mediodorsal nucleus of the thalamus may have fewer neurons in schizophrenia patients in comparison to controls. Studies of the basal ganglia are somewhat limited. Whereas one study did not find any absolute volume differences in the striatum as a whole or individually in the caudate, putamen, or nucleus accumbens, a second group reported an increase in left striatal volume in schizophrenia patients. A third report on the ultrastructure of the caudate nucleus using electron microscopy ound abnormalities in synaptic morphology and dystrophic and reactive changes in astrocytes. Regarding midbrain dopaminergic nuclei, decreased volume of the lateral substantia nigra, and a decrease in the average volume of the nerve cell bodies in the medial segment have been observed. Several other studies have found no significant brainstem pathology or relatively nonspecific findings. Clearly, more research needs to be devoted to the brainstem, given the importance of ascending catecholamine and serotonin systems in regulating the activity of forebrain structures, and the clinical data implicating these neurochemical systems in schizophrenia.

Gliosis Of all these subtle yet potentially important cytoarchitectural findings, one of the most critical observations is the apparent absence of gliosis. The importance of this stems from theoretical implication that reduced volume of brain regions and other abnormalities are not the result of an active pathological process: instead, they are likely to be secondary to very early developmental processes. The issue of whether gliosis is present has been addressed by many postmortem studies over

the past century. Of these, at least a dozen recent studies have used methodologically superior quantitative techniques. While several have noted increased gliosis, the large majority has found no differences between brains from patients with schizophrenia and those from normal controls. These include studies using several different techniques for counting glial cell number, such as the Holzer stain, Nissl stain, and immunoreactivity for glial fibrillary acidic protein. Some methodological questions about the ability of some techniques to detect the effects of chronic gliosis persist; it seems unlikely, however, that clinically relevant gliosis would be obscured.

The wide variety of potentially important findings must be approached with a healthy skepticism. Several common problems plague almost all postmortem volumetric and cell counting studies in schizophrenia. First, standard stereological techniques, using serial sections at regular intervals through the rostrocaudal extent of the mesial temporal lobe, are infrequently applied. Fortunately, more recent studies are employing stereology with greater frequency. Moreover, rarely, if ever, is the time of fixation carefully controlled, so that there is a wide variation within and across studies. Tissue shrinkage, which affects tissue volume and cell density, and maybe quality of cell staining, varies with the duration of fixation. Nevertheless, postmortem studies point to subtle volume reductions in the hippocampal formation in schizophrenia. The precise neuropathological changes that underlie this volume reduction remain controversial.

NEUROCHEMISTRY

Dopamine One of the most important observations in twentieth-century psychiatry is that dopamine antagonists ameliorate symptoms of schizophrenia. The implication that too much dopamine causes psychosis has dominated research for well over two generations and continues to exert a profound impact. In its most basic form, the dopamine hypothesis states that an excess of subcortical dopamine neurotransmission leads to psychotic symptoms. Observations that the prefrontal cortex modulates subcortical dopamine release have established a compelling link between cortical abnormalities and changes in the dopamine system. A current version of the dopamine hypothesis is that dopamine is dysregulated; levels may be reduced in the prefrontal cortex and altered in complex ways in subcortical and limbic regions. Reduced cortical dopamine could explain hypofrontality, impaired cognition, and negative symptoms (such as anhedonia and lack of motivation). Altered subcortical and limbic dopamine, on the other hand, could cause positive symptoms (such as hallucinations and delusions). Theories about the role of dopamine in schizophrenia have advanced in tandem with the increased understanding of the neurobiology of dopamine.

Neurobiology of Dopamine Dopamine (Fig. 12.4-4) is synthesized from tyrosine through dopa. The first step, the conversion of tyrosine to dopa by tyrosine hydroxylase, is the rate-limiting step, and is subject to feedback regulation. The major metabolic product of dopamine catabolism in humans is homovanillic acid, and, to a lesser extent dihydroxyphenylacetic acid and 3-methoxytyramine. Concentrations of these metabolites have been examined in the brain, cerebral spinal fluid (CSF), plasma, and urine of patients with schizophrenia to look for evidence of increased or decreased dopamine neurotransmission.

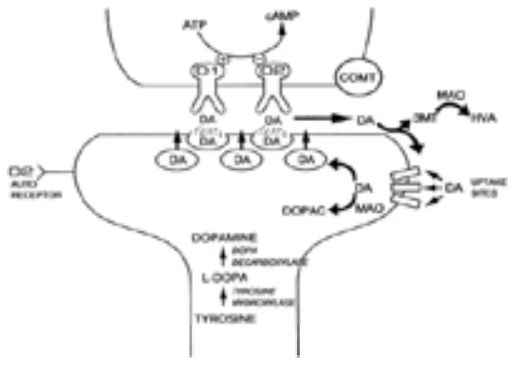

FIGURE 12.4-4 Dopamine metabolism and synaptic structure. In this schematic synapse, dopamine is released into the synaptic cleft where it can act on D_1 or D_2 postsynaptic receptors. Synaptic dopamine is inactivated by reuptake pumps or by catabolism via COMT and MAO. Presynaptic D_2 autoreceptors modulate dopamine synthesis and release in the striatum. (Drawn by Kyle Christensen.)

Dopamine cell bodies are primarily located in two midbrain nuclei: the ubstantia nigra (pars compacta) and ventral tegmental area. Projections from these nuclei have three primary target regions, and are named accordingly. The nigrostriatal tract carries nigral dopaminergic projections to subcortical motor control areas of the striatum (caudate and putamen in humans). The nigrostriatal projections come primarily from the substantia nigra but also, to a lesser extent, from the ventral tegmental area. Mesolimbic dopamine projections from this area target a number of limbic regions, such as the nucleus accumbens and temporal lobes. The mesocortical dopamine pathway projects primarily from the ventral tegmental area to the prefrontal cortex. A fourth dopamine tract is found entirely within the hypothalamus. In addition to different target regions, these separate projection systems function independently to some degree and are regulated by different mechanisms.

Dopamine exerts its effects through at least five receptor types, D_1 through D_5, identified on the basis of their deoxyribonucleic acid (DNA) sequence. Most pharmacological functions of dopamine receptors characterized so far are attributed to D_1 and D_2 receptors. Much less is known about the actions of D_3, D_4, and D_5 receptors. The D_1 family includes D_1 and D_5, while the D_2 family includes D_2, D_3, and D_4 receptors. Genes for the D_2 family have a number of introns, leading to alternative splicing and several isoforms. For example, the D_2 receptor has two common splice variants, a long and short form, usually both expressed in the same cell. The D_4 receptor has numerous polymorphisms, including longer and shorter forms, although these do not arise through alternative splicing. Different isoforms of the D_2 family may have different affinities for second messenger systems, presumably leading to variations in biological effects. Introns or alternative splicing variants for the D_1 family of receptors have not yet been identified.

D_1 and D_2 receptors are found predominantly on the primary efferent neurons of the striatum, and limbic system (e.g., the nucleus accumbens), prefrontal cortex, and other cortical regions. D_2 receptors are also located on the presynaptic dopamine terminals in target regions and dopamine cell bodies in the midbrain. These autoreceptors regulate dopamine synthesis, neuronal firing, and release. The latter two autoreceptors are not on mesocortical nerve terminals in the prefrontal cortex. D_3 receptors are expressed predominantly in subcortical limbic regions, such as the islands of Calleja and nucleus accumbens in the rodent, but are also seen in the hippocampus. D_4 receptors are thought to be presynaptic regulators of glutamate release on projections from cortical areas to the striatum and some limbic regions. D_5 receptors are found in limited distribution in the thalamus, hippocampus, and hypothalamus.

The role of the dopamine system in the overall economy of the brain is not well understood. The relation between dopamine cell loss and Parkinson's disease established its role in regulating motor activity. The link between dopamine and drugs of abuse suggest a critical role in motivation and reward. Increasingly sophisticated electrophysiological studies have shown that activation of subcortical dopamine pathways alert the organism to changes associated with the prediction of future salient and rewarding events. This function is essential for predicting future events, which allows an organism the ability to plan and control interactions with the environment. Furthermore, prefrontal cortical dopamine is critically involved with working memory, a key component for higher-level information processing tasks. Thus, dopamine is involved in motor behavior, motivation, reward, and a variety of higher cognitive tasks, all of which have been implicated in schizophrenia. Clearly, the dopamine system has a complex molecular, cellular, and physiological neurobiology, and this underlies an equally complex functional role in normal brain and behavioral function.

Dopamine and Schizophrenia Evidence for the dopamine hypothesis of schizophrenia comes from a variety of sources. One approach has been to examine the effects of different medications on schizophrenic symptoms. Drugs that block D_2 receptors reduce psychotic symptoms; dopamine agonists worsen symptoms. These observations form the cornerstone of the dopamine hypothesis. A second approach has been to look at various indices of dopaminergic neurotransmission in patients with schizophrenia. Such indices include measures of presynaptic activity, such as the major dopamine metabolites, dihydroxyphenylacetic acid and homovanillic acid, as well as postsynaptic markers, primarily dopamine receptors. Metabolite studies have examined homovanillic acid in urine, plasma, CSF, and autopsied brain. Receptor studies have been performed on postmortem brain tissue and in living patients using PET and SPECT. More recent methods have been used to assess in vivo presynaptic dopamine levels and dopamine release using both PET and SPECT. Dopamine neurotransmission could be altered by changes in any one of a number of neuronal functions, including synthesis, degradation, release, uptake, receptor binding, or effects on second and third messenger systems. Although several decades of research have not provided definitive affirmation of the dopamine hypothesis, increasingly sophisticated methods to assess in vivo dopamine

activity are beginning to yield important clues.

The notion that dopamine neurotransmission is increased in schizophrenia derives its most compelling support from clinical observations on the effects of drugs that impact psychotic symptoms. The introduction of antipsychotic medications in 1954 was a dramatic breakthrough in psychiatry and initiated an intense search for their mechanism of action. In 1963 antipsychotic medications were found to increase the concentrations of dopamine metabolites. It was suggested that increased metabolite concentrations were a compensatory response to the blockade of dopamine receptors by antipsychotic agents and a subsequent reduction in dopamine neurotransmission. The idea that these drugs reduced dopamine neurotransmission was further supported by the observation that they also induced parkinsonian adverse effects, symptoms that had recently been linked to the loss of midbrain dopamine neurons. In 1977, following pharmacological characterization of the D_2 receptor, a striking correlation was reported between the relative clinical potencies of all clinically available antipsychotic medications and their ability to block D_2 receptors. This landmark finding convincingly demonstrated that antipsychotic effects were mediated by D_2 receptor blockade.

While the correlation between clinical potency and D_2 blockade for antipsychotic medications was compelling, several problems emerged. D_2 blockade occurs within hours of administration, but the antipsychotic effects can take days or weeks to develop; this suggests that a secondary process is required. Studies of the chronic effects of neuroleptics then led to the observation that, after several weeks, dopamine neurons themselves stopped firing. After short-term administration of antipsychotic medications there is an initial increase in dopamine neuronal firing as neurons attempt to overcome D_2 blockade; eventually this overexcitation leads to the phenomenon of depolarization block, where depolarized neurons simply stop firing. Reduced neuronal firing was thought to markedly reduce dopamine release, leading to reduced dopamine neurotransmission. For some time, the depolarization block theory was crucial in supporting the view that antipsychotic drugs exert their therapeutic effects by reducing dopamine neurotransmission. Subsequently, a number of studies have not found reduced dopamine release after long-term treatment with antipsychotic medication. While methodological issues are still debated, this suggests that some process other than a simple reduction in dopamine release may underlie the therapeutic effects of these medications.

Other observations have been difficult to reconcile with the dopamine hypothesis. For example, many symptoms such as cognitive deficits, anhedonia, and alogia typically fail to respond to treatment with antipsychotic medications, suggesting that other processes are involved. A second problem relates to the unique clinical effects of clozapine (Clozaril). Clozapine has been shown to benefit patients who do not respond to dopamine receptor antagonists. The dopamine hypothesis, on the other hand, implies that D_2 blockers should be equally efficacious. The unique clinical effects of clozapine suggest that it may have a different mechanism of action. Clozapine's effects have been attributed to several properties, such as its antagonism of serotonin receptors or its combination of D_1, D_2, and D_4 blockade. Drugs developed to mimic different aspects of clozapine's receptor-binding profile, such as risperidone (Risperdal), olanzapine (Zyprexa), and quetiapine (Seroquel), share some of clozapine's “atypical” characteristics.

A second line of evidence supporting the dopamine hypothesis comes from observing the effects of dopamine agonists. Chronic amphetamine abuse, for example, increases dopamine release and can lead to a psychosis similar to paranoid schizophrenia. Amphetamine-induced psychotic disorder, however, lacks other features associated with schizophrenia, such as negative symptoms and cognitive impairment. Furthermore, psychotic symptoms only develop after prolonged use (and typically at high doses), whereas dopamine neurotransmission is increased shortly after a single dose of amphetamine. This suggests that repeated increases in dopamine release produce secondary changes that are more directly responsible for the psychosis.

METABOLITE STUDIES The search for more direct evidence of altered dopamine release in schizophrenia led to investigations of dopamine and its metabolites in urine, plasma, CSF, and postmortem brain tissue. Consistent with the basic dopamine hypothesis, several studies of plasma homovanillic acid have found increases in unmedicated schizophrenia patients compared with controls. These studies sometimes report correlations between concentrations of homovanillic acid and severity of psychosis. Furthermore, antipsychotic medications appear to reduce plasma homovanillic acid over time, correlating with patients' improvement. Methodological problems, however, cloud the interpretation of studies using plasma homovanillic acid. It is unclear whether plasma homovanillic acid correlates with its concentrations in limbic brain regions, areas most likely to underlie the production of psychotic symptoms.

Investigators have also looked at dopamine metabolite levels in CSF. While most studies have failed to find significant changes, several have reported a correlation between concentration of homovanillic acid and severity of psychotic symptoms. Studies of medication-free patients have tended to show a reduction in dopamine metabolites. Negative correlations have been found between concentrations of homovanillic acid in CSF and ventricular enlargement and severity of negative symptoms (e.g., anhedonia and flat affect). Prefrontal cognitive deficits have also been associated with reduced CSF homovanillic acid, perhaps consistent with a model of subcortical dopaminergic overactivity and prefrontal cortical hypoactivity; methodological issues make the interpretation of CSF studies problematic. First, dopamine and metabolite concentrations in the CSF are affected by a number of variables that are not commonly controlled. These include diet, time of day, height, and motor activity. Second, increased ventricular volume itself could affect the concentration of homovanillic acid. Third, CSF monoamine concentrations appear to have little relation to either regional brain levels of dopamine or, more importantly, to more direct measures of dopamine neurotransmission. Certainly if dopamine transmission in the prefrontal cortex is reduced and subcortical transmission is increased, it is difficult to predict what would happen to CSF concentration. Nevertheless, CSF data is often interpreted as supporting the notion that too much dopamine is related to positive symptoms whereas too little underlies negative symptoms.

More direct assessments of dopamine neurotransmission have come from postmortem studies of dopamine metabolites. Increased dopamine or homovanillic acid or both have been reported in a number of brain regions, although reports are often inconsistent. For example, one study found increased dopamine in the left amygdala, a second reported increases in the nucleus accumbens, and a third found increases in the caudate but not the accumbens. Increased homovanillic acid has been found in the cortex, accumbens, and caudate. The latter finding has been attributed to the effects of previous treatment with antipsychotic medications. At this point no clear consensus can be derived from studies of dopamine metabolites.

DOPAMINE RECEPTOR STUDIES A number of studies using postmortem brain tissue have shown increased numbers of D_2 dopamine binding sites in the brains of schizophrenia patients. A major confounding issue is whether this increase is a primary alteration in schizophrenia or secondary to long-term treatment with antipsychotic agents, known to cause rapid D_2 upregulation in animals. Studies in nonmedicated and medication-naive patients are conflicting. A number of studies of patients off medication for at least 1 month have found increased D_2 receptors, although several have not. It has been suggested that treatment with antipsychotic medications cannot account for the marked increase and bimodal distribution of D_2 receptors seen in patients who had been treated. Imbalances between D_1 and D_2 receptors have also been reported. Recent studies of D_3 receptors have suggested that D_3 mRNA may be processed abnormally in cortical neurons of patients with schizophrenia, resulting in reductions in the normal D_3 mRNA transcript. On the other hand, a postmortem study of striatal D_3 receptor binding found a significant increase in patients who were medication free for 1 month. D_4 receptors have been harder to assay because of the lack of specific ligands. While two reports using an indirect method have found evidence of increased D_4 receptor density, assays of mRNA for D_4 using highly specific antisense probes have not found increased levels.

Neuroimaging techniques have been used to measure indices of dopamine neurotransmission in living human patients. Striatal D_2 receptors have been assayed in medication-free patients by several groups using PET; the results, however, have been conflicting. One study found increased receptor numbers while two others did not. These studies used different PET ligands to measure D_2 receptor density, perhaps accounting for the conflicting results. One of the PET ligands binds only to D_2 and D_3 receptors; the second also binds to D_4 receptors. The discrepant PET findings have been attributed to an increase in D_4 receptors, consistent with postmortem studies. More recently, in vivo neuroimaging methods have been refined to assay presynaptic indices of dopamine storage and release. In this paradigm, radioactive D_2 ligand binding is examined at baseline and following a pharmacological challenge with amphetamine. The dramatic increase in dopamine release caused by amphetamine displaces the postsynaptic binding of the D_2 ligand. The washoff of the D_2 ligand can thus be used as an index of dopamine release. Unmedicated patients with schizophrenia show reduced ligand binding after amphetamine, but not at baseline. This suggests that patients with schizophrenia have increased synaptic dopamine following amphetamine. One explanation for this is that presynaptic stores may be increased; another possibility is that synaptic reuptake is reduced. Although methodological issues continue to be refined, this promising lead implies that subtle aspects of dopamine neurotransmission may be altered.

ANIMAL MODELS Animal studies have been invaluable in efforts to understand normal and abnormal function of the dopamine system. Of particular relevance for schizophrenia research are studies that attempt to model dysfunctional dopamine systems in a way that may shed light on the neurobiology of psychosis.

Initial attempts to develop relevant animal models began with repeated, high doses of stimulants (such as amphetamine), based on the association between stimulant abuse and psychosis in humans. Repeated stimulant treatment was also thought to model repeated stress, an apparent trigger of psychotic relapse. Remarkably, stimulants increase the sensitivity of the mesolimbic dopamine system to stress, a process referred to as *sensitization*. Furthermore, in some paradigms stimulants can reduce presynaptic indices of dopamine activity, which has led to speculations that repeated increases in dopaminergic transmission (e.g., from stress) could lead to sensitization in limbic regions and long-term dopamine depletion in prefrontal regions. Thus, long-term administration of stimulant may provide a model to explore the

interactions between known triggers of psychosis and dysfunctional dopamine systems.

Another promising line of animal research suggests that alterations in dopamine neurotransmission in one region may be secondary to primary deficits in another. For example, depletion of dopamine from prefrontal regions can increase dopamine metabolism in the striatum of rats. This suggests that a primary reduction of prefrontal dopamine in humans could theoretically lead to secondary alterations in subcortical dopamine. Reduced prefrontal dopamine could certainly explain the hypofrontality and negative symptoms that characterize schizophrenia. Although no direct evidence has shown that there are dopamine abnormalities in these regions, the indirect evidence reviewed above is suggestive. In a related line of research, structural damage to cortical and limbic regions has been shown to change subcortical dopamine neurotransmission. For example, within the limbic system lesions of the hippocampus or amygdala alter dopamine neurotransmission in the nucleus accumbens and prefrontal cortex. Such observations have been critical in attempts to relate structural and functional changes in frontal, temporal, and hippocampal regions with abnormalities in the dopamine system. They suggest that information-processing deficits in frontal and limbic regions have marked effects on subcortical processes, including dopamine neurotransmission.

The dopamine hypothesis continues to exert a profound effect on research in schizophrenia. The discovery of new subtypes of dopamine receptors along with new neuroimaging approaches offer improved methods to study the function and pathophysiology of this system in humans. Particularly important for schizophrenia research is the finding that dopamine subsystems are interconnected and that damage to different brain regions previously implicated in schizophrenia can have marked effects of dopamine neurotransmission. At present, a variety of indirect data suggest that prefrontal dopamine neurotransmission may be reduced whereas subcortical dopamine is dysregulated in schizophrenia. Whether these changes are real and whether they are secondary to cortical or limbic dysfunction remains to be seen.

Glutamate Interest in glutamate's role in the pathophysiology of schizophrenia has developed relatively recently. This interest was spurred primarily by two observations. First, acute ingestion of phencyclidine (PCP), a glutamate antagonist, produces a syndrome similar to schizophrenia. Second, glutamate is an essential neurotransmitter in those neural networks that may be involved in schizophrenia. Subsequently, a variety of postmortem and clinical data have been garnered in support of a glutamatergic abnormality.

Neurobiology of Glutamate Glutamate is one of the most prevalent neurotransmitters in the brain. Virtually all neurons in the brain are affected when glutamate is applied. A nonessential amino acid that does not cross the blood-brain barrier, it can be synthesized in the brain from glutamine. The dominant mode of inactivation of synaptic glutamate is via reuptake by specific, high-affinity uptake sites.

The four classes of glutamate receptors have been identified and named after their affinity for specific ligands: *N*-methyl-D-aspartate (NMDA), a-amino-3-hydroxy-5-methylisoxazole-4-proprionic acid (AMPA), kainic acid (KA), and L-aminophosphono-butyric acid (AP4). The first three are ionotropic receptors; their effects are mediated by changes in ionic conductance through neuronal membranes, including sodium, potassium, and calcium. The ionotopic receptors have been implicated in neurotoxicity following ischemia, mediated in part by increased intracellular calcium influx and apoptosis. The NMDA receptor is functionally different from the others and has been implicated in long-term potentiation (a process related to memory) in the hippocampus. Paradoxically, NMDA blockade can also result in neurotoxicity, apparently modulated by interneurons and activation of non-NMDA glutamate receptors. The last type of glutamate receptor, labeled by AP4, is a metabotropic receptor, a member of the family of G-protein–linked receptors. The metabotropic receptors modulate activation of second messengers, such as phospoinositide and cyclic adenosine monophosphate (cAMP), which can produce long-term, modulatory effects. Major advances in understanding the molecular biology of these receptors is increasing the understanding of their function.

The NMDA receptor is a complex protein that has particular relevance for schizophrenia research. Blockade of the NMDA receptor by phencyclidine (PCP), a noncompetitive antagonist, produces symptoms similar to those seen in schizophrenia. NMDA receptor activation is excitatory, reducing postsynaptic membrane potential. PCP binds to a site within the open NMDA ion channel, thus blocking ionic flux. The mechanism by which NMDA antagonism produces psychotic symptoms is unclear; one theory is that NMDA antagonists exert their psychotomimetic effects via NMDA receptors' role in regulating striatal and limbic dopamine neurotransmission. Of note, NMDA receptor density is highest in the hippocampus and prefrontal cortex, two areas already implicated in the pathophysiology of schizophrenia. Altered neurotransmission in these regions could also play a role in PCP's effects.

The NMDA receptor has a number of modulatory sites that regulate ionic conductance. Endogenous modulators include glycine, zinc, magnesium, and the polyamine spermidine. The glycine modulatory site has become a target for drug development. Increasing NMDA neurotransmission by increased glycine binding has been hypothesized to reduce symptoms of schizophrenia. Several studies have attempted to do so using glycine agonists such as milacemide or cylcoserine, and the results have been mixed. Another potential pharmacological target is the high-affinity glycine uptake pump. Antagonists of this site should increase synaptic glycine concentrations, enhancing NMDA neurotransmission. Similarly, antagonists of the glutamate reuptake pump could boost NMDA receptor activation. It is unclear whether ongoing efforts to develop antagonists at these sites will lead to therapeutic agents for patients with schizophrenia. A major difficulty with increasing NMDA neurotransmission is its narrow range of physiological responsivity. If NMDA stimulation is too high, seizures or neurotoxicity can result.

Glutamate is relevant to the neurochemistry of schizophrenia because of its role in key neural networks. Projections to and from cortical and hippocampal pyramidal neurons use glutamate as a primary neurotransmitter. These include projections to subcortical structures such as the striatum, nucleus accumbens, and ventral tegmental area; output from these areas is strongly modulated by glutamate. Thalamic projections to the cortex also employ glutamate as the major neurotransmitter. Glutamate neurotransmission is important not only for rapid synaptic transmission between these regions, but also for experience-dependent cortical plasticity and memory. This is particularly true for the voltage-sensitive NMDA receptor, a likely candidate for modulating memory traces at Hebbian synapses. Glutamate's essential role in key neural networks, memory and cortical plasticity, thus make it a likely candidate for involvement in altered information processing in schizophrenia.

Glutamate in Schizophrenia Acute intoxication with the NMDA antagonist, PCP, produces hallucinations, thought disorder, negative symptoms, and cognitive deficits. In comparison, dopamine agonists, such as amphetamine, primarily induce paranoid delusions, and only after long-term use. The differences in these drug-induced psychoses suggest that glutamatergic neurotransmission could be more proximal to the pathological processes mediating psychosis. The search for more direct evidence has focused on CSF and postmortem studies of brain tissue.

Studies of glutamate levels in CSF and brain have been mixed. An initial, pioneering study of CSF found low levels of glutamate in patients compared with controls. Possible methodological problems make this data difficult to interpret, however, and three subsequent studies have been unable to replicate the finding. Two studies have looked at glutamate levels in postmortem brain tissue. One found no differences whereas the other found specific reductions in the hippocampus and prefrontal cortex in patients with schizophrenia. The latter study also looked at a neuropeptide co-localized with glutamate *N*-acetylaspartylglutamate [NAAG]. The NAAG pathway has recently been identified as an important comodulator of glutamate neurotransmission. The reported changes in NAAG and its metabolism in brains of patients with schizophrenia open up a provocative new area to explore possible alterations in glutamate neurotransmission.

Postmortem receptor studies have been more promising. In general, these studies have tended to find increased receptor binding in prefrontal regions and reductions in temporal areas. Two reports have found increased kainate binding in the medial frontal cortex; a third found increases in orbitofrontal NMDA receptors. An increase of prefrontal cortical glutamate uptake sites has also been described. A recent molecular study using in situ hybridization and probes for all five NMDA receptor subunits, while not finding an overall increase in receptor mRNA did find a 53 percent increase in the expression of a subunit (NR2D), suggesting a change in the functional properties of prefrontal NMDA receptors.

In the temporal lobe, several abnormalities of the glutamate system have been published. Autoradiographic studies have reported that KA receptor binding is reduced, particularly in the hippocampus. Consistent with this finding, reduced expression of mRNA for receptor subunits has been found in temporal lobe areas. Reduced density of temporal lobe AMPA receptors has been seen, but less consistently. In a recent extension of this work, mRNA transcripts for *Glu* R1 and *Glu* R2 were assayed; these transcripts code for AMPA receptor subunits. Consistent with receptor studies, reductions were seen in the hippocampus and other temporal lobe areas. Finally, the glutamate reuptake site has been assayed in the temporal lobe as an index of presynaptic glutamate terminal number. Reduced levels of mRNA for the reuptake site suggest a possible reduction in terminal number and thus in axonal projections. Regarding other brain regions, some receptor studies have performed on material from the basal ganglia. Increases in AMPA receptors and reduced NMDA receptors have been reported; some, studies, but not all, have found reduced glutamate uptake sites.

Taken together, the postmortem literature is notable for a myriad of findings implicating alterations in glutamatergic neurotransmission. However, given the typical small number of brains studied and large number of variables, replication of specific findings is critical. Some have theorized that there is a loss of glutamatergic neurons in temporal areas, consistent with structural neuroimaging findings of reduced volume. In this schema, increased glutamate receptors in the cortex and putamen are hypothesized to be secondary to reduced glutamatergic inputs or neurotransmission. The increased focus on glutamate in postmortem studies will bring

increasingly sophisticated assessment of this neural system.

Serotonin The idea that serotonin may play a role in schizophrenia was first postulated when the hallucinogen lysergic acid diethylamide (LSD) was found to block serotonin receptors. Since then, basic studies have begun to unravel the surprising complexity of this system and have provided new targets for investigation. Studies of schizophrenia have looked at a variety of parameters, including plasma serotonin levels, brain receptor levels, and clinical response to serotonergic drugs. Two findings are particularly promising: first, data from postmortem studies have found changes in frontal cortical receptor number; second, new “atypical” antipsychotic medications that are both serotonergic and dopaminergic antagonists appear to have clinical advantages over pure D_2 antagonists. These developments have increased the focus on serotonin in schizophrenia.

Basic Neurobiology Serotonin (5-hydroxytryptamine) is synthesized from tryptophan and is broken down into 5-hydroxyindolic acetic acid (5-HIAA) by monoamine oxidase (MAO). Tryptophan is an essential amino acid; dietary intake of tryptophan can affect CNS synthesis of serotonin. Serotonin synthesis is also modulated by autoreceptors on nerve terminals. Synaptic serotonin is inactivated primarily by reuptake pumps on presynaptic neurons and glia; following uptake, serotonin is repackaged into vesicles or broken down to 5-HIAA. Both serotonin itself and its uptake pumps are found in blood platelets, where they play a role in clotting. In the CNS, serotonin neuronal cell bodies are located in the brainstem in nine separate nuclei. Axons from these cells project through the median forebrain bundle to virtually all regions of the CNS, including the cortex, limbic regions, and the striatum.

The effects of serotonin are mediated by an ever-increasing number of receptor subtypes. Currently, seven classes of serotonin receptors have been characterized: serotonin (5-hydroxytryptamine [5-HT])-type 1 (5-HT_1) through 5-HT_7. Ten subtypes have been described in the 5-HT_1 family (5-HT_{1a} through 5-HT_{1e}), three in the 5-HT_2 family (5-HT_{2a} through 5-HT_{2c}) and one for 5-HT_3. Most relevant for schizophrenia are the 5-HT_2 and 5-HT_3 subtypes. $5HT_2$ receptors are found in the prefrontal cortex, striatum, and nucleus accumbens; 5-HT_3 receptors are found in cortical, limbic, and subcortical areas, such as the amygdala and hippocampus.

The serotonin system subserves a bewildering array of physiological and behavioral functions. For example, somatodendritic 5-HT_2 receptors regulate dopaminergic neuronal firing. Striatal nerve terminal serotonin receptors inhibit dopamine release. Behaviorally, serotonin has effects on cardiovascular, respiratory and motor activity, emesis, sexual behavior, aggression, anxiety, mood, and pain. Frontal serotonin, in concert with dopamine, may play an important role in the modulation of attention and arousal. Recently, basic research using aplysia has shown that serotonin plays a critical role in synaptic mechanisms associated with learning and memory; it may also have important neurotrophic effects during development and in the adult organism.

Serotonin in Schizophrenia The earliest studies to examine serotonin in schizophrenia looked at peripheral measures, such as serotonin concentrations in plasma and uptake in platelets. These studies found increased concentrations in plasma and, less consistently, reduced uptake in platelets. Studies of CSF metabolites have been mixed and suffer from the same methodological confounds described for dopamine. More direct measures of CNS neurotransmission include postmortem assays of serotonin activity, including concentrations in brain tissue; receptor-binding density; reuptake site binding; and levels of mRNA for receptor subtypes, reuptake sites, and synthetic enzymes for serotonin itself.

Although there have been multiple reports of abnormal serotonin levels in a variety of neural structures, only two findings have been replicated: increased levels in the putamen and increased levels in the globus pallidus. One difficulty with this approach is that measurement of neurotransmitters and their metabolites is notoriously unreliable because of their instability in postmortem tissue. In comparison, receptors, reuptake sites, and the mRNA for receptors, reuptake sites, and synthetic enzymes are more stable. Of studies looking at these parameters, the 5-HT_2 subclass has received the most attention. Following an initial report of a reduction in prefrontal cortex in the density of this receptor, two other research groups replicated this finding although a third did not. Whereas this abnormality may be intrinsic to schizophrenia, it is also possible that reduced 5-HT_2 receptor density is a consequence of therapy with antipsychotic drugs. The density of reuptake sites for serotonin also appear to be reduced in schizophrenia, particularly in frontal and anterior cingulate cortices.

Studies looking at the mechanism of action of atypical antipsychotic drugs, such as clozapine, have fueled much of the recent interest in serotonin's role in schizophrenia. Clozapine has a variety of therapeutic properties different from the dopamine receptor antagonists. These could be due to clozapine's ability to block 5-HT_{2a}, 5-HT_{2c}, 5-HT_3, 5-HT_6, or 5-HT_7 receptors, or to increased serotonin release in the prefrontal cortex. When one compares serotonin-dopamine antagonists, which share some of clozapine's properties, such as the reduced liability to produce parkinsonian symptoms, two impressive similarities are their 5-HT_2-binding affinity and the ratio of 5-HT_2 to D_2 binding. This suggests that serotonergic antagonist properties may account for the improved adverse effects profile and perhaps also the enhanced therapeutic efficacy often attributed to the serotonin dopamine antagonists.

In summary, both postmortem studies and drug trials using 5-HT_2–D_2 antagonists suggest that serotonin may play an important role in schizophrenia. Data implicating frontal and anterior cingulate cortices are particularly striking. It is unclear, however, whether alterations in serotonin neurotransmission are primary or secondary and how they may relate to the other neurobiological processes described. Some preliminary investigations suggest that maternal exposure to toxins can produce long-term changes in serotonin neurotransmission. This raises the possibility that neurodevelopmental insults could alter serotonin neurotransmission in adults. Researchers interested in the mechanisms of amphetamine-induced behavioral sensitization have also begun to suspect that serotonin may play a significant role. If sensitization were to be involved in schizophrenia, as has been suggested, serotonin could be a factor. Although research in serotonin has typically taken a backseat to research on dopamine, its relevance for schizophrenia continues to increase as more is revealed about its many neurobiological properties.

Other Neurotransmitters A wide variety of additional neurochemical systems have been studied in schizophrenia, several of which are noteworthy because of potentially interesting findings or because of how extensively they have been studied. These include GABA, norepinephrine, neurotensin, and cholecystokinin. As with other neurotransmitters, studies of these systems have typically looked at transmitter and metabolite levels in brain, CSF, or plasma, as well as receptor protein and mRNA expression in specific brain regions.

GABA Particularly intriguing is research into the role of GABA, which is the major inhibitory neurotransmitter in the brain. Virtually all neurons are inhibited by GABA, and up to 40 percent of neurons use GABA as their major neurotransmitter. Many GABA neurons are local inhibitory interneurons, but GABA neurons in some regions (such as the striatum) are also primary efferent neurons. GABA is synthesized from glutamate via the enzyme glutamic acid decarboxylase (GAD). GABA acts at two receptor subtypes, $GABA_A$ and $GABA_B$, the former being the more important in the CNS. A variety of drugs act at GABA receptors, including alcohol, benzodiazepines, and barbiturates. Findings implicating GABA in schizophrenia include reduced number of GABAergic cortical interneurons, increased $GABA_A$ receptor density in the prefrontal cortex, and reduced GABA uptake sites in the hippocampus. All three findings are consistent with reduced GABA cell number or GABA neurotransmission. Studies of mRNA have found reduction in prefrontal GAD mRNA but not in prefrontal $GABA_A$ receptor mRNA. The former is consistent with reduced GABA neuronal activity; the latter is not. This preliminary effort suggests that GABA cell number or activity is reduced in schizophrenia. As with other postmortem findings, however, further replication is necessary before they can be accepted with confidence.

Norepinephrine Norepinephrine, another monoamine neurotransmitter, has been intensively studied in schizophrenia, although interest has waned recently. Similar to dopamine and serotonin, norepinphrine neurons are located in the brainstem in a group of nuclei (including the locus ceruleus) that project to a variety of cortical and subcortical regions. Norepinephrine acts at two receptor families, adrenergic and b-adrenergic receptors; at least seven a and three b subtypes have been cloned. Both receptor families exert their effects via changes in G-protein–mediated second messenger systems, including cAMP and phosphoinositol. Two neuropeptide transmitters, galanin and neuropeptide Y, are colocalized in noradrenergic neurons. Norepinephrine and its co-transmitters are involved in a number of physiological and behavioral processes including the sleep-wake cycle, arousal, stress, and memory. Both basic and clinical studies support a role for this system in psychiatric disorders such as anorexia nervosa, bulimia nervosa, anxiety disorders, post-traumatic stress disorder, depressive disorders, substance dependence, and substance withdrawal. Many of the behavioral states mediated by the noradrenergic system are markedly altered in schizophrenia, suggesting a role here as well. However, more direct evidence is lacking and any changes in noradrenergic function in schizophrenia may be secondary to the agitation that frequently accompanies psychosis.

Initial studies of norepinephrine examined concentrations in plasma, CSF, and brain tissue. Both plasma and CSF concentrations of norepinephrine and its metabolite appear to be increased in patients with schizophrenia, although this has not been a consistent finding. Concentrations are reduced with treatment with antipsychotic agents and are correlated with clinical improvement. Recently, increased plasma concentrations have been associated with deficit symptoms whereas reduced plasma levels have been associated with depressive symptoms. These two findings seem contradictory and cast doubt on the usefulness of this approach. Furthermore, conclusions from such studies are limited by the same methodological pitfalls described above for other neurotransmitters, including the confounds of treatment with antipsychotic agents and the meaning of peripheral measures. Studies of brain norephinephrine and its receptors have been mixed, with some finding elevations and others finding no changes. The clinical effects of adrenergic agents have generally not been impressive. At least one report found that the presynaptic a_2-adrenergic receptor agonist clonidine (Catapres) reduces psychotic symptoms, presumably by reducing norepinephrine release. On the other hand, several other

studies did not find this effect, and at least one group has reported therapeutic effects for an a $_2$-adrenergic receptor antagonist, idazoxane. Finally, a number of genetic association studies have looked at the incidence of polymorphisms for genes related to norepinephrine neurotransmission, including dopamine beta hydroxylase and the norepinephrine transporter. Although relatively common polymorphisms have been reported for both, no association with schizophrenia has been reported.

Neuropeptides Two other interesting candidate molecules that have been studied in schizophrenia are the neuropeptides cholecystokinin and neurotensin. Both are found in a number of brain regions implicated in schizophrenia, such as the substantia nigra, nucleus accumbens, hippocampus, and various cortical regions. Both are colocalized with dopamine, GABA, glutamate, and other neurotransmitters. Several studies have reported changes in the levels of the peptides themselves, mRNA, or receptors. For example, the following findings have had some degree of replication: reduced temporal lobe cholecystokinin peptide concentrations, reduced cholecystokinin receptor density in both temporal and frontal regions, and reduced cholecystokinin mRNA in the temporal lobe. In general, further replication is required. Drug trials with the cholecystokinin agonist ceruletide have been mixed. Several open trials were promising, but double-blind trials were not. Unfortunately, it is not certain that ceruletide crosses the blood-brain barrier.

Neurotensin's appeal is due in part to its endogenous antipsychotic-like properties. Not only is it colocalized in dopaminergic neurons, but infusions of neurotensin into the nucleus accumbens block the excitatory effects of stimulants and reduce behavioral activation. Neurotensin levels in the nucleus accumbens are markedly increased by treatment with antipsychotic medication. CSF studies have shown reduced neurotensin concentrations and correlations between reduced concentrations and increased psychopathology in drug-free patients with schizophrenia. However, postmortem studies have not shown differences between patients and controls in concentrations of the peptide itself. Such studies are confounded by the pronounced effects of antipsychotic drugs on central nervous system (CNS) neurotensin. One recent report found a 40 percent reduction of neurotensin receptors in the entorhinal cortex in patients with schizophrenia. Further replication and exclusion of effects of treatment with antipsychotic agents will clarify the significance of this finding.

NEURAL CIRCUITS

The variety of structural, functional, and neurochemical abnormalities described implicate disordered information processing in several interconnected neural pathways in patients with schizophrenia. A description of the anatomical components of these pathways and their possible function will provide a basis for integrating the many abnormalities noted in schizophrenia (Figs. 12.4-5).

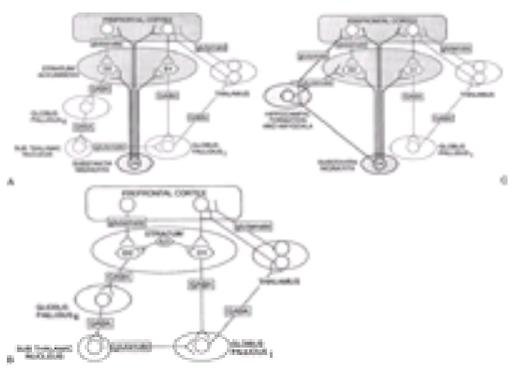

FIGURE 12.4-5 A, Neural networks implicated in the neurobiology of schizophrenia. Cortico-striatal-thalamic pathway. Prefrontal glutamatergic projections synapse on GABAergic striatal neurons that express either D_1 or D_2 receptors. The independent D_1 and D_2 pathways are referred to as the direct and indirect pathways respectively. They have separate efferent pathways projecting to either the globus pallidus, pars externa = E, or pars interna = I. Both pathways ultimately project back to the anterior thalamus. **B**, Ascending dopamine projection pathways modulate circuits in A. Dopamine neurons (DA) from the substantia nigra tend to project mainly to the striatum, while the adjacent ventral tegmental area DA neurons projects primarily to the prefrontal cortex, ventral striatum, and limbic regions. **C**, Limbic projections to circuits from **A** and **B**. The hippocampal formation and amygdala project to the prefrontal cortex and ventral striatum. They receive glutamatergic cortical input and dopamine projections from the VTA. (Drawn by Kyle Christensen.)

As cortical abnormalities have played a dominant role in theories of schizophrenia, understanding the functional connectivity of these areas is important. One of the most intensively studied pathways is the cortico-striato-thalamic loop. The prefrontal cortex, the most highly and recently evolved part of the primate brain, sends a massive glutamatergic projection to subcortical regions, most notably the striatum (putamen and caudate in humans). The striatum in turn sends GABAergic projections through a number of downstream basal ganglia nuclei that ultimately feed into the anterior thalamus. Completing the loop, the anterior thalamus sends a massive glutamatergic projection back to the prefrontal cortex. Several salient features are noteworthy. First, this loop appears to consist of at least five separate but parallel channels processing different types of information (such as cognitive, emotional, and motoric information). Second, output from the striatum is split into two opposing, counterbalancing pathways. The so-called direct and indirect loops are modulated by D_1 and D_2 receptors, respectively. Their coordinated output modulates information returned to the cortex via the anterior thalamus. Third, within the striatum itself, the ventral portion (commonly referred to as the *nucleus accumbens*) receives predominantly limbic inputs, while dorsal regions receive inputs more relevant for motor function. This functional segregation is maintained in downstream projection regions.

A second important system that modulates activity of the cortico-striato-thalamic pathway is the dopamine system. Dopamine neurons in the substantia nigra and ventral tegmental area project to the striatum, nucleus accumbens, and prefrontal cortex. Dopamine modulates cortical output to the striatum via input to glutamatergic pyramidal neurons. In the striatum, dopamine axons synapse on the primary output neurons, the medium-sized, spiny, GABAergic neurons. Coordinated cortical and subcortical dopamine neurotransmission may be important for normal information processing through this loop. Furthermore, dysfunction in one area may produce changes in another. For example, lesions of the prefrontal cortex can induce alterations in subcortical dopamine neurotransmission.

A third neural system interacting with the first two is the limbic system. This complex system involves hippocampus, amygdala, thalamus, hypothalamus, and cingulate gyrus, among others. This immense circuit, subserving functions related to memory and emotional experience, among many others, has direct projections to both prefrontal cortex and ventral striatum. The prefrontal cortex has reciprocal projections back to the mesial temporal lobe and hippocampus. The hippocampus, amygdala, and cingulate have important projections to the ventral (or limbic) aspect of the striatum. This area, in turn, projects to the thalamus via the ventral aspect of the globus pallidus, the pars interna. In this way, three major brain regions—the cortex, limbic system, and basal ganglia—communicate and interact. Information-processing abnormalities in one area, such as in the hippocampus, would have significant downstream effects on other regions, such as prefrontal cortex and striatum.

Structural and functional measures have implicated some abnormality in all three components of these interacting systems. It is uncertain which are primary and which are secondary. It seems very possible that different types of lesions could alter the function of individual components, which could then produce secondary downstream changes in connected circuits.

NEUROBIOLOGICAL MODELS

The essential neurobiological features of schizophrenia may place some constraints on plausible pathophysiological processes. First, there is a major genetic contribution. Many genes are likely to be involved and these may function in part by increasing vulnerability to the deleterious effects of environmental factors. Several environmental factors have been hypothesized to increase the risk of schizophrenia, perhaps by producing subtle brain damage. Structural abnormalities have played an important role in placing theoretical constraints on mechanisms. Since they are present from early in the illness and do not appear to progress, they may predate the onset of illness. Neuropathological data and studies of obstetric and perinatal complications support the idea that an early lesion may account for structural changes. The apparent lack of gliosis in postmortem studies is particularly critical and implicates in utero factors. Structural and functional neuroimaging, as well as neuropsychological data and animal studies present converging evidence for the importance of frontal and temporal regions. Finally, altered dopamine and glutamate neurotransmission are likely to play a part in the expression of psychotic symptoms.

The neurodevelopmental model can account for many of these findings. In short, some process (genetic or environmental) produces damage to selected brain areas

early in life. Temporal lobe regions such as the hippocampus may be particularly vulnerable. Secondary functional abnormalities develop later. As the prefrontal cortex matures in late adolescence, the behavioral and cognitive sequelae of subtle structural deficits become manifest. One result is hypofrontality and cognitive impairment. Alterations in limbic and prefrontal function then produce downstream, secondary alterations in subcortical dopamine, glutamate, and other neurotransmitter systems. Dopamine dysfunction, in particular, may lead to positive psychotic symptoms. The feasibility of this model has received substantial validation from animal studies showing the delayed behavioral and neurobiological effects of minor damage to the hippocampus in neonatal rats. Observations that children at risk for schizophrenia have a number of subtle neuropsychiatric abnormalities, such as deficits in attention, motor control, and social interactions, also support the neurodevelopmental model.

Although the neurodevelopmental hypothesis has been an important organizing heuristic since the mid-1980s several critical issues remain unresolved. First, it remains unclear when structural abnormalities actually develop. Finding such abnormalities in young children who go on to develop schizophrenia would offer strong support for this hypothesis. Alternatively, if these abnormalities develop later in life (e.g., in mid-adolescence), other mechanisms would be implicated. For example, it is unclear whether dendritic “pruning” or an apoptotic mechanism could account for volumetric reductions in areas such as the hippocampus. Observations of reduced neuronal size suggest that factors regulating this parameter could play a role. Second, despite the myriad of findings, the lack of any consistently replicable neurodevelopmental lesion in postmortem studies continues to leave the issue in doubt. It is entirely possible that no single lesion exists. Third, the issue of heterogeneity remains unresolved. Although patients with schizophrenia have structural and functional alterations as a group as compared to controls, it remains unclear whether these are necessary features of the illness. Certainly many patients are in the normal range in some or many of these measures. The same is true for most neurodevelopmental parameters. Many patients have completely normal or even above-average function in childhood and adolescence. Most patients with schizophrenia have no known history of pregnancy, obstetric, or neonatal insults. Is it possible that different patients have abnormalities restricted to differing prefrontal, temporal, or subcortical areas? Such primary lesions could induce secondary dysfunction in connected regions. Fourth, the delayed onset of psychosis presents some problems for the neurodevelopmental model. Although onset is typically in the early 20s, some patients do not develop symptoms until the fourth or even fifth decade of life. It seems most likely that such cases involve mechanisms other than or in addition to neurodevelopmental processes.

Several alternative models have been put forward to deal with some of these problems. For example, structural abnormalities could develop in adolescence, very early in the illness. It is unclear what could account for this, but candidate mechanisms might include reduction in neuronal size or excessive dendritic pruning. Neurotransmitter abnormalities, such as in the dopamine and glutamate systems, may follow. Another possibility is that some cases of schizophrenia are due to increased stress associated with entry into adulthood. This could trigger dopamine abnormalities in genetically vulnerable individuals. Structural abnormalities, in these cases, could be nonspecific vulnerability factors or could be secondary to psychosis itself. A third possibility is that schizophrenia is a heterogeneous illness with several dimensions, none of which is necessary or sufficient. Different domains could involve neurodevelopmental cortical dysfunction, dopamine and glutamate function, cortical regulation of dopamine, and interdependent functioning of a myriad of heteromodal cortical neural networks. In this model, a complex web of genetic and environmental factors could impact on these many neural networks.

One approach toward settling this issue is to examine neurobiological traits associated with schizophrenia. Such traits may be closer to the underlying physiological deficits induced by genes associated with the illness. As such, these traits may have a simpler genetic architecture, making it easier to detect their genes in linkage studies. A number of potential phenotypes have been identified that are clearly familial and thus may have a significant genetic basis. These include impaired sensory gating, eye-tracking dysfunction, perceptual aberrations, schizotypal symptoms, attentional impairment, deficit symptoms, structural brain abnormalities, and cognitive deficits. The feasibility of this approach has been validated by a recent report of linkage using a measure of impaired sensory gating. Suppression of the auditory p50 wave in a sensory gating paradigm has been linked to 15q13–14. This is very close to the a7 nicotinic cholinergic receptor, previously implicated in impaired p50 suppression. Several other preliminary reports have used eye tracking and positive psychotic symptoms. The use of such intermediate phenotypes may also reveal genes that are more important to functional outcome. Unfortunately, the heritability and genetic architecture of most intermediate phenotypes are uncertain, despite a wealth of data showing that many such traits are familial. Studies to assess these parameters and attempt linkage will require phenotyping large numbers of patients.

The underlying neurobiology of schizophrenia remains a mystery. Genetically, the disorder is complex, confounding efforts to locate causative genes. Similarly, the effects of environment are subtle, with no clear major factor emerging. Pregnancy, labor, and delivery complications may play a limited role. Increasingly sophisticated techniques, guided by greater understanding of basic neurobiology, are being used to uncover alterations in a number of brain parameters. Neurobiological abnormalities include reduced volume of several brain structures, sulcal widening, and increased ventricular size. Cortical abnormalities, particularly in the prefrontal and temporal cortices, have also been implicated by cognitive testing and functional neuroimaging. Postmortem studies have failed to find a major lesion or gliosis that could account for structural abnormalities. They have, however, detected a variety of subtle cytoarchitectural changes, perhaps caused by abnormal neurodevelopment. Several neurotransmitters, including dopamine, glutamate, and serotonin, have been implicated. The putative structural, functional, and neurochemical abnormalities can be understood in the context of the neural systems they comprise. These include cortical-striatal-thalamic loops, ascending dopamine projection pathways, and the limbic system. Interconnections between these systems make it difficult to determine which lesions are primary and which are secondary.

The neurodevelopmental model has been a critical organizing heuristic that synthesizes these seemingly disparate observations. This theory suggests that nonspecific lesions in early life, perhaps in utero, produce subtle behavioral anifestations in childhood. The onset of psychosis is delayed until brain maturation reaches later stages in late adolescence. Many questions remain unanswered, however, leaving some aspects of this theory in doubt. Combining techniques such as neuroimaging with molecular genetics provide fertile areas for future research to separate the strands that make up the tangled web of schizophrenia.

SUGGESTED CROSS-REFERENCES

Section 1.2 reviews functional neuroanatomy in greater detail. Section 1.3, Section 1.4, and Section 1.5 contain additional information on dopamine, glutamate, and other neurotransmitters. Section 1.18 describes the basic principles of genetic linkage analysis and Section 1.15 and Section 1.16 provide a more thorough discussion of the principles of neuroimaging.

12.5 SCHIZOPHRENIA: GENETICS

KENNETH S. KENDLER, M.D.

The goal of this section is to provide an overview of the current state of knowledge of the genetics of schizophrenia. The following key questions are relevant. Is schizophrenia a familial disorder? To what extent is any familial aggregation of schizophrenia the result of genetic versus environmental factors? What kinds of psychiatric disorders are transmitted within families? The author believes that genetic factors play an important role in the familial transmission of schizophrenia, thus the following additional questions are pertinent: What are the most likely kinds of genetic transmission mechanisms? and What is the current status of and future prospects for identifying the chromosomal location of specific genes that predispose to schizophrenia?

IS SCHIZOPHRENIA FAMILIAL?

The most basic question in the genetics of schizophrenia is whether the disorder aggregates (or runs) in families. Technically, familial aggregation means that a close relative of an individual with a disorder is at increased risk for that disorder compared to a matched individual chosen at random from the general population. This chapter reviews family studies of schizophrenia examining primarily first-degree relatives (parents, full siblings, and offspring) because little systematic information on more distant relationships has been gathered in recent years.

In a 1967 review paper Edith Zerbin-Rüdin listed 17 major family studies of schizophrenia involving first-degree relatives. By 1980 at least 9 other major studies had been reported. All these studies consistently showed a substantially greater risk for schizophrenia in the close relatives of persons with schizophrenia than would be expected in the general population.

However, nearly all these studies suffered from three methodological limitations. First, because no control groups were used, the rates of schizophrenia in the general population required for comparison had to be derived from the literature. Second, diagnoses were made nonblind, with the research team always knowing that the individual being evaluated was a relative of a schizophrenic individual. Third, neither structured personal interviews nor operationalized diagnostic criteria were used. In fact in many of the early studies it is unclear how many individuals were personally examined and how many were evaluated from indirect information such as reports of relatives or doctors, or from hospital notes.

In the early 1980s several research groups questioned the validity of earlier family studies of schizophrenia. These researchers suggested that the evidence for the familial aggregation of schizophrenia may result from consistent biases in the previous studies. In addition, they were concerned that the diagnostic approach to schizophrenia in these earlier studies might have been overly broad. They argued that the familial aggregation of schizophrenia might be weak or absent when narrowly diagnosed. Since 1980, 11 major family studies of schizophrenia have been reported that used blind diagnoses, control groups, personal interviews, and operationalized diagnostic criteria. These studies permit a more rigorous evaluation than has hitherto been possible of the degree to which schizophrenia aggregates in families.

The key results from these studies are summarized in Table 12.5-1, which contains the diagnostic criteria used in the study, the nature of the control proband group, and the *p* value (i.e., the probability of observing such a difference in the rates of schizophrenia in the two groups by chance, if the true rates were identical). The term *proband* refers to the individual through whom the family was identified for study. A typical family study of schizophrenia would then begin with two types of probands: those with schizophrenia and a matched group of control probands. Relatives of these probands would then be systematically assessed. Table 1 also presents the *lifetimes at risk* in the assessed relatives of schizophrenia and control probands, and the *morbid risk* for schizophrenia in the two groups. Lifetimes at risk is the sum for all assessed relatives of the proportion of their lifetime risk for schizophrenia they have completed thus far. *Morbid risk* (MR) is a statistic commonly used in genetics and equals the total proportion of individuals who would be expected to be affected with a disorder in a given population if all members of that population have completed their age at risk. Finally, the table includes the correlation of liability. If schizophrenia is caused by several genetic and environmental factors that act approximately additively in influencing an individual's liability or predisposition to schizophrenia, then this figure represents the degree of correlation between first-degree relatives in overall risk of the disease. This is a very useful figure because it combines into a single, easily understood statistic the risk figures for schizophrenia in relatives of schizophrenic and control probands. The *higher* the correlation of liability, the *stronger* is the degree of familial aggregation of schizophrenia.

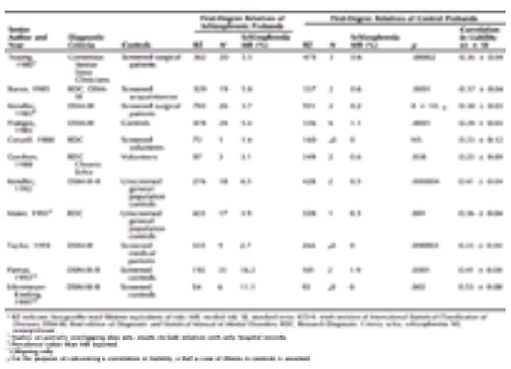

Table 12.5-1 Summary Results of Major Recent Family Studies of Schizophrenia That Included a Normal Control Group, Personal Interviews With Relatives, and Blind Diagnosis of Relatives*

Before turning to the major results summarized in this table, two preliminary comments are in order. First, the sample of relatives studied varies very widely in the different investigations. For example, the lifetimes at risk in relatives of schizophrenic patients range over tenfold, from over 700 to 54. On average, the larger studies will provide more stable statistical estimates for the true risk of schizophrenia in relatives of schizophrenia and control probands. Second, various diagnostic criteria were utilized in the different studies. However, eight studies used criteria from either the third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III), Research Diagnostic Criteria (RDC) (for chronic schizophrenia), or revised third edition of DSM (DSM-III-R) criteria, all of which require at least 6 months of illness, usually with functional impairment, in addition to specified psychotic symptoms. Third, while nine of the studies examined all available first-degree relatives (parents, full-siblings, and offspring), two studies examined only offspring.

There are five major conclusions that can be drawn from the large body of work summarized in the table. First, the risk for schizophrenia in relatives of schizophrenic probands varies widely across studies, from a low of 1.4 percent to a high of 16.2 percent. Much of this fluctuation may probably be attributable to differences in diagnostic criteria or statistical fluctuations in small samples (the lowest risk is found in the smallest study). However, it remains possible that there are true population differences in the risk for schizophrenia in relatives of schizophrenic probands.

Second, the risk for schizophrenia in the relatives of nonpsychiatric control probands is relatively similar across studies, ranging—with the exception of the study of

Parnas et al—from only 0.2 to 1.1 percent, corresponding closely to the range of risks for schizophrenia found in general population studies.

Third, in every study the risk for schizophrenia was higher in the relatives of schizophrenic probands than in relatives of control probands. Across these studies the risk of schizophrenia was, on average, 11 times greater in relatives of schizophrenic probands than in relatives of matched control probands. Fourth, in all but one study, the difference in risk for schizophrenia in the relatives of schizophrenic and control probands was quite unlikely to be attributable to chance (p-value < 0.05). In a number of studies, the p-values were very low (less than 0.001), indicating that such differences in risk would be extremely unlikely to occur by chance.

Finally, although there was some variation, the correlation in liability for all studies fell in the range from +0.23 to +0.53, with a weighted mean across the 11 studies of +0.35. Most of the largest studies that used relatively narrow diagnostic criteria for schizophrenia obtained correlations of liability in the narrow range of +0.32 to +0.41 because the highest and lowest correlations in the table come from the smallest and next to smallest studies, respectively. These results suggest that most of these studies can be seen as replications of one another because they provide similar results on the observed degree of familial aggregation of schizophrenia. The correlation of liability between first-degree relatives in the range of +0.30 to +0.40 indicates a relatively strong degree of familial aggregation.

In conclusion, the questions raised in the early 1980s about the degree of familial aggregation of schizophrenia can now be addressed satisfactorily. The results of a large number of recent, carefully performed family studies support the conclusions of earlier and less methodologically rigorous investigations in finding that schizophrenia strongly aggregates in families. The familial aggregation of schizophrenia appears to be quite substantial when it is defined using modern, relatively narrow diagnostic criteria such as those found in DSM-III-R and DSM-IV. On average, the risk for schizophrenia in the relatives of controls is between 0.5 and 1.0 percent, compared to between 3 and 7 percent in relatives of schizophrenic probands in most studies. The best estimate of the correlation in liability to schizophrenia in first-degree relatives is probably between +0.3 and +0.4.

FAMILIAL AGGREGATION: GENETIC VERSUS ENVIRONMENTAL FACTORS

Twin Studies Resemblance among relatives can be ascribed to shared environment (nurture) or shared genes (nature). A major goal in psychiatric genetics is to determine the degree to which familial aggregation for a disorder like schizophrenia results from environmental versus genetic mechanisms. Although sophisticated analyses of family data can begin to make this discrimination, nearly all that is known about this problem in schizophrenia comes from twin and adoption studies.

Twin studies are based on the assumption that monozygotic (MZ) and dizygotic (DZ) twins share a common environment to approximately the same degree. However, MZ twins are genetically identical, whereas DZ twins (like full siblings) have on average only half of their genes in common. Although the validity of the second assumption is beyond question, the first (equal environment) assumption has been a focus of considerable controversy.

Several studies have shown that measures of the social environment (for example, common friends, attitudes of parents and teachers) are more highly correlated among young MZ twins than among young same-sex DZ twins. These results at first appear to suggest that the equal environment assumption is false. However, there is another possible interpretation. Similarity in environment might make MZ twins more similar, but it is also plausible that by behaving alike, MZ twins seek out or create more similar environments for themselves. These two alternative hypotheses have been empirically evaluated in a number of studies, nearly all of which suggest that the environmental similarity of MZ twins is the *result* and not the cause of their behavioral similarity. Current evidence from an increasingly wide range of studies supports the general validity of the equal environment assumption of twin studies.

Results are available from 13 major twin studies of schizophrenia (Table 12.5-2). None of these, however, meets all the methodological criteria outlined above for family studies and the additional criterion that zygosity assignment be made blind with respect to psychiatric diagnosis. Some studies come closer to this model than others. For example, a variety of different clinicians made diagnoses from blind case abstracts in the original report from the Maudsley twin series of Irving Gottesman and James Shields. These case records have more recently been examined using modern operationalized criteria with similar overall results. In the study by Kenneth Kendler and Dennis Robinette from the National Academy of Sciences-National Research Council (NAS-NRC) Registry, psychiatric diagnoses were collected from a wide variety of clinical settings in which clinicians could not possibly have been aware of any research hypotheses. Furthermore, it could be shown that zygosity assignment was not biased with respect to psychiatric diagnosis. The new Norwegian and Finnish studies used the high-quality twin and psychiatric registries in Norway and Finland and thus should be representative of all treated cases of illness. Whereas the Norwegian study was based on personal psychiatric assessments and performed with structured instruments and DSM-III-R operationalized criteria, the Finnish study used previously recorded hospital and disability diagnoses. The sample size of the Finnish study was relatively large (253 pairs) while the Norwegian sample was much more modest in size (52 pairs). Unfortunately, both studies relied on self-report zygosity measures and the interviews and diagnoses in the Norwegian study were performed nonblind.

* Concordance rates are not age-corrected. Estimates of the heritability of liability are based on population risks for schizophrenia either provided in the study or estimated by the reviewer. For further details regarding figures in this table, see the Kendler et al. (1993) review. For studies with multiple reports, the latest or most complete report was chosen for analysis.
† Cannot be calculated because none of the DZ pairs were concordant.
‡ Correlation in liability in MZ twins is reported rather than the standard heritability of liability; no standard error is available for this estimate.

Table 12.5-2 Concordance With Respect to Probands and the Heritability of Liability to Schizophrenia in the Major Twin Studies Reported to Date

All these studies agree that proband-wise concordance for schizophrenia (the risk for schizophrenia in the cotwins of a schizophrenic proband twin) is much higher in MZ than in DZ twins, but the absolute rates of concordance vary widely. Two factors are probably responsible for most of this variation. First, some studies defined schizophrenia more broadly than others. Second, some studies obtained most of their proband twins from chronically hospitalized populations; others used population-based registries where milder cases would commonly occur. Twin studies have often but not always found a positive relationship between concordance and severity of illness.

Heritability of Liability The diagnostic approach to schizophrenia and the method of ascertaining probands should equally affect concordance rates in MZ and DZ twins. Therefore, a better method of comparing results across studies would be a summary statistic based on concordance in both MZ and DZ twins. One of the best of these is the heritability of liability as calculated from the correlations in liability in MZ and DZ twins. This statistic ranges from 0.0 if genetic factors play no role in susceptibility to a disorder to a maximum of 1.0 if genes entirely determine disease risk. Because this statistic is based on the polygenic multifactorial threshold model, which may or may not be appropriate for schizophrenia, these results should be regarded as only one plausible way of approximating reality. Nonetheless, the major twin studies of schizophrenia agree in estimating the heritability of liability of schizophrenia at between 0.6 and 0.9 (Table 12.5-2). These results suggest that genetic factors play a major role in the familial transmission of schizophrenia.

Genetic theory predicts that if all the familial aggregation of schizophrenia were due to genetic factors, then the heritability of liability should be approximately double the correlation in liability found in first-degree relatives (because, on average, first-degree relatives have half of their genes in common). Comparing the results of Table 12.5-1 and Table 12.5-2 indicates that, at least as a rough approximation, this hypothesis is supported. The range of the heritability of liability to schizophrenia calculated from twin studies is approximately twice the range of the correlation in liability to schizophrenia found in first-degree relatives in most family studies.

Nongenetic Familial Transmission Twin studies also provide two powerful tests for the role of nongenetic familial transmission in the liability to schizophrenia. First, one can ask whether the correlation in liability in DZ twins is more than half that which would be predicted in MZ twins if only additive genetic factors were operating. A review of all major twin studies to date suggests that nongenetic factors may play at most a modest role in the transmission of schizophrenia. Second, the risk for schizophrenia in DZ co-twins can be compared with that in siblings of schizophrenic probands. Although having the same degree of genetic relationship to the affected proband, DZ co-twins certainly share more of the familial environment that do ordinary siblings. Several twin studies have suggested that a difference in risk does exist between these two groups. However, such a difference has not been consistently found across all studies and was *not* found in the recent Norwegian

small-sample twin family study of schizophrenia.

Adoption Studies Adoption studies can clarify the role of genetic and environmental factors in the transmission of schizophrenia by studying two kinds of rare but informative relationships: (1) individuals who are genetically related but do not share familial-environmental factors, and (2) individuals who share familial-environmental factors but are not genetically related. Table 12.5-3 summarizes, in the order discussed, the major adoption studies of schizophrenia, reporting raw data and statistical tests. Our summary here will be organized by the kind of adoption design utilized.

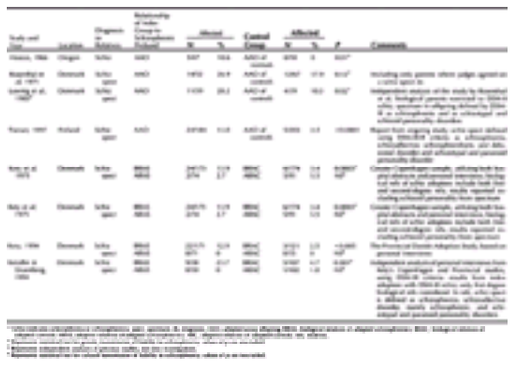

Table 12.5-3 Summary Results of Major Adoption Studies of Schizophrenia*

Affected Biological Parent Design Three studies have compared the adopted-away offspring of schizophrenic parents with the adopted-away offspring of matched controls. In the first of these, Leonard Heston found a significant excess of schizophrenia in adopted-away offspring of schizophrenic versus control mothers. The second such study was performed in Denmark under the direction of David Rosenthal and found similar results, which, however, fell short of statistical significance, particularly when only parents with a consensus diagnosis of schizophrenia or schizophrenia spectrum were included. This study has been the subject of a blind reanalysis using DSM-III criteria, which, when including only biological parents with a consensus diagnosis of schizophrenia from the original investigators, found a significant excess of schizophrenia spectrum in adopted-away offspring of schizophrenic versus control parents. The third and by far the largest such study is still under way in Finland under the direction of Pekka Tienari. Preliminary results indicate a highly statistically significant excess of schizophrenia and schizophrenia spectrum disorders in the adopted-away offspring of schizophrenic mothers compared to the adopted-away offspring of matched control mothers.

Affected Adoptee Design Another major adoption strategy used for studying schizophrenia begins with ill adoptees rather than with ill parents. The full implementation of this design permits two separate experiments: (1) a test for the etiological role of shared environmental factors by comparing the nonbiological adoptive relatives of the schizophrenic with the control adoptees and (2) a test for the etiological role of genetic factors by comparing the biological relatives of the schizophrenic with control adoptees who were raised in households away from their ill relatives. This strategy has been used by Seymour Kety and colleagues in a series of adoption studies carried out in Denmark. The first sample, called the *Copenhagen sample*, began with 34 adoptees located in Copenhagen who received a consensus diagnosis of chronic, borderline, or acute schizophrenia. These adoptees and their matched controls had been separated from their biological parents at an early age and raised by individuals with whom they had no biological relationship. The first report on this series was based on hospital abstracts of all relatives located by the population and psychiatric registries available in Denmark. Schizophrenia and related disorders were significantly concentrated only in the biological relatives of the schizophrenic adoptees. The next phase of this project involved personal interviews of all available and cooperative relatives. After these interviews had been dictated into English and blinded, a diagnostic review also indicated a substantial concentration of schizophrenia spectrum disorders only in the biological relatives of the schizophrenic adoptees.

A second sample beginning with 41 schizophrenia spectrum adoptees from outside of Copenhagen (termed the *Provincial sample*) has also been collected. On the basis of personal interviews with biological and adoptive relatives, the results basically replicated the parallel findings from the Copenhagen sample. Schizophrenia and the spectrum disorders were significantly more common in the biological relatives of schizophrenic versus control probands, while these disorders were equally uncommon in the two groups of adoptive relatives. In an independent review of the interviews from both the Copenhagen and the Provincial samples, using DSM-III criteria, Kendler and Gruenberg replicated and extended all the major earlier findings of Kety and his coworkers.

Vertical Cultural Transmission Because studies of twins contain no parent-offspring pairs, they are not helpful in clarifying whether parents influence their children's risk for schizophrenia in ways that are other than genetic. However, several adoption strategies have been used to clarify the role of parent-offspring environmental transmission (termed *vertical cultural transmission*) in schizophrenia. First, if offspring of schizophrenic persons in part “learn” schizophrenia from their parents, then decreasing the amount of contact between schizophrenic parents and their children should decrease their risk for illness; however, two studies have produced results inconsistent with this hypothesis. Jerry Higgins and coworkers compared the adopted-away offspring of schizophrenic parents with the naturally reared offspring of schizophrenics. Although the sample size was small (23 offspring in each group), follow-up personal interviews indicated a nonsignificant excess of schizophrenia in the adopted-away offspring compared to those children reared by a schizophrenic parent. In a variation of a full adoption study, a similar design was utilized in Israel to compare 25 offspring of schizophrenic parents reared in a kibbutz (where children are raised together in children's houses, yet have considerable contact with their parents) with 25 offspring of schizophrenic parents raised in conventional nuclear-family settings elsewhere in Israel. A follow-up interview in adulthood with these offspring revealed that the risk for DSM-III schizophrenia was actually higher (nonsignificantly) in the kibbutz-reared offspring (13 percent) than in the town-reared offspring (8.7 percent). When the schizophrenia spectrum disorders were included this difference was even greater (26.1 percent versus 13.0 percent) although still short of statistical significance. Both these results are inconsistent with the vertical cultural transmission hypothesis.

A second way to address the vertical cultural transmission hypothesis is to look at the risk for schizophrenia in the adopted-away offspring of normal individuals reared by schizophrenic parents. Although limited by a small sample size and a small number of parents with typical schizophrenia, Paul Wender and coworkers found no evidence for increased rates of illness in such adoptees.

Third, vertical cultural transmission of schizophrenia would predict that among adopted individuals who become schizophrenic, schizophrenia should be overrepresented in their adoptive parents, who would culturally “transmit” schizophrenia. In Kety's Copenhagen and Provincial samples, no excess cases of schizophrenia or related spectrum conditions were seen in the adoptive parents of the schizophrenic adoptees. In separate samples Wender et al twice studied psychopathology in the adoptive parents of schizophrenic adoptees. The first of these studies found evidence for an excess of severe psychopathology in the adoptive parents of schizophrenics. In the second study, which the authors believed was better controlled, no such increase was found.

Fourth, since step-siblings of schizophrenics would be exposed to the same schizophrenogenic rearing environment as the schizophrenic person but would lack the biological relationship to the parents, vertical cultural transmission would also predict an excess of schizophrenia in the step-siblings of schizophrenic persons. Two studies have been unable to find an excess risk for schizophrenia in relatively small samples of step-siblings of schizophrenic probands.

In summary, twin and adoption studies provide strong and consistent evidence that genetic factors play a major role in the familial aggregation of schizophrenia. Evidence for a role for nongenetic familial factors is less clear; some studies suggest that they may contribute modestly to the familial aggregation of schizophrenia, but the majority of studies find no evidence for significant nongenetic familial factors for schizophrenia.

PSYCHIATRIC DISORDERS TRANSMITTED WITHIN FAMILIES

The first systematic family study of schizophrenia, performed by Ernst Rüdin in Emil Kraepelin's newly established Psychiatric Institute in Munich in 1916, found that siblings of schizophrenic patients had increased rates not only of schizophrenia but also of other potentially related psychotic disorders as well. Since that time, a major focus of family, twin, and adoption studies of schizophrenia has been to clarify the nature of the psychiatric syndromes that occur in excess frequency in relatives of schizophrenic patients. This effort has been greatly aided by the emergence of operationalized diagnostic criteria in psychiatry, which permit more precise and reliable diagnoses.

Hypotheses On the level of psychopathological syndromes, four heuristic hypotheses can be articulated about the nature of the liability to schizophrenia that is

transmitted in families: (1) a general (nonspecific) liability to all psychiatric illnesses; (2) a liability to poor psychosocial functioning, oddness, and suspiciousness (schizophrenialike personality disorders); (3) a liability to many forms of psychosis; and (4) a specific liability to typical schizophrenia. These hypotheses are useful because each generates a different prediction about the kinds of psychiatric disorders that should be seen in excess in families of schizophrenic persons.

Nonspecific Liability for All Psychiatric Disorders The first hypothesis predicts that the risk for all major forms of psychiatric illness should be increased in relatives of schizophrenic persons. The hypothesis would be consistent with the unitary hypothesis of mental disorders, which postulates that all psychiatric illness is on a single continuum with schizophrenia at the most deviant end. This hypothesis can be best evaluated in modern family studies and in reanalyses of major adoption studies that have used similar diagnostic criteria and normal control groups.

In the modern family studies that have examined this question, there is nearly uniform agreement that the rates of anxiety disorders and substance dependence disorders are *not* increased in relatives of schizophrenic versus matched control probands. The question of the familial relationship between schizophrenia and affective illness is more controversial. The majority of family and adoption studies that have examined this issue report similar rates for unipolar and bipolar illness in relatives of schizophrenic and control probands. However, at least three recent studies have found a significantly greater risk for unipolar illness in the relatives of schizophrenic probands. The reason for these discrepant findings remain a subject of debate.

Schizophrenia-Like Personality Disorders Both Kraepelin and Eugen Bleuler, the two chief architects of our concept of schizophrenia noted that some close relatives of patients with schizophrenia, although never psychotic, had odd or eccentric personalities that were clinically reminiscent of schizophrenia. Since that time, similar observations have been made by a number of clinicians and researchers. The first and probably the most influential rigorous study of what may be termed these *schizophrenia-related personality disorders* was made by Kety and colleagues in the Danish Adoption Studies referred to previously. Based on a blind diagnostic review with their own diagnostic criteria, Kety and colleagues found a statistically significant excess rate of borderline and uncertain schizophrenia in the biological relatives of schizophrenic versus control adoptees.

More recent applications of operationalized criteria have replicated and extended these earlier findings in support of the second hypothesis. Since 1983 11 family studies have examined the risk for *schizophrenia spectrum*, defined as schizotypal or paranoid personality disorder using DSM-III or DSM-III-R criteria, in relatives of schizophrenic and matched normal control probands (Table 12.5-4). These studies included two reanalyses of different Danish Adoption samples, a Finnish adoption sample, four family studies conducted in the United States, and one family study each conducted in Greece, Ireland, and Germany. The absolute rates of schizotypal and paranoid personality disorder in relatives of both schizophrenic and control probands differ widely across studies. This might be expected because of the quite different approaches used to assess these personality disorder syndromes. However, every study found that schizotypal or paranoid personality was more common in relatives of schizophrenic versus control probands and this difference was statistically significant in 9 of the 11 studies. In aggregate, these results provide strong support for the second hypothesis articulated—that the familial liability to schizophrenia is in part reflected by a set of personality traits related to social isolation, oddness, and suspiciousness.

Author and Year	Study Group	Relatives of Schizophrenic Probands			Relatives of Control Probands			P
		SPD or PPD			SPD or PPD			
		N[a]	N	MR ± SE	N[a]	N	MR ± SE	
Lowing, 1983	Adopted-away offspring	39	6	15.4 ± 5.0	39	3	7.7 ± 4.3	.29

Kendler, 1991	Nuclear family study	319	26	8.2 ± 1.5	580	10	1.7 ± 0.5	.000003
Parnas, 1993	Nuclear family offspring only	192	41	21.3 ± 3.0	191	5	3.0 ± 2.2	$<.0001$
Maier, 1994	Nuclear family study	289	6	2.1 ± 0.8	320	1	0.3 ± 0.3	.04
Erlenmeyer-Kimling, 1995[b]	Nuclear family offspring only	44	4	9.1 ± 4.3	90	1	1.1 ± 0.1	.02

[a] MR indicates lifetime morbidity risk; SPD, schizotypal personality disorder; PPD, paranoid personality disorder; MR, morbid risk; SE, standard error.
[b] Prevalence reported rather than MR.

Table 12.5-4 Summary Results of Major Family and Adoption Studies Using Personal Interviews to Examine Risk for DSM-III and DSM-III-R Schizotypal or Paranoid Personality Disorder in First-Degree Relatives of Schizophrenic and Normal Control Probands

General Liability to Psychosis or Specific Liability to Typical Schizophrenia Recent family and adoption studies of schizophrenia have also provided us with substantial data in favor of the third hypothesis presented—that what is transmitted in families of individuals with schizophrenia is a liability to many forms of psychosis. In most but not all the studies that have examined this question, the risk for nonschizophrenic psychotic disorders (e.g., schizophreniform disorder, schizoaffective disorder, delusional disorder, and psychotic disorder not otherwise specified) is increased in relatives of schizophrenic probands compared to the risk seen in relatives of controls. Furthermore, although examined in fewer studies, the risk for schizophrenia appears to be usually increased in the relatives of probands with nonschizophrenic psychotic disorders.

Another specific test of the third hypothesis is to examine the frequency of psychotic affective illness in relatives of schizophrenic patients. In large-scale family studies in Iowa and in Ireland, the author and colleagues found that while relatives of patients with schizophrenia were not at increased risk for affective illness, if affectively ill, they were more than twice as likely to become psychotic as affectively ill relatives of controls. Furthermore, compared to controls, in both studies the relatives of probands with psychotic affective illness were at increased risk for schizophrenia.

Results to date provide strong evidence against the validity of the first and fourth hypotheses. The familial predisposition to schizophrenia is neither completely nonspecific nor highly specific. Results are available to strongly support the second hypothesis and also to provide some evidence in favor of the third hypothesis. Current evidence suggests that the familial liability to schizophrenia increases not only the risk for schizophrenia as it is narrowly defined but also for schizotypal and paranoid personality disorder and probably several nonschizophrenic psychotic illnesses. These findings provide an increasingly complex but informative picture of the nature of the transmitted liability to schizophrenia.

MOST LIKELY MECHANISMS OF KINDS OF GENETIC TRANSMISSION MECHANISMS

The conclusion that genes account for a substantial proportion of the risk for schizophrenia and related psychiatric disorders naturally leads to a desire to understand the mechanisms that underlie such genetic transmission. Is the risk for schizophrenia the result of many genes of small individual effect or can a single gene, acting alone, transmit a major risk of developing schizophrenia? For many years, genetic epidemiological studies have been carried out with the goal of answering these questions. Unfortunately, for reasons we will discuss fourth most of these questions have not yet been definitively answered.

The major genetic-epidemiological approach to this question prior to the advent of linkage studies was statistical modeling either of risk figures for the various classes of relatives of schizophrenia or of the observed pattern of schizophrenia within systematically collected samples of nuclear families or extended pedigrees. This latter technique is called *complex segregation analysis*. In contrast to linkage analysis, complex segregation analysis examines phenotypes only, and *not* genetic marker information. Both these strategies compare the observed patterns of co-occurrence of schizophrenia among family members of close versus more distant genetic relatives with the degree of sharing expected under alternative genetic models.

Studies of the patterns of risk for schizophrenia in major classes of relatives (e.g., monozygotic and dizygotic co-twins, parents, siblings, offspring, nieces/nephews) have usually concluded that the familial transmission of schizophrenia *cannot* be explained solely by a single major locus (SML). In particular, the concordance rate in monozygotic twins (~50 percent) is too high, relative to the risk in siblings and dizygotic twins (5–10 percent). Such a pattern is more consistent with multiple interacting (or epistatic) loci.

With regard to complex segregation analysis, the results to date have been frustratingly inconclusive; however, they have been more frequently inconsistent than consistent with an SML etiology for schizophrenia. Given the genetic complexity of schizophrenia, it is likely that even the most mathematically sophisticated methods of complex segregation analyses are analytic tools too blunt to provide definitive answers.

CURRENT STATUS AND FUTURE PROSPECTS FOR IDENTIFYING SPECIFIC GENES THAT PREDISPOSE TO SCHIZOPHRENIA

Two fundamentally distinct strategies have been employed in attempts to find specific genes that confer susceptibility to schizophrenia: tests of *linkage* and *association*. What follows is a review of the current progress using both these methods.

Linkage Studies of Schizophrenia Linkage has proven to be an immensely powerful method for simple or Mendelian disorders in which a small number of families can usually unambiguously produce strong evidence for linkage to a small chromosomal region. As discussed later, despite much effort such a result has not emerged for schizophrenia. Why? As outlined in Table 12.5-5, schizophrenia differs from Mendelian disorders in at least five critical ways, all of which make successful linkage studies much more difficult.

Characteristics	Mendelian Disorders	Schizophrenia
Penetrance*	Usually complete—MZ concordance ~100%	Incomplete—MZ concordance 30%–70%
Phenocopies	Usually absent	Present
Diagnostic boundaries	Clear	Uncertain
Locus heterogeneity within families	Never	Uncertain, but likely
Locus heterogeneity across families	Variable, but often absent	Uncertain, but likely

* The probability of illness given the disease-predisposing genotype.

Table 12.5-5 Characteristics of Classical Mendelian Disorders Versus Schizophrenia

First, most Mendelian disorders are *fully penetrant*. That is, if you inherit a "disease gene" and live through the period of risk, you will nearly always suffer from the disorder. As outlined above, the pattern of illness in families—in which first-degree relatives of schizophrenic probands have a risk of schizophrenia of ~5 to 8 percent—and the concordance rate in monozygotic twins (40 to 55%) are inconsistent with the action of a highly penetrant SML. Unlike in Alzheimer's disease when a well-recognized series of pedigrees exist in which the disorder segregates as a Mendelian dominant, no one has ascertained pedigrees in which schizophrenia is transmitted as a classical Mendelian disorder. Finally, the offspring of unaffected MZ cotwins have an elevated risk of illness, suggesting that cases of schizophrenia cannot be simply divided into "genetic" and "sporadic" forms. These results all suggest that, in aggregate, genes that exist for schizophrenia have *reduced penetrance*. That is, it is possible to carry a susceptibility gene or genes for schizophrenia and not manifest the illness.

Second, for most Mendelian conditions, in all individuals who manifest typical symptoms of the disease, the symptoms are caused by the disease gene. This is not true for schizophrenia as schizophrenia-like symptoms can be produced by drugs of abuse and more rarely by metabolic or neurological conditions; these are called *phenocopies*.

Third, in nearly all Mendelian disorders, disease development is independent of the environment. This is not the case in schizophrenia, however, when several environmental risk factors, including season of birth, obstetric complications, and intrauterine influenza infections have been shown to increase the risk of illness.

Fourth, in most Mendelian disorders there is an obvious discontinuity between affected and unaffected individuals. Diagnostic boundaries are less clearly delineated for psychiatric illness and are the subject of continued debate in linkage studies. The correct phenotypic boundaries for schizophrenia to use in linkage and association studies are not known.

Fifth, the disease genes that cause Mendelian disorders are sufficiently rare that for all practical purposes the same disease locus will be responsible for all the cases of illness in a pedigree. Schizophrenia is much more common and it is plausible, although unproven, that two or more loci contribute to disease susceptibility in many high-density families.

Across families the situation with Mendelian disorders is variable. In most disorders (e.g., Huntington's disease, cystic fibrosis) mutations at a single locus are responsible for all known cases of illness. However, for some Mendelian syndromes (e.g., limb-girdle muscular dystrophy and retinitis pigmentosa) a number of distinct loci, usually on different chromosomes, have been found in different families. Given that schizophrenia is not a disease but a broad behavioral syndrome, and given the great complexity of the human brain, it is plausible that mutations in many different genes might result in the condition we call schizophrenia.

The tight 1:1 relationship that exists between disease gene and phenotype that is characteristic of Mendelian genetic disorders does *not* apply to schizophrenia. Locus heterogeneity both within and between families is likely to further complicate this picture. These problems all mean that the signal:noise ratio for linkage studies will be much lower for schizophrenia. As is true in any experimental design, the lower the signal:noise ratio the larger the sample size required to detect an effect reliably. This principle is particularly applicable to linkage studies of complex diseases like schizophrenia. As has been demonstrated by a range of formal power analyses, much larger sample sizes are likely be required to detect linkage reliably for schizophrenia than were needed for the genetically simple Mendelian disorders.

Developments and Early Results The field of linkage studies of schizophrenia is in flux and changing rapidly. Certainly the most important development in the last several years has been the emergence of a small handful of replicated findings. Given the vast number of statistical tests that are now performed in most linkage studies (many markers, several diagnostic models, several genetic models, often several different linkage programs), the true error rate emerging from any individual study is nearly impossible to quantify with precision. It remains a major concern that results of quite high apparent statistical significance could occur by chance alone because so many individual tests are performed.

Thus, replication is critical. However, there remain many justifications for nonreplication, including genetic variation between populations and differences in sample size, composition, and diagnostic approach. Given the evidence of replication across several groups for regions on 22q, 6p, and 8p, many would argue that it is increasingly unlikely that all these regions represent false positives. It is difficult to conceive of some inbuilt bias that would produce spuriously positive results across multiple groups in the same chromosomal region.

A further important development in the field has been the recent emergence of results from total genome scans for other complex disorders including juvenile-onset diabetes mellitus, multiple sclerosis, and asthma. These studies may hold important lessons for our struggles with schizophrenia. For juvenile-onset diabetes and multiple sclerosis, a "major" gene appears to exist in the HLA region that has been detected in nearly all studies. However, in other regions, nonreplication across groups is as frequent as replication and this is the pattern seen in initial studies of asthma. A recent study of asthma performed a genome scan in sibling pairs from three different U.S. ethnic groups; almost no replication for putative regions of linkage was seen across these three samples.

These results suggest that the difficulties in detecting replicable linkages for schizophrenia may not be unique to the psychiatric disorders, but rather may reflect a general pattern of problems associated with linkage studies of complex disorders. When the simple and powerful one-to-one relationship between gene and phenotype that is seen in Mendelian disorders breaks down, linkage studies change from being relatively straightforward although arduous tasks to uncertain and murky endeavors. Detecting genes of modest-effect size for complex moderately heritable diseases is likely be a difficult and sometimes frustrating task.

The first linkage study of schizophrenia was reported by Constantinidis in 1958. This study of 36 pairs of siblings was unusual in that in addition to blood groups, it used as "markers" a wide array of phenotypic traits such as hair color, handedness, and hair whorl. Seven further linkage studies of schizophrenia published between 1973 and 1987 examined, in relatively small samples of sib pairs or pedigrees, single markers (dopamine-b-hydroxylase, Gc, and albinism), HLA or a limited range of traditional polymorphisms (e.g., blood groups, proteins, and red cell enzymes).

Although prior evidence for linkage in schizophrenia had been reported (e.g., Turner reported a logarithm of the odds [LOD] score for HLA and "schizotaxia" of 2.57,

which could not be replicated by subsequent investigators), the first widely noted positive evidence for linkage in schizophrenia and the first study to use DNA polymorphisms was reported by Sherrington et al in 1988. Following up on the report of an association of schizophrenia with a partial trisomy of chromosome 5q, these researchers examined the proximal portion of the trisomy, including the 5q11.2 breakpoint, with 2 RFLP polymorphisms in seven British and Icelandic families. The strong evidence they reported for linkage in this region (5q11-13) (LOD scores maximizing over 6 with a broad phenotypic definition), could not, however, be replicated by many other groups nor by the original investigators themselves.

Current State of the Field Space limitations preclude an exhaustive review of linkage studies of schizophrenia here. Instead selective current developments are reviewed. Several complete or nearly complete genome scans for schizophrenia (in which markers are placed at 10- to 20-cM intervals over the entire human genome) have now been completed or published on relatively small high-density family sets. None of these scans have revealed evidence for a large single major locus for schizophrenia. Consistent with the evidence just reviewed, these results suggest that the existence of a single susceptibility locus that accounts for a large majority of the genetic variance for schizophrenia is unlikely.

Within the last 3 years we have seen the first tentative evidence for replicated linkages for schizophrenia susceptibility loci. To date, three regions appear most promising: 22q12-13, 6p24-22, and 8p22-21. It should be noted, however, that the interpretation of these results is quite controversial, particularly as the definition of *replication* for linkage to a complex trait remains uncertain.

22q12-13.1 In 1994 Ann Pulver and colleagues reported that, in a preliminary genome scan of 240 randomly distributed markers in 39 multiplex schizophrenia families ascertained through the Maryland Epidemiology Sample, the strongest evidence for linkage was found for three markers spanning ~23 cM in the 22q13.1 region: D22S268, IL2RB, and D22S307. The maximum homogeneity LOD score (which assumes that all families were segregating a susceptibility gene for schizophrenia in this region) using their initial genetic model was modest: 1.54 for IL2RB. By altering their genetic model across a range of parameters, they were able to maximize the LOD score, again at IL2RB at 2.82. No evidence for linkage heterogeneity was found.

Pulver organized an attempted replication study of this finding with three other research groups from Virginia, the United Kingdom, and France that examined these three markers on 22q in a total of 217 multiplex schizophrenia pedigrees. Overall, the evidence for linkage was not confirmed by the new samples, although some subsequent analyses by the Virginia group produced weakly positive findings.

Quickly following these reports, a number of attempted replications by other individual groups were published. Two of these reports were positive, including a maximum LOD of 2.09 in nine Mormon pedigrees to marker D22S276 (~4 cM telomeric of IL2RB) and a maximum LOD of 1.51 at marker D22S278 (~7 cM centromeric of IL2RB) in 23 high-density British and Welsh pedigrees. Three other reports were largely negative: in 23 British and Icelandic pedigrees, 105 multiplex American families, and 30 German and Israeli families. In addition, Pulver and her colleagues followed up with a report when their family number had increased to 57. They found the 22q region remained most significant in their genome scan, although their most positive marker shifted from IL2RB to D22S278.

These reports were followed by a large collaborative data-pooling effort led by Michael Gill. Eleven groups contributed with the typing of a single marker, D22S278, which they analyzed by the sib-pair method. Using all available data (620 sib pairs), the excess sharing of alleles in affected sib pairs was modest, but significantly deviated from chance expectation ($p = 0.006$). If they used only the sib pairs where both parents were also typed (296 pairs), the evidence in favor of linkage was somewhat stronger ($p = 0.001$). Although 25 percent of random siblings would be expected to share both alleles at a locus identical by descent, the investigators found that 31 to 32 percent of the sib pairs concordant for schizophrenia shared their alleles at the D22S278 marker. The authors calculated that if this locus truly impacts on the liability to schizophrenia, it is likely of rather small effect, being responsible for ~2 percent of the variance in liability.

Another line of research has impacted on the interest in this region on 22q. Microdeletions in this region are responsible for a range of congenital malformation syndromes, including DiGeorge syndrome and velo-cardio-facial syndrome (VCFS). Individuals with VCFS demonstrate excess rates of psychopathology, although some debate remains as to whether these syndromes more closely resemble schizophrenia or bipolar illness. M. Karayiorgou et al found that 2 of 100 schizophrenic patients had microdeletions in this region, a finding that is in excess of the estimated general population frequency of such deletions of 1 of 4000.

6p24-22 The first evidence for linkage for schizophrenia to the 6p region came from the early phases of a genome scan in the 265 small to medium-sized families constituting the Irish Study of High-Density Schizophrenia Families. In the initial publication of this finding in 1995, 16 markers were examined over a 38-cM interval. When a narrow diagnostic model was used, the evidence for linkage was modest (max LOD = 1.18), but increased substantially as the diagnostic definition broadened to include other disorders within the schizophrenia spectrum (max LOD = 3.51 at D6S296). Evidence for linkage fell when the definition was broadened further to include nonspectrum disorders such as anxiety conditions and alcoholism. Using multipoint linkage analysis and a larger number of markers, the relationship between diagnostic breadth and evidence for linkage in this sample is illustrated in Figure 12.5-1.

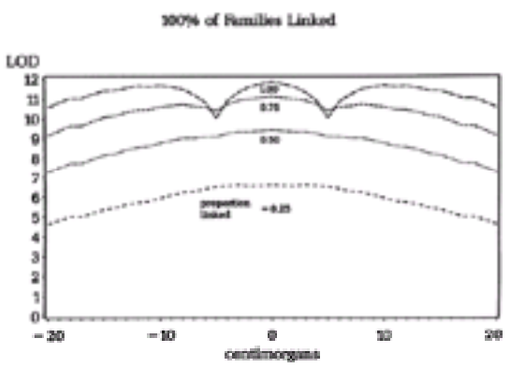

FIGURE 12.5-1 Linkage with homogeneity. LOD scores were obtained from computer analysis of 25 simulated nuclear families (described in the text) in which a disease gene is located at the 0.0 centimorgan map position in all families (genetic homogeneity) and flanked on both sides by genetic marker loci located about 5 centimorgans on either side. Support for four alternative tests of linkage are shown. The hypotheses differ in the hypothesized proportion of families in the collection of families that might contain a major gene conferring susceptibility to schizophrenia. Those hypotheses of linkage with varying levels of genetic heterogeneity are contrasted with the null hypothesis that none of the families contains such a gene (proportion linked = 0.0). When all families are actually linked to the candidate region, as in this example, all four hypotheses show strong support for linkage. However, because LOD scores are based on a $\log_{10}$ scale, the LOD score of 12.0 in support of the true hypothesis (proportion linked = 1.00) provides over one million times (10_6) greater odds of linkage than the hypothesis that receives the lowest support (proportion linked = 0.25), which has an LOD score of 6.0.

Strong evidence for linkage heterogeneity was found—perhaps because of the large sample size. Using several methods, the proportion of families carrying a pathogenic mutation at this putative vulnerability locus was estimated at 15 to 30 percent.

Eleven other published reports on this region have appeared from individual groups. Seven of these studies provide additional evidence of variable strength for a susceptibility locus for schizophrenia in this region; four do not. Briefly, the positive results include: (1) in 43 German and Israeli pedigrees, a maximum LOD of 2.2 near marker D6S274 (~15 cM centromeric of D6S296); (2) in a collaborative sample of 5 large pedigrees and 65 multiplex families, a nonparametric p value for linkage of 0.005 at marker D6S274; (3) in 57 pedigrees from Maryland, a maximum LOD of 1.17 at D6S296 and a sib-pair analysis at the same marker at $p = 0.004$; (4) in 10 German families, modest evidence for linkage (max LODs ranging from 1.41 to 2.08 over a large interval from markers D6S274 to D6S459), which increased substantially when eye-tracking dysfunction was examined (max LOD of 3.51 at D6S271—over 30 cM centromeric to D6S296); (5) an LOD of 2.49 in one mixed French-Canadian family containing cases of both schizophrenia and mood disorder; (6) initially negative results using 5 markers in 19 Southern African Bantu-speaking families which produced mildly positive findings on reanalysis with other statistical methods; and (7) strong evidence for linkage to a quantitative trait reflecting positive symptoms of schizophrenia in 10 moderately large Canadian families of Celtic origin. The negative results include an examination of 4 markers in the region in 45 pedigrees from the United States and Australia, 2 markers in 23 British and Icelandic pedigrees, 17 markers in 211 U.S. families, and 9 markers in 86 Welsh and English families.

In 1996, results of a 14-group collaborative effort on linkage in the 6p region were published. Most of the groups that had previously reported their findings individually

participated in this collaborative effort. Typing 5 markers on 6p on over 400 new families (excluding the Irish sample in which the linkage was first found) and using a narrow diagnostic definition of schizophrenia, a maximum LOD score of 2.19 (which equals a *p* value of ~0.001) was found. It is noteworthy that these modest results for linkage, which were interpreted as suggestive but not definitive, were relatively widely dispersed amongst the groups. For one particular model, for example, modestly positive results (LOD >0.3) were seen in the 6p region by 9 of the 13 new samples examined.

8p22-21 Pulver et al were also the first to report evidence for linkage of schizophrenia to the 8p region. In the 57 high-density schizophrenia families that she and her colleagues ascertained in Maryland, 18 markers were typed over an 81 cM region. Using a relatively narrow definition of schizophrenia, they found evidence for linkage over a ~15 cM interval from markers D8S258 to D8S136. The maximum LOD score was 2.35 at D8S136. Using an analysis based on affected sib-pairs, maximum evidence for linkage (at $p = 0.00004$) was found at D8S258.

Three other reports from individual groups have examined linkage for schizophrenia in this genomic region. A genome scan of five large Icelandic pedigrees found modest evidence for linkage ($p = 0.04$) at marker D8S298 (which maps between D8S258 to D8S136). In 25 Welsh and English families, however, examining 4 markers in this region Kunugi et al could find no substantial evidence for linkage. By contrast, results from the Irish Study of High-Density Schizophrenia Families were quite positive. Examining 15 markers in this region in 265 multiplex families, the strongest evidence for linkage was found for marker D8S1715 (which maps 1-2 cM telomeric of D8S258—maximum LOD = 2.52). Multipoint analysis—which produced the strongest evidence for linkage using a broad definition of the schizophrenia spectrum—demonstrated a 10cM region with LOD scores above 1.90, from markers D8S1715 to D8S1739 (which is ~4 cM centromeric of D8S136). Again, given such a large number of families, strong evidence was found for linkage heterogeneity, with results suggesting that a susceptibility locus in this region was present in only around 10 to 25 percent of families.

The fourteen-group collaborative effort also examined 5 markers in the 8p22-21 region. The maximum LOD score obtained (excluding the families of Pulver et al in which the initial linkage was first found) was 2.22 ($p = 0.001$), which again is suggestive but not definitive. Of the 13 groups that reported new results from this region, positive evidence for linkage (defined as a maximum LOD >0.30) was found in 10.

22q, 6p, and 8p Table 12.5-6 summarizes the current status of linkage findings for these three regions. Results in each of these areas share three features: (1) they have been replicated in at least two other samples in addition to the one in which they were first reported, (2) they have not been replicated in all studies, and (3) a collaborative effort has pooled results across many groups and produced suggestive results.

Replications	22q12–13.1	6p24–22	8p22–21
Initial finding	Pulver et al, 1994 Max LOD = 2.82	Straub et al, 1995 Max LOD = 3.51	Pulver et al, 1995 Max LOD = 2.35
Number of replication attempts:			
Single groups	5	8	3
Number positive	2	4	2
Multigroup	2	1	1
	3 groups, largely negative; 11 groups, 1 marker	14 groups, 5 markers	14 groups, 5 markers
	$p = .006$	$p = .001$	$p = .001$

Table 12.5-6 Current* Potentially Replicated Linkages in Schizophrenia

Other Linkage Regions of Interest: Dopamine Receptors, X Chromosome, and 5q22-31 Many other linkage reports for schizophrenia have been published since 1990. The largest single collection of such reports has examined the five types of dopamine receptors (D_1 through D_5), with at least ten reports examining the 11q22-23 region containing the D_2 receptor, five reports each examining the 3q13.3 region containing the D_3 receptor and the 11p15 region containing the D_4 receptor, and at least two reports examining the 5q35.1 region containing the D_1 receptor, the 4p16 region containing the D_5 receptor, and the 5p15.3 region containing the dopamine transporter gene. These studies have been consistently negative. Genetic variation in or around the genes coding for the dopamine receptors and transporter do not appear to play a major role in the etiology of schizophrenia. Other negative linkage reports include the $GABA_A$ receptor subunit genes; the glutamate GluR5, GluR6, and NMDAR1 subunit genes; and the $5\text{-}HT_2$ receptor.

Based in part on the observation of an excess of same-sex affected sibling pairs, particularly in families where the illness appears to be paternally transmitted, several investigations have been conducted for linkage of schizophrenia to markers in the pseudo-autosomal region—with mixed results.

Finally, linkage in the 5q21-31 region was recently independently found by two groups. In the genome scan of the Irish study, marker D5S818 in 5q22 produced the second best of the first 223 markers tested. Thirteen additional markers were typed over ~45 cM. The largest two-point LOD score found was with marker D5S393 (LOD = 3.04) and assumed a narrow phenotypic definition (schizophrenia plus poor-outcome schizoaffective disorder.) Multipoint analysis produced substantial evidence for linkage (LOD > 2) over ~20 cM, from markers D5S818 to IL-9, with the peak at D5S804 (LOD = 3.35). Evidence for heterogeneity was found, with estimates that between 10 to 25 percent of the families were segregating a mutation at this locus. At the same time, Schwab and colleagues in Germany, in a study on 44 nuclear families found a maximum multipoint LOD score calculated from affected sibling pairs of 1.8 around marker D5S399, which is only ~3 cM distal to IL-9.

Association Studies of Schizophrenia Association studies examine whether individuals affected by a disease more frequently have a particular allele at some "candidate" genetic locus than individuals not affected by the disease. This association can occur for two reasons. Either the allele being studied directly influences risk for the disorder or, more commonly, the allele is in linkage disequilibrium (LD) with the disease-predisposing mutation. In addition, association can occur for spurious reasons unrelated to disease etiology, such as population stratification. While linkage—the co-segregation of a marker and a disease—is a family-based phenomenon, linkage disequilibrium is a population phenomenon and relies on the specific population history of the marker and disease mutation. It will be seen when a marker is close enough to the disease gene so that the original association created when either the disease or marker gene mutated or entered into a population through a population bottle-neck has not had time to be broken apart by genetic recombination. Association studies have two important advantages when compared to linkage studies. First, association studies can study individual patients. Second, under many circumstances, association studies are considerably more powerful than linkage studies at detecting genes of modest effect. However, association studies have two disadvantages. First, they "scan" much smaller regions of the genome that do linkage studies. The practical effect of this is that association studies must be used for candidates genes only. Currently a genome scan using the association method is not technically feasible. Also, obtaining proper controls for association studies can be difficult and if done improperly can lead to false-positives results. Recently, a new approach to association studies has been adopted that solves this problem. By studying individual patients and their parents, researchers can use as a "control group" the parental genes that did not get transmitted to the patient.

Certainly the longest history of LD studies in schizophrenia have involved the HLA region on chromosome 6p. The earlier literature suggested the possibility of replicated positive associations with HLA A9 and B5 and negative associations with BW35. Furthermore, the positive association with the A9 allele was particularly noted in cases of paranoid schizophrenia. More recent reports using molecular genetic genotyping methods have focused on possible associations of schizophrenia with DQB1 and DRB1 HLA loci.

As polymorphic markers became available near or within neurotransmitter receptors, many reports have examined the association between schizophrenia and serotonin and especially dopamine receptors. Sometimes these studies employed polymorphisms within the gene, such as the Ser_{311}/Cys_{311} structural polymorphism within the D2 receptor gene, a glycine-to-serine missense polymorphism at position 9 in the N-terminal extracellular domain of the D3 receptor and the 48 base-pair sequence repeat in the D4 receptor. Few replicated findings have emerged to date; however, there is a suggestion in some but not all studies of excess homozygosity at the D3 receptor gene in patients with schizophrenia. A European multicenter collaborative group recently reported evidence for a modest association (OR ~ 1.2) between schizophrenia and the T102C polymorphism in the serotonin type 2a receptor. Whereas association studies remain of major interest in studies attempting to clarify the nature of the genetic liability to schizophrenia, it is probably fair to conclude that a powerful, widely replicated finding has yet to emerge with this technique.

Anticipation and Expanded Trinucleotide Repeats In the last decade a new mutational class of expandable trinucleotide repeat (TNR) sequences have been shown to be etiologic in a number of human genetic disorders, including several—such as fragile X and Huntington's disease—which are predominantly

neuropsychiatric in their manifestations. A feature of these disorders is *anticipation*—that the age at onset of the illness decreases and its severity increases across generations. In most of these disorders, anticipation has been clearly related to expansions of the TNR.

Anticipation in neuropsychiatric disorders has been observed and commented upon since the early 1800s, when it formed one of the foundations of the *degeneration theory* of psychiatric illness popular in nineteenth-century France. However, Mott, a student of Pearson, dismissed anticipation as a methodologic artifact early in this century. Motivated by the possibility that schizophrenia might result from TNR expansions, a number of recent studies have examined whether the age at onset of schizophrenia demonstrates anticipation—that is, decreases across generations.

Most studies that have examined this question have found evidence in support of anticipation; the interpretation of these results has been more difficult. A number of potential artifacts could explain earlier ages at onset in children than in their parents, aunts, or uncles; several of these artifacts are very difficult to control for. While opinions differ in this field, there is still cause for skepticism on whether "true" anticipation has been conclusively demonstrated for schizophrenia. This is perhaps an increasingly moot point as investigators are now trying to directly detect expanded TNR in patients with schizophrenia.

A number of studies have attempted to directly assess expanded repeats using Repeat Expansion Detection (RED). Several groups have produced evidence for expanded CAG/CTG repeats using the RED method in schizophrenic versus control subjects. However, the significance of these findings remains uncertain, for at least two reasons. First, no correlation was observed in one of the best studied samples between the presence of expanded repeats and either clinical features of illness or age at onset. Second, the RED technique itself is entirely nonspecific and the significance of the detection of repeat expansions, which may occur anywhere in the entire human genome, remains unclear.

FUTURE DIRECTIONS

The evidence is strong that schizophrenia is a familial disorder and that the familial aggregation of schizophrenia is due largely, although probably not entirely, to genetic factors. Whatever the familial predisposition that operates for schizophrenia, it not only "codes" for the classic, psychotic disorder but also increases liability to "schizophrenia-like" personality disorders and probably for some other nonschizophrenic nonaffective psychoses. Two decades of research using statistical methods have failed to clearly delineate the mode of transmission of schizophrenia, a result that is understandable given its complexity.

Advances in molecular biology have opened up realistic opportunities to localize on the human genome the specific genes that influence the liability to schizophrenia. Association studies have yet to provide convincing evidence for the role of a range of candidate genes in the etiology of schizophrenia. Genome scan strategies have, however, provided at least three regions, on chromosomes 6, 8, and 22 where at least three groups have found evidence for linkage. Although false-positive findings cannot be ruled out, it is likely that one or more of these regions do contain one or more susceptibility genes for schizophrenia. The hope is that more comprehensive mapping studies, coupled with advances in sequencing and positional cloning technology, will in the next few years produce the identification of one or more specific gene defects that predispose to the development of schizophrenia.

Whereas gene identification will itself represent a major advance, it will also represent the beginning of several new lines of research including (1) rational drug design based on knowledge of basic pathophysiology, (2) characterization of genotype-phenotype relationships based on knowledge of specific pathogenic mutations, (3) identification of environmental risk factors that interact with specific genes, and (4) realistic prevention research based on our ability to identify high-risk individuals.

12.6 SCHIZOPHRENIA: PSYCHODYNAMIC TO NEURODYNAMIC THEORIES

THOMAS H. MCGLASHAN, M.D., AND RALPH E. HOFFMAN, M.D.

Schizophrenia is unarguably one of the most devastating of the mental illnesses. It often strikes early in life, and onset can signal the presence of an irreversible vulnerability toward psychosis that creates a lifetime of anguish and burden for patients and their loved ones. Equally devastating is the profound alienation that accompanies the disorder's emergence because the symptoms can be strange, unreal, and frequently impossible to connect with empathically. The derailment from normality is profound; in no other disorder is there the sense that one is literally losing his or her mind. Yet it is hard not to conclude that such a travesty is transpiring when one's thoughts become another's voice, one's will becomes enslaved by outside forces, one's capacity to focus and think straight shatters like broken glass, one's wellspring of initiative dries up, and one's apprehension of this tragic change becomes submerged beneath waves of denial, passivity, and nonreactive apathy.

Because schizophrenia is disabling and strange, the disorder has had many explanations and has been the object of more attempts to render it meaningful than any other mental illness. Prior to Galileo, most of these explanations were found in religious texts. From Galileo to Emil Kraepelin, the explanations were found in medical texts alongside neurological disorders and idiocy. Inspired by psychoanalytic thinking, by the early twentieth century the nature and cause of schizophrenia was explained as functional. No longer supernatural or organic in etiology, schizophrenia became a clash of ideas, of wishes, of learned habits (i.e., psychological in its genesis and manifestations). From this milieu came the various psychodynamic theories of schizophrenia. By the late twentieth century, the organic substructures underlying psychological processes received greater attention, leading to models focusing at the mind-body interface, here labeled the neurodynamic theories of schizophrenia.

Neurodynamic theories assert that in addition to psychodynamics, one must look at the neurobiological structures that generate psychology to comprehend symptom formation in schizophrenia more fully. To use the computer metaphor, symptoms arise in schizophrenia because of shifts or defects in the hardware of mentation as well as from conflicts and warps in the software of psychology. This hardware consists of biologically programed neuronal networks in dynamic communication via chemical and electrical connections, hence the term *neurodynamic*.

While purely psychological theories have advanced our understanding of schizophrenia to some degree, this body of thought has not progressed much in the past 30 years. Modern thinking about the psychodynamic contributions to psychopathology has increasingly recognized the central influence of nature as well as experience. The authors feel that schizophrenia, more than any other psychiatric disorder, challenges the boundaries of what is meant by psychodynamic and argue that a broad definition that includes both organic and psychological contributions to mental phenomena is most valid, certainly for schizophrenia and possibly for many other mental disorders as well.

Historically, the 1911 publication of Sigmund Freud's case of Daniel Paul Schreber probably marks the formal beginning of the systematic psychodynamic theories of schizophrenia. For the next 50 years, virtually all thinking in this realm was connected with the various psychanalytic schools, here labeled the classical, interpersonal, and developmental. The next major body of theory emerged from psychoanalytic theories around the middle of the century as family transaction models. Shortly thereafter, following the biological revolution in psychiatry and genetic studies of schizophrenia, the neurodynamic theories emerged, introduced by the stress-diathesis, or vulnerability-stress, hypothesis. Finally, the advent of artificial intelligence and computer simulations of brain functioning gave rise to the most recent parallel distributed processing model of schizophrenic symptom formation.

THEORY

A rigorous and operationally oriented definition of theory envisions it as a set of assumptions and definitions that can generate testable and refutable hypotheses or predictions about a phenomenon. This form of theory constitutes the backbone of modern scientific empiricism. It is not, however, the form of theory that characterized the psychodynamic theories of schizophrenia. The latter are, according to Joseph Lichtenberg, an aesthetically oriented set of assertions explaining something in a manner that is “balanced, logical, and comprehensive while at the same time parsimonious in its assumptions.” Few, if any, of the psychodynamic theories considered here could be operationalized and tested. They are too abstract or based on data collected empathically rather than objectively. None of them can be validated on the basis of empirical data per se. While these theories in general must conform to rules of evidence, their veracity derives from their capacity to help one understand schizophrenia. These theories are compelling in proportion to the degree to which they generate meanings about schizophrenia that make communicable sense and that are useful in one's empathic encounters with afflicted patients. The validity here is face validity and stems from a theory's vividness, connectedness, and depth as well as its parsimonious integration of complexity. Such theory is also useful in alerting doctor and patient as listeners and hunters for what is missing from the latter's experience.

Psychodynamic theory is not, however, useful in posing a series of testable hypotheses that can build a path of knowledge toward a specific causality of schizophrenia. The psychodynamic theories reviewed here ultimately failed at this task and have receded in importance as a result. They remain an important contribution to the total picture of the patient, however, insofar as they provide us with usefully parsimonious metalevel descriptions of both normal and schizophrenic mental phenomena and mechanisms.

CLASSICAL PSYCHOANALYTIC MODELS

Sigmund Freud The classical psychoanalytic model postulates that manifest psychopathology is generated by active and sustained psychological conflict between drive-created wishful impulses and antithetical wishes, reality, or conscience. This conflict generates defenses against the wishful impulse, and these defenses can often be seen in the form of symptoms. Any or all of this drama may be carried on outside of awareness (i.e., unconsciously).

This model finds its most complete elaboration in the structural theory, which postulates the existence of three functional entities in the mind. The *id* is the wellspring of peremptory sexual and aggressive drives and wishes. It is largely unconscious and primitive in structure. The superego, or conscience and ego ideal, is the repository of rules and values learned (internalized) from parents and society during development. It is also largely unconscious but makes its presence known through the affects of guilt and shame. The *ego* is a group of psychological functions that mediate adaptation between the person and the environment (e.g., reality testing) and among conflicting psychological forces within the person (e.g., repression of forbidden impulses). The ego is complex and develops slowly over the course of life. Many of its functions (e.g., defense) are activated by anxiety, the danger signal generated by conflict among psychological forces or with reality. Ego functions, too, operate mostly out of awareness.

Freud postulated that these structures develop during infancy and childhood and are in place by the end of the oedipal period (ages 3 to 5 years). The person at this point has a stable, integrated ego, seen as a sense of self that is enduring and cohesive. Conflict within and among these structures produces the symptomatic and character neuroses. Freud regarded schizophrenia as deriving from psychological development arrested prior to the oedipal stage, prior to development of an integrated ego. According to Freud, this arrest severely compromised the schizophrenic patient's capacity to relate and rendered psychoanalytic treatment problematic, if not impossible.

Although he had virtually no clinical experience with schizophrenic patients, Freud was the first analyst to elaborate a systematic psychodynamic model for this

syndrome. He formulated two models—one emphasizing conflict and defense and the other emphasizing deficiency—as the cause of schizophrenic symptoms.

The conflict-defense model basically explains schizophrenic symptoms by use of the structural model. In this model schizophrenia, like all psychopathology, is the result of conflict and defense. The difference between schizophrenia and the neuroses is purely quantitative, not qualitative. Schizophrenic conflict is more intense and requires frequent use of primitive (i.e., developmentally early) defenses such as denial and projection, which frequently involve a break with reality. The ego functioning of the schizophrenic patient regresses to developmentally earlier stages or levels of organization, the exact level being determined (or fixated) by one or more past psychological traumas. The difference between schizophrenia and neurosis lies in the depth of regression and the point of fixation, which Freud placed in the preoedipal phase of development.

Freud used a deficiency (or deficit) model to explain schizophrenic symptom formation in the case of Schreber. Freud worked from Schreber's published autobiographical account of his paranoid psychosis. Clinically, Schreber's illness began with hypochondriacal preoccupations. These were followed by an apocalyptic panic leading to catatonia, personality change, and symptoms of psychosis, particularly, grandiose and paranoid delusions.

Freud, who was elaborating his libido theory at the time, explained Schreber's psychosis as follows. Conflict initiates the sequence, as it does in all psychopathology. In schizophrenia, however, another process supersedes defense. This process is described as the patient's withdrawal of libidinal or energic investments (cathexes) from the real outside world, especially people (objects, in psychoanalytic parlance). There is a concomitant withdrawal of libidinal investments from the inner, fantasied, mental representations or images of this world and these people. In the developing schizophrenic process, the withdrawn libidinal energy increasingly becomes invested in the patient's self-image, seen clinically as self-aggrandizement or megalomania, or invested in the patient's body image, seen clinically as hypochondriasis. In neurosis, a similar process of withdrawal from real, external relations occurs in response to conflict, but here, the withdrawn libido remains invested in the fantasied objects.

This withdrawal reaches a state so profound as to constitute a break with external reality and relationships and with internal object representations and relationships in fantasy. At this stage, one can see the apocalyptic panic clinically. It represents a projection outward of this internal catastrophe or collapse of psychological investments. This collapse and profound withdrawal constitutes the deficit of schizophrenia. It renders the patient incapable of relationships, including transference, and thus precludes treatment by psychoanalysis. Following this catastrophe, the patient tries to recover and reinvest libido. Since there has been a break with reality, however, these efforts produce the well-known symptoms of schizophrenia, especially hallucinations, delusions, and disordered thinking. The patient has reinvested interest and attention but in objects that are not part of the real world.

In Freud's defense theory, the sequence of conflict, anxiety, and defense is regarded as sufficient to account for schizophrenic psychopathology. In the deficit theory, conflict and anxiety initiate pathogenesis but trigger a withdrawal process that is qualitatively different from defense. Freud never resolved the difference between his two theories. He seemed to say that schizophrenic people are very much like normal and neurotic people in some ways but profoundly different in others. His two theories formed the nidus for much subsequent controversy.

Freud's other theoretical contributions to schizophrenia concern the psychodynamics of delusion formation. Early in his career, he postulated the mechanism of projection, whereby the subject's wish is disavowed and projected onto (or attributed to) another person (the object). Later he suggested that delusions of persecution arise from latent homosexual impulses that undergo reversal and projection. Thus, the situation “I (a man) love him (a man)” is reversed to “I do not love him; I hate him” and projected into “He hates (and persecutes) me.” Later in his career, Freud maintained that the hostility inherent in any form of intense ambivalence toward an object could be projected into feelings of being persecuted by that object.

Paul Federn If Freud was the first major psychodynamic theoretician of schizophrenia, Paul Federn was the first major psychodynamic clinician of schizophrenia. A contemporary of Freud's, he disagreed with his Viennese colleague's pessimism about the schizophrenic patient's capacity to develop transference and to be treated by psychoanalytically informed therapy. He treated many schizophrenic patients and developed techniques that were half a century ahead of his time.

Federn greatly expanded the notion of ego set down by Freud in the structural theory. He was perhaps the first psychoanalytic theoretician to introduce the notion of self. To him, the ego was not just a collection of psychological functions. It also had its own existential being or ego feeling. The various ego functions aggregate into a sum or self that has a feeling of permanence and continuity vis-a-vis time, space, and causality. This is ego feeling, the totality of feeling an individual has of his or her own living being. Ego feeling as subject is “I.” Ego feeling as object is “self.”

Federn also elaborated the concept of ego boundary originally introduced by Viktor Tausk. To Federn, each person possessed an inner and an outer ego boundary. The outer boundary consists of the ego versus the external world; it divides and distinguishes mental phenomena from real phenomena. The inner boundary consists of the repression barrier or the line between conscious and unconscious experience. According to his scheme, which utilized Freud's libido theory, schizophrenia is a disease of the ego. The psychopathological process involves a loss of investments in ego boundaries. Attenuation at the inner boundary means derepression or a reemergence of developmentally earlier (archaic) ego states. Attenuation at the outer boundary means a loss of the distinction between mental and real, seen in the typical schizophrenic symptoms. Mature and archaic ego states, however, can coexist, thus making it possible for the patient to adjust to the real world while still symptomatic and to engage in psychodynamically oriented therapeutic discourse despite illness.

Federn's basically descriptive model follows the theme of defect. Nevertheless, his concepts prefigure the later distinction between psychotic and nonpsychotic aspects of the patient's personality. For him, the schizophrenic process is never total. Furthermore, by highlighting the self phenomenology in the ego of Freud's structural model, Federn anticipated the development of self psychology.

Heinz Hartmann Working within Freud's classical structural theory, Heinz Hartmann was impressed with the ego's complexity and versatility, its strength in opposition to the drives, and its primary aim of serving reality adaptation and survival. Defenses such as intellectualization and sublimation, could also be coping devices. He regarded humans as biological organisms phylogenetically equipped at birth for adaptation to an average expectable environment. This includes primary ego functions like perception, memory, and motility, which are not derived from conflict. Also, ego functions developing later out of conflicts can become autonomous of id and superego or free of conflict to function independently and to serve adaptation. Such functions include language, intellect, thinking, will, judgment, attention, affectivity, reality testing, intention, and object relations in addition to the defenses and primary functions already mentioned. The existence of psychopathology indicates that these ego functions can become reinstinctualized or involved in conflict situations.

The ego, according to Hartmann, also possesses a synthetic function, its aim being to promote homeostasis, or a harmonious equilibrium between the drives of sex and aggression, among the intrapsychic tripartite systems of id, ego, and superego, and between the individual and his or her environment. This supraordinate integrative function carries echoes of Federn's ego feeling. Hartmann, however, regarded the self as an idea (representation) rather than an entity or functioning mental system.

Compared with his extensive contributions to general psychodynamic theory, Hartmann's specific postulates regarding schizophrenia are abbreviated, perhaps because such patients did not constitute a large part of his practice. His theory was a mixture of defense and defect. Like Freud, Hartmann felt that schizophrenic symptoms can result from conflicts secondary to intolerable realities or amplified drive pressures. In addition, he postulated an inborn primary defect in the ego of the preschizophrenic patient that renders the ego incapable of neutralizing certain drive pressures, especially aggression. Aggression generated later in life by conflict or narcissistic injury floods this ego (especially its synthetic functioning) and draws it easily into conflict. The ensuing regression is substantial and mobilizes primitive defenses such as denial and projection, which are viewed as the symptoms of schizophrenia. Not all ego functions regress to the same extent, however, thus accounting for the heterogeneity of the clinical picture.

Hartmann's theory added the importance of aggression to the pathogenesis of schizophrenia. It also placed the source of the syndrome in the preschizophrenic patient's constitution, thus marking such people as qualitatively different from those who later develop normally or neurotically. Finally, Hartmann conceptualized the ego as multidimensional. Schizophrenia affects ego functioning selectively and can therefore be graded in severity. In Hartmann's scheme, it is possible to have greater or lesser degrees of schizophrenia. Overall, he emphasized the biological underpinnings of many psychological functions and thus presaged later neurodynamic theories of schizophrenia.

INTERPERSONAL MODELS

Harry Stack Sullivan While psychodynamic in structure, the interpersonal model of Harry Stack Sullivan, differs fundamentally from psychoanalytic drive theory in content. Drive theory works from the perspective of the person as an individual encountering and shaping the world according to inner arising drives and satisfactions.

Interpersonal theory elaborates the perspective of the individual as a social creature who, from the very beginning, is object related and relationship seeking. Sullivan's model still postulates motivational drives and needs—namely, the need for satisfaction, (mostly biological, in the form of hunger and lust), and the need for security, (mostly psychosocial, in the form of power). All of these needs require interaction with at least one other human being and serve to mediate the interpersonal exchange.

The developmental aspect of Sullivan's theory regards the human infant as being without a psychology separate from the initial mother-infant dyad. Psychological awareness consists of successive discoveries of one's self in relationship with significant others (objects). The first self consists of a we, not an I. Development proceeds according to an increasingly complex hierarchy of needs, all interactional. These are the needs for maternal contact in infancy, parental mirroring in childhood, peer play in latency, chum closeness in early adolescence, and sexual intimacy in late adolescence and beyond.

Anxiety, the affect driving psychopathology, was viewed by Sullivan as external to the infant but imparted to the latter by an anxious parent, usually mother. Anxiety in the interpersonal situation develops three self-states: a good me (low anxiety), a bad me (high anxiety), and a not me (intolerable anxiety). Not-me anxiety is extreme awe, dread, loathing, or panic—so dysphoric as to be experienced rarely, as in nightmares or during severe schizophrenic end-of-the-world panic experiences.

Anxiety leads to the organization of defensive structures, which Sullivan described as self-dynamism or self systems. These function to maximize satisfactions and to maintain security or to minimize anxiety through the use of “security operations” such as selective inattention (dissociation), sublimation, or projection. The self system, in content, is what one takes oneself to be. This is largely secondary to what others take one to be (i.e., it consists mostly of reflected appraisals). The self system security operations establish and protect this content of the self system. In the face of anxiety, this leads to the creation of fantasied defensive self-other constellations such as the self as helpless but deserving and the other as magical and merciful, the self as victimized and hurt and the other as powerful and persecutory, and the self as special and the other as idealizing. Such illusory configurations become superimposed upon and distort a person's here-and-now relationships, a process akin to transference, which Sullivan labeled parataxic distortion.

Sullivan's psychodynamic theory of schizophrenia was informed by extensive clinical experience with acutely and subacutely affected inpatients. These disorders he regarded in the Meyerian tradition as purely functional reactions to encounters between the person and the environment. Central to the psychopathological process is a disturbance in the capacity to relate to others that is not biological in origin but reflects the history of the patient's interactions with significant others, especially with the mother in the formative years. The syndrome itself represents a massive dissociation caused by intense anxiety generated by low self-esteem during interpersonal experience. Sullivan acknowledged the probable existence of hereditary or organic determinants in some disorders, such as chronic process schizophrenia. He did not, however, consider them to be schizophrenia per se, or at least the subtype of schizophrenia to which he felt his theory applied.

The pathogenesis of schizophrenia, according to Sullivan's etiological scheme, begins with a mother who is more anxious than normal and who imparts this tension to her child as excessive not-me experiences. The child's self system, developing around the time of speech acquisition, overcompensates with excessive dissociation and warps its own further development. The adolescent surge of new sexual needs (lust dynamism) assaults this compromised self system. The defensive wall of selective inattention fractures; not-me disorganizing anxiety returns, and panic ensures. This state of terror is characterized not only by the uncanny eruption into awareness of developmentally primitive states of mind, but also by collapse of the integrated self systems into what Sullivan described as “an exceedingly unpleasant form of nothingness.” The afflicted person's primary urgencies at this point are to avoid the not-me menace and to reorganize the self to reestablish meaning and become human again. This reorganization, known as schizophrenia, is effected at the price of reality testing.

According to Sullivan, schizophrenia is more than a disorder. It is also an adaptive strategy for avoiding fragmentation and chaos (panic and terror) and for reconstructing a self with human identity, meaning, and purpose, no matter how fantastic that defensive self-other constellation may be. It is better, for example, to be the helpless victim of tyrannical persecutors than to be nothing at all. One must have character, even if it manifests as caricature. With schizophrenia, the needs for satisfaction and reality are secondary to the needs for security and self meaning.

The descriptive aspects of Sullivan's theory highlight the self, both as a content (idea) and as a functional system. Though Federn may have been the first to describe the self as part of a psychodynamic system (as ego feeling), Sullivan was the first to postulate its functional centrality to human psychology. To him, creating and maintaining the integrity and functional alacrity of a self are primary motivating forces of human beings. With schizophrenia, in fact, the drive for meaning exerts hegemony over all other needs. Sullivan viewed schizophrenia as the result of cumulative experiential traumas during development. His own bias was to regard the preschizophrenic infant as a tabula rasa on which mother's anxieties became etched. The source of pathogenic anxiety is clearly external to the infant, and schizophrenia is seen as an adaptive attempt to cope with that dysphoric milieu.

OBJECT-RELATIONS MODELS

The British object-relations school operated independently of Sullivan but pursued many of the same ideas, regarding humans as inherently social or object related. Their major spokespersons are Melanie Klein and W. R. D. Fairbairn. Latter-day American theorists contributing to a psychodynamic understanding drew heavily on theories of human development. Their major proponents are Margaret Mahler and Ping-Nie Pao.

Melanie Klein For Klein, psychodynamic conflict involved love versus hate in relationships (rather than the tension between wish and reality of classical psychoanalysis). She emphasized the importance of fantasy, both conscious and unconscious, in determining behavior. Such fantasy usually takes the form of a drama involving the self relating with another, constellations that have come to be labeled *internal object relationships*. She added two coping or defense mechanisms to the ego's repertoire: splitting and projective identification. During infancy, these mechanisms promote development and adaptation; during adulthood, they signal trouble. Klein related psychopathology to an overabundance of aggression and hate in relationships. Envy (mostly innate) is especially pathogenic, because it is directed at good objects and their capacity to give, thus destroying hope by devaluing healthy relationships.

Klein conceived of human development as a hierarchy of relational patterns (i.e., positions rather than phases). Two positions, both within the first year of life, are central to normal development—or to later psychopathology: the paranoid position, wherein aggressive, dysphoric interpersonal experiences are split off and projected onto significant others who are then regarded anxiously as persecutory and the depressive position, the infant's guilty recognition of personal responsibility for being the aggressive persecutor at times. While the accuracy of this scheme may be questionable vis-a-vis contemporary infant observation, it is compelling in its description of two mental constellations frequently encountered in patients with severe psychopathology.

Klein's theory of schizophrenia closely followed her developmental scheme. She regarded the potential schizophrenic patient as endowed with strong sadistic and envious impulses that rendered the infant prone to intense paranoid anxieties and, therefore, to the overuse of withdrawal, splitting, and projective identification. Such infants never negotiate the depressed position and remain fixated at the paranoid position, to which they regress in the face of later stress after further development through adolescence.

W.R.D. Fairbairn To Fairbairn, the primary aim of human behavior was contact with another, even if it was unpleasant. He viewed psychopathology entirely from a developmental perspective as the product of failure to establish good object relationships in infancy. Maternal absence or withdrawal during the paranoid-schizoid position leads infants to regard their love as noxious or bad. The resultant schizoid conflict—to love or not to love—sets off a withdrawal from relatedness in reality with compensatory investments in defensive internal object relations. These, like Sullivan's fantasied self-other constellations, provide a sense of security and continuity that is missing in real relationships, especially the earliest ones with parents. Fairbairn conceived of schizophrenia on a continuum with schizoid psychopathology, the difference being one of degree. The schizophrenic patient withdraws loving investments to such an extent that emotional contact with others and with external reality is renounced.

Margaret Mahler Mahler clearly related early developmental experiences to later mental function. Her developmental phases of autism, symbiosis, and separation-individuation captured the attention and imagination of many theorists who saw different forms of psychopathology corresponding to different levels in her developmental progression. Schizophrenia, for example, is regarded as corresponding to Mahler's autistic phase of development. It is assumed or postulated that the preschizophrenic infant fails to form an adequate and stable symbiosis with the mothering object, a developmental failure rendering the child's image of mother inconstant. This developmental failure leaves the individual vulnerable to regression when facing the second and final phase of individuation in late adolescence. The regression itself goes back to the preverbal, presymbiotic stage of autism with loss of ego boundaries, merger experiences, and replacement of reality by autistic fantasy.

Ping-Nie Pao Pao attempted to synthesize the theoretical threads of many schools and forebearers. Based upon extensive clinical experience, he subtyped schizophrenic patients into those with acute cases, for whom conflict plays a more pivotal role, and those with chronic cases, with higher genetic-biological loading.

Pao, like Freud, was impressed with the catastrophic panic experience that signaled the onset of the schizophrenic process and symptom formation. This process is precipitated by psychodynamic conflicts no different in content from those experienced by all people. In the schizophrenia-vulnerable person, however, these conflicts no longer generate neurotic levels of anxiety but at some point catalyze a crisis known as organismic panic, a term modeled after Mahler's developmental observations of states of extreme infantile distress. This panic brings with it paralysis of the ego's integrative capacity and fragmentation of the sense of continuity of self. The latter process constitutes an unbearable loss of a basic sense of safety, leading the ego to mobilize primitive or regressive defenses to reestablish and protect a sense of self, albeit pathologically. This attempt at adaptation or recovery results in postpanic emergence of a different personality, either pieced together with or distorted by psychotic symptoms. Typical delusions, for example, help to construct a new sense of meaningful self and, though often very unpleasant, are clung to tenaciously because their loss threatens return of disorganization and panic.

Pao's etiological-developmental theory attempts to explain the origin of the schizophrenic vulnerability or organismic panic and regression. Like other relationalists, he placed etiology in the experiences of early development. Aberrant constitution and inappropriate mothering combine to generate a series of failed emotional cuings within the dyad, leading to frequent episodes of infantile organismic distress or “pain in being held and pain in being laid down.” Cumulative exposures to such distress bend further development in maladaptive directions, including a tendency toward primitive defensive, impaired capacity for instinctual neutralization; an inability to maintain a sense of reality constancy, heightened aggressive responses to frustration; and heightened wishes for closeness with others, coupled with a dread of self dissolution in symbiosis (the need-fear dilemma originally described by Donald Burnham, Arthur Gladstone, and Robert Gibson). These vulnerabilities lie dormant and do not produce symptoms until the advent of adolescent drive demands and stress.

CRITIQUE OF PSYCHOANALYTIC THEORIES

Psychoanalytic theories of schizophrenia have become increasingly criticized in recent years, especially by analysts such as Martin Willick, mainly because the traumatic-developmental perspective on etiology lacks credibility. Virtually all psychoanalytic theorists postulate an experiential disharmony between the mother and her preschizophrenic infant. Whether this derives from genetic or constitutional factors in the infant or from psychological factors in the parent is secondary, as the purported central pathogenic elements are dysphoric experiences that become internalized as aberrant psychological structures. Explicitly or implicitly, the psychogenic models of schizophrenia regard these experiences as sufficient to explain most, if not all, cases of the syndrome.

Several considerations cast doubt on this postulate. First, recent findings from infant and childhood development challenge many of the assumptions put forth by psychoanalytic developmentalists. For example, normal development is not like pathological stages projected backward. Infants and children are active, stimulus seeking, and socially oriented from day one. Stages such as the narcissistic, autistic, symbiotic, or schizoid-paranoid are not observed, so it is doubtful that schizophrenia could represent regression to one or more of them. Schizophrenia does represent a regression of mental capacity insofar as mentation becomes less complex, especially during active phases. However, as Willick points out, regressive phenomena can result from a primary disturbance in brain function later in life rather than represent a return to experientially determined earlier fixation. Also, infants and children are far more powerfully and intricately preprogrammed for adaptation and survival than psychoanalytic theorists assumed; almost without exception they saw infants as helpless, utterly dependent, and mindless creatures of infinite malleability. The fact that many infants and children survive despite unusually bleak or traumatic rearing suggests that factors orthogonal to nurture may be operative.

Second, clearly some people who develop schizophrenia as adults come from basically healthy families and undergo normal growth and development—a direct challenge to trauma hypotheses of etiology. Furthermore, the reported childhood suffering of schizophrenic patients is often no more severe or profound than that of patients with other forms of mental illness, suggesting the necessary presence of additional, nonexperiential, pathogenic factors. For example, why might similar adverse life circumstances result in anxiety or depression in one person and hallucinations and thought disorder in another?

Finally, the psychogenic theories have difficulty explaining why in most cases of schizophrenia some two decades intervene between the purported pathogenic infantile traumatic experiences and the onset of overt symptoms. If the experiences postulated by these theories do indeed occur, one might expect to see symptom formation at the time followed by predictable and nonrepressible (i.e., observable) deformities in subsequent development, at least in some cases. An infantile catastrophe severe enough to produce an illness of the magnitude of schizophrenia is not likely to go unnoticed, yet such catastrophes and their immediate behavioral consequences have not been documented.

Generally, psychoanalytic theories of schizophrenia (especially those with a more descriptive perspective) continue to inform and help clinicians understand the patients they encounter. In this context, they are worthy of study. Furthermore, while exploring the past with schizophrenic patients may no longer be expected to yield etiological or historical truth, it does provide meaningful metaphors that can be useful in the empathic dialogue between doctor and patient.

FAMILY DYNAMICS AND TRANSACTION MODELS

The family transaction models of schizophrenia represent attempts to understand and explain the syndrome as the transmission of aberrant interactions from the family to the patient. The models are compatible with object-relation-oriented psychoanalytic psychogenic theories in assuming that psychopathology is determined largely by experience and learning within the family during growth and development. The models differ, however, in their respective hypothesis-generating and hypothesis-validating databases. For psychoanalytic theories, the data are the associations of individual patients for family transaction theories, the data are observed interactions in families with one or more schizophrenic members.

These models emerged following World War II, when clinical work with the families of schizophrenic patients revealed with increasing frequency that irrationality was not limited to the identified patient. Unusual and unpredictable interactions were observed between dyads within the family or among family members as an entire unit. Motivated by the idea that these interactions might be schizophrenogenic, several clinical investigators began describing these families and their transaction patterns in some detail.

Gregory Bateson and Donald Jackson Gregory Bateson and Donald Jackson outlined a form of family interaction that they labeled the *double bind*. The interaction usually occurs between a parent and the schizophrenic offspring; it consists of the former giving the latter incompatible (if not antithetical) messages (e.g., stiffly avoiding a physical embrace while asking, “Why don't you show me more affection?”). This sets up an inescapable damned-if-you-do-and-damned-if-you-don't situation, or double bind, in which the offspring feels paralyzed. Bateson and Jackson hypothesized that repeated exposure to such a dilemma generates or aggravates the schizophrenic state.

Ruth and Theodore Lidz Ruth and Theodore Lidz studied the characteristics of families that had a schizophrenic offspring. They looked for and observed disorders in the relationships among family members, especially the triad of mother, father, and schizophrenic child. They described several irrational patterns, such as marital schism between parents who remain married because of pathological interdependence despite considerable overt conflict; marital skew between parents who hide chronic disagreement behind a facade of harmony; permeable generational boundaries, where one parent requires the schizophrenic child to assume a parental role; eroticized parent-child relatedness, wherein one parent treats the schizophrenic child as a peer or contemporary; and emotional divorce, in which family members fail to acknowledge and confirm one another's psychological integrity. The Lidzs asserted that such rrational family functioning sufficed to account for schizophrenia in certain offspring exposed over their formative years.

Lyman Wynne and Margaret Singer Lyman Wynne, Margaret Singer, and colleagues explored communication and cooperation within families with a schizophrenic offspring. From their careful observational work came the concept of communication deviance. This includes parental communications that lack commitment to ideas and percepts; parental communications that are unclear because they are filled with idiosyncratic themes and ideas or have language anomalies, discursive speech, and problems with closure; and parental communications that reflect an inability to establish or maintain a shared focus of attention during transactions with another family member. Among parental communications, they identified two common forms: an amorphous style in which communications are vague, indefinite, and loose and a fragmented style in which communications are easily disrupted, are poorly integrated, and lack closure. They also described familial displays of mutuality, hostility, or both, which serve as facades hiding antithetical themes and conflicts.

Unlike most other family transactional theorists, Wynne and Singer were able to operationalize their concepts into reliable measures, thus allowing their hypotheses to be tested more systematically. They found communication deviance to be more specific to families of schizophrenic patients than to families of patients with depression, personality disorders, neuroses, or no pathology. Furthermore, amorphous patterns of communication deviance correlated more frequently with process schizophrenia, and the fragmented patterns with reactive schizophrenia. They also found significant quantitative correlations between the amount of communication deviance in the parents and the severity of psychopathology in their offspring. For example, schizophrenic offspring were in families in which both parents had high levels of communication deviance; normal and neurotic offspring were in families in which both parents had low levels; and borderline offspring were in families in

which one parent's level was high and the other parent's was low.

Expressed Emotion More recently, family investigators have described several family factors that interact powerfully with schizophrenia, either to precipitate its emergence or to aggravate its course. One factor, called expressed emotion, consists of critical or emotionally overinvolved attitudes and behaviors displayed by parents toward their ill offspring. Another family transactional factor of interest and current study is negative affective style. It includes four kinds of parental behavior: criticism, guilt induction, intrusiveness, and inadequate support. Schizophrenic patients living with families with high expressed emotion or negative affective style relapse significantly more often than those living in families with low expressed emotion or normal affective style.

Critique of Family Transaction School Like the psychoanalytic theories of schizophrenia, the family transaction theories have come under considerable criticism as etiological models. With the exception of communication deviance, few of the family transactions described above are demonstrably specific to schizophrenia. Furthermore, the observed irrational transactions among these families may possibly derive from the necessity of dealing with a child whose deviance is independently determined, thus reversing the hypothesized causal vector. In the absence of hard etiological data, assuming that families transmit and concentrate their irrationalities on a designated family member–victim is a nonproductive assignation of blame that does little to advance understanding but much to undermine working alliances between professionals and afflicted families.

Like the psychoanalytic theories of schizophrenia, the family transaction theories remain viable and useful as descriptive constructs. While irrational behaviors in the families of schizophrenic patients may not cause the illness, these behaviors are nevertheless present and real in their evocative effects. As demonstrated by the expressed emotion and affective style studies, the family's emotional milieu can profoundly influence the onset or course of schizophrenia. Family transactional stress may not be causative. However, strong evidence, indicates that it can be powerfully facilitative in both pathological as well as therapeutic directions. As such, the family theories also fit well into the earliest neurodynamic theory of schizophrenia: the vulnerability-stress, or stress-diathesis, hypothesis.

STRESS-DIATHESIS MODELS

Antecedents The first neurodynamic model, the stress-diathesis hypothesis, views schizophrenia dynamically as a product of interacting forces, some genetic or biological and some psychological, some innate or constitutional and some learned through experience. Unlike the purely psychodynamic theories, nature is more important, as suggested by genetic studies and the efficacy of biological treatments. Both nature and experience, however, are considered necessary to describe and understand schizophrenia.

The Finnish adoption study of Pekka Tienari and colleagues illustrates this model. Comparing adopted-away children of schizophrenic mothers (high genetic-risk probands) with adopted-away children of nonschizophrenic mothers (low genetic-risk controls), they found that schizophrenia developed only in probands with genetic vulnerability who were raised in adoptive families in which the emotional environment was demonstrably stressful. None of the high genetic-risk probands raised in less stressful adoptive families developed psychosis. Likewise, none of the low genetic-risk probands raised in unhealthy adoptive families developed psychosis, although many developed other forms of psychopathology. These results strongly suggest that both a stressful rearing environment and an innate vulnerability to schizophrenia are necessary to generate the syndrome.

The concept of such an interaction began with Freud. Describing the origin of neurosis in *On the History of the Psycho-Analytic Movement*, he wrote:

> Disposition and experience are here linked up in an indissoluble etiological unit. For disposition exaggerates impressions which otherwise have been completely commonplace and have no effect, so that they become traumas giving rise to stimulations and fixations; while experiences awaken factors in the disposition which, without them, might have long remained dormant and perhaps never have developed.

Freud could well have been writing about the origins of psychosis. Certainly, subsequent psychoanalytic theorists took this model seriously in explaining schizophrenia, especially those that emphasized deficit. The true conceptual fathers of today's stress-diathesis model of schizophrenia, however, are Sandor Rado and Paul Meehl.

Rado hypothesized that schizophrenia begins with an inherited disposition, or genotype. Interaction of this genotype with the environment produces the schizophrenia phenotype, a personality type or trait called the schizotype. Central to this trait is an inherent incapacity to experience pleasure. “In the schizotype the machinery of psychodynamic integration is strikingly inadequate, because one of its essential components, the organizing action of pleasure—its motivational strength—is innately defective.” This defect impairs the development of initiative and leads to schizo-adaptations such as compensatory overdependence on others (especially parents) and the elaboration of intricate cognitive processes devoid of affect. Anhedonia results in weak emotional bonds and leads to attenuated relationships. A well-compensated schizotypical person retains a stable schizoid personality. One of poorly compensated schizotype develops exaggerated, bizarre behaviors. Schizophrenia proper represents a decompensated schizotype with adaptive incompetence. The nature and severity of the schizo-adaptation depends on genotypic loading and the degree of familial and environmental stress.

To Meehl, the inherited schizophrenic phenotype (which he labeled schizotaxia) consists of a defect in neural integration. This defect plus social learning (environment) leads to an abnormally organized personality (the schizotype) characterized by cognitive slippage (thought disorder), anhedonia, ambivalence, and aversion to human relationships. Further progression from schizotypy to schizophrenia is a function of the nature and severity of environmental stress versus the availability of help and support.

Model This hypothetically pathogenic interaction between nature and experience came to be known as the stress-diathesis model. As currently conceived, this model accepts that the relative roles of nature and nurture in the etiology of schizophrenia will remain obscure until there are markers for genetic predisposition or constitutional vulnerability. It shifts emphasis from the etiological role of psychodynamic factors to their role in facilitating and preventing the expression of the disease process.

Vulnerability to schizophrenia is seen as an enduring proclivity toward developing clinical symptoms. It is a stable trait independent of nonenduring psychopathological states, meaning that it is present premorbidly, at onset, during symptomatic efflorescence, and during remission. This trait should not, however, be regarded as developmentally static or fixed. Rather, vulnerability may be shaped epigenetically at each developmental phase. Aspects of vulnerability are undoubtedly genetic. Some may be acquired biologically throughout intrauterine, birth, and postnatal complications. Season of birth may also contribute, for reasons yet to be ascertained. The evidence for psychosocially acquired vulnerability is meager at present, but this hypothesis cannot be ruled out.

The stress side of this model postulates that a variety of stressors (i.e. internal or external events requiring adaptation) can convert vulnerability into symptoms. Therefore, coping strengths or supports that diminish stress should minimize or prevent clinical expression of vulnerability.

Following the model, the vicissitudes of schizophrenia are determined by the nature of vulnerability and stress and by the individual's strengths and environmental supports. Interaction of sufficient stress with sufficient vulnerability can lead to transient, intermediate (prodromal) states of dysfunction that amplify existing cognitive, affective-autonomic, and social-coping deficits. This compromised mental state, in turn, interacts negatively with stressors and magnifies their effect in a downward spiraling deterioration that culminates in a full-blown clinical syndrome.

Vulnerabilities to Schizophrenia Finding, mapping, and integrating these vulnerabilities have become a central effort in current schizophrenia research. Virtually all of this investigation has focused on demonstrable phenotypic manifestations of hypothetical genotypic vulnerabilities in children and adolescents at risk for schizophrenia. The list of these vulnerabilities is extensive and grows each year. First are deficits in processing complex information, in maintaining a steady focus of attention, in distinguishing between relevant and irrelevant stimuli, and in forming consistent abstractions. Second are dysfunctions in psychophysiology, suggesting deficits in sensory inhibition and poor control over autonomic responsibility, especially to aversive stimuli. Third are impairments in social competence, such as processing interpersonal stimuli, eye contact, assertiveness, or conversational capacity. These deficits probably reflect both a core disturbance of schizophrenia (vulnerability) and the social outcomes of severe psychopathology. In the past, the source of these difficulties was often attributed to such external elements as neuroleptic drugs or institutions, a perspective that unduly diverted attention from their primacy in the disorder. Fourth are general coping deficits such as overevaluating threat, underestimating internal resources, and extensive use of denial.

Phenotypic manifestations of vulnerability may not be observable premorbidly, especially if the genotypic vulnerability has variable onset of expression. Huntington's disease, for example, is an adult-onset neurological deterioration leading to psychosis and dementia; in a similar fashion, many cases of schizophrenia could result from a genotype whose phenotypic expression is not triggered until late adolescence or early adulthood. This phenotype may be a deficit in the neurophysiological

maturation of self systems during adolescence or a still later-onset neural deterioration or inhibition of these same systems in adulthood. Early-onset genotypes may help to account for patients with easily identifiable phenotypic deviations that begin in childhood as schizotypal aberrations and progress to chronic process schizophrenia later on. Later-onset genotypes may help explain the sudden occurrence of schizophrenia later in life in persons with normal growth and development and healthy premorbid personalities.

Stressors Systematic studies of the stresses that affect the course of schizophrenia, aside from the family environment, have focused on social class and culture, social networks and life events. Socioeconomic and cultural factors have a long history of empirical association with schizophrenia. One of the most replicated findings in the schizophrenia literature is the clustering of schizophrenic patients in the lowest social classes, especially in urban communities. Few now hold that a poor socioeconomic environment causes schizophrenia, but few doubt that it has a major impact on its course. Poverty, ignorance, unemployment, social isolation, poor nutrition, and marginal health care are powerful chronic stressors that lead to frequent breakdown in vulnerable persons.

Schizophrenia and social network are highly interactive, cross-sectionally and longitudinally. Schizophrenic patients usually have social networks that are smaller, less interconnected, simpler, more dependent, casual, nonintimate, and peopled with family as opposed to peers. The interplay between schizophrenia and social networks appears to be circular rather than linear. Initially, the major vector is schizophrenia on social network. Following the appearance of clinical symptoms, however, social network is likely to exert a powerful influence on the subsequent vicissitudes of schizophrenia.

Stressful life events have demonstrated association with schizophrenia, but it may not always be necessary or direct. Questions often arise concerning whether stress has different effects on disease onset and recurrence and whether a stressful event precedes illness or represents a product of symptom exacerbation. Convention dichotomizes stressful events into those that are ambient, nonindependent, or chronic and those that are independent or acute. The former are stresses associated with everyday living, such as family, work, poverty, physical disability, and mental deficit; the latter are stresses associated with largely external or unusual changes, such as loss, death, acute illness, and moves, especially if these changes are unanticipated, undesired, and uncontrolled. Research suggests a high frequency of such events shortly before schizophrenia onset or symptom exacerbation. Furthermore, there appears to be an important interaction between maintenance antipsychotic medication and life-event stress. Patients in the community without medication are vulnerable to both acute and chronic stress. Patients taking medication, however, appear to be protected against either type of stress but are likely to suffer relapse if both types occur concurrently.

NEURONAL NETWORK MODEL

The latest neurodynamic model of schizophrenia hypothesizes with greater specificity the neuroanatomic nature of the vulnerability to schizophrenia and its biophysical contribution to symptom formation. It is build upon postulates that most human mentation arises from neuronal networks organized in parallel distributed processing systems. Furthermore, these systems can, under certain physiological conditions, generate thoughts or feelings in ways orthogonal to the normal processes by which psychology is generated. This pathological development, called “memory parasitism,” can produce mentations that are literally products of aberrant connectedness among the neurons of the brain and are experienced and interpreted psychodynamically as unintended and alien by the bearer of the brain. The physical conditions conducive to such developments are unknown but hypothesized to involve a loss of parallel distributed processing neural circuit density from perinatal insults or from a genetically or developmentally programed excessive pruning of connections between cortical nerve cells.

Parallel Distributed Processing Model Mental events are basically neuronally constructed representations of experience as memory. Memories in general are accessible to consciousness in a manner that is content addressable, i.e., the brain can use part of a memory to access the memory in its entirety. Artificial intelligence researchers such as Donald Hebb, Warren McCulloch, Walter Pitts, John Hopfield, and James McClelland and David Rumelhart have discovered that certain types of computer-assisted computations retrieve content-addressable information in a fashion that partially simulates nature. These systems are composed of large numbers of very simple computing units, generally referred to as “neurons,” which are densely interconnected via synapses. There is no single command unit; the effectiveness of the network as a whole reflects the cooperative interactions of its parts. Each neuron simultaneously receives information from a large number of other neurons and computes its response to these inputs in parallel with the computations of the other neurons of the system. No one-to-one correspondence exists between a memory and activation of a particular neuron. Instead, a memory corresponds to a pattern of activation involving many neurons of the network; memories are created by modifying functional connections among arrays of neurons. Networks that store and retrieve information on the basis of distributed patterns of activation are referred to as parallel distributed processing systems.

An increasing body of neurobiological research suggests that the functional architecture of the mammalian cerebral cortex can be broken down into a number of linked parallel distributed processing-type neuronal assemblies. Of special interest is the long-term memory system, which probably involves the brain's hippocampal and cortical areas. The hippocampus is active during a critical “gestational” period (ranging from minutes to hours), during which input information is distributed to interconnected circuits linking frontal, parietal, and sensory-association cortical areas. If hippocampal functioning is temporarily impaired, memories due to be distributed will be permanently lost. However, once information is functionally linked within the cortex, its retrieval seems not to require an intact functioning hippocampus. Activating a posterior sensory area via an image representation or a frontal area via an abstract concept such as a goal or generalization can immediately “seed” widely distributed cortical circuits to yield complex memories.

Parallel distributed processing systems with content-addressable mnemonic representations probably constitute the nemodynamic underpinning that is normal mental activity and psychology. The psychoanalytic method of free association, for example, relies on the content addressability of mental representations. Freud first observed that human mentation follows patterns that are seldom logical or governed by the rational rules of secondary process. More often than not, mental representations are connected by condensations, displacements, and symbolizations of mnemic content, whether that content is concrete imagery, stories, or abstract theories. These are the primary processes of mentation postulated by Freud to underlie the formation of dreams and neurotic-level symptoms. Content addressability is a new term for an old psychoanalytic postulate that every mental event (thinking, feeling, acting) is overdetermined and can be attained via multiple pathways. This is Robert Waelder's principle of multiple function, wherein a vast array of related factors (e.g., id, ego, superego) must be considered in understanding any behavior. The functional dynamics of parallel distributed processing systems also suggest that an enormous amount of neuronal activity accompanies any single mental event or idea, thus accounting for the dynamic unconscious of psychoanalysis.

Attractor Dynamics in Parallel Distributed Processing Systems Most psychiatric syndromes include some form of repetitively reproduced mental content ranging from obsessional thoughts to the idea fixe of psychotic delusions. Such repetitive memories can be produced in simulated parallel distributed processing systems on the basis of “attractor dynamics.” As noted by Hopfield, these systems tend to be attracted to particular activation patterns, which are low-energy states of the system. *Energy* here is defined on the basis of a branch of physics known as statistical mechanics. Statistical energy corresponds to the degree of disorder in the system. Neurons that interact freely in a parallel distributed processing network will tend to be attracted to activation patterns that minimize its statistical energy. These patterns correspond to the memories of the system, which tend to be reproduced because of these energy minima. Particularly strong memories correspond to very deep energy minima that tend to pull new information to the existing activation pattern to the exclusion of other activation patterns. That is, a memory with a particular deep-energy minimum strives relentlessly to express itself. It is called “parasitic” because it coerces a wide range of input information into a single memory-activation pattern.

One of the authors (R. H.) demonstrated that computer-simulated parallel distributed processing models can provide an account of how such pathological memories are induced. Under varying circumstances described below, a memory can be created that does not reflect any specific prior experience. These spurious memories are not linked to naturally occurring and stored input-activation patterns, but are created de novo by the brain itself and can be triggered by the most irrelevant internal or external cures. These memories link or condense quite disparate contents and may appear at times to be the products of primary process. However, they cannot be grasped by the empathic primary processes of others, i.e., they remain strange and beyond understanding in Karl Jasper's sense of being self-evident or common to human experience. These memories tie together representations or fragments of representations that are ordinarily not linked even by the weakest and most remote primary process pathways, hence the term “loose association.” In a sense, they are violations of content addressability, in which associations are no longer free but are constrained by disturbed attractor dynamics.

Parasitic memories are the product of biophysical energic processes, not primary and secondary psychological processes. At the same time they arise in the midst of other neural networks that are not compromised and that generate normal and abnormal psychology in the usual way (i.e., by primary and secondary processes). As such, persons experiencing parasitic memories may feel as if parts of their brain or mind are functioning out of their control. They may experience these unintended mental events as if someone else were putting thoughts into their minds. Such post hoc reasoning that an outside force is inserting thoughts into one's mind may reflect the difficult task of describing and making sense of the experience of one's mind being repeatedly “captured” by a perseverative attractor seemingly acting according to its own will. In this fashion “parasitic” memories in a parallel distributed processing system can account for many of the seemingly bizarre symptoms of schizophrenia.

Pathophysiology of Memory How might such memories come about? In computer-based parallel distributed processing systems, parasitic memories are known to

derive from two different types of “pathology.” First, parasitic memories can be produced when the system attempts to store too many memories for its capacity. Second, parasitic memories can be produced when an insufficient number of synaptic connections link the neurons of the system. It is further hypothesized that these two types of pathology are “located” in the system of long-term memory storage and recall involving the hippocampus and diffuse cortical circuits of the brain.

There is considerable recent interest in pathology involving the hippocampus in schizophrenia. Neuroradiological and postmortem studies have suggested reduced hippocampal volume and disarray of its pyramidal cells in some schizophrenic patients. Reductions in pyramidal cell number, functional efficiency, or information transfer capacity—perhaps occurring secondary to prenatal complications such as viral infection—could downsize memory storage capability in the hippocampus, thereby rendering it vulnerable, as a parallel distributed processing system, to the induction of memory parasitism.

A second form of schizophrenia may reflect abnormalities in postnatal brain development. Considerable evidence in humans and other primates now indicates that following birth, an overabundance of corticocortical connections exists; these connections are then selectively pruned and shaped during later developmental periods. In humans pruning of cortical synapses seems to extend well into adolescence for connections involving frontal areas. Moreover, the continued elaboration and pruning away of cortical synapses probably continues, albeit at a much reduced rate, throughout adulthood.

These developmental studies, when considered in light of parallel distributed processing simulations, suggest a second mechanism leading to parasitic or spurious memories—reductions in corticocortical connections which are a part of these developmental processes. As suggested by Erwin Feinberg, if excessive developmentally induced pruning of these connections leads to a form of schizophrenia, a ready explanation for this age of onset and involvement in frontal areas is provided; synapse pruning is most prolonged in frontal areas, and the end of adolescence is when the effects of this pruning process would first be fully felt.

An example of a specific model of psychotic symptomatology that is empirically testable has been described by Hoffman and colleagues. A neural network was created to simulate certain aspects of speech perception. Pruning connections between the working memory component of the network caused perceptions to emerge spontaneously. This observation thus provides a model for hallucinated speech (“voices”). The model also permitted simulation of the hypodopaminergic state, and this neuromodulatory state tended to eliminate voices. The testability of the model derived from the fact that hallucinogenic networks also demonstrated subtle but definite speech perception impairments. Empirical study with actual schizophrenic patients demonstrated these speech perception impairments, which were not detected in schizophrenic patients who did not hallucinate. These simulations suggest that hallucinated voices correspond to parasitic memories that usurp working memory circuits of speech perception.

Implications The parallel distributed processing paradigm is neurodynamic because it postulates the creation of symptoms, at least in part, on the basis of defects in the hardware of the brain. Purely psychodynamic paradigms account for pathology solely as a reflection of aberrant “software” or conflicting functional programs in the mind. The parallel distributing processing model regards psychodynamics as necessary but often not sufficient to explain most schizophrenic symptoms. It is a model at the mind-body interface and views psychotic psychopathology as the product of a complex interaction of skewed mentation arising organically with normal or abnormal psychology arising psychodynamically.

The model remains speculative but offers an advantage of being falsifiable. Many of the functional and neuroanatomic predictions of this model may be subject to hypothesis testing and validation, thus bringing theorizing about schizophrenia closer to the realm of scientific empiricism.

In terms of sheer volume, the bulk of psychodynamic theories belong to psychoanalysis. In terms of content, the major issues have not changed much since Freud posited two theories—the structural-conflict theory and the withdrawal-deficit theory. By never integrating these two, Freud seemed to be saying that schizophrenia may be both, in part explained by intrapsychic conflict and in part by something else. Psychodynamic theories became more elaborate over the ensuing years, yet one can still follow the thematic threads of Freud's original part-explanations. Conflict theory has seen a line of development polarized toward object relations, experiential learning within the family, stressors that interact with vulnerability, and the psychological sequelae of organically disturbed neural circuitry. Deficit theory has seen a line of development polarized toward individual drives, complex constitutional inborn factors, the physical vulnerabilities of the stress-diathesis model, and the hard-wiring defects of parallel distributed processing neural networks. Today, these threads are each regarded as valid facets of the overall phenomenon. Both are necessary for a comprehensible and potentially workable theory of schizophrenia.

While none of these psychodynamic models of schizophrenia has solved the mystery of its etiology, each system has offered cogent hypotheses or educated guesses. The neurodynamic models see nature as primary or at least as initiating a process of negative interaction with environmental experience, which becomes pathogenic sooner or later in life, depending on the onset trigger of the genotype. The family transactional model, at least as originally conceived, sees nature or experience as primary and, frequently, as sufficient for generating schizophrenia. Psychoanalytic models have posited one or the other or both. Since Sullivan and Mahler, however, the emphasis has shifted more uniformly toward the etiological primacy of traumatic nurturing experiences during early development, a shift that has come under increasing criticism as outlined.

Overall, the impressive evidence for the existence of genetic and constitutional factors in schizophrenia has raised questions about the etiological hegemony of experience and learning in early development. Hypothetically, some (if not many) cases of schizophrenia may possibly arise from an adolescent-onset neurological dysfunction or deterioration in people who are, up to that point, developmentally normal. Such a process, along the model of overpruned parallel distributed processing neural networks, selectively inhibits or destroys later developmental levels of personality, especially those neuronal networks involved with structures, functions, and representations of the self. In response, the individual falls back on more primitively organized levels of personality and development. Such regression is compensatory and adaptive rather than primary and motivated. It does not occur because of developmental fixation but because simpler developmental levels and patterns may be the only ones left.

IMPLICATIONS FOR TREATMENT

Psychodynamic theories of schizophrenia carry with them distinct implications for treatment. Early proponents of the psychoanalytic conflict model advocated the classical techniques of clarification, confrontation, and interpretation. Early proponents of the psychoanalytic deficit model introduced additional strategies. Federn, for example, felt that the usual psychoanalytic techniques aimed at depression, whereas with schizophrenia, the goal was to foster rerepression. As such, he encouraged positive transference, avoided negative transference, protected patients from undue anxiety and insomnia, taught them to improve their capacities for attention and thinking, exhorted them to give up unrealistic life goals, provided support beyond analytic hours in the form of a skilled nurse-assistant available to the patients at home, and offered consultation to the patient's family (recognizing the importance of the home environment to outcome).

Proponents of the family transactional theories uniformly advocate family therapy in some form. Those that view the family milieu as causing schizophrenia usually regard the entire family as the patients or as the problem and focus interventions accordingly. Those that regard the family as facilitative rather than etiological emphasize the positive and negative effects that domestic tensions can have on the course of the identified patient. Technical strategies in the first instance are more interpretive. In the second instance, they are more psychoeducational.

Proponents of the stress-diathesis and parallel distributed processing models advocate any intervention that enhances strength and support and minimizes stress and vulnerability. This includes psychobiological as well as psychodynamic treatments. The neurodynamic models are the only ones that formally (i.e., theoretically) incorporate biology and endorse it therapeutically. They also define psychodynamic treatment more liberally. Any and all forms of psychosocial intervention, from individual psychotherapy to social skills training, are potentially useful, depending on the modality's track record of efficacy with the specific clinical situation or condition.

Conflict psychodynamic models, in keeping with their bias toward object relations and development in the family, emphasize the therapeutic centrality of the doctor-patient relationship. This relationship is facilitating, parental, soothing, mirroring, and protective, and the patient grows by internalizing the interactions that transpire within the dyad. The patient's actual interpersonal experience of the therapist is crucial: the therapist's reality and benignity serve as reality tests for the patient's transferentially distorted images.

Deficit psychodynamic models, in keeping with their bias toward the patient as an individual with phenotypic abnormalities, emphasize the therapeutic centrality of cognitive perspective and control. The goal of treatment is to enhance the power of the ego by expanding its knowledge and control over the inner drives and psychopathological idiosyncracies. Enlightenment replaces unconscious defense with conscious choice. Therapy from this perspective focuses primarily upon developing the patient's cognitive systems through psychoeducation, training, and rehabilitation. The patient comes to realize that something is wrong, what that something is, and how it can be dealt with.

The conflict psychodynamicists once eschewed deficit theories as therapeutically nihilistic, insisting that there was no way to make up for a biological defect by psychological means. Such an assertion may be literally correct but operationally erroneous. For example, psychological manipulation cannot make paraplegics walk under their own power, but it can train them in prosthetic ambulation, and it can enhance their adaptation and quality of life. Whatever the origin of schizophrenia, its successful psychological treatment involves both the resolution of intrapsychic conflict through insight and the acquisition of psychic structure through affective relationships. If the core of schizophrenia is psychological, then treatment addresses the sick self; if the core is defect, then treatment addresses the healthy self. In the former, it minimizes weakness; in the latter, it maximizes strength. In most cases, it does both.

BIOPSYCHOSOCIAL MODEL

One body of theory encompasses all of the foregoing twentieth-century trends—the biopsychosocial medical model of George Engel. According to this model, each individual patient consists of and participates in multiple systems that are related but also distinct from each other. Common systems are subatomic particles, atoms, molecules, organelles, cells, tissues, organs, organ systems, central nervous system, individual, dyad, family, community, culture and subculture, society and nation, and biosphere. In understanding health and disease, all systems are relevant. Each system of this model has a functional structure, one of its purposes being the reduction of complexity and randomness to protect that system's integrity. The functional structure of the psychological systems in this model consists of meanings that serve to order experience through understanding and explanation.

Psychodynamic approaches to treatment should not ignore biology because the latter exists outside the realm of empathy and meaning. Biological approaches to treatment should not justify psychological retreat from patients because conflict cannot be teased apart by electrophoresis. Finally, treatment advocates of both approaches should be aware of patients' social, cultural, and political need for a place of dignity and safety within society. That is, patients also require adequate attention at the social level of the biopsychosocial system.

Schizophrenia presents most dramatically at the psychological level as a loss or distortion of the self as a meaningful entity. Despite this, schizophrenia is not entirely or even essentially psychological in its nature. Accordingly, proper medical attention to this disorder should be aimed at any and all relevant systems in the biopsychosocial hierarchy. Whatever schizophrenia may be, it is profoundly disabling and usually chronic. Anything therapeutic that works with sufficient safety is relevant, whether it is biological, psychological, or sociological.

SUGGESTED CROSS-REFERENCES

The relevance of brain structure and function in schizophrenia is discussed in Section 12.3; neurobiology is discussed in Section 12.4; and genetics in schizophrenia is discussed in Section 12.5. Somatic treatment is discussed in Section 12.8, psychosocial treatment in Section 12.9, and individual psychotherapy in Section 12.10. Theories of personality and psychopathology are discussed in Chapter 6. Schizophrenia in childhood is discussed in Chapter 38, and schizophrenia in late life is discussed in Section 51.3f.

12.7 SCHIZOPHRENIA: CLINICAL FEATURES

ROBERT CANCRO, M.D., MED.D.SC., AND HEINZ E. LEHMANN, M.D.

The major public health problem faced by psychiatry is the group of disorders that constitutes the diagnostic category of schizophrenia. These disorders affect approximately 1 percent of the population and most commonly have their onset in early adult life. More importantly, they usually leave the patient with varying degrees of cognitive, affective, and psychosocial impairment. This combination of impairments prevents most patients from achieving their full potential. In all known societies, adulthood is defined in terms of work and procreation. Individuals diagnosed with schizophrenia are frequently unable to perform the complex work tasks seen in the industrialized nations. The more severely impaired are not even able to perform the simpler work tasks associated with developing nations. Interpersonal relationships are frequently impaired enough to prevent courtship and subsequent marriage and procreation. The result is that people with these disorders are denied the social and personal benefits of adulthood to a considerable degree.

No objective criteria exist for the diagnosis of schizophrenia. No characteristic morphological changes in the brains of patients with schizophrenia have been demonstrated; no specific laboratory findings signal its presence; no consistent premorbid history, course, or outcome can be ascertained; and no single cause is known. However, a group of symptoms and signs are basic to and characteristic of schizophrenia; certain drugs, many with a common neurophysiological property, can often eliminate those symptoms almost selectively, and there is enough consensus about its diagnosis, treatment, and prognosis among experienced clinicians to warrant the acceptance of the concept of schizophrenia as a syndrome.

HISTORY

Emil Kraepelin Emil Kraepelin (Fig. 12.7-1) translated Benedict A. Morel's *demence precoce* to *dementia precox*, a term that emphasized the distinct cognitive process (dementia) and early onset (precox) of the disorder. Patients with dementia precox were described as having a long-term deteriorating course and the common clinical symptoms of hallucinations and delusions. Kraepelin distinguished these patients from those classified as having manic-bipolar psychosis who underwent distinct episodes of illness alternating with periods of normal functioning. The major symptoms of patients with paranoia were persistent persecutory delusions, and these patients were described as lacking the deteriorating course of dementia precox and the intermittent symptoms of manic-depressive psychosis. Although Kraepelin had acknowledged that about 4 percent of his patients recovered completely and 13 percent had significant remissions, later researchers sometimes mistakenly stated that he had considered dementia precox to have an inevitable deteriorating course.

FIGURE 12.7-1 Emil Kraepelin, 1856–1926. (Courtesy of National Library of Medicine, Bethesda, MD.)

Eugen Bleuler Eugen Bleuler (Fig. 12.7-2) coined the term *schizophrenia*, which replaced *dementia precox* in the literature. He chose the term to express the presence of schisms between thought, emotion, and behavior in patients with the disorder. Bleuler stressed that, unlike Kraepelin's concept of dementia precox, schizophrenia need not have a deteriorating course. Before the publication of the third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III), the incidence of schizophrenia increased in the United States (where psychiatrists followed Bleuler's principles) to perhaps as much as twice the incidence in Europe (where psychiatrists followed Kraepelin's principles). After publication of DSM-III, the diagnosis of schizophrenia in the United States moved toward Kraepelin's concept. Bleuler's term *schizophrenia*, however, has become the internationally accepted label for the disorder. This term is often misconstrued, especially by laypeople, to mean split personality. Split personality, now called *dissociative identity disorder*, is categorized in the fourth edition of DSM (DSM-IV) as a dissociative disorder and differs completely from schizophrenia.

FIGURE 12.7-2 Eugen Bleuler, 1857–1939. (Courtesy of National Library of Medicine, Bethesda, MD.)

The Four As Bleuler identified specific fundamental (or primary) symptoms of schizophrenia to develop his theory about the internal mental schisms of patients. These symptoms included associational disturbances (especially looseness), affective disturbances, autism, and ambivalence, summarized as the four As: associations, affect, autism and ambivalence. Bleuler also identified accessory (secondary) symptoms, which included those Kraepelin saw as major indicators of

dementia precox: hallucinations and delusions.

Manfred Bleuler Manfred Bleuler, Eugene Bleuler's son, stressed the essential psychotic nature of the schizophrenic disorders. He recognized that patients might not be psychotic at any given moment but considered that the diagnosis of schizophrenia should only be made when psychosis had been present at some time in the history of the illness. He stated that patients whose primary characteristics were impaired memory or intellectual function were not schizophrenic. Schizophrenia in his conceptualization tended to be chronic and did not show a tendency toward rapid recovery. He felt that a major element of the illness was the coexistence of both psychotic and normal mental processes in the same person at the same time. He emphasized that the mechanisms he described in patients with schizophrenia could be found to some degree in normal people as well. In his conceptualization what was specific for the schizophrenic disorders was the patient's inability to distinguish between the inner and outer realities, as if an individual could not distinguish between dreams and waking experiences. This inability allowed the simultaneous presence of incompatible components to coexist within the patient's personality and consciousness. Bleuler's conceptualization of etiology was that the genetic component was not necessarily pathological but that the particular constellation of genes in these individuals left them more vulnerable to stress.

Adolph Meyer Adolph Meyer emphasized the reactive nature of the schizophrenic disorders. He felt that the illness involved a biological predisposition of the individual and environmental stresses that interacted with it to produce the illness. In this Meyerian vision, neither the stress nor the diathesis alone sufficed to produce illness; vulnerable individuals had to face an adequate and appropriate stress at the right developmental phase of their life. Emphasizing the fortuitous element of life events in the etiopathogeneses of these illnesses led to a more optimistic view of the disorders and raised the possibility that eliminating certain stresses at certain developmental phases could markedly reduce the frequency of the illness. The reaction-pattern approach was carried to an extreme by some workers who believed that enough stress could produce a schizophrenic disorder in anyone. These workers unfortunately failed to recognize the importance placed by Meyer on the preexisting diathesis.

Other Theorists Harry Stack Sullivan, Ernst Kretschmer, Gabriel Langfeldt, Kurt Schneider, and Karl Jaspers added much to the understanding of schizophrenia. Sullivan, who founded the interpersonal psychoanalytic school, emphasized social isolation as a cause and a symptom of schizophrenia. Kretschmer compiled data to support the idea that schizophrenia occurred more often among people with asthenic, athletic, or dysplastic body types rather than among people with pyknic body types; the latter, he thought, were more likely to incur bipolar disorders. These observations may seem strange, but they are not inconsistent with a superficial impression of body types in many homeless persons.

Langfeldt classified patients with major psychotic symptoms into two groups, those with true schizophrenia and those with schizophrenic-like psychosis. In his description of *true schizophrenia*, Langfeldt stressed several factors: insidious onset, feelings of derealization and depersonalization, autism, and emotional blunting. Researchers after Langfeldt gave true schizophrenia other names: nuclear schizophrenia, process schizophrenia, and nonremitting schizophrenia.

Schneider described a number of first-rank symptoms of schizophrenia. They are not identical to Eugene Bleuler's fundamental signs nor do they mean the same thing. The Schneider first-rank symptoms of schizophrenia are not pathognomonic for the disease but are of great pragmatic value in making a diagnosis. When a number of those symptoms are present in a patient in whom other pathology—of toxic or organic origin—can be excluded, then a diagnosis of schizophrenia is indicated. Schneider's first-rank symptoms include hearing one's own thoughts spoken aloud, auditory hallucinations that comment on the patient's behavior, somatic hallucinations, the experience of having one's thoughts controlled, spreading one's thoughts to others, delusions, and the experience of having one's actions controlled or influenced from the outside.

Jaspers, a psychiatrist and philosopher, played a major role in developing existential psychoanalysis. In his view, psychopathology had no fixed concepts or basic principles. Thus his theories of schizophrenia were free of traditional concepts like subject and object, cause and effect, and reality and fantasy, and his philosophic attitude led to an interest in the content of psychiatric patients' delusions. The emphasis on attempting to understand the phenomenology of the schizophrenic experience can be traced to Jaspers.

COMPARATIVE NOSOLOGY

DSM DSM-III and the revised third edition of DSM (DSM-III-R) were major efforts to increase reliability over the earlier versions. It was recognized that independent validation was not yet attainable and therefore the goal of reliability was seen to be of great importance. That emphasis was also reflected in the development of DSM-IV. DSM-IV requires the presence of at least two characteristic symptoms for a significant portion of time during a 1-month period (or less if the patient responded successfully to treatment). The list of characteristic symptoms includes delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior, and negative symptoms (e.g., anhedonia, mutism). One symptom suffices for a diagnosis if that one symptom consists of bizarre delusions, hallucinations of a voice sustaining a running commentary on the person's behavior or thoughts, or hallucinations of two or more voices conversing with each other.

DSM-IV requires social and occupational deterioration. There must be a diminution in functional level in both social and occupational activities following the onset of illness. These functional disturbances must last for at least 6 months. That 6-month period may include the 1 month of symptoms necessary to fulfill the requirement of characteristic symptoms plus prodromal or residual symptoms or both. Finally, DSM-IV requires diagnostic exclusion of mood disorders with psychotic features and schizoaffective disorder. The disorder may not be a consequence of substance abuse or a general medical disorder.

ICD The definition of schizophrenia in the tenth revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) parallels that in DSM-IV.

> The schizophrenic disorders are characterized in general by fundamental and characteristic distortions of thinking and perception, and affects that are inappropriate or blunted. Clear consciousness and intellectual capacity are usually maintained, although certain cognitive deficits may evolve in the course of time. The most important psychopathological phenomena include thought echo; thought insertion or withdrawal; thought broadcasting; delusional perception and delusions of control; influence or passivity; hallucinatory voices commenting on or discussing the patient in the third person; thought disorders and negative symptoms.
>
> The course of schizophrenic disorders can be either continuous or episodic with progressive or stable deficits, or there can be one or more episodes with complete or incomplete remission. The diagnosis of schizophrenia should not be made in the presence of extensive depressive or manic symptoms unless it is clear that schizophrenic symptoms antedate the affective disturbance. Nor should schizophrenia be diagnosed in the presence of overt brain disease or during states of drug intoxication or withdrawal.

DIAGNOSIS

The DSM-IV diagnostic criteria include course specifiers that offer clinicians several options and describe actual clinical situations (Table 12.7-1). The presence of hallucinations or delusions is not necessary for the diagnosis of schizophrenia; a patient's disorder is diagnosed as schizophrenia when the patient exhibits two of the symptoms listed as symptoms 3 through 5 in criterion A. Criterion B requires that impaired functioning, although not deteriorations, be present during the active phase of the illness. DSM-IV stipulates that symptoms must persist for at least 6 months and that a diagnosis of schizoaffective disorder or mood disorder must be absent. ICD-10 lists certain symptoms as the general criteria for all forms of schizophrenia with the exception of simple schizophrenia. At least one of the following must be present: (1) thought echo, thought insertion or withdrawal, or thought broadcasting; or (2) delusions of control, influence or passivity, clearly referred to body or limb movements or specific thoughts, actions or sensations, delusional perception; (3) hallucinatory voices giving a running commentary on the patient's behavior or discussing the patient between themselves, or other types of hallucinatory voices coming from some part of the body; and (4) persistent delusions of other kinds that are culturally inappropriate and completely impossible, (e.g., being able to control the weather or being in communication with aliens from another world).

Table 12.7-1 DSM-IV Diagnostic Criteria for Schizophrenia

The diagnosis can also be made if at least two of the following are present: (1) persistent hallucinations in any modality, when occurring every day for at least one month, when accompanied by delusions (which may be fleeting or half-formed) without clear affective content, or when accompanied by persistent overvalued ideas; (2) neologisms, breaks or interpolations in the train of thought resulting in incoherence or irrelevant speech; (3) catatonic behavior, such as excitement, posturing or waxy flexibility, negativism, mutism and stupor; and (4) negative symptoms, such as marked apathy, paucity of speech, and blunting and incongruity of emotional responses (it must be clear that these are not due to depression or to antipsychotic medication).

The ICD-10 criteria, used throughout the world, are listed in Table 12.7-2.

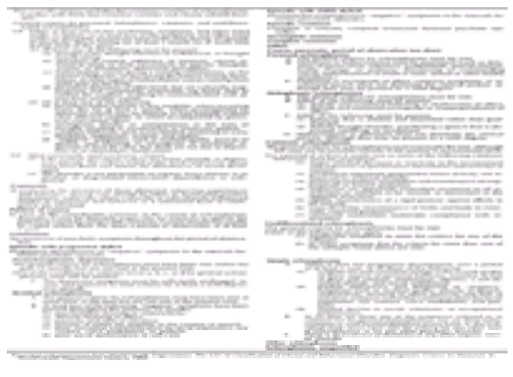

Table 12.7-2 ICD-10 Diagnostic Criteria for Schizophrenia

Key Symptoms The presence of some key symptoms for schizophrenia (e.g., blunting of emotional response or a strikingly inappropriate emotional response) weighs heavily in favor of a diagnosis of schizophrenia. But what is emotional blunting, and what is an inappropriate emotional reaction? For example, is the embarrassed adolescent's sheepish or defying smile an inappropriate emotional reaction? Considerable clinical experience is required to be certain about the presence of such symptoms.

Loosening of Associations The loosening of associations—the specific thought disorder of the schizophrenic—is perhaps one of the most valuable diagnostic criteria, but a good knowledge of psychopathology is required to be sure of its presence and to avoid confusing it with other forms of disturbed thinking, such as manic flight of ideas, disintegration of thought processes due to clouding of consciousness, and impaired reasoning due to fatigue or distraction. It is not sufficient to ask a patient the meaning of a proverb and then, on the basis of one's personal impression, declare that the patient has a pronounced schizophrenic thinking disturbance. It is sometimes impossible to distinguish, on the basis of a proverb test, between the disordered thinking of a schizophrenic and a manic patient, except for the greater verbosity of the manic.

Bizarre Behavior The patient's behavior may furnish significant clues for the diagnosis of schizophrenia. Bizarre postures and grimacing are certainly characteristic of schizophrenic conditions, but identifying a bizarre posture is not always easy. Religious rituals and special positions for meditation or dancing with which the observer is not familiar may be called bizarre. But in a recent case of a withdrawn, suicidal young girl, a possible diagnosis of depression was ruled out in favor of schizophrenia when the girl began eating raw chicken, pouring hot tea over herself, and openly trying to get into bed with her brother-in-law during a weekend home visit.

True catalepsy may be almost pathognomonic of schizophrenia, but it is not a common symptom. A stupor strongly suggests catatonic schizophrenia, but hysteria or a depressive stupor must be carefully ruled out in the differential diagnosis.

The deterioration of social habits, even involving the smearing of feces, does not suffice for the diagnosis of schizophrenia. Such deterioration can occur in various toxic and organic psychoses, temporarily in hysterical twilight states, and even at the peak of a manic episode in bipolar I disorder.

Pronounced social withdrawal also occurs under many conditions, ranging from simple sulking to anxiety and depression (Fig. 12.7-3). Sustained passivity and lack of spontaneity should suggest the diagnosis of schizophrenia only if organic and depressive conditions can be definitely ruled out.

FIGURE 12.7-3 “Schizophrenic Withdrawal.” (Courtesy of Sid Bernstein, Research Facility, Orangeburg, NY.)

Stereotypes and verbigeration strongly suggest schizophrenia, but they occur almost exclusively in chronic, institutionalized patients and are rarely seen today. Frequent and lengthy staring into a mirror and other odd mannerisms also strongly suggest a diagnosis of schizophrenia.

SUBTYPES

DSM-IV classifies the subtypes of schizophrenia as paranoid, disorganized, catatonic, and undifferentied, and residual, predominantly on the basis of clinical presentation (Table 12.7-3). These subtypes are not closely correlated with different prognoses; for such differentiation, specific predictors of prognosis are best consulted. ICD-10, by contrast, uses nine subtypes: paranoid schizophrenia, hebephrenia, catatonic schizophrenia, undifferentiated schizophrenia, simple schizophrenia, other schizophrenia, residual schizophrenia, post schizophrenic depression and schizophrenia, unspecified, with eight possibilities for classifying the course of the disorder, ranging from continuous to complete remission.

Table 12.7-3 DSM-IV Diagnostic Criteria for Schizophrenia Subtypes

Catatonic Type The catatonic type of schizophrenia is dominated by prominent psychomotor disturbances. In addition to meeting the general criteria for schizophrenia, there must be a period of least 2 weeks of catatonic behavior that can be either stuporous or excited. The behavioral disturbance can also involve posturing, negativism, rigidity, waxy flexibility, or command automatism.

Catatonic schizophrenia occurs in two forms: inhibited or stuporous catatonia and excited catatonia. The essential feature of both forms is the marked abnormality of motor behavior.

Stuporous Catatonia Patients with stuporous catatonia may be in a state of complete stupor or may show a pronounced decrease in spontaneous movements and activity. They may be mute or nearly so or may show distinct negativism, stereotypes, echopraxia, or automatic obedience. However, even after standing or sitting motionless for long periods of time, they may suddenly and without provocation have a brief outburst of destructive, unprovoked violence. Occasionally, patients with catatonic schizophrenia exhibit catalepsy or waxy flexibility (Fig. 12.7-4).

FIGURE 12.7-4 Chronic catatonic patient. This patient is immobile, demonstrating waxy flexibility. Her arm is in an uncomfortable position, elevated without support, and her stony facial expression has a *Schnauzkrampf*, or frozen pout. (Courtesy of Heinz E. Lehmann.)

Patients in a state of complete catatonic stupor usually can be aroused from it dramatically by intravenous injection of a short-acting barbiturate. Within minutes the frozen facial expression changes to one of normal animation. They begin to talk and move about normally and in many instances become relatively lucid for an hour or two. The total inhibition of patients in catatonic stupor may result from excessive cerebral excitatory processes. As in a car engine racing so wildly that one cannot put it in gear, that excess prevents the person from performing and behaving in a normal manner until the excessive cerebral functions have been reduced by a chemical agent that depresses brain metabolism and nervous impulses. But, spectacular as the immediate results seem to be, the technique has no significant therapeutic value.

A young, unmarried woman, age 20, was admitted to a psychiatric hospital because she had become violent toward her parents, had been observed gazing into space with a rapt expression, and had been talking to invisible persons. She had been seen to strike odd postures. Her speech had become incoherent.

She had been a good student in high school, then went to business school and, a year before admission to the hospital started to work in an office as a stenographer. She had always been shy, and although she was quite attractive, she had not been dating much. Another girl, who worked in the same office, told the patient about boys and petting and began to exert a great deal of influence over her. The second girl would communicate with her from across the room. Even when they went home at night, the patient would get voice messages telling her to do certain things. Then pictures began to appear on the wall, most of them ugly and sneering. Those pictures had names—one was named shyness, another distress, another envy. Her office friend sent her messages to knock on the wall, to hit the pictures.

The patient was agitated, noisy, and uncooperative in the hospital for several weeks after she arrived, and required sedation. She was given a course of insulin coma therapy, with no significant or sustained improvement. Later she received several courses of electroconvulsive treatment, which also failed to influence the schizophrenic process to any significant degree. Ten years later, when antipsychotic drugs became available, she received pharmacotherapy.

Despite all those therapeutic efforts, her condition throughout her many years of stay in a mental hospital has remained one of chronic catatonic stupor. She is mute and practically devoid of any spontaneity, but she responds to simple requests. She stays in the same position for hours or sits curled-up in a chair. Her facial expression is fixed and stony.

Excited Catatonia Patients with excited catatonia are in a state of extreme psychomotor agitation. They talk and shout almost continuously. Their verbal productions are often incoherent, and their behavior seems to be influenced more by inner stimuli than by their environment. Patients in catatonic excitement urgently require physical and medical control, since they are often destructive and violent to others, and their dangerous excitement can cause them to injure themselves or collapse from complete exhaustion.

An unmarried man, aged 27, had been working as a teacher and was admitted to a psychiatric hospital because he had become increasingly agitated and irrational after several nights of wakefulness. He was extremely talkative and ran about aimlessly. His behavior became very strange; for instance, he tried to clean everything in the house, moved his wristwatch up to his shoulder, stripped his clothes off, chewed large wads of paper in the belief that it was good for him, talked about killing himself, and then said that he might already be dead.

He heard voices ordering him about incessantly, and he frequently laughed without any apparent cause. After chewing the paper he would spit in it and then drink his saliva. He rolled into odd postures on the bed, with his tongue sticking out. He started to jump and dance when taken to the bathroom by a nursing assistant for a shower and destroyed the bathroom furnishings. His gait was manneristic. His speech was utterly incomprehensible. He refused to take any medication and had to be sedated by parenteral medication.

He remained noisy, excited, destructive, and irrational in his behavior for a month; then he improved in response to high dosages of antipsychotic medication and a few electroconvulsive treatments. Three months after admission he was discharged from the hospital, symptom free, with good insight into the nature of his illness. For more than 10 years he has been employed as a teacher.

Periodic Catatonia A rare but intriguing form of catatonia, periodic catatonia, was described by R. Gjessing in 1938. According to Gjessing, patients affected with the disorder have periodic recurrences of stuporous or excited catatonic states. Each recurrence of catatonic behavior is associated with an extreme shift in the patient's metabolic nitrogen balance. Most cases of periodic catatonia seen in recent years responded well to antipsychotic medication, and relapses were usually prevented by maintenance medication.

Disorganized Type The disorganized (formerly called hebephrenic) subtype is characterized by a marked regression to primitive, disinhibited, and unorganized behavior. Hebephrenic patients are usually active but in an aimless, nonconstructive manner. Their thought disorder is pronounced, and contact with reality is extremely poor. Personal appearance and social behavior are dilapidated, emotional responses are inappropriate, and they often burst out laughing for no apparent reason. Incongruous grinning and grimacing are common in these patients, whose behavior is best described as silly or fatuous (Fig. 12.7-5).

FIGURE 12.7-5 A 44-year-old chronic schizophrenic woman showing characteristic mannerism and facial grimacing. (Courtesy of New York Academy of Medicine.)

A 15-year-old girl attended a summer camp where she had difficulties in getting along with the other children and developed animosity toward one of the counselors. On her return home, she refused to listen to her parents, and she heard the voice of a man talking to her, although she could not see him. She rapidly began to show bizarre behavior, characterized by grimacing, violent outbursts, and inability to take care of herself.

Her school record had always been good, and she was fluent in three languages. Her parents described her as having been a quiet, rather shut-in child, with no abnormal traits in childhood. Family relations were reported as having been satisfactory.

When the patient was admitted to a psychiatric hospital, her speech was incoherent. She showed marked disturbances of formal thinking and blocking of thoughts. She was impulsive and seemed to be hallucinating. She stated that she heard voices in her right ear and that a popular singer was running after her with a knife. She also thought that her father was intent on killing her and that she was pregnant because she had hugged one of the residents.

Two months of neuroleptic treatment brought no apparent improvement. She was then given a course of intensive electroconvulsive therapy and continuous sleep treatment. Over a period of a year, she received close to 200 electroconvulsive treatments and 50 subcoma insulin treatments, with little improvement. She was then transferred to another mental hospital, where her behavior has remained very disturbed for almost 20 years.

She is often incontinent and most of the time neglects her physical appearance. Occasionally she spends hours dressing herself, looking in the mirror, and putting on excessive makeup. At times, she has been discovered eating her feces. Occasionally, she adopts the role of a singer or a dancer. She makes statements like “Will I live forever? Nurse, I didn't throw my love away. It is in my stomach, and it hurts.” In the dining room she attempts to grasp the genitals of male patients. High doses of neuroleptics are continuously required to control her behavior. The ultimate prognosis is very poor.

Paranoid Type The paranoid type of schizophrenia is characterized mainly by the presence of delusions of persecution or grandeur. Patients with paranoid schizophrenia are usually older than patients with catatonia or hebephrenia when they break down (i.e., they are usually in their late 20s or their 30s). Patients who have been well up to that age have usually established a place and an identity for themselves in the community. Their ego resources are greater than those of catatonic and hebephrenic patients. Paranoid schizophrenics show less regression of mental faculties, emotional response, and behavior than those with the other subtypes of schizophrenia.

Typical patients with paranoid schizophrenia are tense, suspicious, guarded, and reserved. They are often hostile and aggressive. They usually conduct themselves quite well socially, and their intelligence in areas not invaded by delusions may remain high. Paul Murphy, an American chess champion in the first half of the nineteenth century and one of the greatest chess masters in history, developed paranoid schizophrenia in his middle 20s and was hospitalized for years. But even many years after he had become ill, he played an original and masterful game of chess if he could be persuaded to accept the challenge.

A woman wrote the letter that is reproduced in part below. Like many patients with schizophrenia, this patient is tortured by the experience of being influenced in her bodily functions through fiendish devices used by her enemies.

Dear Dr. P.T.,

It is with the nurse's knowledge that I write this letter to you, regretting at the same to trouble you about a maladjustment that need not occur. I am at a loss to understand why those who are responsible are permitted to indulge in this peculiar pastime. Perhaps those with some authority do not desire to check it, but I realize, in any case, that it is rather difficult to do so inasmuch as when one person is checked, she passes the job on to someone else—I refer to this instrument that they use that completely locks up the intestines and prevents them from elimination at all even with a laxative, which is useless to take in such circumstances. It also twists me between my legs occasioning much discomfort, preventing proper rest in bed when my body is so tightened up that it is impossible to relax. I spoke to you several days ago about unexplainable solutions being injected into my body and my rest disturbed continually during the night. You agreed that if any treatments were ordered they should not take place at these hours. I think you said you would find out about any such requirement or order. Well, the hour of interference has changed—interference is the right word to use, because the one whoever is responsible is doing a great deal of harm. I am awakened every morning to the exact minute about 5:30. About 6:00 I drop off again until 7 AM (breakfast not until 8 AM). During this interval some person interferes with both passages of my body, and I find myself going around the rest of the day like a tank—full of burning Salt Water but quite unable to eliminate. At 5:30 I am quite comfortable but if I rose at this time, I suppose something would take place in the washroom—as these things so often do. The bladder is also interfered with, as is indeed every organ in my body with which I have never had any previous trouble. This has taken place nearly every day this week. If they do not get a chance just before I retire, some person in my room, by arrangement I suppose, awaits for me to get out of bed and as soon as I turn my back to them quickly uses this instrument, so as to insure this locked-up condition of the abdominal region. Because of so much interference, it is sometimes necessary for me to encourage the bladder to completely empty by means of the application of heat in the form of towels rung out in hot water and this is only effective in a standing up position—there is obviously some solution injected and as soon as I have withdrawn it in this manner I am very comfortable, but am not allowed to remain that way long. Something has also taken place this week which has been done once before on this ward and once in West House where it was frowned upon after discovery. I have been fixed up—temporarily, I hope, if the above results are going to continue—with two separate outlets for urination, which almost appears to come through two holes in the pelvic bone. All these months, as the previous nurses know, I have had to endure endless damage by interference with the pelvic. Perhaps they have got tired of that at last—and now it has to be something else, and when they get tired of that what next? . . .. There are other means of displacing the intestines, not only by instruments in the hands of other inmates, but by other mechanical tricks probably operated by the same people.

Undifferentiated Type Frequently, patients who clearly have schizophrenia do not fit easily into one of the other types. DSM-IV classifies those patients as having undifferentiated type.

Residual Type According to DSM-IV, the residual type of schizophrenia is characterized by the presence of continuing evidence of the schizophrenic disturbances in the absence of a complete set of active symptoms or of sufficient symptoms to meet the diagnosis of another type of schizophrenia. Emotional blunting, social withdrawal, eccentric behavior, illogical thinking, and mild loosening of associations commonly appear in the residual type. When delusions or hallucinations occur, they are neither prominent nor accompanied by strong affect.

OTHER TYPES AND RELATED SYNDROMES

Simple Deteriorative Disorder Simple deteriorative disorder (simple schizophrenia) is characterized by a gradual, insidious loss of drive, interest, ambition, and initiative (Table 12.7-4). Hallucinations and delusions are uncommon, and if those symptoms do occur, they do not persist. Patients with simple deteriorative disorder withdraw from contact with other people, tend to stay in their rooms, avoid meeting or eating with other members of the family, stop working, and stop seeing friends. If they are still in school, their marks drop to a low level, even if they were consistently high in the past.

A. Progressive development over a period of at least a year of all of the following:
   (1) marked decline in occupational or academic functioning
   (2) gradual appearance and deepening of negative symptoms such as affective flattening, alogia, and avolition
   (3) poor interpersonal rapport, social isolation, or social withdrawal
B. Criterion A for schizophrenia has never been met.
C. The symptoms are not better accounted for by schizotypal or schizoid personality disorder, a psychotic disorder, a mood disorder, an anxiety disorder, a dementia, or mental retardation and are not due to the direct physiological effects of a substance or a general medical condition.

Table 12.7-4 DSM-IV Research Criteria for Simple Deteriorative Disorder (Simple Schizophrenia)

These patients avoid going out into the street during the day but may go for long walks alone at 2:00 or 3:00 AM. They tend to sleep until noon or later, after staying up alone most of the night. During the early stages of the illness they may have many somatic complaints, variously described as fatigue, nervousness, neurosis, psychosomatic disease, and laziness. Patients are often treated for a year or more before the correct diagnosis is made. In many cases patients with simple deteriorative disorder later become homeless. They become increasingly shallow in their emotional responses and are quite content to drift aimlessly through life as long as they are left alone.

Although patients appear to be indifferent to their environment, they may react with sudden rage to persistent nagging by family members. The immediate reason for admission of patients with simple schizophrenia to a hospital is often an outburst of violence directed against their mothers or fathers for a trivial reason.

An unmarried man, 27 years old, was brought to a mental hospital because he had on several occasions become violent toward his father. For a few weeks he had hallucinations and heard voices. The voices eventually ceased, but he then adopted a strange way of life. He would sit up all night, sleep all day, and become very angry when his father tried to get him out of bed. He did not shave or wash for weeks, smoked continuously, ate very irregularly, and drank enormous quantities of tea.

In the hospital he adjusted rapidly to the new environment and was generally cooperative. He showed no marked abnormalities of mental state or behavior, except for his lack of concern about most things. He kept to himself as much as possible and conversed little with patients and staff. His personal hygiene had to be supervised by the nursing staff; otherwise he would quickly become dirty and very untidy.

Twenty years after his admission to the hospital, he is described as shiftless, and careless, sullen, and unreasonable. He lies on a couch all day. Antipsychotic drug treatment has failed to alter his mental state or behavior. Although many efforts have been made to get him to accept therapeutic work assignments, he refuses to consider any kind of regular occupation. In the summer he wanders about the hospital grounds or lies under a tree. In the winter he wanders through the tunnels connecting the various hospital buildings and is often seen stretched out for hours under the warm pipes that carry steam through the tunnels.

Patients with simple deteriorative disorder may resemble personalities of the schizoid type. The distinguishing feature is the disorder makes its appearance at some time during or after puberty and from then on goes on to definite deterioration; personality deviations usually start earlier and remain the same over the years.

To meet the ICD-10 diagnostic criteria for simple schizophrenia, the individual must show over a period of at least 1 year all of the following manifestations: (1) a significant and consistent change in the overall quality of some aspect of personal behavior such as loss of drive and interest; (2) gradual appearance and deepening of negative symptoms such as marked apathy; and (3) a marked decline in social, scholastic, or occupational performance.

Postpsychotic Depressive Disorder of Schizophrenia The clinical boundaries of the diagnosis are hard to define operationally. The symptoms of postpsychotic depressive disorder of schizophrenia can closely resemble the symptoms of the residual phase of schizophrenia as well as the side effects of commonly used

antipsychotic medications. Distinguishing the diagnosis from schizoaffective disorder, depressive type, is also difficult. The DSM-IV criteria (see Table 14.6-25) specify that the criteria for a major depressive episode be met and that the symptoms occur only during the residual phase of schizophrenia. The symptoms cannot be substance induced or part of a mood disorder due to a general medical condition.

ICD-10 describes a category called postschizophrenic depression. This is a depressive episode that may be prolonged, arising in the aftermath of a schizophrenic illness. The general criteria for schizophrenia must be met, and the depressive symptoms must be sufficiently prolonged or severe to meet the criteria for at least a mild depressive episode. These depressive states are associated with an increased risk of suicide.

Early-Onset Schizophrenia Most patients suffering from schizophrenia develop it in late adolescence and early adulthood. A small minority of patients manifest a similar syndrome in childhood. Such children may at first present diagnostic problems, particularly with differentiation from mental retardation and autistic disorder. Recent studies have established that the diagnosis of childhood schizophrenia may be based on the same symptoms used for adult schizophrenia. What characterizes childhood schizophrenia is not the nature but the dramatic intensity of its symptoms. Its onset is usually insidious, its course tends to be chronic, and the prognosis is mostly unfavorable. Briefly, it resembles the typical Kraepelinian case of dementia precox. What gives childhood schizophrenia unique importance for research is the observation that anatomical features of the brain that are often associated with adult-onset schizophrenia (e.g., enlarged ventricles) are also present in this early-onset form of the disease. Neurobiological studies of children with schizophrenia may therefore provide significant clues to the developmental pathogenesis of adult-onset schizophrenia.

Late-Onset Schizophrenia Late-onset schizophrenia is usually defined as an illness that is clinically indistinguishable from schizophrenia but has an onset after age 45. Since DSM-IV no longer uses an age cutoff, this distinction may no longer be relevant. This condition tends to appear more frequently in women and also tends to be characterized by a predominance of paranoid symptoms. The prognosis is favorable, and these patients usually do well on antipsychotic medication.

Bouffée Délirante (Acute Delusional Psychosis) Since it has been recognized that tardive dyskinesia may develop as a serious complication in a significant minority of patients with schizophrenia on maintenance therapy with antipsychotic drugs, it has become even more important to make a correct initial diagnosis. In French psychiatry the condition known as acute delusional psychosis, or *bouffée délirante*, is not included in the diagnosis of schizophrenia. Rather, *bouffée délirante* is considered a disease entity in its own right, a psychiatric disorder that does not require maintenance pharmacotherapy.

The following are essential criteria for the diagnosis of *bouffée délirante*, not all of which need to be present: (1) frequent background of personality disorder; (2) absence of a schizoid premorbid personality; (3) sudden onset; (4) duration of less than 3 months; (5) spontaneous return to premorbid level of adjustment, even without specific antipsychotic treatment; (6) polymorphous symptoms, a disorderly (kaleidoscopic) succession of differing delusional contents; (7) a fascinating intensity of the delusional experience; (8) oscillations between insight and delusion; (9) mood alterations and fluctuations; (10) increase in delusions in sleep-related states; and (11) sudden termination after days or weeks (rarely months).

Accordingly, *bouffée délirante* episodes belong to the schizophrenic spectrum disorders. In American clinical practice those episodes are usually diagnosed as schizophreniform disorder (see Table 13.1-3, schizoaffective disorder (see Table 13.1-1), or brief reactive psychosis (see Table 13.1-4). French psychiatrists report that about 40 percent of patients with the diagnosis *bouffée délirante* are later reclassified as suffering from schizophrenia.

Schizoaffective Disorder Schizoaffective disorder appears to lie conceptually between schizophrenia and the mood disorders. This category is quite ambiguous because it is the middle ground between two almost arbitrary groupings of patients. DSM-IV requires concurrent symptoms that meet the major criteria for schizophrenia and for a major depressive episode or manic episode or mixed episode. There must be a period of illness of at least 2 weeks, with characteristic delusions and hallucinations and the absence of prominent mood symptoms. Patients who carry this label tend to have a better prognosis.

Oneiroid In the oneiroid state patients feel and behave as though they were in a dream. (*Oneiros* is the Greek word for dream). Patients may be deeply perplexed and not fully oriented in time and place. During the state of clouded consciousness, they may experience feelings of ecstasy and rapidly shifting hallucinated scenes. Illusionary distortions of their perceptional processes (including time perception) and the symptomatic picture may resemble those of a hysterical twilight state. During oneiroid reactions, the observer can most clearly detect the patient's peculiar “double bookkeeping”—patients may be convinced that they are traveling through space on a satellite and at the same time conscientiously follow the regular hospital routine. The patient with oneiroid schizophrenia acknowledges everyday realities but gives priority to contingencies of reality (Fig. 12.7-6). Oneiroid states are usually limited in duration and occur most frequently in acute schizophrenic episodes.

FIGURE 12.7-6 A 25-year-old schizophrenic man produced this eerie-looking mixture of commercial poster and existential quandary about time. (Courtesy of Heinz E. Lehmann.)

OTHER DIAGNOSTIC CRITERIA

A variety of research clinicians, some of whom were mentioned above (e.g., Langfeldt, Schneider, and Jaspers), constructed their own criteria to discriminate for essential features of schizophrenia. However, a number of other diagnostic systems for schizophrenia have been developed (Table 12.7-5).

Table 12.7-5 Essential Features of Various Diagnostic Criteria for Schizophrenia

SIGNS AND SYMPTOMS

General Appearance and Behavior While no specific behaviors or appearances are unique to schizophrenia, experienced clinicians still speak of the precox feeling

(i.e., a failure to emotionally contact with the patient). Schizophrenia patients often give a history of being more sensitive than the average person. This sensitivity involves not only increased responsiveness to sensory stimuli but also increased sensitivity to emotional stimuli and, in particular, critical experiences. Experimental evidence indicates that some individuals who later develop schizophrenia do not screen out stimuli as effectively as normal people, which allows excessive input of stimuli to the nervous system. The failure of selective inhibition can play an important role in symptom production.

Patients with chronic schizophrenia tend to show a neglected personal appearance. Their efforts at grooming tend to be minimal. They show poor regard for the social amenities and act as if they are deliberately turning away from society. As a group, schizophrenia patients are characterized by social withdrawal. They may form emotional attachments with other people, but they cannot communicate the quality and strength of those attachments in a manner that is understandable to other people. Unfortunately, this tends to create a lack of empathy or sympathy toward the patient, which further isolates the patient from family and health care providers.

A common feature in schizophrenia is the loss of ego boundaries. These patients have difficulty determining where they end and where the outside world begins. This leaves them vulnerable to misinterpretation of external events that can be interpreted as affecting them directly.

Many patients show what appears to be an amotivational syndrome. The patient may show a lack of interest in the normal activities of daily living. Nevertheless, a loss of motivation should not be confused with the sudden or gradual intellectual dysfunction that can occur in this disorder. This intellectual dysfunction can lead to failure in school of a young person of good intelligence, which can be misinterpreted as not trying hard enough. This failure may be the earliest diagnostic sign of a developing schizophrenia.

Speech Disorders What has been historically referred to as thought disorder is more correctly identified as a speech disorder. It is assumed that the disorders of language reflect an underlying disorder of thinking. A variety of features have been reported by clinicians for the last 100 years as characteristic of this syndrome. These include the loss of the logical relations between antecedent and subsequent associations that is termed *loosening of associations*. Words can be combined on the basis of sound rather than on meaning called *clang association*. New words may be generated, which are called *neologisms* (Fig. 12.7-7). *Verbigeration* involves the use of words in a stereotypically repetitive fashion. *Echolalia* involves the repetition of the examiner's words. *Thought blocking* involves the sudden and inexplicable blocking of thoughts manifested by the patient's inability to speak.

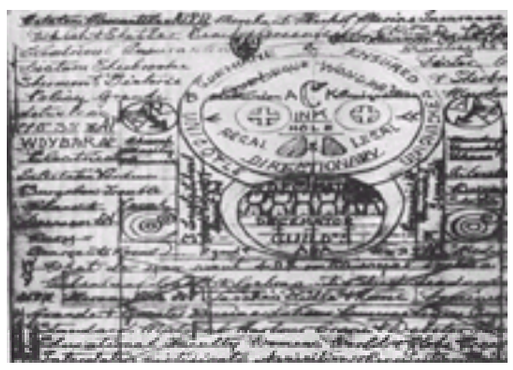

FIGURE 12.7-7 A schizophrenic woman expresses her incoherent thinking combined with neologisms in this drawing. (Courtesy of Heinz E. Lehmann.)

Loosening of associations is based on the late nineteenth-century association theory. According to association theory, language is determined by purpose. This purposefulness is often lost in schizophrenic speech. A sentence completion test illustrates the point. The sentence to be completed was “The man fell on the street . . ..” The patient's response was “because of World War I.” Although the thought of falling might be associated with falling in combat, it was an inappropriate association for the stimulus.

It can be helpful to look at disorders of association as disorders of the word and disorders of the sentence. Disorders of the word range from loss of symbolic meaning of the word as in clang associations to inability to maintain the correct semantic context for a word to approximate use of words, to the creation of new words. Disorders of the sentence include associative failures and failures of system placement. Most words have multiple meanings. Even a simple question such as “Where is your husband?” must be answered in terms of the frame of reference. In one context the question might ask for the physical location of the husband, and in another context it might ask for his identification in his graduating class picture. An example of system shifting was reported by Silvano Arieti. Commenting on the Japanese attack on Pearl Harbor, a patient said, “The next time they may attack Diamond Harbor or Emerald Harbor.” The patient had lost the contextual system of Pearl Harbor as a geographical military base and had substituted a contextual system in which pearls are precious stones.

Incoherence Language appears to be a means of self-expression in schizophrenia rather than a means of communication. Verbal productions are often empty or obscure. Schizophrenic speech contains more words that do not belong than does normal speech. In speech samples, patients with schizophrenia tend to repeat the same words more frequently than do nonschizophrenic people. When normal individuals are asked to fill in the deleted word in a continuous passage they are more likely to be correct when judging normal speech than when judging schizophrenic speech.

The following proclamation was written by a woman with schizophrenia. The repetitive phrases, distorted syntax, and numerous non sequiturs render the text sometimes incoherent. Nevertheless, the paranoid grandiosity, the hostility of the writer, and the content of her delusions are clearly expressed.

> The French Force orders from now on to the German Force to respect the Queen Sacre in Christianity as well as the Queen in France and in other countries, ill treated and destroyed in all countries since the beginning of this century in Europe and allied countries. The Queens are the copartners in masonry of the order of Grand Masters and by doing so the prosperity and balance of the world have been destroyed, they have been destroyed for homosexuality which is the emblem or grand mastery really instead of being distinguished from the criminals who kill the soul and commit the crime of homosexuality of destroying the emblem of grand mastery. The attack on the Queen Sacre in Masonry comes from an inversion of data in the German spying service in 1903 in the class of sorcerers of this organization, deciding that the Chateau de Chambord en France was going to be the Castle not of the saint to be, but of sorceress and killing in soul that child many times without the effect desired obtained.

The following is an example of what may be called concise abstruseness, which sometimes characterizes the communications of patients with schizophrenia and is often used to express undisguished sexual preoccupation. This patient's short apologetic note is to a psychiatrist whom she had bluntly propositioned on frequent occasions. (In this instance she got revenge against him for his rejection by pulling up expensive flowers in his garden.) She had previously inserted a screwdriver into her vagina and later expressed continuing guilt for having done so. The note expresses her sexually laden message briefly and (in her way) to the point. But the letter can be deciphered only with difficulty by the nonschizophrenic person who has not learned to understand the patient's autistic language.

> Dear doctor,
>
> I wasn't thinking too well when I was speaking to you but I do believe you were the postman whom I spent the night with. It is still Dr. David . . . in my heart. Am sick because of the screw driver. Please no hard feelings. Kiss your penis did. I would not harm you . . ..

The following brief transcript from a videotaped interview with a young man with schizophrenia illustrates his autistic preoccupation with sex and death; there seems to be some clang association between “feet” and “foetus.” The patient was puzzled that his interviewer had difficulties following him.

> the fleur de Lys is a castrated ace—you see, the design is the feet—the same as a woman's foetus—now you take five French safes and you put them together between four coffins—that's what it represents

Neologisms Occasionally, patients with schizophrenia create a completely new expression, a neologism, when they need to express a concept for which no ordinary

word exists.

> A woman with schizophrenia who had been hospitalized for several years kept repeating (in an otherwise quite rational conversation) the word "polamolalittersjitterstittersleelitla." Her psychiatrist asked her to spell it out, and she proceeded to explain the meaning of the various components, which she insisted were to be used as one word. "Polamolalitters" was intended to recall the disease poliomyelitis, because the patient wanted to indicate that she felt she was suffering from a serious disease affecting her nervous system; the component "litters" stood for untidiness or messiness, the way she felt inside; "jitterstitters" reflected her inner nervousness and lack of ease; "leelita" was a reference to the French *le lit la* (that bed there), meaning that she both depended on and felt handicapped by her illness. That single neologistic production thus enabled the patient to express—in a condensed, autistic manner—information about her preoccupations and apprehensions that otherwise would have taken a whole paragraph to explain in common language.

Mutism Functional inhibition of speech and vocalization may last for hours or days, but before the use of modern treatment methods, it often used to last for years in patients with catatonic schizophrenia. Many of these patients tend to be monosyllabic and answer questions as briefly as possible. They attempt to restrict contact with the interviewer as much as possible without being altogether uncooperative.

Echolalia Occasionally, patients with schizophrenia exhibit echolalia, repeating in their answers to the interviewer's questions many of the same words the questioner has used.

> Examiner: How did you sleep last night?
>
> Patient: I slept well last night.
>
> Examiner: Can you tell me the name of your head nurse?"
>
> The name of my head nurse is Miss Brown.

Echolalia seems to signal two facts, patients are aware of some shortcomings in their ideation and they are striving to maintain active rapport with the interviewer. They act much like someone learning a new language who answers the teacher's questions with as many of the teacher's words in the strange language as they can possibly manage.

Verbigeration This rare symptom is found almost exclusively in chronic and very regressed patients with schizophrenia. It consists of the senseless repetition of the same words or phrases, and it may go on for days (Fig. 12.7-8). Like neologisms and echolalia, verbigeration is a rare symptom today and is almost restricted to long-term institutionalized schizophrenia patients. Many psychiatrists working with schizophrenia patients in the community may never encounter these manifestations of deterioration.

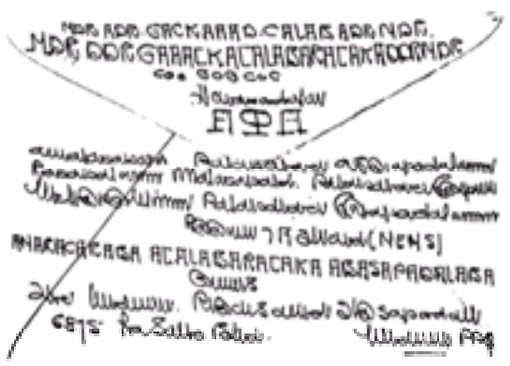

FIGURE 12.7-8 Sample of a chronic schizophrenic's noncommunicative writing. This addressed envelope illustrates manneristic writing, verbigeration, and possibly neologisms. Although the script appears to be exotic, the Arabic numerals and the English street name are recognizable. (Courtesy of Heinz E. Lehmann.)

Stilted Language Some patients with schizophrenia make extraordinary efforts to maintain their social relations, to maintain their relatively stable adjustment. But they may betray their rigidity and artificiality in their interpersonal relations by a peculiarly stilted and grotesquely quaint language.

The following excerpt from a letter written by a physician with schizophrenia who was hospitalized for more than 15 years but is now living by himself in an apartment is an example of such stilted language.

> My dear friend and Professor,
>
> A hearty and cheerful. (Please turn the page over) and a magnanimous good morning to you on this first Wednesday of a glorious New Year: And I do hope that our great and our good Lord and our dearly beloved and kind Shepherd, (kindly read page three now). Will be gracious unto both me and thee. I am sure that He be gracious unto both of us; He has some sound common sense. His being, this morning . . . I have not yet heard (Kindly turn over to 4 now) from any one of my own colleagues when I am leaving noble institution of the healing arts; Nor with whom: Nor through which one of the portals. Though I am sure that you—as much as (Kindly turn to page five, now) one else . . . must be able to enlighten me; very soon, my good old friend . . .

Behavioral Disorders Many patients with schizophrenia show a quantitative change in their activity, most commonly manifested as a reduction in energy, spontaneity, and initiative. In acute stages patients may become excited and show increased activity but usually only in the early phases of the illness. In a qualitative sense their behavior is often poorly coordinated, unpredictable, eccentric, and inappropriate. Even before the development of antipsychotic drugs patients conveyed an awkwardness and stiffness of movement. The great dancer Nijinsky lost his natural gracefulness with the onset of his schizophrenia.

Mannerisms Many patients with schizophrenia exhibit mannerisms of speech and movement. Grimacing is noticeable to varying degrees and at times may appear almost as a tic, particularly in the perioral regions. These perioral movements were reported and described by Kraepelin long before the use of neuroleptic drugs. He considered it a pathognomonic sign for poor prognosis in schizophrenia.

Stuporous States Stuporous states used to be common in the catatonic subtype of schizophrenia. Today they are quite rare and respond quite quickly to modern treatment when they are found. Similarly, catalepsy or waxy flexibility is almost unknown today, whereas 40 years ago it was common. It consists of a waxlike yielding of the movable parts of the body to any effort made to place them in certain positions. Once placed in the position, the patient remains in that position for a long time—even if the position is physically uncomfortable (Fig. 12.7-9). While these extreme examples of stupor and waxy flexibility have essentially disappeared, many chronic patients show a lack of spontaneity and movement that bears an attenuated resemblance to the more severe conditions described above.

FIGURE 12.7-9 A patient exhibiting catatonic posturing. (Reprinted with permission from Davison GC, Neale JM: *Abnormal Psychology: An Experimental Clinical Approach*. Wiley, New York, 1974.)

Echopraxia The motor symptom echopraxia is analogous to echolalia in the verbal sphere. It is the imitation of movements and gestures of the person the patient is observing.

Negativism Negativism refers to a patient's unwillingness to cooperate without any apparent reason for that lack of cooperation. It does not appear to be related to fatigue, depression, suspicion, or anger. Negativism may even take the form of unwillingness to follow a request for a physical movement. It can become so severe that the patient will do the opposite of what is asked. For example, when asked to raise an arm, they may lower it.

Stereotyped Behavior Stereotyped behavior is primarily seen in patients with chronic schizophrenia, including those in the community. At times it may take a motoric form and be expressed in a repetitive pattern of walking or pacing. It may also be demonstrated in repetitive strange gestures, which may or may not have a magical meaning to the patient. Finally, in language one can have the repetition of phrases or comments for long periods. This is separate from preservation and distinct from verbigeration. Interestingly, when schizophrenia patients are engaged psychosocially, this symptom tends to diminish. It appears to be a consequence of psychosocial isolation.

Deteriorated Appearance and Manners Patients with schizophrenia tend to neglect their appearance. This extends not only to elements of personal hygiene such as bathing, but even to changing their clothing. They can appear indifferent to the social amenities, such as returning a greeting. Frequently, they exhibit bad table manners despite the fact that in their premorbid condition they did not do so. Prior to the advent of antipsychotic drugs, regressed patients with schizophrenia could frequently be seen masturbating openly in hospital wards without apparent concern about the public nature of their act.

Affective Features Both quantitative and qualitative changes in affect may occur in patients with schizophrenia.

Reduced Emotional Responses Most commonly, patients show a quantitative change in the intensity of their emotional responses. Many patients with schizophrenia appear indifferent and apathetic. Others show diminished emotional intensity, described as emotional restriction or blunting. This quantitative aspect, which has been emphasized by Bleuler, is common in schizophrenia.

In judging emotional depth, one must consider the cultural background of the patient. A normal emotional expression in one culture may appear to be a reduced emotional response in another. Cultures differ dramatically in their willingness to accept a public display of emotion; therefore, the examiner should have some knowledge of the cultural background of the patient being assessed. Often the patient and family are the best informants; they may be able to describe changes from the premorbid emotional state before they become obvious to even an experienced clinician.

Anhedonia Anhedonia is a particularly distressing symptom. Sandor Rado considered anhedonia to be a cardinal feature of schizophrenia. There is frequently a diminution in the patient's ability to experience pleasure and, in some severe cases, even to imagine a pleasant feeling. Patients may not meet the criteria for the diagnosis of clinical depression but will describe an emotional emptiness or barrenness. Anhedonia can become unbearable enough to contribute to a suicide attempt.

Inappropriate Responses A common finding in schizophrenia is a failure of congruence between an emotional expression and the ideational content. A patient with schizophrenia may talk about the death of a family member with a broad smile. This loss of harmony between the affective display and the ideational content is more common in chronic patients. Loss of congruence creates marked discomfort in the observer and contributes to the tendency of family and friends to remove themselves from contact with the patient. Psychological testing has demonstrated that patients with schizophrenia frequently cannot recognize the emotional state expressed in photographs of faces. This inability to recognize emotional cues in others may be expressed in the patient's inability to show their own emotional experiences in ways that are understood by others. The degree of emotional blunting and inappropriateness of emotional responses are excellent measures of the extent to which the illness has invaded the person's personality and contributed to its deterioration. Severe blunting and inappropriateness are associated with chronic schizophrenia.

Unusual Emotions Schizophrenia is characterized frequently by alterations in emotional reactions to external stimuli and often demonstrates peculiarities of emotions infrequently seen in normal states. Particularly during acute decompensations, patients may describe states of exaltation with feelings of omnipotence, oceanic feelings of oneness with the universe, religious ecstasies, and terrifying apprehensions about the disintegration of their own personality or body. It is not unusual to see intense anxiety about the impending end of the universe. These experiences are rare in normal individuals, except when under the influence of psychotomimetic drugs.

Emotional Sensitivity Many individuals who eventually develop schizophrenia premorbidly demonstrate a hypersensitivity to rejection. Much of the premorbid tendency toward social isolation can be understood as an avoidance mechanism to reduce the risk of rejection. After the onset of the disorder most patients continue to display extreme sensitivity to criticism and rejection. They may react to the tone or content of the therapist's intervention with a marked exacerbation of positive symptoms.

> An intelligent, well-mannered young woman suffering from chronic schizophrenia, who had improved to the point where she could live autonomously in her own apartment, had invited some friends to dinner. The dinner was well prepared and the evening enjoyable, until the friends invaded the patient's kitchen with forceful enthusiasm, and insisted on washing the dishes. Their hostess became enraged and ordered all guests to leave her home immediately. She later explained to her therapist that she felt humiliated and hurt by what she felt was a rude demonstration of her guests' conviction that she would never be able to make order in her own kitchen by herself.

Those who have worked extensively with patients with schizophrenia know that they are extremely sensitive. They are easily hurt by even slightly aggressive or rejecting behavior by others—behavior that in most cases would hardly be noticed by a person of normal sensitivity or, if noticed, would not lead to traumatic experiences.

> For example, a father's refusal to let his son with schizophrenia watch a particular program on television caused the son, who was not known to be a violent or impulsive person, to knife his father to death. In another case a psychiatrist's refusal to see a patient with schizophrenia at the moment the patient requested it (the patient was told he would be seen 3 hours later) caused the patient to commit suicide. Another patient with schizophrenia in remission committed suicide when his parents refused to include him on a 2-week trip to Florida.

Perceptual Disorders Various perceptual disorders occur in schizophrenia. It may be hypothesized that those disorders result from the patient's constant exposure to an overwhelming influx of sensory stimuli. Although normal persons have a fundamental, pervasive feeling of familiarity with the environment to which they have become accustomed and adapted—a necessary background for all normal perception—patients with schizophrenia may experience a haunting unfamiliarity with their environment. That unfamiliarity sometimes comes over them with a sudden jolt; at other times they experience a continuous feeling of strange remoteness, alienation,

and lack of contact (Fig. 12.7-10).

FIGURE 12.7-10 A symbolic representation of alienation that may be very severe in schizophrenia. (Courtesy of Erich Hartmann.)

Spontaneously reported sensory disturbances, mostly optical but also acoustic, olfactory, and gustatory, were observed in 15 percent of a large sample of patients with schizophrenia. The disturbances included hypersensitivity to light, changes in the perception of other people's faces and figures, misperception of movement, hypersensitivity to sound or smell or taste, and other changes in those senses.

Because of the unpredictable variability of the patient's experiences, the gestalt of the visual world are broken into disjointed parts. These patients frequently see objects and people change their dimensions, outlines, and brightness from minute to minute or even from second to second before their eyes. Déjà vu experiences may intrude and produce an uneasy feeling of spurious familiarity. Time may lose any structure or meaning, and the experience of passing time may extend or contract. These changes can be shown in experimental investigations on size and brightness constancy, on critical flicker-fusion frequency, on time estimation, and on many other perceptual functions (Fig. 12.7-11).

FIGURE 12.7-11 Drawings of a house made by a young man during an acute schizophrenic illness. **A** was drawn on admission to the hospital. **B** was drawn after 1 week of phenothiazine treatment. The percept house in the first drawing is fragmented. The windows are displaced, the roof is lying on the ground, beside the walls. In the second drawing, the structure and the perspective of the house are restored. (Courtesy of Heinz E. Lehmann.)

Hallucinations Sensory experiences or perceptions without corresponding external stimuli are common symptoms of schizophrenia. Most common are auditory hallucinations, the hearing of voices. Sometimes the voices are those of God or the devil; sometimes they are the voices of relatives or neighbors. Frequently, the patient can neither recognize nor understand them. Most characteristically, two or more voices discuss the patient in the third person. Frequently, the voices address the patient, comment on the patient's activities and surroundings, or are threatening or obscene and very disturbing to the patient. They may represent some evil outside power over which the patient has no control. Many patients with schizophrenia hear their own thoughts. When they are reading silently, for example, they may be quite disturbed by hearing every word clearly spoken to them.

Patients with schizophrenia experience visual hallucinations less frequently than auditory hallucinations, but they are not rare. Patients suffering from medically caused visual hallucinations experience them primarily at night or during limited periods of the day. They get relief only in sleep. Visual hallucinations that occur in schizophrenia are usually seen nearby, clearly defined, in color, life size, in three dimensions, and moving (Fig. 12.7-12). Visual hallucinations almost never occur by themselves but in combination with hallucinations in one of the other sensory modalities. Tactile, olfactory, and gustatory hallucinations are less common than visual hallucinations. Patients with schizophrenia often experience cenesthetic somatic hallucinations, sensations of altered states in body organs without any special receptor apparatus to explain the sensations (e.g., a burning sensation in the brain, a pushing sensation in the abdominal blood vessels, or a cutting sensation in the bone marrow. Hallucinations may absorb all or much of the patients' attention and may control their behavior to a considerable extent. While they are listening to voices, they may be preoccupied and oblivious to the environment. They may react with laughter or anger or terror and may carry on lengthy conversations with the voices.

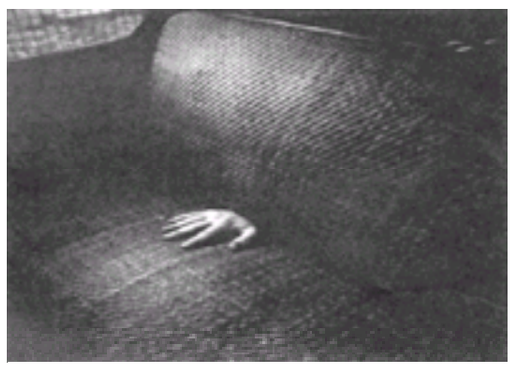

FIGURE 12.7-12 This photograph may symbolize the fantasy world of the schizophrenic. Not all psychiatrists are willing or able to attempt to empathize with that world, which can be a valuable therapeutic technique in some cases. (Courtesy of Arthur Tress.)

Modern treatment methods, particularly pharmacotherapy and social therapies that engage patients in various activities all day, have robbed hallucinations of much of their vividness and persistence. Also, many patients today know what hallucinations are and realize that hearing voices may be considered pathological and they will be considered crazy. Thus, present-day schizophrenia patients are much less likely to discuss their hallucinations openly than they were only 20 years ago.

Dream Content Studies of the dream content of patients with schizophrenia have shown that their dreams are less coherent, less complex, and less bizarre than those of normal persons. The incidence of dreams with color is apparently somewhat higher in patients with schizophrenia than in normal persons. Family members appear more often in dreams, and friends less often. The incidence of pleasant emotions in dreams of patients is similar to that for normal persons, but unpleasant

emotions are more common in the dreams of patients with schizophrenia than in the dreams of normal persons.

Thought Disorders

Delusions By definition, delusions are false ideas that cannot be corrected by reasoning and that are idiosyncratic for the patient (i.e., not part of the patient's cultural environment). They are common symptoms of schizophrenia.

Most frequent are delusions of persecution, which are a key symptom in the paranoid type of schizophrenia. The conviction of being controlled by some unseen mysterious power that exercises its influence from a distance is almost pathognomonic for schizophrenia (Fig. 12.7-13). It occurs at one time or another, in most, if not all, patients with schizophrenia, and for many it is a daily experience. Patients who are convinced that they are being persecuted by powerful agencies often harbor delusions of grandeur; they must be very important if so much effort is spent on their persecution. In connection with their experiences of being physically controlled by unseen forces, many patients with schizophrenia have elaborate delusions that their minds are controlled by telepathy or hypnotism. Modern patients whose delusions have kept up with the scientific times may be preoccupied with atomic power, X-rays, or spaceships that take control over their mind and body. Many patients with schizophrenia have delusional fantasies about the destruction of the world. The radio waves of the 1930s have been replaced by the alien creatures of the new millennium.

FIGURE 12.7-13 In schizophrenia, irrational and idiosyncratic ideas create a fearful world that is difficult for others to experience or understand, as symbolized above. (Courtesy of Arthur Tress.)

> Further to my investigation and research . . .. I would like to inform you that the tadpole in the eyes moves or floats around with the movement of the iris . . .. The tadpole reveals the photographic and its spirit the parabiological matter. From experience the Spirit is more deadly than the vision—the vision could bring on a person a berserk or manic attitude if he is unaware of its tricks—it could also be a danger to schizoid, alcoholic, and neurotic personalities.
>
> Further to the tadpole, it is luminous in the dark at times and flashes rings of light when both eyes are closed.
>
> Have you any idea if science could produce a solution that could cover the iris and eradicate the tadpole and the luminous matter?
>
> I repeat again, this is a diabolical science deliberately done to destroy human nature.
>
> Yours sincerely,
>
> J.M.

A delusional idea may occur with extraordinary rapidity. The patient may experience it as an illumination of the intellect in which the meaning of certain matters suddenly becomes clear. The total certainty is diagnostic of the delusional nature of the belief. There is a variation over time in the degree of certainty about the belief. At times the patient believes but is not absolutely certain, and at other times the patient cannot entertain any doubt in the belief system.

Phases of Cognitive Disturbance K. Conrad studied the development of delusions in patients with schizophrenia. In the first phase of the schizophrenic process, which he called “trema” (German for stage fright), patients become aware that something ominous is happening to them. Somehow, the world around them is changing, and they feel locked in, harassed, and powerless. They may make desperate attempts to regain control through elaborate schemes of body and character building.

Table 12.7-6 contains the schedule that a young man, aged 19, set for himself in a desperate last attempt to achieve a sense of security 3 months before he was admitted to a mental hospital in an acute catatonic stupor.

Time	Activity
7:00–8:00	Cold bath, toiletries, bed, dress
8:00–8:15	Encyclopedia (memorize three facts)
8:15–8:30	Handwriting
8:30–8:45	Brisk walk
8:45–9:00	Breakfast (one apple, one dish of bran, two glasses of milk, two glasses of water)
9:00–10:00	Hearing, sight, and scent
10:00–11:00	European, financial, and sport news
11:00–12:00	Wax floors and clean door knobs
12:00–1:00	Cold bath and exercises
1:00–1:30	Geometry
1:30–1:45	Vegetable lunch (very light)
1:45–2:45	Music
2:45–3:45	Walk as far as Atwater and then back to library
3:45–4:45	Study at library
5:00–6:00	Accounting
6:00–6:20	Cold bath
6:20–6:35	Vegetable supper
6:35–8:05	Accounting
8:05–9:00	Hearing, sight, and scent
9:00–9:30	Strength and Health Magazine
9:30–10:00	Wardrobe
10:00–10:20	Cold bath
10:20–10:40	Study vocabulary (12 words)
10:40–11:00	Undress and toiletries
11:00–11:15	Breathing exercises
11:15–11:30	Prior improvement in mental latitude in diary

Table 12.7-6 Schedule of a Person with Catatonic Schizophrenia

During the trema phase patients are anxious, irritable, and often depressed. That phase may last for only a few days, but it sometimes lasts for weeks or months. In the latter stages of the trema phase, patients may be in a delusional mood that makes them see their environment in a new and strange light, appearances are changed and familiarity is lost. A description of such an experience is given in the following excerpt from a patient's account, after recovery, of his schizophrenic attack.

> I suddenly realized that I just didn't have a clue where I was. I came to consciousness still driving along 401 highway but I had a vague suspicion that I might be nearing Montreal. I made a real effort to stay alert, but I seemed to keep drifting back to my former thoughts. Why had Edith said that I should believe in fairy tales? Was Joan really not dead but in a mental institution? Why had I been so cold that night in my car (the thermostat broke) and what was the significance of coldness, magnetism, and love?
>
> I imagine what I have recorded represents about 10 percent of my thoughts. They flashed through my mind so rapidly and with such turmoil that I became aware my thoughts were running out of control. And I felt that I wanted to see Dr. Wilson . . . Again on the same stretch of Highway 401 I lost the knowledge of location. The trigger again was through theories of cosmic matter in the aurora borealis—the Northern Lights; and the meaning of the Southern Cross.

The trema phase is followed by the epiphany phase, a Greek expression suggesting sudden revelation. Conrad postulated two phases after the apophanous: the apocalyptic fragmented phase and the terminal phase, in which the patient becomes vegetable-like. In the apophanous phase the patient suddenly becomes sure of certain new “facts.”

> A taxi driver this morning touched his cap with his right hand; this meant that he knew where the patient had been last night. A newspaper was lying on the stairs; this meant that his reputation would be ruined before nightfall. A man was feeding two squirrels in the park, indicating that the patient's future would be decided in 2 weeks. A television announcer makes a verbal slip; this broadcasts that the patient is stupid.

Conrad called such delusions *autochthonous*, meaning that they are primary and irreducible. They appear de novo and seem to have little or no connection with the patient's life history or specific stresses and conflicts.

Why do patients believe in the reality of these delusions? What evidence supports the farfetched connections they make? Patients always give the same answer, “I know it.” That direct, immediate, total certainty is the irrational, pathological aspect of the primary delusional experience. That certainty—“I know it”—cannot be explained by analyzing the patient's conscious psychic content. Many leading German psychiatrists, such as Jaspers, have stressed the difference between the primary pathological possibility of having delusions and the contents of delusions, which may have distinct, analyzable meaning based on the patient's psychological conflicts, drives, and needs.

Disturbances of Thinking Disturbances of thinking and conceptualization are one of the most characteristic features of schizophrenia. The feature common to all manifestations of schizophrenia thought disorder is that patients think and reason on their autistic terms according to their own intricate private rules of logic. Schizophrenic patients may be highly intelligent, certainly not confused, and they may be painstaking in their abstractions and deductions. But their thought processes are strange and do not lead to conclusions based on reality or universal logic (Fig. 12.7-14). The first author found that about 70 percent of patients with schizophrenia showed a typical schizophrenic thought disorder, and those who did usually had a withdrawn personality. He hypothesized that premorbid withdrawal characteristics already contained the thought disorder that emerged later.

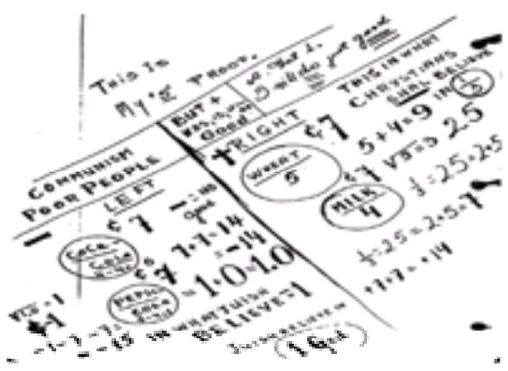

FIGURE 12.7-14 Schizophrenic patient's schema illustrates his fragmented, abstract, and overly inclusive thinking and preoccupation with religious ideologies and mathematical proofs. (Courtesy of Heinz E. Lehmann.)

One study emphasized the fact that the patient with schizophrenia may consider two things identical merely because they have identical predicates or properties. By contrast, in normal logical thought, identity is based on identical subjects and not on identical predicates. The patient with schizophrenia may reason (to quote Silvano Ariete), “The Virgin Mary was a virgin; I'm a virgin; therefore, I'm the Virgin Mary.” However, this particular fallacy is not specific for schizophrenia and is commonly committed by college students who are distracted or fatigued. Arieti believed that schizophrenic cognition uses isolated segments and parts, rather than the whole of the concept.

Patients with schizophrenia may reason: “John is Peter's father; therefore, Peter is John's father.” Such symmetrical reasoning is sometimes justified (e.g., John is Peter's brother, therefore, Peter is John's brother), but at other times such symmetrical conclusions are not justified, and patients not seem to know when they may apply them and when they may not.

Patients with schizophrenia use archaic modes of mystical or magical thinking. Such primitive modes of thinking are closely related to the psychoanalytic concept of primary thought processes that are at work in normal dreaming and allow condensation, reversal, substitution, displacement, and other distortions of conceptual relations impossible in rationally controlled thought. Jung, in fact, compared the psychic processes of schizophrenic patients who are awake to those of normal persons who are dreaming with their eyes open.

Kurt Goldstein described a concretization of thought and a loss of the abstract attitude as typical of schizophrenic thinking. Patients lose their ability to generalize correctly and exhibit in the ordering of their concepts a defect similar to a loss of the figure-ground relation in perceptual performance. That defect is often brought out by the simple clinical test of asking a patient to interpret a well-known proverb. One patient interpreted the saying “A stitch in time saves nine” as “I should sew nine buttons on my coat,” an overly personalized and concrete explanation.

Norman Cameron identified overinclusion as a typical feature of schizophrenic thought disorder. In contrast to patients whose mental functions are impaired by an organic brain lesion and who tend to omit important items in thought and speech, patients with schizophrenia tend to include many irrelevant items in their ideational and verbal behavior. That tendency seems to result from a loosening of associations in the schizophrenia patient. Studies have shown that overinclusive thinking is not a learning defect but an impairment of a central filtering process that normally inhibits external sensations and internal thoughts that are irrelevant to a given focus of attention. Only a well-functioning filtering-inhibiting process makes rational thinking possible. Overinclusive thinking usually develops within the setting of a delusional mood, when things look different, sensations are more intense, and everything seems to have some strange special significance (Fig. 12.7-15).

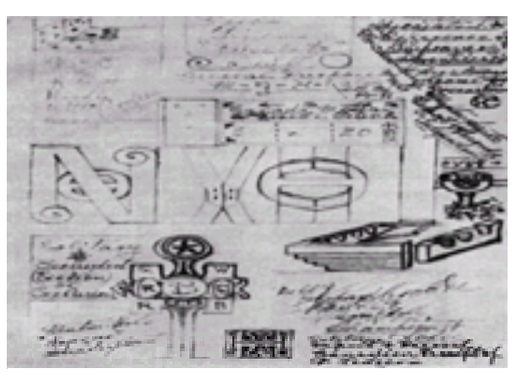

FIGURE 12.7-15 This drawing, carefully executed by a schizophrenic woman, graphically expresses her incoherent thinking and her tendency to perseveration of ideas, combined with an ability to accomplish quite complex drafting. Similar drawings may be produced when normal people doodle while their attention is not focused on what they are doing. (Courtesy of Heinz E. Lehmann.)

David Shakow demonstrated in a series of experiments that patients with schizophrenia cannot hold a set as well as a normal person can. That inability becomes

evident when patients are tested for their reaction time in responding to a stimulus preceded by a ready signal. Introduction of a ready signal shortens the reaction time of a normal person to the stimulus that may follow the signal within 10 to 15 seconds. The patients' reaction time remains the same, whether or not they are warned of the coming stimulus.

Somatic Findings

Physiological Testing A significant proportion of the patients who carry the diagnosis of schizophrenia exhibit neurological test abnormalities. The neurological findings that can be identified in approximately half the population tend to be soft signs. A careful history will also reveal that a significant percentage of patients with the diagnosis of schizophrenia experienced difficult labors and various obstetrical complications at birth. The patient's childhood developmental milestones tend to be delayed. School and work performance tends to be less adequate than that of their siblings.

One of the earliest signs of a developing schizophrenic illness is the loss of the normal gracefulness of body movements. This was reported before the advent of antipsychotic drugs, and it should not be confused with the dystonias seen secondary to medication. Perioral tremors were reported long before the use of dopamine receptor antagonists and should not be confused with tardive dyskinesia. All of these signs are associated with poor prognosis.

During the onset of an acute schizophrenic episode patients show increased autonomic tone, manifested in dilated pupils, moist palms, and moderate tachycardia. Systolic blood pressure tends to be elevated. Interestingly enough, there are few sleep disturbances after the acute stage of illness, although schizophrenic sleep is characterized by a tendency towards reduction of stage 4 sleep.

Water Intoxication Routine laboratory tests of patients sometimes find a low specific gravity of urine and a low sodium concentration in serum. Retrospectively, it may be noted that the patient seems always to be at the water fountain. The syndrome of self-induced water intoxication should then be considered, particularly in the differential diagnosis of seizures in schizophrenic patients. As many as 20 percent of patients with a diagnosis of chronic schizophrenia drink excessive amounts of water, and 4 percent of the chronic population suffer from chronic hyponatremia and episodic water intoxication. The workup for increased water intake should include repeated daily weighing and tests for inappropriate secretion of antidiuretic hormone, whose secretion is sometimes altered by treatment with antipsychotic agents, carbamazepine (Tegretol), lithium (Eskalith), or other drugs.

Constitutional Characteristics The relationship between body build and personality structure has been studied intensively for many years. Early studies showed that the diagnosis of schizophrenia occurred more frequently in persons of asthenic, athletic, and dysplastic body types than in the pyknic type. The pyknic type was believed to be more likely to develop manic-depressive psychosis. Although these observations may seem peculiar today, this perspective was prevalent in the 1930s. In the United States workers such as William Sheldon made extensive studies of the relationship between body type and mental illness. Using more-precise methods for measuring body types, he reclassified people into ectomorphic, mesomorphic, and endomorphic (Fig. 12.7-16). In this classification schizophrenics were more likely to be ectomorphs or mesomorphs.

FIGURE 12.7-16 Sheldon's method of dividing people into distinct body types. **A**, Endomorphic, characterized by roundness and excess subcutaneous fat deposits. **B**, Mesomorphic, characterized by excess muscular tissue. **C**, Ectomorphic, characterized by minimal muscular and subcutaneous tissues.

In urban areas today a high percentage of patients diagnosed with schizophrenia also suffer from concomitant substance abuse—alcohol, drugs, or both. The substance abuse appears to be a form of self-medication, which unfortunately leads to additional problems for the patients.

Two major eye abnormalities occur in schizophrenia. The first is a tendency toward frequent blinking, which is reduced with neuroleptic medication. This increased blink rate may reflect increased dopaminergic tone in the nervous system. The second is that in attempting to follow a moving object smoothly, abnormal saccades occur in approximately one-half to three-quarters of patients studied. Abnormal smooth pursuit may be a neurophysiologic marker for certain aspects of the pathophysiology of some patients with schizophrenia.

Abnormalities of prosody are quite common in patients with schizophrenia. This can be conceptualized as a neurological disorder of the parietal lobe. Considerable evidence from imaging studies indicates that the temporoparietal region is important in the pathophysiology of these disorders.

Imaging studies, including quantitative electroencephalography, reveal problems in having different brain areas work together in a synchronized fashion. This failure of coherent and integrated activity of different cell ensembles may well be the cardinal pathophysiologic finding of this group of disorders.

Suicide and Violence Suicide is surprisingly common in this population. The frequency of attempts varies to up to 40 percent of the population. About 10 percent of people diagnosed with schizophrenia commit suicide during the first 10 years of the illness. The risk of suicide is higher in men, particularly those with the paranoid type. The sudden, otherwise unexplained suicides of university students may be related to their experiencing cognitive dysfunction and positive symptoms that they fear to mention to anyone and that go undiagnosed and untreated. Suicide of an individual with a diagnosis of schizophrenia is much less predictable than it is for someone with depression.

> A 32-year-old man with chronic schizophrenia who lived at the home of his parents and was compliant with treatment committed suicide in a bizarre way while his parents were on a 2-week trip to Florida. The parents had taken such trips previously on several occasions. In a rambling suicide note the patient indicated that he resented not having been asked to accompany them.

Suicide is a significant danger for patients with schizophrenia. Probably more patients with schizophrenia than with bipolar I disorder commit suicide, although the immediate risk of suicide is relatively greater among the latter. Patients with schizophrenia may commit suicide because they are deeply depressed or they may kill themselves in response to the relentless commands they receive from hallucinatory voices.

> A patient with schizophrenia who had jumped to the street from a third-floor balcony sustained several fractures but lived to say that for many days a man's voice had told him persistently to jump out of a window. He did not want to die, and he resisted the voice for as long as he could, but he finally had to yield to its demands.

Patients with schizophrenia are more violent as a group than the general population. This is particularly a problem with patients with the paranoid type who may act quite suddenly and impulsively on a delusional idea. Patients with paranoia tend to be intelligent and capable of forming plans; therefore, they represent a much greater risk than individuals who are disorganized and cannot plan an effective attack. Despite earlier beliefs, command hallucinations do not appear to play a particularly important role in violence. Violence between patients in hospitals frequently results from the attacking patient's mistaken belief that another patient is behaving in a threatening way or getting physically too close. Studies have revealed that violence in a hospital setting can result from undiagnosed neuroleptic-induced acute akathisia. Persistently violent inpatients often do well on special treatment units that provide a more structured program and a less-crowded

environment. The patients who fail to respond to this kind of care usually show neurological signs in addition to their diagnosis.

Unfortunately, it is exceedingly difficult to prevent most schizophrenic homicides, since there is usually no clear warning. Most of the homicides come as a horrifying surprise. Patients who are known to be paranoid with homicidal tendencies should not, as a rule, be allowed to move about freely as long as they retain their delusions and their aggressive tension. But, like the patient who hanged himself without previously manifesting any observable depression, the homicidal schizophrenia patient may appear to be relaxed, even apathetic, and then, within a day or two, kill somebody.

The number of homicides committed by patients with schizophrenia may increase during the next few years. As a result of the gradual reduction in the hospital confinement of patients with schizophrenia, many of them are treated with modern methods of therapy in the community, where it is often impossible to control and supervise their pharmacotherapy and to prevent recurrences of paranoid homicidal behavior.

> A man with schizophrenia who had been going home on weekends for many months was told by his sister that she would no longer ask permission to take him out of the hospital if he would not do his part of the housework—for instance, help with the dishes. On the next weekend visit, the patient killed his sister and his mother. He had shown no signs of disturbance whatsoever during the preceding week, had been sleeping well, and had been attending occupational therapy classes as usual.
>
> A 19-year-old boy was discharged from a mental hospital in what seemed to be a residual state of chronic schizophrenia of the undifferentiated type. He stabbed his father to death when the father, during a state of intoxication, told the patient that he was too much of a bother around the house and that he might as well return to the hospital.
>
> A man with schizophrenia, whose condition had not yet been diagnosed, complained to a general practitioner about various physical ailments. When the physician finally told him that he should not come anymore because there was nothing else he could do for him, the patient quietly left the office. He returned a few hours later and killed the doctor.

Rejection Careful analysis of these unpredictable suicides and homicides leads to the conclusion that the most significant single factor in most of them was a traumatic experience of rejection. The pathological sensitivity of persons with schizophrenia makes them extraordinarily vulnerable to all common life stresses. Rejection, particularly by members of their own family, seems to be more traumatic for them than most other stresses. The act of rejection may seem trivial, and it is often not deliberate on the part of those who reject the patient. In fact, they are practically never aware of it, and the patient may not show any immediate reaction to the rejection at the time.

It may be significant that four of the second author's patients with schizophrenia who committed homicide harbored the delusion that their parents were adoptive parents rather than real parents. That delusion in itself seems to reflect a deep-seated feeling of being rejected by the parents.

Prepsychotic Personality A clinical evaluation must always consider the patient's prepsychotic personality. The clinical, but not typical, history is that of a schizoid personality—quiet, passive children with few friends; daydreaming, introverted, and shut-in adolescents and adults. They are often reported as having been especially good children because they were always obedient and never in any mischief. In school they were good in spelling but poor in arithmetic. They made few friends as children and their deficient friendship was particularly noticeable in adolescence.

Typical schizoid adolescents have few dates, do not usually learn to dance, and have no close boyfriends or girlfriends. They are not interested in petting or other heterosexual or homosexual activities but are often disturbed about masturbation. They avoid competitive sports but like to go to the movies, watch television, or listen to music. They may be avid readers of books on philosophy and psychology.

Less than 25 percent of patients with schizophrenia have a history of the type of schizoid personality described above. The former assumption that schizophrenia is genetically transmitted either as the disease proper or as a schizoid character structure is now changing to the concept of genetic transmission of schizophrenic spectrum diseases (including various personality and neurotic disorders) and a variety of conditions—even valuable traits, such as creative ability. About 90 percent of patients diagnosed with schizophrenia have no known family history of the disease.

Precox Feeling Some clinicians believe they can diagnose a precox feeling. That feeling consists of an intuitive experience by the examiner that determines whether or not it is possible to empathize with the patient. Patients whose emotional distance makes it impossible to establish an empathic rapport are classified as having schizophrenia, providing other criteria are met. The reliability of this approach is questionable and even though important, the use of the examiner's feeling as a diagnostic criteria should be discouraged.

Positive-Negative Distinction The distinction between manifestations of schizophrenia that appear to represent a loss of function (e.g., emotional blunting, poverty of speech) and such symptoms as delusions and hallucinations has been part of the diagnostic process at least since Kraepelin, whose concept of an avolitional syndrome was the predecessor of the concept. Bleuler's division of symptoms into fundamental and accessory types may be seen as supporting that separation, with certain of the negative symptoms assigned diagnostic primacy. However, Kraepelin agreed in principle with Bleuler on the distinction between fundamental and accessory symptoms. In 1913 Kraepelin stated

> the former [fundamental symptoms] constitute the real characteristics of the clinical state and can be demonstrated in each individual case more or less distinctly; the latter [accessory symptoms] may be present but may also be absent; they are not caused by the character of the morbid process but by circumstances which are in loose connection with it . . . [F]rom this point of view the weakening of judgment, of mental activity and of creative ability, the dulling of emotional interest and the loss of energy, lastly, the loosening of the inner unity of the psychic life would have to be reckoned among the fundamental disorders of dementia praecox, while the remaining morbid symptoms, especially hallucinations and delusions . . .. would be regarded more as secondary accompanying phenomena . . ..

As psychiatric nosology has been modified over the past decades, largely in the service of greater reliability, the positive symptoms (designated accessory symptoms by Bleuler) have assumed principal importance in the diagnostic criteria used internationally and in the United States from DSM-III onward.

Two distinct psychopathological processes were postulated in 1980. Type I schizophrenia was characterized by predominantly positive symptoms, good premorbid functioning, sudden onset, normal brain structures by computed tomography (CT), good response to treatment, and a better long-term course. Type II schizophrenia was characterized mainly by negative symptoms, an insidious onset, poor premorbid functioning, abnormalities on CT scans, a tendency to drug resistance, and a poorer long-term course and outcome, often resulting in behavioral deterioration. Other similar groupings include negative and positive schizophrenia (Table 12.7-7) and deficit and nondeficit forms of schizophrenia. The past decade saw a large number of investigations into possible relations between those syndromes and a variety of issues, including course and outcome, neurotransmitter hypotheses, brain imaging findings, and family studies.

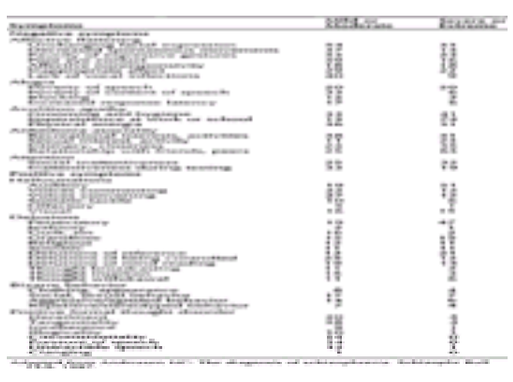

Table 12.7-7 Percentage of Patients With Negative and Positive Symptoms (111 Consecutively Admitted Schizophrenic Patients)

Scales have been developed to measure negative symptoms that have acceptable interrater reliability. Those scales invariably designate flat affect and poverty of speech among the negative symptoms and generally also include anhedonia, apathy, and avolition. Thought disorder, bizarre behavior, and inappropriate affect are more variable in such classifications.

A recent review summarized and compared findings in patients with negative and positive symptoms. Those with negative symptoms experienced an earlier onset of schizophrenia, tended to be male and unmarried, had worse premorbid functioning, had more motor abnormalities, and were more likely to be concordant for illness if an identical twin. In view of those findings, negative symptoms have been reintroduced into the diagnostic classifications as one of the characteristic symptom complexes necessary for the diagnosis of schizophrenia.

Certain manifestations simulate negative symptoms but are a consequence of medication, depression, institutionalization, or other life circumstances. These manifestations must be distinguished from the core negative symptoms of schizophrenia. Moreover, most patients present with a mixture of positive and negative symptoms, which vary in degree over time.

DIFFERENTIAL DIAGNOSIS

Hallucinations and Delusions Another reason for the greater tendency to diagnose schizophrenia in North America than in other countries is that many North American psychiatrists take it for granted that a patient who is hallucinating or who expresses paranoid delusions must be schizophrenic if no organic brain disease can be detected. For example, in a survey of psychiatrists in the United States delusions ranked second of the top 10 symptoms indicating schizophrenia and hallucinations fifth; psychiatrists in Great Britain list delusions in eighth place and hallucinations are not among the first 10 symptoms.

The clinician must not forget that the presence of delusions and hallucinations confirms only the presence of psychosis, not that of schizophrenia. Between 10 and 15 percent of bipolar I disorder patients have hallucinations or delusions. These symptoms indicate a serious loss of contact with reality, a principal criterion for the diagnosis of a psychotic condition, which may or may not be schizophrenic. At times schizophrenia-like symptoms frequently occur in cyclothymic disorder, and delusions and hallucinations may occur in other nonschizophrenic psychiatric conditions (e.g., delusional disorder, psychotic disorder, brief hysterical twilight states, toxic conditions, and mental disorders due to a medical general condition).

Diagnosing schizophrenia simply because delusions and hallucinations are present is like making the diagnosis of a coronary occlusion solely on the basis of pain in the chest or the diagnosis of typhoid fever only on the presence of sustained pyrexia. Single symptoms should certainly suggest conditions in which such symptoms frequently occur, but unless specific, conclusive tests exist for disease processes, a final differential diagnosis must always be based on the complete clinical picture.

Sensory and perceptual disorders, such as hallucinations, may indeed give good diagnostic clues. However, not all types of hallucinations point toward schizophrenia. There are important qualifications regarding the modality, the time, and the content of the hallucinations. Experiences of being controlled by outside forces or having strange, continuous, somatic (cenesthetic) hallucinations or auditory, verbal hallucinations (particularly if the voices are coming from God or the devil or address the patient in the second person or talk about him) may support a diagnosis of schizophrenia. Perceptual distortions of time or objects in space point toward a diagnosis of schizophrenia, but only if they have been present at least several days; otherwise, they may have a toxic origin. The time factor also applies to loss of ego boundaries and the experience of having one's thoughts spread to others.

The presence of delusions provides strong presumptive evidence for schizophrenia only if those delusions have strange, magical, esoteric, or bizarre content. A person who is convinced that he is deliberately discriminated against by his foreman at the factory, that his wife is running around with other men, or that his wife is trying to poison him may have paranoid delusions, but they are not necessarily due to schizophrenia. On the other hand, a man who is convinced that he is the victim of a Pentagon-directed plot to destroy his brain by special death rays beamed at him from space satellites or that he is the Virgin Mary expresses delusions that, by their very bizarre character, point definitely in the direction of schizophrenia.

The diagnosis of schizophrenia cannot be made entirely on the basis of observation, logical reasoning, or objective measurement. It still requires a careful and comprehensive clinical evaluation. Such an evaluation must take into account the presence or absence of certain key schizophrenic symptoms, the patient's prepsychotic personality, the physical findings, the family genetic history, the social environment, the various aspects a good clinical anamnesis may reveal about the natural history of the disease, and any possible precipitating factors.

Catatonia Several investigators have emphasized that catatonia is not a disease entity or exclusively a subtype of schizophrenia but is instead a nonspecific syndrome that occurs quite frequently in other psychiatric conditions such as mania. In one study of 123 patients who satisfied the criteria for manic episode, following catatonic signs were present: sterotypy, echopraxia, and stupor. Others have reported the presence of a typical catatonic syndrome in organic brain diseases (e.g., cerebral aneurysm).

Anxiety Disorders Hysterical symptoms are common in schizophrenic breakdown; thus, the presence of hysterical, dissociative, or even conversion symptoms does not rule out a diagnosis of schizophrenia. Schizophrenic breakdown is preceded by a period of marked tension and anxiety, which may last only a few days or extend over many months. During the acute and subacute stages of a schizophrenic attack, anxiety and depression may color the clinical picture significantly, again without excluding the overruling diagnosis of schizophrenia, which in some cases has not yet diminished the patient's emotional reaction to the onslaught of the psychotic attack. Obsessive symptoms are common in schizophrenia, and what appears to be obsessive-compulsive disorder can develop into schizophrenia.

Bipolar I Disorder The differential diagnosis between schizophrenia and bipolar I disorder should not present many difficulties. The behavior of excited catatonic persons is directed primarily by their own qualitatively disordered mental process. Their actions are unpredictable and appear senseless, affect is difficult to understand, and verbal productions may be irrational and incoherent. Patients with mania, on the other hand, are distractible, and most of their actions are determined by their immediate environment. Their activity resembles that of an excessively busy person, rushing from one superficial job to another. Their affect is clearly one of playful euphoria or angry irritability but always outgoing and expansive. Their verbal productions are accelerated and increased in number, and they reveal a quantitative disorder of association processes, rather than the intrinsic, qualitative thought disorder of the patient with schizophrenia. Nevertheless, several investigators have raised the question, mainly on the basis of a favorable outcome, of whether schizophrenic episodes of relatively short duration are associated with mood disorders.

Depressive conditions should not be diagnosed as schizophrenic unless some unmistakably schizophrenic symptoms are present. In schizoaffective disorders (which may resemble bipolar disorders), the presence of clearly schizophrenic symptoms, such as schizophrenic thought disorder, places the reactions in the diagnostic category of schizophrenia.

Delusional Disorders Since delusions of persecution or grandeur are essential symptoms in both the paranoid type of schizophrenia and in the paranoid type of delusional disorders, the differential diagnosis between the two conditions must be carefully considered when paranoid symptoms prevail. The diagnostic decision must be based on the presence or absence of the essential features of schizophrenia and its paranoid type.

Adolescent Disorders Any psychiatric disorder that occurs during adolescence assumes a certain schizophrenic coloring, since many of the features characteristic of nonschizophrenic adolescent turbulence—exaltation, intense preoccupation with abstract ideas, unpredictable variations of mood, daydreaming, introspection, shyness—are often seen in schizophrenia. Therefore, it is not unusual to misdiagnose a manic or depressive phase of a bipolar disorder as schizophrenia if the patient's first attack occurs in late adolescence. The rule that bipolar disorders do not occur in late adolescence is not always true; later recurrences of that mental disorder may cease to display symptoms resembling schizophrenia, and the correct diagnosis can then be made.

PSYCHOLOGICAL TESTS

There are no psychological tests for schizophrenia comparable to the definitive biological or immunological tests for pregnancy and syphilis. There are only psychological tests that are more or less compatible with a diagnosis of schizophrenia and make the diagnosis more or less probable. Tests can rarely establish a diagnosis by themselves, divorced from the clinical findings.

The clinical psychologist's tests differ from clinical observation and interview; the method of test administration is uniform and the final evaluation of the test findings is based on comparisons with statistical norms, at least with psychometric test instruments. In most clinical centers certain psychological test batteries are routinely used to indicate, confirm, or rule out a diagnosis of schizophrenia. These test batteries are usually composed of projective tests, psychometric tests, and personality inventories. The most frequently used projective tests are the Rorschach test, some drawing tests, and the Thematic Apperception Test (TAT). The most commonly used psychometric tests are the Wechsler Adult Intelligence Scale (WAIS) and some tests that probe concept formation and the organization of thought processes. The most widely used personality inventory is the Minnesota Multiphasic Personality Inventory-(MMP-2), a self-report questionnaire that renders profiles of psychopathology or response styles.

Effects of Medications Many patients with schizophrenia today have received some form of pharmacotherapy before they are seen by a psychiatrist. If they were given adequate dosages of antipsychotic drugs in the early stages of a schizophrenic attack, important key symptoms (e.g. the experience of being controlled, thought hearing, delusions, hallucinations, and inappropriate behavior) may have subsided within 2 or 3 days, and the disorder the psychiatrist now faces may lack all or most of its more specific distinguishing features. The dilemma is similar to that of making an accurate diagnosis of an acute abdominal condition after opioids have been administered or of diagnosing a septicemia after administration of antibiotics. The possible effect of previous antipsychotic pharmacotherapy on key schizophrenic symptoms must always be taken into account when making a differential diagnosis.

Substance-Related Disorders Another drug factor that may render a differential diagnosis of schizophrenia more difficult today is the widespread nonmedical use of amphetamines, crack cocaine, hallucinogens, and drugs with similar effects. Many young people who develop psychotic symptoms have a history of using these drugs. Amphetamines, amphetamine-like drugs, and cocaine in high doses can produce psychotic (usually paranoid) conditions that mimic schizophrenia in their symptoms and course so closely that a differential diagnosis may be impossible in some cases. Fortunately, treatment is the same for amphetamine-induced psychotic disorder and for paranoid schizophrenia. With hallucinogens, the psychotic symptoms may have more of a toxic character, with vivid nonauditory hallucinations and sometimes clouding of consciousness. Differentiating drug-induced psychosis from schizophrenic psychosis may sometimes be difficult. Schizophrenic symptoms seem to develop about 4 years earlier in drug users than in nonusers; thus, drugs may play a precipitating role in the onset of schizophrenia.

Cultural Factors An entirely new set of differential diagnostic problems has been generated by special lifestyles and philosophies, such as beliefs borrowed from Eastern cultures.

> A 20-year-old college dropout was arrested in front of a gas station, where he was meditating and blocking traffic. (Inappropriate and bizarre behavior?) When he was arrested, he responded by laughing. (Inappropriate emotional reaction?) At the police station he expressed his need to “laugh or fuck” to “prevent thinking.” (Bizarre and irrelevant, probably autistic, reasoning?) The police concluded that he was clearly insane and delivered him to a mental hospital.
>
> The young man told the psychiatrist who examined him that he was a Zen Buddhist and that thinking and analyzing things inhibited true growth of personality, according to his philosophy. He was convinced that the two best ways of preventing himself from getting lost in thinking were “laughing and fucking,” because both were incompatible with thinking. “Sort of reciprocal inhibition, if you believe in that stuff.” Under certain circumstances (e.g., in the police station) he could use only the laughing method. He tried to make things “buddhaful;” his smile indicated that that was a pun and not a neologism. Why had he chosen the gas station as a place to meditate? “Well, that's where the winds of Karma blew me.” After 30 minutes he terminated the interview by walking out of the room, remarking that he was becoming upset by the “very bad vibrations” he was getting from the psychiatrist.
>
> After a few day's observation the man was discharged. The psychiatrist suspected that he might develop schizophrenia eventually, but there were no grounds for making the diagnosis at the time.

COURSE AND PROGNOSIS

Course

Natural History Using the term natural history is almost arbitrary in describing a heterogeneous group of disorders with differences in cause, onset, pathogenesis, course, and outcome. It is possible, however, to describe the more common clinical patterns, even though they do not attain the frequency necessary to serve as absolute diagnostic criteria.

Mode of Onset Onset of the schizophrenic disorders ranges from acute to subacute to insidious. Onset usually occurs in late adolescence or early adulthood, somewhat earlier in men and later in women. Commonly following a prolonged period of increasing social withdrawal and turning inward to philosophical or religious interests or both, is the onset of psychotic illness. These individuals frequently show a childhood developmental pattern in which they tend to play by themselves, have few playmates, avoid eye contact, and be somewhat awkward in their motor activities. They tend to achieve developmental milestones later and frequently show poorer school performance than their siblings. About the time of onset of illness there is frequently social deterioriation as well as a loss of interest in personal grooming and hygiene.

The prodromal period may continue for weeks and up to several years before the symptoms suffice to make a diagnosis. When properly recognized this long prodromal period offers an opportunity for early intervention. Studies are under way to evaluate the use of low-dosage antipsychotic treatment in high-risk individuals showing prodromal signs. However, some individuals have very short prodromal periods before the onset of a psychotic state. In these latter individuals the progression to psychosis is more obvious, while in the former cases the progression is almost imperceptible. Nevertheless, despite the variability the first psychotic episode is frequently associated with a stressful life event such as going off to college.

Characteristic of most psychotic states is the loss of reality testing and insight. As a consequence, a psychotic episode is often heralded by an increasing dissonance between persons and their social environment. As the members of the social environment become increasingly concerned it is not unusual for them to use some form of coercion to bring the patient to medical attention.

Episodic Course Some patients with schizophrenia may have five or more psychotic attacks, usually of the catatonic type, without suffering any obvious personality damage, but because the risk of developing a schizophrenic defect increases after each additional schizophrenic attack, today's therapeutic challenge is to use all available measures to prevent relapses.

In Russia, psychiatrists place special diagnostic importance on the occurrence of relapse and base their criteria for the differentiation of various types of schizophrenia on the character of the course of the illness. Three main types of schizophrenia are distinguished in Russia: (1) continuous, with subtypes of sluggish, progressive, and malignant schizophrenia; (2) periodic, not progressive; and (3) shiftlike progressive, again with subtypes mild, progressive, and malignant. Russian psychiatrists assume that these differences in the course of schizophrenia are also related to differences in cause, symptom formation, and response to treatment.

PROGNOSIS

Table 12.7-8 lists features of schizophrenia that weigh toward a good or poor prognosis. It has been clinical knowledge since Kraepelin and Bleuler that the hebephrenic and simple types of schizophrenia have the poorest prognoses, that paranoid reactions have an intermediate prognosis, and that acute catatonic reactions have the best prognosis but that catatonic patients who go on to chronicity usually continue to regress and may become markedly deteriorated.

Good Prognosis	Poor Prognosis
Late onset	Young onset
Obvious precipitating factors	No precipitating factors
Acute onset	Insidious onset
Good premorbid social, sexual, and work histories	Poor premorbid social, sexual, and work histories
Mood disorder symptoms (especially depressive disorders)	Withdrawn, autistic behavior
Married	Single, divorced, or widowed
Family history of mood disorders	Family history of schizophrenia
Good support systems	Poor support systems
Positive symptoms	Negative symptoms Neurological signs and symptoms History of perinatal trauma No remissions in 3 years Many relapses History of assaultiveness

Table 12.7-8 Features Weighing Toward Good to Poor Prognosis in Schizophrenia

Modern pharmacotherapy has changed many of the old prognostic patterns. Today, a paranoid type schizophrenia patient's chances of making a good recovery are at least equal to those with the catatonic type. Even patients with the disorganized type often have good remissions after a few months of pharmacotherapy. The simple deteriorative disorder patient is still the least responsive to modern biological therapies. The more sudden the onset of a schizophrenic attack, the better are the chances for a good remission or complete recovery. If a precipitating event has clearly triggered the breakdown, the chances for a favorable outcome are also relatively better.

As a rule, the younger a patient is at the onset of schizophrenic psychosis, the worse is the prognosis. Patients with onset in childhood or early puberty seldom recover completely. Some investigators believe that there may be two major groups of people with schizophrenia: those with difficulties in childhood before the onset of schizophrenic symptoms and those with a history of normal childhood. The first group is characterized by lower I.Q.s, a higher incidence of difficulties in school, poor peer group adjustment, an earlier age of first psychiatric contact, evidence of possible minimal brain damage, and a poor prognosis.

A history of good adjustment in the important areas of social, sexual, and occupational functioning before the breakdown also indicated a favorable prognosis. Married men with schizophrenia have a better prognosis than do single, divorced, or widowed patients; the fact that they are married is evidence that interpersonal bonds may serve as a bridge for a return to the community. Patients who relate easily to people in their environment and who are capable of emotional warmth and natural emotional reactions have a good chance for reintegration. The presence of depression as in schizophrenia also improves the prognosis. Conversely, sustained emotional withdrawal and aloofness or shallow and inappropriate affective responses are ominous prognostic signs. In 1968 this first author and Felix Sugerman drew attention to the significance of formal thought disorder and of reaction time performance for the prognosis in patients with schizophrenia. They found that a combination of test results for thought disorder and motor reaction time, combined with the presence or absence of depression and marital status, gave the most important clues to the final outcome in their sample of schizophrenia patients. In 1973 a report concluded from an extended follow-up study of patients with schizophrenia that most of them seemed to reach a plateau about 5 years after their first breakdown and that those who had not remitted after 2 to 3 years faced a guarded outlook.

However, one must not assume that the prognostic indicators that are relatively well established for schizophrenia patients in Western culture are universally valid. A different cultural setting may produce different results. For example, one study examined admission data and 12-year outcomes for Moslem Indian, Hindu Indian, and African schizophrenia patients on the island of Mauritius and found that only for the small Moslem Indian sample were prognostic criteria comparable to those of a British sample. In the Hindu Indian and non-Indian groups, the results were no better than chance. Depression was not associated with recovery; sudden onset was a favorable factor in the Indian group but not in the others; flatness of affect was not highly associated with chronicity. Only the absence of a good work history gave the expected results. But two features that are not known to have prognostic significance in the West, psychosomatic symptoms and somatic disease, had a strong association with chronicity in the Hindu Indian and African groups of the Mauritius schizophrenia patients.

Family The family plays an important role in a patient's prognosis. A number of studies in recent years have shown that many patients with schizophrenia come from deeply disturbed families. Before making a prognosis one should determine whether the patient is accepted by the family and whether the dynamic pattern of communication within the family is adequate or characterized by irrationality, deficient sharing of foci of attentions, or the production of double-bind messages.

Relapses A new prognostic factor has emerged in the past few years, the patient's cooperation and conscientiousness in following prescribed drug maintenance therapy. Many patients with schizophrenia can be rendered relatively symptom free within a few weeks or months, but about 60 percent of them can be maintained in that condition only with continued drug therapy after they have been discharged into the community. Placebo-controlled maintenance studies have established this point well. The more often patients neglect taking their maintenance medications (i.e., the worse their compliance), the more likely they are to suffer relapse.

Several important observations have been made about the factors that determine whether a patient in remission will suffer a relapse. The most important protective factor is undoubtedly maintenance therapy with antipsychotic drugs. One study noted a history of sudden social or psychological traumas (e.g., the death of a parent, moving from one apartment to another) during the 3 weeks preceeding schizophrenic relapses in about 60 percent of cases.

The type of home in which the patient in remission resides plays a vital role. In one American study patients with schizophrenia fared better in conjugal homes than in parental homes, but some British investigators made the opposite observation in their sample. Most importantly, clear correlations exist between exposure to expressed negative critical emotions in the household of a patient with schizophrenia in remission and the likelihood of relapse. The critical time limit seemed to be about 35 hours of such exposure a week. When that time limit was exceeded, even maintenance drug therapy was often inadequate in preventing relapse.

Deterioration The risk of personality deterioration increases with each schizophrenic relapse. Schizophrenic recoveries are often called remissions because many of the patients later relapse. Although patients may remit again, each schizophrenic attack carries a greater probability of some permanent personality damage. Risk of personality deterioration increases rapidly after the second relapse. However, chronic schizophrenia does not inevitably lead to intellectual deterioration. In fact, in one sample, patients with chronic schizophrenia retained or improved their mean intelligence scores in spite of old age and prolonged institutionalization over a period of 14 years. In a group of schizophrenia patients who were followed over a 10-year period, schizophrenic symptoms decreased by 15 percent.

Final Outcome A schizophrenia patient's chances for a favorable outcome of the psychosis are estimated today to be about 4 to 5 times better than they were before World War 1. Kraepelin reported in 1913 that nearly 13 percent of his patients with dementia precox recovered from their first attack, but most of them later relapsed. Altogether, only about 15 percent ultimately had passable social remissions, usually with slight-to-moderate personality damage. Today, with good follow-up therapy and well-controlled maintenance drug treatment, only some 10 to 15 percent of patients in remission relapse within a year, compared with about 65 to 70 percent who relapse during the same period without such follow-up treatment. There are five possible outcomes for the patient with schizophrenia: full and permanent recovery; full remission, with one or more future relapses; social remission with personality defect and with the patient either capable of self-care and self-support or dependent on protection and supervision; stable chronicity; and deterioration to a terminal stage.

Deterioration to a Terminal Stage A vegetable-like existence is rare among patients with schizophrenia who have become ill during the past 25 years. Modern biological and social therapies are generally successful in preventing at least the terminal stage of deterioration, which was the most probable outcome of schizophrenia in Kraepelin's time and which was probably due to the ravages of institutionalization more than to schizophrenia. The modern mental hospital has few patients who illustrate this terminal stage of schizophrenia. Almost all patients with the symptoms and signs of extreme regression of behavior, affect, and ideation were admitted 30 or more years ago.

Stable Chronicity Despite all intensive therapeutic efforts, many patients with schizophrenia remain in a state of stable chronicity, although they do not regress to a terminal stage of deterioration. Their psychotic symptoms may make it necessary to keep them hospitalized or, if the symptoms are not severe, they may reside outside the mental hospital. They remain definitely incapacitated, with clearly visible signs and symptoms of active mental disease. In a study of schizophrenia patients from 1913 to 1923, when virtually no treatment was available for chronic schizophrenia, clinicians reported that some patients who had been chronically ill for almost 10 years occasionally had spontaneous remissions that lasted for years.

The combination of institutionalism and poverty frequently works to the detriment of the patient, and it is often difficult to determine how much of the patient's defective

functioning is due to each of these factors. However, many patients do not seem to be much better off in the community than in the hospital. It has been estimated that unemployed patients with chronic schizophrenia living outside the hospital spend about 30 percent of their time doing nothing, which is approximately what one observes in chronic schizophrenic patients residing in a modern hospital. The casual observer in big cities (not only in the poor districts) encounters many of those formerly hospitalized schizophrenic patients along the sidewalks, talking to themselves and passers by, gesticulating, preaching, or just sitting around.

It is difficult to estimate how many patients with schizophrenia today will end up in this category of stable chronicity, but under good therapeutic conditions, the percentage almost certainly will not exceed 30 to 40 percent. The remainder of the patients will either remit or recover.

Remission and Social Recovery Many patients with schizophrenia today fall into the categories of stable remission with personality defect and full remission with relapse. Schizophrenic personality defects and schizophrenic residual states are characterized by a reduction of ambition, initiative, available energy, and emotional responsiveness. Persons in that state may be more withdrawn, more aloof, and more selfish than they were before the onset of illness. They may neglect their personal appearance, and they almost certainly go down on the occupational ladder. Professional persons may, at first, still hold professional positions, but positions with reduced responsibility and less scope for personal initiative. They may eventually end up doing menial work well below their educational level. Persons with schizophrenic personality defect cannot readily assume responsibility. They cannot cope with competitive pressures and cannot tolerate time pressure. They are best suited for quite, routine work they can perform independently from others and at their own pace. Some former schizophrenia patients, therefore, prefer to do night-shift work, because it is less demanding and often permits them to work alone.

The personality defect may be so pronounced that patients cannot take charge of their own affairs and require continuous protective supervision and sheltered work conditions. If the personality defect is less pronounced, patients may be capable of acting independently and supporting themselves, although usually at a lower occupational level than before the illness. Sometimes the personality defect is so slight that only the patient's family and close friends recognize the subtle changes that have taken place—a diminished capacity for enthusiasm, lessened spontaneity, decreased initiative, and a decline in creative imagination. In most daily life situations the patient may even function socially at an apparently normal level.

Full and Permanent Recovery The prospect for full and permanent recovery from a schizophrenic episode is probably considerably brighter today than it was a half century ago, when the chances for such complete recovery were only 2 to 4 percent. Under careful supervision, antipsychotic drugs can now prevent relapse that could not have been prevented before the advent of those drugs. Only with maintenance drug therapy has it become possible to prevent relapses and thereby greatly reduce the risk of personality deterioration in many patients. Nevertheless, the introduction of modern treatment methods over the years has not yet significantly increased the actual number of full, permanent recoveries.

Occupational Rehabilitation Studies found that about 60 percent of schizophrenia patients were employed 75 percent of the time over a 5-year period. A follow-up study of a sample of 108 schizophrenia first-admission patients for 5 years revealed that they had been working for 65 percent of that period. Of a series of 188 discharged patients, 67 percent were employed for more than half of the 1-year follow-up period. Other studies found that more than half of a group of male schizophrenia patients had been employed more than half of the 5-year follow-up period. Among 100 hospitalized patients with schizophrenia followed for 5 years after discharge, 18 percent of the patients had not been employed at all during the follow-up period, but the other patients had been employed, on average, for 57 percent of the follow-up period.

FUTURE DIRECTIONS

Schizophrenia as currently diagnosed does not inevitably lead to severe deterioration but it is usually chronic and psychologically disabling to a significant degree. The better the premorbid social adjustment, the better the prognosis. Individuals who had good interpersonal skills and good psychosocial adaptation premorbidly do better than those who showed premorbid withdrawal. The outcome of schizophrenia tends to be worse in terms of functional level than it is in the affective disorders. Like the mood disorders, it is associated with an increased risk of suicide but a much shorter life expectancy, because suicide tends to occur in young adulthood. While the disorder tends to plateau clinically after about 5 years, it does not tend to remit in symptomatology until after the age of 50. Evidence suggests that patients do better in a rural and less demanding environment than they do in a complex urban culture. While it is possible to be more reassuring today than it was in the preneuroleptic era, the prognosis for full psychosocial recovery is still guarded, and families must be informed honestly of what can be expected.

SUGGESTED CROSS-REFERENCES

The other sections in this chapter on schizophrenia have a bearing on this section. A general discussion of clinical manifestations of psychiatric disorders appears in Chapter 8. Perception and cognition are discussed in Section 3.1. Psychological tests are discussed in Section 7.4 and Section 7.5. DSM-IV is discussed in Section 9.1. Delusional disorders are discussed in Section 13.2, schizoaffective disorders in Section 13.1, mood disorders in Chapter 14, cognitive disorders in Chapter 10, and somatoform disorders in Chapter 16. Personality disorders are discussed in Chapter 24, impulse-control disorders in Chapter 22, and unusual acute and transient psychotic disorders in Section 13.3. Suicide is discussed in Section 29.1. Antipsychotic drugs are covered in Section 31.17 and Section 31.26.

CHAPTER 12. SCHIZOPHRENIA

12.8 SCHIZOPHRENIA: SOMATIC TREATMENT

STEPHEN R. MARDER, M.D.

The somatic treatment of schizophrenia has changed substantially during the 1990s. Until 1990 when clozapine (Clozaril) was introduced in the United States, all available antipsychotic drugs had a similar range of efficacy and were associated with neurological side effects that seriously interfered with their effectiveness. Clozapine was the first of a new generation of antipsychotics that are associated with far fewer extrapyramidal side effects than older drugs and perhaps have better efficacy. Although clozapine's association with agranulocytosis has limited the number of patients who receive it, this agent plays an important role in the treatment of severe psychosis. The introduction of risperidone (Risperdal) in 1994, olanzapine (Zyprexa) in 1996, quetiapine (Seroquel) in 1997, and ziprasidone (Zeldex) in 1998 have given clinicians new alternatives for treating a large number of patients with schizophrenia. The overall impact of these changes on the course of schizophrenia remains to be seen.

HISTORY

The history of somatic therapies in schizophrenia can be divided into two eras: before the discovery of chlorpromazine (Thorazine), the first clearly effective antipsychotic drug, and after. Prior to the introduction of antipsychotics in the early 1950s, several treatments had been administered to individuals with psychotic illness, with results that are difficult to interpret because careful research methods in psychiatry had not been developed. During the late nineteenth and early twentieth century schizophrenia was believed to deteriorate inevitably into dementia. As a result, patients were frequently hospitalized for long periods. Somatic treatments were used to help control the most severe symptoms of the disorder and to make hospitals safer. Sedating agents such as bromides and barbiturates were used to control agitation, and physical treatments such as hydrotherapy and wet sheet packs were also used for their calming effects. In the early 1920s sleep treatment with barbiturates was introduced. This treatment was based on the observation that symptoms tended to improve following an overdose of barbiturates. The method involved maintaining patients in a highly sedated state for days, during which they would awaken only for necessary activities such as eating and personal hygiene.

Insulin coma treatment was introduced during the 1930s. Patients were administered gradually increasing doses of insulin until a coma occurred. After being monitored for an hour the patient was administered glucose, which terminated the coma. Patients were commonly administered as many as 20 comas. Insulin coma was widely used in the treatment of psychosis, suggesting that it may have been somewhat effective. Unfortunately, it never received adequate research trials, and it remains unclear if the treatment was effective. It was abandoned when antipsychotics were introduced.

Prefrontal lobotomy was proposed as a treatment for serious mental illnesses by Egas Moniz in 1935. The support for this treatment came from animal studies in which frontal lobe extirpations in monkeys resulted in an animal that appeared less easily frustrated. The use of frontal lobotomy was common prior to the introduction of effective antipsychotics, although there is a remarkable lack of controlled studies comparing psychosurgery with other treatments. Although reports suggest that lobotomy may have been effective in reducing severe psychotic symptoms, they also resulted in deteriorations in other areas. Following lobotomies patients frequently demonstrated personality deterioration with impulsive and psychopathic behaviors as well as impaired concept formation and ability to plan. Psychosurgery was abandoned as a treatment for schizophrenia after the introduction of effective antipsychotic medications.

Convulsive therapies were developed after it was observed that some patients improved after a seizure. Drugs such as camphor and metrazol were used initially to induce seizures but were abandoned after Ugo Cerletti and Lucio Bini proposed the use of electrically induced convulsions. In its early days electroconvulsive therapy (ECT) was administered without anesthetics or muscle relaxants. The lack of anesthetics inspired fear in many patients, and the lack of muscle relaxants led to injuries from forceful muscle contractions. ECT administered with anesthesia and muscle relaxants continues to have a role in certain types of schizophrenia.

The first effective antipsychotic medications were probably derived from extracts of the rauwolfia plant. Publications from the 1930s and 1940s suggest that these agents were effective for both hypertension and psychosis. Reserpine (Serpasil) the most potent of the rauwolfia alkaloids, was introduced in the early 1950s and was widely prescribed in the United States and elsewhere for schizophrenia and other psychotic illnesses. Studies comparing reserpine with dopamine receptor antagonists suggested that their efficacies were similar. However, reserpine's adverse effects, particularly depression, led most clinicians to prefer the dopamine receptor antagonists. Thus, reserpine is only rarely used for managing psychosis.

The discovery of the phenothiazine chlorpromazine in the early 1950s may be the most important single contribution to the treatment of psychiatric illness. Laborit, a surgeon in Paris, noticed that administering chlorpromazine to patients prior to surgery resulted in an unusual state in which they seemed less anxious regarding the procedure. In 1952 he convinced Jean Delay and Pierre Deniker and other psychiatrists to administer chlorpromazine to psychotic and excited patients—the effects were extraordinary. Chlorpromazine was effective in reducing hallucinations and delusions as well as excitement. It also caused adverse effects that resembled parkinsonism. The use of chlorpromazine spread rapidly through the psychiatric hospitals in Paris and eventually to the rest of the world. Since chlorpromazine was relatively easy to administer to large numbers of patients, it was partially responsible for a substantial reduction in the number of patients in psychiatric hospitals.

Thioridazine and fluphenazine (Permitil, Proloxin) as well as other classes of drugs such as the butyrophenones (e.g., haloperidol [Haldol]) and the thioxanthenes (e.g., thiothixene [Navan]) were developed after the introduction of chlorpromazine. Although these newer agents differed in their potency and their adverse effect profiles, all had similar effectiveness. Clozapine, the first effective antipsychotic with negligible extrapyramidal effects was discovered in 1958 and first studied in the 1960s. However, in 1976 it was found to be associated with a substantial risk of agranulocytosis, which resulted in delays in its introduction. In 1990 clozapine finally became available in the United States, but its use was restricted to patients who responded poorly to other agents. Risperidone, olanzapine, quetiapine, ziprasidone, and other agents with affinity for both dopamine and serotonin receptors cause minimal extrapyramidal side effects and are not associated with a risk of agranulocytosis. These newer agents are replacing older drugs as the standard treatments for schizophrenia.

PHASES OF TREATMENT IN SCHIZOPHRENIA

Somatic treatment varies depending on the phase of a patient's illness. The acute stage is usually characterized by psychotic symptoms that require immediate clinical attention. These symptoms may represent a first psychotic episode or, more commonly, a relapse in an individual who has experienced multiple episodes. Treatment during this phase focuses on alleviating the most-severe psychotic symptoms. Following the acute phase, which usually lasts from 4 to 8 weeks, patients usually enter a stabilization phase in which acute symptoms have been controlled, but patients remain at risk for relapse if treatment is interrupted or if they are exposed to stress. During this phase, treatment focuses on consolidating therapeutic gains with treatments similar to those used in the acute stage. This phase may last as long as 6 months following recovery from acute symptoms. The third stage is the stable, or maintenance, phase when the illness is in relative remission. The goals during this phase are to prevent psychotic relapse and to assist patients in improving their level of functioning.

FOCUS OF TREATMENT

Patients with schizophrenia can demonstrate large differences in the severity of their psychopathology as well as in the type of symptoms they demonstrate. As a result, treatment strategies should be individualized to the characteristics of each patient's illness. Recent studies indicate that psychopathology in schizophrenia can

be classified into three dimensions: psychotic, negative, and disorganized. Psychotic symptoms include hallucinations, ideas of reference, and delusions. These are symptoms that tend to result in hospitalization and to disrupt the lives of patients. Negative symptoms include decreased motivation, emotional blunting, and impoverished speech and thought; these symptoms are associated with the social and vocational impairments of schizophrenia. Disorganized symptoms include disorganized speech and behavior as well as impairments in attention and information processing; these symptoms are also associated with the social and vocational impairments of schizophrenia.

Antipsychotic drugs are most effective in treating the psychotic dimension. As a result, clinicians adjusted their expectations about the goals of pharmacotherapy in schizophrenia. Although some improvement in the other dimensions often occurred with drug treatment, clinicians were usually satisfied when psychotic symptoms were minimized. These expectations changed following the introduction of clozapine. A proportion of patients who improved with clozapine demonstrated changes in other dimensions as well, including better social and vocational adjustments. Similar improvements have been reported on other serotonin-dopamine antagonists. In addition, other studies (discussed later) suggested that both negative and cognitive symptoms improved with these newer medications.

EFFECTIVENESS OF ANTIPSYCHOTIC MEDICATIONS

A large body of evidence supports the effectiveness of antipsychotics for schizophrenia. Many of these studies were carried out in the 1960s when there was skepticism that these agents were truly antipsychotic rather than more effective tranquilizers. An evaluation of these studies by the 1995 Schizophrenia Patient Outcomes Research Team (PORT) found that about 70 percent of patients treated with an antipsychotic achieved remission. In contrast, only about 25 percent of patients treated with placebo remitted. Most studies compared one or more antipsychotic with either a placebo or an agent such as phenobarbital that served as a control; antipsychotic drugs were found to be more effective than either placebo or tranquilizers.

EFFECTIVENESS OF ECT IN SCHIZOPHRENIA

ECT has been studied in both acute and chronic schizophrenia. Studies in patients with recent-onset schizophrenia indicate that ECT is about as effective as antipsychotic medications and more effective than psychotherapy. Other studies suggest that supplementing antipsychotic medications with ECT is more effective than antipsychotic medications alone. Studies of ECT in chronic schizophrenia have been less promising. Anecdotal reports indicate that ECT is effective in patients who respond poorly to antipsychotic medications. Overall these results suggest that ECT probably has a limited role in schizophrenia. Patients should first receive trials of antipsychotic medications; if these medications are ineffective, acutely ill patients can be treated with ECT. Antipsychotic medications should be administered during and following ECT treatment.

TREATMENT OF ACUTE EPISODES

Indications for Somatic Treatment Nearly all patients with acute psychotic symptoms benefit from an antipsychotic medication. Aside from relieving symptoms, evidence indicates that lengthy delays in initiating drug treatment may alter the long-term course of schizophrenia. This evidence is summarized in a scholarly review by Richard J. Wyatt, who found that treatment delays—usually of 6 months or more—were associated with a greater need for hospital treatment and a worse social and vocational outcome. Many of the studies reviewed by Wyatt have important limitations such as lack of randomization and comparing individuals treated during different decades. However, for ethical reasons a definitive study will never be carried out to determine if withholding treatment worsens the long-term course of schizophrenia so it is probably prudent for clinicians to consider the possibility that untreated psychosis can result in a type of permanent damage.

These data do not mean that all patients need to be treated immediately. In some circumstances the management of a patient may be better if drug treatment is delayed for several days. A brief delay may permit clinicians to make a more thorough diagnostic evaluation and rule out causes of abnormal behavior such as substance abuse, extreme stress, medical illnesses, and other psychiatric illnesses.

Assessment Whenever possible, patients should receive a physical examination with a neurological examination, a mental status examination, and a laboratory evaluation before medications are started. A urine screen for drugs of abuse and blood tests for complete blood count (CBC) electrolytes, glucose, and liver, renal, and thyroid function should be ordered. Other evaluations that should be considered are pregnancy tests in women, electrocardiograms (ECGs) when cardiac disease or age is a factor, and human immunodeficiency virus (HIV) and syphilis tests when relevant. The presence of movement disorders—particularly preexisting tardive dyskinesia—should be assessed because they may influence the selection of an antipsychotic.

Antipsychotics are relatively safe drugs so treatment can usually begin before the results of laboratory tests are known. An exception is clozapine treatment, which should only begin after the patient is known to have a normal CBC. Under emergent conditions—for example, when patients refuse to cooperate with an evaluation—antipsychotics can be administered prior to a medical evaluation.

Selection of an Antipsychotic Drug The introduction of new antipsychotic agents has made the selection of an antipsychotic much more complicated. Prior to the development of the new antipsychotics, all the drugs were equally effective for schizophrenia. Many clinicians believed that different subtypes of schizophrenia responded differently to different antipsychotics. For example, it was proposed that more agitated patients responded better to more-sedating drugs whereas more withdrawn patients responded better to less-sedating agents; however, controlled trials failed to support this. The differences among antipsychotics were confined to their side effects, the available formulations, and, to some extent, their cost. The newer antipsychotics challenged this view, suggesting that certain populations of individuals with schizophrenia were likely to do better on a newer antipsychotic.

Antipsychotic drugs can be categorized into two main groups: the older conventional ones, which have also been called *dopamine receptor antagonists* and the newer second-generation drugs which have been called *serotonin-dopamine antagonists (SDAs)*, or more broadly, atypical antipsychotics. This textbook uses the terms *dopamine receptor antagonist* and *SDA*, which refer to the theory that the antipsychotic effects of dopamine receptor antagonists result from the blockade of dopamine type 2 (D2) receptors. The SDAs differ in having effects related to their ratio of D_2 and serotonin (5-hydroxytrptamine [5-HT]) type 2A ($5\text{-}HT_{2A}$) antagonism. The dopamine receptor antagonists are further categorized as being low-, mid- or high-potency, with the higher-potency drugs having a greater affinity for D_2 receptors and a greater tendency to cause extrapyramidal side effects. Low-potency drugs are less likely to cause extrapyramidal side effects, but more likely to cause postural hypotension, sedation, and anticholinergic effects.

A number of factors should be considered in selecting an antipsychotic medication. Perhaps the most important consideration should be the patient's prior experience with drug treatment. This includes both the patient's clinical and subjective response. Regarding the subjective response, studies by Theodore Van Putten and others found that a patient's early response to a query such as “How does this medication agree with you?” was a powerful predictor of whether that patient would comply with taking that particular medication. In other words, if the patient has uncomfortable side effects on a medication, compliance is likely to be poor if that medication is prescribed.

Prior to the introduction of the SDAs few options were available for patients who developed extrapyramidal effects. At times, dosage reduction or changing the patient to a lower-potency dopamine receptor antagonist may be helpful. Unfortunately, many patients experience extrapyramidal or other adverse effects at the lowest effective dosage that is clinically effective. The introduction of the SDAs provides an opportunity for treating these individuals with agents that seldom cause extrapyramidal side effects at their effective dosage.

With these factors in mind, clinicians should consider the factors included in Table 12.8-1. In some cases these recommendations are based on incomplete data. For example, it remains unproven that patients with prominent negative or cognitive symptoms will respond better to an SDA than to a dopamine receptor antagonist. Haloperidol is recommended for pregnant patients because more data support its safety and not because it has proved safer than other drugs.

Factors	Considerations
Subjective response	A dyphoric subjective response to a particular drug predicts poor compliance with that drug
Sensitivity to extrapyrimidal adverse effects	A serotonin-dopamine antagonist (SDA)
Tardive dyskinesia	Clozapine or (possibly another SDA)
Poor medication compliance or high risk of relapse	Injectable form of a long-acting antagonist (haloperidol or fluphenazine)
Pregnancy	Probably haloperidol (most data supporting its safety)
Cognitive symptoms	Possibly an SDA
Negative symptoms	Possibly an SDA

Table 12.8-1 Factors Influencing Antipsychotic Drug Selection

An important nonclinical factor is the cost of the drug; the SDAs are much more expensive. However, evidence indicates that the higher drug costs of these agents may be offset by other factors. Studies from the Department of Veterans Affairs and State Hospitals in Connecticut found that patients treated with clozapine required fewer hospital days than patients treated with a conventional dopamine receptor antagonist. As a result, the reduction in hospital days compensated for the higher drug cost associated with clozapine treatment. Similar results from other studies suggest that the higher costs of risperidone and olanzapine may also be partially offset by a reduced need for hospitalization.

In selecting a drug for first-episode patients, clinicians should give a high priority to minimizing adverse effects. Many of these individuals are ambivalent about drug treatment and may discontinue antipsychotics when they experience relatively mild adverse effects. Unpleasant experiences with medications during this initial episode may be frightening to these individuals and may influence their future attitudes toward pharmacotherapy. These considerations may lead to the selection of an SDA or a relatively low dosage of a high-potency dopamine receptor antagonist. A number of studies indicate that both olanzapine and risperidone are effective for first-episode patients.

Route of Administration The decision regarding route of administration is usually straightforward. Under most conditions, patients should be treated with an oral antipsychotic agent. Most antipsychotic drugs have half-lives that permit a single daily dose. Short-acting intramuscular drugs are useful when the patient refuses oral dosing and when a rapid onset is helpful. Intramuscular administration of most antipsychotics results in peak plasma concentrations in about 30 minutes, with clinical effects emerging within 15 to 30 minutes. Most orally administered dopamine receptor antagonists yield a peak plasma concentration 1 to 4 hours following administration.

Antipsychotic medications can also be administered as long-acting injectable compounds. These drugs differ from short-acting compounds in that they have a very gradual onset of action and are eliminated very slowly. This route of administration is helpful for long-term maintenance therapy, but not for acute treatment because clinicians cannot titrate dosage against adverse effects or clinical effects when the onset of clinical effects may occur weeks or months after a drug or dosage change.

Prescribing Antipsychotics Prior to prescribing an antipsychotic drug, clinicians should describe the medication, its target symptoms, and its possible side effects. It is particularly important to describe adverse effects such as akathisia, which can be misinterpreted as agitation under some circumstances. Patients who are severely disturbed may be unable to participate meaningfully in this discussion. However, most patients benefit from information about the goals of treatment and important risks associated with antipsychotic medication. Patients with schizophrenia may be suspicious so it is particularly important to emphasize that they can participate in interpreting medication effects. Because psychotic individuals may be dependent on the help and support of their families, it is frequently helpful to involve one or more family members in decisions about drug treatment.

In some settings and locations patients must give written or verbal consent prior to receiving an antipsychotic medication. This can be a dilemma for patients who are conceptually disorganized and find it difficult to understand the risks and benefits of drug treatment. Under these circumstances, clinicians should adjust the complexity of the discussion to the patient's state of mind. Thus, it may be appropriate to provide a limited amount of information that focuses on the most common acute adverse effects of the medication when the patient is most seriously impaired. As the patient improves, clinicians may then elaborate on the costs and benefits of medication. For example, detailed discussions about tardive dyskinesia, an adverse effect associated with chronic treatment, may be deferred until the patient has improved and long-term maintenance is being considered.

Psychiatrists must also evaluate whether acutely disturbed patients can participate meaningfully in decisions about their medication. Clinicians should become familiar with local and state laws that affect a patient's right to refuse or accept drug treatment. The most difficult situation is when a patient who desperately needs medication refuses it. Under some conditions, family members who have been educated about schizophrenia may be helpful in convincing patients to accept medication. Every locality has provisions for treating patients against their will under emergency conditions; some areas permit involuntary treatment when certain conditions are met. As patients improve, the great majority eventually accept their own need for medication.

Dosage Selection Finding the best dosage of an antipsychotic is both difficult and important. It is important because these agents, particularly the dopamine receptor antagonists, may cause adverse effects at their effective dosages. Often the clinician must weigh the therapeutic advantages of a particular dosage against uncomfortable or disabling side effects. Figure 12.8-1, from a study by Theodore Van Putten and his colleagues, displays dose-response curves for fluphenazine for both clinical improvement and disabling side effects. These two curves are close together, which indicates that it may be difficult for the clinician to find a dosage that results in clinical improvement without substantial adverse effects.

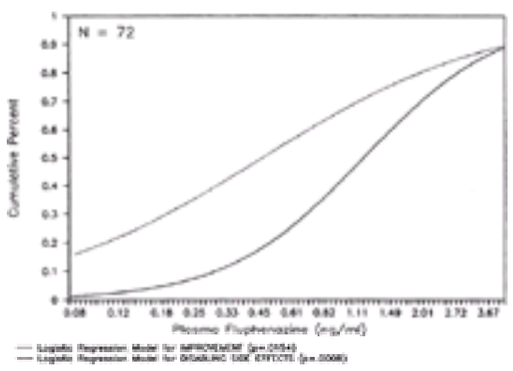

FIGURE 12.8-1 Improvement and disabling side effects as a function of plasma fluphenazine concentration.

Finding the right dosage is difficult because the physician cannot titrate dosage against clinical effects because of the delay between a clinical intervention and the patient's clinical response. Some individuals experience a delay of days or even weeks between the time treatment is started and when the patient eventually responds. These studies are supported by findings indicating that the neurochemical response to an antipsychotic agent is complex and includes an initial blockade of central dopamine receptors, followed by delayed decrease in dopamine turnover.

Although high doses of dopamine receptor antagonists can be associated with extrapyramidal side effects, some patients can tolerate antipsychotics at very high dosages. This is particularly true of nonsedating, high-potency drugs, which has led clinicians to raise the prescribed dosage in hope that higher dosages will lead to greater improvement than moderate dosages. This belief resulted in a substantial increase in the average dosage of antipsychotic drugs prescribed in the United States during the 1970s and 1980s. Many psychiatrists during this period routinely prescribed dosages above 1000 mg a day of chlorpromazine equivalents (20 mg of

haloperidol), whereas others reserved high-dosage treatment for patients who remained symptomatic on lower dosages of medication.

A number of dosage comparison studies have failed to support the routine use of higher doses; that is, when groups of patients are assigned to higher dosages (e.g., more than 2000 mg a day of chlorpromazine or 40 mg a day of haloperidol), the rate of improvement and the amount of improvement are no greater than for those assigned to more moderate dosages. Clinicians are sometimes impressed by individuals who require these higher dosages, suggesting that there is a small group of patients who should be treated with high dosages. However, most patients who receive these high dosages are only partial responders to an antipsychotic and have endured dosage increases that were not associated with improvement.

Dosage comparison studies indicate that dosages below 300 mg a day of chlorpromazine (or 5 mg a day of fluphenazine or haloperidol) are likely to be too low for many psychotic patients. At the same time doses above 1000 mg a day of chlorpromazine (or 20 mg a day of fluphenazine or haloperidol) are seldom necessary and may lead to substantial adverse effects.

Only limited data from controlled trials exist to assist clinicians in finding the best dose of clozapine. The mean dose of clozapine prescribed differs between Europe and the United States, with European physicians commonly prescribing less than 300 mg of clozapine daily and clinicians in the United States often prescribing 500 mg or more. These experiences support the practice of treating most clozapine patients with doses in the range of 300 to 500 mg daily. However, adverse effects, particularly sedation and orthostatic hypotension, are often limiting factors that prevent clinicians from reaching a targeted dosage. Although some patients have an optimal response at dosages between 600 and 900 mg daily, the risk of seizures increases substantially in this dosage range. More-recent studies suggest that patients are more likely to respond to clozapine when plasma concentrations are 350 ng/mL or higher, suggesting that measuring plasma concentrations may be useful for poor responders.

Large multicenter trials indicate that risperidone is most effective at 4 to 8 mg daily. Higher doses may lead to extrapyramidal effects without increased effectiveness. In the United States, the average dosage of risperidone prescribed for schizophrenia is slightly more than 4 mg daily. This suggests that a reasonable practice would be to manage patients with schizophrenia with 4 mg of risperidone and increase the dosage if they fail to respond after 4 to 6 weeks.

Most patients with acute schizophrenia can be managed on dosages between 15 and 25 mg daily of olanzapine. Some individuals respond well to as little as 5 or 10 mg daily. Quetiapine is usually effective when dosages are between 150 and 600 mg daily. Ziprasidone is effective at dosages of 80 to 160 mg daily.

A number of recent findings suggest a reasonable strategy for treating acute schizophrenia. The dose of an antipsychotic that is likely to be effective is the dose that occupies an appropriate number of D_2 receptors. For dopamine receptor antagonists this is approximately 80 percent of receptors. The therapeutic response depends upon processes that occur after these receptors have been occupied for a period of time. This observation is supported by findings from both position emission tomography (PET) scanning and the measurement of plasma homovanillic acid, which suggest that clinical improvement is not associated with the immediate effects of the drug on dopamine receptors, but on processes that occur later. Therefore, the goal in the first days of treatment is to prescribe a drug dosage that occupies an adequate proportion of dopamine receptors and to keep the patient comfortable until the drug is effective. If a patient does not respond in the first week or two, this does not indicate that the current treatment is inadequate. Since most patients on antipsychotic drugs improve during the first 6 weeks, patients should be observed for this interval before a drug is changed. Also, the strategy of using medications on an as-needed basis as a guide to finding the optimal dosage makes very little sense because the immediate and delayed responses to the drug are very different.

A comparison of some antipsychotic drugs is presented in Table 12.8-2.

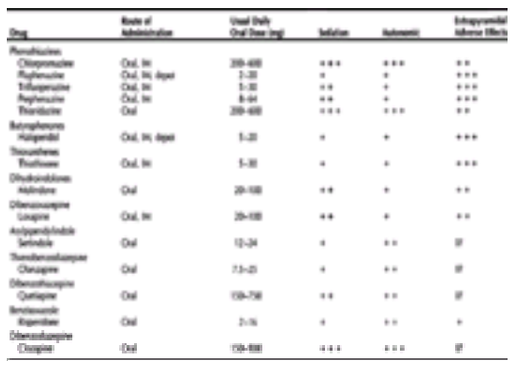

Table 12.8-2 Selected Antipsychotic Drugs

Managing Agitation in Acute Psychosis Agitation in acute schizophrenia can result from disturbing psychotic symptoms such as frightening delusions or suspiciousness or from other causes, including stimulant abuse or extrapyramidal side effects, particularly akathisia. Patients with akathisia can appear agitated when they experience a subjective feeling of motor restlessness. Differentiating akathisia from psychotic agitation can be difficult, particularly when patients cannot describe their internal experience. A trial with an anticholinergic antiparkinson medication or propranolol may be helpful in making the discrimination.

Clinicians have a number of options for managing agitation that results from psychosis. Antipsychotic drugs and benzodiazepines can result in relatively rapid calming when psychotic patients are agitated. An advantage of an antipsychotic agent is that a single intramuscular injection of a high-potency drug such as haloperidol or fluphenazine can result in calming without excess sedation. Low-potency antipsychotics are often associated with sedation and postural hypotension, particularly when they are administered intramuscularly. The disadvantage of high-potency drugs is that extrapyramidal effects can result from a single injection or, more often, from repeated injections. In younger patients, excessive amounts of injected high-potency drugs can lead to dystonia, which may increase the patient's agitation.

A reasonable intervention for the agitated patient is to treat the agitation with either an intramuscular or oral antipsychotic. If the situation is urgent, intravenous or intramuscular drug administration will lead to more rapid calming. The patient should be started on a regimen of oral antipsychotic the same day. If further treatment of agitation is necessary, benzodiazepines may be administered. Lorazepam (Ativan) has the advantage of reliable absorption when it is administered either orally or intramuscularly. The combination of lorazepam with a high-potency antipsychotic agent has been found to be safer and more effective than large doses of antipsychotics in controlling excitement and motor agitation. Moreover, the use of benzodiazepines may reduce the amount of antipsychotic medication that is needed to control psychotic patients.

MANAGING ADVERSE EFFECTS

Patients frequently experience the adverse effects of an antipsychotic agent before they experience clinical improvement. Whereas a clinical response may be delayed for days or weeks after drugs are started, adverse effects often begin almost immediately. For low-potency drugs, these adverse effects are likely to include sedation, postural hypotension, and anticholinergic effects, whereas high-potency drugs are likely to cause extrapyramidal side effects.

This early onset of adverse effects is important because a patient's interpretation of a drug's effectiveness is often associated with how that drug makes them feel. Moreover, one of the challenges of treating the acutely psychotic is maintaining the trust of individuals who may misinterpret experiences and become suspicious. Warning patients about the potential side effects of medication can lead to prompt management and often improves the trust between patient and clinician. Moreover, minimizing the adverse effects may do long-lasting damage to the patient-clinician relationship because one of the powerful predictors of drug reluctance or drug refusal is an earlier experience of adverse effects.

Extrapyramidal Side Effects The most common form of extrapyramidal side effect is neuroleptic-induced acute akathisia, an adverse effect consisting of a subjective feeling of restlessness along with restless movements, usually in the legs or feet. Patients who experience severe akathisia often pace continuously or move their feet restlessly while they are sitting. Some complain that they are unable to feel comfortable, regardless of what they do. Severe akathisia can make patients feel anxious or irritable, and some reports suggest that severe akathisia can result in aggressive or suicidal acts. Researchers have estimated that 25 to 75 percent of patients treated with a high-potency dopamine receptor antagonist experience akathisia. This adverse effect can be difficult to assess and is frequently misdiagnosed as

anxiety or agitation. Akathisia is also thought to be a correlate of poor antipsychotic drug response.

Because patients may experience akathisia as irritability or agitation, asking patients whether they are restless or if they have difficulty sitting still can be helpful in early stages of treatment. At this point, a dosage adjustment, a b-adrenergic receptor antagonist, or an anticholinergic drug may provide considerable relief. Also, patients who have a history of developing severe akathisia that responds poorly to these treatments are likely to do better if they are treated with a new antipsychotic such as clozapine, risperidone, or sertindole.

Neuroleptic-induced acute dystonia is probably the most frightening extrapyramidal side effect. It consists of intermittent or sustained muscular spasms and abnormal postures affecting mainly the musculature of the head and neck, but sometimes the trunk and lower extremities. Common forms of dystonia include abnormal positioning of the neck, impaired swallowing (dysphagia), hypertonic or enlarged tongue, and deviations of the eyes (oculogyric crisis). These reactions usually appear within the first few days of therapy. Dystonias are more likely to occur in younger patients, particularly males in their teens or 20s.

Neuroleptic-induced parkinsonism consists of tremor, muscular rigidity, and a decrease in spontaneous movements, features that resemble the movement disorder in idiopathic parkinsonism. Examination usually reveals a positive glabella tap. This motor disturbance affects about 30 percent of patients who are chronically treated with traditional antipsychotics. The first evidence of drug-induced parkinsonism may be a diminished arm swing or decreased facial expressiveness. Risk factors for antipsychotic-induced parkinsonism include increasing age, dosage, a history of parkinsonism, and underlying basal ganglia damage.

When patients develop neuroleptic-induced parkinsonism, clinicians have a number of alternatives. These include reducing the dosage of the antipsychotic (which is most commonly a dopamine receptor agonist), adding an antiparkinsonism medication, or changing the patient to an SDA that is less likely to cause extrapyramidal adverse effects. The most effective antiparkinsonism medications are the anticholinergic drugs. Although these medications are frequently effective, they also cause their own adverse effects including dry mouth, constipation, blurred vision, and often memory loss. Also, these drugs are often only partially effective, leaving patients with substantial lingering extrapyramidal side effects. Centrally acting b-adrenergic receptor antagonists such as propranolol (Inderal) are frequently effective for treating akathisia; most patients respond to daily dosages between 30 and 90 mg.

Clinicians may consider prescribing prophylactic antiparkinsonism medications for patients who are likely to experience disturbing extrapyramidal effects. These include patients who have a history of extrapyramidal sensitivity or those who are being treated with relatively high dosages of high-potency drugs. Prophylactic antiparkinsonism medications may also be indicated when high-potency drugs are prescribed for young men who tend to have an increased vulnerability for developing dystonias; these patients may also be candidates for the newer drugs.

Some individuals are highly sensitive to extrapyramidal adverse effects at doses that are necessary to control their psychosis. For many of these patients, the adverse effects of the medication may seem worse than the illness itself. These patients should routinely be treated with an SDA because these agents result in substantially fewer extrapyramidal adverse effects than the dopamine receptor antagonists do. These highly sensitive individuals may actually experience extrapyramidal side effects on an SDA. Risperidone may cause extrapyramidal effects at higher dosages, (e.g., above 6 mg) and olanzapine, quetiapine, and ziprasidone may cause akathisia at their higher dosages.

Tardive Dyskinesia and Other Tardive Syndromes Chronic treatment with an antipsychotic—usually for 6 months or more—can result in movement disorders including neuroleptic-induced tardive dyskinesia and other tardive disorders. Tardive dyskinesias commonly consist of abnormal, involuntary movements of the mouth, tongue, trunk, and extremities. The oral-facial movements occur in about three-fourths of patients with tardive dyskinesia and may include lip smacking, sucking, and puckering as well as facial grimacing. Other movements may include irregular movements of the limbs, particularly choreoathetoid-like movements of the fingers and toes and slow, writhing movements of the trunk. Younger patients with tardive dyskinesia tend to develop slower athetoid movements of the trunk, extremities, and neck.

The abnormal movements of tardive dyskinesia are usually reduced by voluntary movements of the affected areas and are increased by voluntary movements of unaffected areas. The abnormal movements of tardive dyskinesia are usually increased with emotional arousal and absent when the individual is asleep. According to the research criteria in DSM-IV the abnormal movements should be present for at least 4 weeks and patients should have been exposed to an antipsychotic agent for at least 3 months (see Table 31.4-5). The onset of the abnormal movements should occur either while the patient is receiving an antipsychotic agent, within 4 weeks of discontinuing an oral agent, or 8 weeks after the withdrawal of a depot antipsychotic drug.

Prevalence surveys indicate that 20 to 30 percent of patients who are chronically treated with a dopamine receptor antagonist exhibit symptoms of tardive dyskinesia. Three to 5 percent of young patients receiving a dopamine receptor antagonist develop tardive dyskinesia each year. The risk in elderly patients is much higher. Although seriously disabling dyskinesia is uncommon, a small proportion of patients have trouble walking, breathing, eating, and talking. Individuals who are more sensitive to acute extrapyramidal effects appear to be more vulnerable to developing tardive dyskinesia. Patients with cognitive disorders and mood disorders may also be more vulnerable to developing tardive dyskinesia than those with schizophrenia.

All dopamine receptor antagonists are associated with a risk of tardive dyskinesia. Evidence from prospective studies indicates that clozapine is associated with a substantially lower risk than dopamine receptor antagonists. Anecdotal evidence indicates that clozapine can decrease abnormal movements in some patients with tardive dyskinesia. At this time it is unclear if the other SDAs are also associated with a lower risk than the dopamine receptor antagonists. The argument has been made that because these drugs are less likely to cause extrapyramidal side effects, they are less likely to cause tardive dyskinesia. For risperidone and olanzapine, prospective studies indicate new cases of tardive dyskinesia develop at a lower rate on these agents than on haloperidol. However, these studies are relatively small and include few cases of tardive dyskinesia. Until these findings are replicated with these agents or other SDAs, clozapine is the drug of choice for individuals who suffer from disabling tardive dyskinesia.

A Task Force on Tardive Dyskinesia of the American Psychiatric Association recently made a number of recommendations for preventing and managing tardive dyskinesia. These include (1) establishing objective evidence that antipsychotic medications are effective for an individual; (2) using the lowest effective dosage of an antipsychotic drug; (3) prescribing cautiously with children, elderly patients, and patients with mood disorders; (4) examining patients on a regular basis for evidence of tardive dyskinesia; (5) considering alternatives to antipsychotic agents, obtaining informed consent, and also considering dosage reduction in patients who develop tardive dyskinesia; (6) if the tardive dyskinesia worsens consider a number of options, including discontinuing the antipsychotic drug, switching to a different drug, or a trial of clozapine.

Regular monitoring for tardive dyskinesia should be a component of management strategies with antipsychotic drugs. The monitoring should be particularly careful for patients who have an increased risk for tardive dyskinesia, including elderly patients, patients who are sensitive to extrapyramidal side effects, and individuals with affective illness. Routine monitoring should include examination every 3 to 6 months, and high-risk groups should be monitored every 3 months.

A summary of extrapyramidal syndromes is presented in Table 12.8-3.

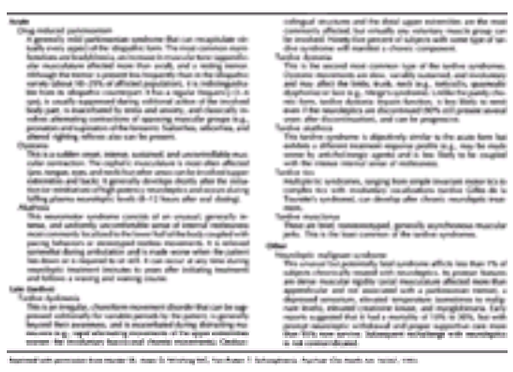

Table 12.8-3 The Drug-Induced Extrapyramidal Syndromes

Other Adverse Effects Sedation and postural hypotension can be important adverse effects for patients who are being treated with low-potency DRAs, such as chlorpromazine and thioridazine, and clozapine. These effects are often most severe during the initial dosing with these medications, so it may be weeks before patients treated with these medications—particularly clozapine—reach a therapeutic dosage. Although most patients develop tolerance to sedation and postural hypotension, sedation may continue to be a problem. Daytime drowsiness may interfere with such patients attempts to return to community life.

All of the dopamine receptor antagonists as well as risperidone increase prolactin concentrations, which can result in galactorrhea and irregular menses. Evidence suggests that prolactin elevation may impair libido in men and women. Fortunately, clozapine, olanzapine, quetiapine, and ziprasidone do not appear to elevate prolactin above normal concentrations. As a result, patients who demonstrate these symptoms on a dopamine receptor antagonist or risperidone and have high prolactin concentration should instead be given an agent that does not increase prolactin concentration.

Many antipsychotic drugs cause disturbances in sexual function including ejaculatory or erectile disturbances in men and decreased libido in women; these effects result in a substantial amount of noncompliance in men. Thus clinicians should discuss issues of sexual functioning with patients and intervene when possible. It is unclear if any of the SDAs are associated with a reduced or greater risk of sexual dysfunction than the dopamine receptor antagonists.

Adverse Effects of Clozapine Clozapine has a number of adverse effects that make it a difficult drug to administer. The most serious adverse effect is a risk of agranulocytosis, a potentially fatal condition that occurs in approximately 1 percent of patients treated with clozapine. As a result, patients who receive clozapine in the United States are required to be in a program of weekly blood monitoring for as long as they receive the drug.

Clozapine is also associated with a higher risk of seizures than other antipsychotics. The risk reaches nearly 5 percent at doses over 600 mg. Patients who develop seizures while on clozapine can usually be managed by reducing the dosage and adding an anticonvulsant, usually a form of valproic acid (Depakene) or divalproex (Depakote). Other adverse effects with clozapine include hypersalivation, sedation, tachycardia, weight gain, fever, and postural hypotension.

NEGATIVE AND COGNITIVE SYMPTOMS

Negative symptoms and cognitive impairment are associated with a substantial number of the social and vocational impairments of schizophrenia. This observation has resulted in a reappraisal of the goals of treatment, with a greater emphasis being placed on treatment strategies for decreasing the severity of these impairments. Most of the attention has focused on negative symptoms.

Carpenter has made an important contribution to this area by classifying negative symptoms into primary and secondary categories. *Secondary negative symptoms* are those that may result from other conditions, such as depression or extrapyramidal side effects. The latter are a common cause of secondary negative symptoms, particularly when patients are experiencing akinesia, an adverse effect that can be manifest in decreased speech, decreased motivation, and decreased spontaneous gestures. In addition, positive or psychotic symptoms may result in secondary negative symptoms. A common example is the patient who is withdrawn or uncommunicative as a result of suspiciousness.

The management of secondary negative symptoms begins with the management of the condition that caused these symptoms. For depression this may include the addition of an antidepressant medication; for extrapyramidal effects this may involve the addition of an antiparkinson medication, a dose reduction, or a change to an antipsychotic—usually an SDA—that is associated with less extrapyramidal adverse effects.

If the previously mentioned causes of secondary negative symptoms have been ruled out, the patient is likely to be demonstrating a type of enduring primary negative symptom. Some evidence suggests that the SDAs are more effective in treating negative symptoms than conventional agents. However, it is unclear if these effects are related to a reduction in secondary negative symptoms. Until this issue is decided by adequate controlled studies, it is reasonable for clinicians to consider prescribing an SDA to patients who have substantial negative symptoms.

Patients with schizophrenia frequently suffer from impairments in attention and information processing. These cognitive impairments can also interfere with their social and vocational rehabilitation, even when their psychotic symptoms have been well controlled. As with negative symptoms, cognitive impairments can be due to other causes such as substance abuse or drug effects of medications. The anticholinergic effects of either an antipsychotic or an antiparkinsonism medication such as biperiden (Akineton) or benztropine (Cogentin) can cause cognitive impairments that are difficult to distinguish from symptoms that are part of the schizophrenia. Decreasing the use of anticholinergic medication by changing to drugs that do not require antiparkinsonism medications—particularly SDAs—may be helpful. Evidence also suggests that clozapine, risperidone, olanzapine and other SDAs may be more effective at treating cognitive impairments than dopamine receptor antagonists. For example, a recent study found risperidone effective in improving verbal working memory. Others have reported that clozapine is effective for improving verbal fluency. Olanzapine has resulted in improvements in a number of cognitive measures. If confirmed, these findings will support the practice of treating cognitively impaired patients with schizophrenia with an SDA.

STRATEGIES FOR POOR RESPONDERS

When patients with acute schizophrenia receive an antipsychotic medication approximately 60 percent improve to the extent that they will achieve a complete remission or experience only mild symptoms; the remaining 40 percent of patients improve, but still demonstrate variable levels of positive symptoms that are resistant to the medications. Rather than categorizing patients into responders and nonresponders, it is more accurate to consider the degree to which the illness is improved by medication. Some resistant patients are so severely ill that they require chronic institutionalization; others respond to an antipsychotic drug with substantial suppression of their psychotic symptoms but demonstrate persistent hallucinations or delusions.

Before considering a patient a poor responder to a particular drug one must be certain that they received an adequate trial of the medication. A 6-week rial on an adequate dosage of an antipsychotic agent is considered reasonable for most patients. If patients demonstrate even mild improvement during this period, it may be reasonable to wait because data indicate that patients may improve at a steady rate for 3 to 6 months. It may be also be helpful to confirm that the patient is receiving an adequate amount of the drug by monitoring the plasma concentration. Information about therapeutic plasma concentrations is available for a number of antipsychotic drugs including haloperidol, clozapine, fluphenazine, trifluoperazine (Stelazine), and perphenazine (Trilafon). A very low plasma concentration may indicate that a patient has been noncompliant or, more commonly, only partially compliant. It may also suggest that the patient is a rapid metabolizer of the drug or that the drug is not being adequately absorbed. Under these conditions increasing the dose may be helpful. If the level is already relatively high, clinicians should consider whether adverse effects may be interfering with therapeutic response.

If the patient is responding poorly, many clinicians will consider raising the dosage above the usual therapeutic level. The use of high dosage in poor medication responders has been studied under a number of circumstances. Nearly all studies found that higher dosages were not associated with greater improvement than conventional dosages, which suggests that changing to another drug is more likely to be helpful than increasing the dosage.

A patient who has responded poorly to a conventional dopamine receptor antagonist is unlikely to do well on another dopamine receptor antagonist. Studies suggest that a poor response to one dopamine receptor antagonist is likely to be followed by a poor response to another; thus, changing to an SDA is more likely to be helpful.

Substantial evidence indicates that clozapine is effective for patients who respond poorly to dopamine receptor antagonists. Double-blind studies comparing clozapine to other antipsychotic agents indicated that clozapine had the clearest advantages over conventional drugs in patients with the most severe psychotic symptoms as well as those who had previously responded poorly to other antipsychotic drugs. The most definitive evidence of clozapine's advantages in this population comes from a multicenter trial reported by John Kane in which clozapine was compared with chlorpromazine. This study was conducted on severely psychotic patients who had failed in trials with at least three antipsychotic drugs. Clozapine was significantly more effective than chlorpromazine in nearly every dimension of psychopathology, including both positive and negative symptoms. This study found that 30 percent of patients treated with clozapine met improvement criteria by the end of the 6-week trial. Studies of longer duration indicate that 60 percent of patients are likely to meet these same improvement criteria when patients are maintained on clozapine for 6 months.

There is also evidence suggesting that risperidone and olanzapine may be helpful when a dopamine receptor antagonist is only partially effective. A Swiss study found that clozapine and risperidone were equally effective in a treatment-resistant population, but risperidone's side effects were more easily tolerated. Another study found that risperidone was somewhat more effective than haloperidol in a similar population and that risperidone was better tolerated. A multicenter comparison of olanzapine and haloperidol in a largely treatment-resistant group of patients found that olanzapine was more effective for both positive and negative symptoms. Taken

together these studies support the practice of trying patients on risperidone or olanzapine when they have responded poorly to a dopamine receptor antagonist.

When switching patients from one antipsychotic to another clinicians should be aware that abrupt changes in drugs and dosage can have serious adverse effects in some individuals. For example, abrupt discontinuation or rapid dosage reduction of low-potency antipsychotics such as clozapine or chlorpromazine can lead to withdrawal adverse effects such as nausea or diarrhea. Anecdotal reports indicate that rapid discontinuation of clozapine can lead to severe psychotic relapse. When treatment is started with some antipsychotics such as clozapine or quetiapine, dosage titration often requires days or even weeks. For individuals who are being changed to treatment with one of these agents, the best strategy usually entails continuing the first agent until the patient is receiving a clinically effective dosage of the second drug. For these reasons, the best methods for switching drugs usually involve a cross-titration in which the patient is gradually changed from one antipsychotic to the other.

MAINTENANCE THERAPY

During the stable or maintenance phase, patients are usually in a relative state of remission, with only minimal psychotic symptoms. The goals during this stage are to prevent patients from suffering psychotic relapse and to assist them to improve their level of functioning. Pharmacotherapy plays an important part in both of these goals. Medications are effective in preventing or delaying psychotic relapse and may also be an important adjunct in managing functional impairments that may interfere with rehabilitation; unfortunately, the adverse effects of medications can undermine these goals.

Drug and Route of Administration for Maintenance Therapy Stable patients maintained on an antipsychotic drug have a much lower relapse rate than patients whose medications are discontinued. Although studies differ, most suggest that 16 to 23 percent of patients a year experience a relapse while receiving medications and 53 to 72 percent relapse without medications. Clinicians are often tempted to discontinue medications in patients who have een well and stable for prolonged periods; unfortunately, these patients also have high relapse rates when their medications are discontinued. Other evidence indicates that patients who experience relapses while they are receiving an antipsychotic drug have milder episodes than patients who relapse on no medication. Donald Johnson has reported that patients whose medications are discontinued are more likely to show dangerous behavior and are more likely to be admitted involuntarily.

These observations about the effectiveness of continuing antipsychotic medication in stable patients have led to the recommendation that most patients with schizophrenia should receive an antipsychotic to prevent relapse. In 1989 the duration of maintenance was considered at an international consensus conference. This consensus group recommended 1 to 2 years of maintenance for patients following a first episode. Although this may be somewhat longer than current practice in many settings, it was recommended because individuals at this stage of their illness may have the most to gain if relapse can be prevented or delayed. First-episode patients may be working or involved in educational programs, both of which can be jeopardized by a second psychotic episode. The consensus conference also recommended that multiepisode patients receive maintenance antipsychotic for at least 5 years. For patients with a history of serious suicide attempts or violent, aggressive behavior, maintenance treatment with neuroleptics may be indicated for longer periods—perhaps indefinitely. The first 3 to 6 months following an acute episode was considered a period of stabilization when patients may not demonstrate acute symptoms but may nevertheless remain more vulnerable to relapse. The consensus conference recommended that following this stabilization period gradual dosage reduction should be implemented at the rate of approximately 20 percent every 6 months until a minimal maintenance dosage level is reached.

There is also evidence that long-acting depot antipsychotic drugs may be the most effective agents for preventing relapse. A number of double-blind and uncontrolled trials have compared oral and depot treatment. The uncontrolled trials usually compared individuals who were assigned to a depot with those assigned to oral medications; patients assigned to depot medication usually demonstrated much lower rates of relapse. The results are less clear for well-designed double-blind studies. However, these studies tended to use highly selected groups of cooperative patients who were carefully monitored, which would tend to undermine the advantages of depot medications by excluding the patients who were most likely to benefit from this form of treatment: that is, patients with compliance problems. Nevertheless, even under these conditions, in a meta-analysis of six studies Janicak found an advantage in favor of depot treatment.

Dosage Reduction Strategies Concerns about the long-term adverse effects of antipsychotic medications—particularly extrapyramidal effects and tardive dyskinesia—have led to a search for methods of treating patients with the lowest effective dose of medication. One strategy proposes using substantially lower antipsychotic dosages during maintenance treatment than those prescribed for initial short-term treatment. Studies indicate that many patients do well when they are treated with dosages that are approximately 20 percent of an initial treatment dosage. The low dosages were in the range of 4 to 10 mg of fluphenazine decanoate administered every 2 weeks. In 1997 Nina Schooler and her coworkers published the results from the Treatment Strategies in Schizophrenia multicenter study. Their 2-year comparison of low and conventional dosages found that low dosages in this range resulted in relapse rates that were slightly higher than those with conventional dosages but within an acceptable range. Moreover, other studies suggest that lower dosages are associated with milder side effects and better patient compliance.

Another strategy, termed targeted or intermittent therapy, proposes gradually reducing and finally discontinuing the medications in stable patients. Patients are then monitored carefully, and medications are reintroduced if early signs of relapse appear. Controlled trials with this strategy have mostly shown discouraging results. Relapse rates were relatively high as were rates of rehospitalization. These results were confirmed in the Treatment Strategies Study in which rates of rehospitalization were significantly elevated in the targeted treatment group.

Still another strategy combines the features of low- and targeted-dose strategies. In this method patients are treated with the same low doses of a depot drug that were used in the low-dose studies. Patients are monitored for early prodromal signs of relapse, and if these symptoms appear, patients are treated with oral medication. Results suggest that this is an effective strategy for making low-dose treatment safer.

Although the SDAs may be excellent drugs for maintenance treatment, few controlled long-term trials have evaluated their effectiveness. Nevertheless, risperidone, olanzapine, quetiapine, and ziprasidone appear to have important advantages. Concern about adverse effects should be substantially less, which would allow clinicians to treat patients with dosages that should be associated with very low relapse rates. If findings suggesting that SDAs are associated with a reduced risk of tardive dyskinesia are confirmed, this advantage will provide a compelling reason to select these newer agents. Also, the improved side-effect profile may result in better medication compliance.

The SDAs also have serious adverse effects that are likely to be important concerns during long-term treatment. Some of the newer agents—particularly olanzapine and clozapine—can result in substantial weight gain. Risperidone can cause some extrapyramidal effects and may cause problems related to increased prolactin concentrations such as irregular menstrual periods and galactorrhea. An important disadvantage of the SDAs is the lack of availability of long-acting formulations that are useful for patients who are unreliable pill takers.

INTEGRATING PHARMACOTHERAPY AND PSYCHOSOCIAL TREATMENT

Most patients with schizophrenia will benefit from a combination of pharmacotherapy and psychosocial treatments. Recent improvements in both domains suggest that the overall outcome of this disorder can be improved if patients receive the optimal forms of both treatments at the appropriate stage of their illness. Research studies and clinical experience suggest that psychosocial treatments are probably most effective when patients have recovered from severe psychotic episodes. During the acute psychotic phase clinical management should emphasize maintaining patient cooperativeness and trust. This is particularly important when there is overt suspiciousness or a tendency to misinterpret the intentions of the treatment team. A successful strategy is likely to include clear explanations of the rationale for treatment and possible drug adverse effects. Family members may be important allies in ensuring cooperation, and family psychoeducation programs have been demonstrated to be helpful during this phase.

It is difficult to generalize about the interactions of drugs and psychosocial treatments for stable patients because psychosocial treatments can vary greatly in terms of content and goals. Nevertheless, a number of important treatment principles can be drawn from the literature on combining treatments. The first is that psychosocial treatments are most likely to be effective when patients have been effectively stabilized on drugs. Early studies by Hogarty ndicated that psychosocial treatments could actually lead to a worse outcome when outpatients with schizophrenia were treated with a placebo. Other studies indicate that patients are most likely to respond to psychosocial treatments when their condition is stable. For example, a recent study with social skills training found that patients who received pharmacotherapy that minimized the proportion of time that they were in a psychotic state also demonstrated the greatest improvements in social adjustment.

Psychosocial treatments may also improve patient response to pharmacotherapy by improving medication compliance. This was suggested in a study in which patients received a form of family treatment that also encouraged medication compliance. Other studies have indicated that psychosocial treatments—particularly family treatment—may decrease the amount of stress that the patient experiences within the family and that this, in turn, decreases the amount of antipsychotic

medication required by the patient.

The introduction of the newer antipsychotics may result in much greater interest in psychosocial interventions. Patients who receive the newer agents may be better candidates for psychosocial treatments when treatment with these agents is associated with improvements in negative and cognitive symptoms as well as reduced adverse effects. Also, patients who improve on clozapine, risperidone, olanzapine, or other drugs may initially appear ready to return to community life. However, these individuals then experience a series of frustrating failures at work, school, or social relationships, which indicate that drug therapy alone may not suffice to prepare them for their new roles.

SUGGESTED CROSS-REFERENCES

For further information related to assessment of the patient with schizophrenia see Section 7.3 on typical signs and symptoms of psychiatric illness and Section 7.8 on psychiatric rating scales. Chapter 12 on schizophrenia is important for a full understanding of the syndrome. To appreciate the antipsychotic medications see Section 31.17 and Section 31.26 on antipsychotic drugs. As other medicines are used to augment antipsychotic medications, see the other sections of Chapter 31 on biological therapies.

12.9 SCHIZOPHRENIA: PSYCHOSOCIAL TREATMENT

JUAN BUSTILLO, M.D., SAMUEL J. KEITH, M.D. AND JOHN LAURIELLO, M.D.

Central to the enthusiasm for psychosocial treatments has been the question of whether applying psychosocial treatment to an illness like schizophrenia implies a belief in a psychosocial origin or causality of the disorder. For the era of the 1960s the belief systems of the time posited such causality as schizophrenogenic mothers, double-binds, and familial pathogenesis. Elements observed in families with a schizophrenic member were linked to causality in a post hoc or *propter hoc* manner. While few hold tenaciously to such concepts now, the pain and suffering inflicted on families during that period of thought still resonates through the professional community. It was a time when families were accused of causing schizophrenia, excluded from the treatment process, and forced to pay the financial and psychological price for both. As an almost predictable result of such accusations and attributions, the families of the severely mentally ill joined forces to fight the remnants of such thinking. However, by 1979, when the National Alliance for Mentally Ill was founded, much of this thinking had receded and the theory that such illnesses were biologically determined and should be biologically treated was proposed. Proposals even surfaced to move research on illnesses like schizophrenia from the National Institute of Mental Health to the National Institute of Neurologic Diseases and Stroke because this would be a more appropriate place for a neurobiological illness to be treated. Psychosocial treatments were frequently seen as merely a means to increase medication compliance and were looked at by some family advocates as psychiatry's new means of blaming the family for causing this illness.

Fortunately, this was also an era of rapid growth in research studies on psychosocial treatments, and it would eventually be the data that preserved and advanced the knowledge and utilization of psychosocial treatments. Psychiatry has been fortunate in possessing one of the richest and most extensive data bases in all of medical science. The role of clinical trials in establishing which treatments are effective for which populations has become one that mental health professionals have thoroughly embraced. The field has moved away from blind belief systems and the great-person hypothesis (i.e., if a great person said to do it a certain way, that was the way it was done) toward testable and tested hypotheses.

GENERAL CONSIDERATIONS

The assumption that psychosocial treatments have the ability to effect change carries with it the possibility that the change can go in either a positive or negative direction. It is important to examine the potential for gains and losses for specific modalities. Intensive individual psychotherapy brought about a level of intensity that may have been too high for people suffering from severe psychosis. The intensity of the environment is a critical factor in modulating treatment impact. There is substantial literature from England that has tried to link an overinvolved, intense, hostile, critical environment (i.e., *expressed emotion*) with poor outcome in schizophrenia. Originally this type of environment was associated with families of origin and was correctly perceived by families as disguised finger pointing. Additional studies were able to point out that others, including care providers, were certainly able to produce similar environments iatrogenically. One leading British investigator has noted that in a total push rehabilitation program in which treatment is very intensive with high expectations, he was able to produce dramatic relapse rates in an otherwise well-stabilized population. From the other side of intensity, however, comes the clear demonstration that institutional environments lacking almost completely in stimulation will produce rather striking negative symptoms of schizophrenia. The psychosocial treatment of schizophrenia includes the role of individual, group, and family therapies; the forms of vocational rehabilitation; and the various service delivery models available.

INDIVIDUAL PSYCHOTHERAPY

It is important to note that psychiatric research has always questioned the efficacy of the treatments for mental illness. The 1960s began with intensive individual psychotherapy serving as the main treatment for schizophrenia with little faith placed in other possible treatments. The first major study to question this belief was conducted at Camarillo State Hospital, California, and involved five modalities: antipsychotic medication alone, antipsychotic medication plus individual psychotherapy, individual psychotherapy alone, electroconvulsive therapy (ECT), and milieu alone. The results of this study showed that modalities that contained the antipsychotic medication did best; the effect of ECT was intermediate; and the modalities that did not use antipsychotic medication (individual psychotherapy alone and milieu alone) did the poorest. Traditional psychodynamic advocates criticized the study for using inexperienced therapists, setting it in a state hospital, not continuing the pharmacology into the community, and because the psychotherapy was not intensive enough (twice a week). A study was conducted to answer these criticisms in the 1980s in Boston at McLean Hospital and Boston University using therapists with more than 3 years of experience with intensive psychotherapy with schizophrenia patients; the pharmacology was continued into the community and the intensive therapy was conducted three times a week. The results of this study, which compared the intensive form of psychotherapy with a supportive form given 60 minutes each week, were quite striking: the more severely ill patients dropped out of the intensive psychotherapy, but not out of the supportive version; despite this differential attrition, in only one outcome measure—ego functioning—intensive treatment had an advantage. Overall any advantages at all favored the supportive group. Intensive individual psychotherapy for schizophrenia would continue to be practiced (for a small group of functional patients who were relatively stable and could afford it), but not based on evidence that it was effective for the general population of schizophrenia patients.

This research on psychosocial treatments moved the field away from the idea that greater intensity was better. Moreover, with the rise of biological psychiatry the field could no longer assume pure psychological causes for schizophrenia. This was now an era that looked toward genetic linkage, enlarged lateral ventricles, and hypofrontality of cerebral functioning. However, in the daily struggles with life, persons suffering from schizophrenia think little of these biological variables but rather about their relationships, their ability to be financially self-supporting, and the skills needed to navigate the complex society they live in. Treatments need to be used that first eliminate symptoms and prevent relapse, after which the skills of daily living and relating need to be achieved.

Researchers at the University of Pittsburgh have recently published the results of a 3-year randomized trial of individual interpersonal therapy for schizophrenia compared to family therapy, combined treatment and supportive therapy. Personal therapy was conducted weekly following an incremental approach individualized for the patients' stage of recovery: The initial phase focused on the relationship between stress and symptoms; the intermediate phase emphasized learning to use relaxation and cognitive reframing techniques when stressed; the advanced phase (which generally started 18 months into treatment) focused on seeking social and vocational initiatives in the community and applying what was learned in interpersonal therapy. Social adjustment (a composite measure including work performance, leisure, and interpersonal relationships) clearly favored the interpersonal therapy group. The greatest differential improvement took place in the last two years of treatment, however there were no advantages in relapse for interpersonal therapy. Relapse rates were low, only 29 percent in 3 years.

GROUP THERAPY

The systematic provision of care for persons with schizophrenia in a group setting has followed the general principles of both psychodynamic and behavioral (learning) theories. The behavioral approach has resulted in well-structured interventions (social skills training, social problem-solving, and cognitive remediation) that are often delivered in a group setting. The psychodynamic group therapies, like the individually based approaches, exist along a continuum between intensive and supportive forms. There have been no studies to date comparable to the Boston Psychotherapy Study on individual therapy of schizophrenia in methodological rigor that test the efficacy of intensive versus supportive group therapy.

A few studies have evaluated the effects of adding group therapy (mostly supportive form) to standard antipsychotic medication in a controlled design. For inpatients, the advantage of adding group therapy appears almost negligible. In one of the better-designed studies, investigators evaluated insight-oriented group therapy during the first 3 weeks of hospitalization. The comparison conditions were a task-oriented group and an unstructured control group. Patients with psychosis in the

insight-oriented group did particularly poorly, with an actual worsening in symptoms ratings. Addition of group therapy to medication for outpatients also suggests very limited effects. The one outpatient study with a large sample (N = 100) that actually compared group with individual therapy for the treatment of schizophrenia found advantages in psychopathology and social adjustment ratings for group treatment after 2 years. Nevertheless, this study was more a naturalistic evaluation of effectiveness in a clinic setting than a true efficacy study. There was no attempt to standardize both interventions or to ensure that the patients received optimal and equivalent pharmacotherapy. In summary, there is little empirical evidence and no compelling theoretical reason to justify submitting an acutely psychotic inpatient to a potentially intrusive and overstimulating group intervention. Similarly, the evidence for a specific psychodynamic effect of group treatment in schizophrenia is quite limited. Supportive outpatient group therapy most likely has a modest effect and will probably continue to be used as a practical setting to monitor symptoms and medication compliance and to provide ongoing education for the person with schizophrenia.

FAMILY THERAPY

The role of the family in the treatment of schizophrenia has gone through a number of changes. The present context sees the family as very important clinically. First, it has been clearly demonstrated that even as passive participants, family members are extraordinarily important in providing the clinical treatment team with accurate information on how the patient is doing. It is clear that families identify impending signs of relapse much earlier in the illness than do patients, who tend to lack insight into the onset of the psychotic process. The scientific investigations on family therapy since the 1970s, however, have gone much further than passive participation in the treatment process; families have been invited to become active members of the clinical treatment team.

Families are perhaps the most consistent factor in a patient's life. Over 60 percent of patients discharged from a psychiatric facility return to their families of origin. Early in the course of the illness, this figure is much higher. Further, even patients who do not reside with their parents frequently remain in close contact with them. With today's shrinking resources for psychiatric care, the family represents a resource that could not be easily replaced. Many families are interested in participating in a treatment program, particularly early in the treatment process and particularly if they are welcomed and valued.

There must, however, be a series of caveats in regard to the involvement of the family in the treatment process. First, mental health systems have looked to many types of facilities to house the mentally ill. It should not be a part of a family's role to turn their home into a psychiatric ward. Many families will want to have their family member at home; some will not. Both positions should be given equal respect. Further, the family should not be seen as the long-term caregiver; their energies and good will should be used in the development of transitional strategies or burnout will occur with rapid demoralization and an increasing likelihood of patient relapse. Third, it cannot be emphasized enough how sensitive families are to criticism. The historical context in which they were disparaged has made them justifiably suspicious of their role vis-a-vis psychiatry; this is compounded by their natural feelings of guilt and responsibility. All efforts must be directed initially at reducing this guilt to its lowest possible level. The treatment focus should be on what families can do positively. The negative factors that need to change must do so in the context of an accepting clinical alliance.

It was first noted in a landmark study in Ventura, California, how the addition of a family component over a brief 6-week period provided significant protection against relapse regardless of the medication status of the patient. The effect of this family involvement was present at the end of 6 months despite the brevity of the therapy. This particular family therapy focused on clarity of communication and limited problemsolving.

The next contribution to establishing the importance of the role of the family in the treatment of schizophrenia came from studies conducted in the United Kingdom. *Expressed emotion* describes a critical, overinvolved environment that led to relapse rates exceeding 50 percent in its presence and 20 percent in its absence. These findings have now been replicated across many cultures and countries worldwide and a number of strategies were developed to take advantage of this new information. These strategies differed in where the treatment was delivered (inpatient setting, clinic, or home), whether the patient was acutely ill or stabilized, whether the patient and family were seen as an individual unit or in groups, and what the family treatment was compared to.

The first generation of studies produced remarkably homogeneous results. Studies were done that added family therapy to energetic social treatments, to medication programs, and to other forms of common treatments. Each of these was able to find a major benefit from the addition of family therapy. The one study done on an inpatient unit with the family therapy added to a well-conducted inpatient program also found significant positive results from this addition. There have also been studies that compared family therapy to individual therapy. One that was conducted in Los Angeles compared individual psychotherapy to a form of behavioral family therapy conducted in the home. The results of this study in terms of symptom exacerbation and relapse were strikingly in favor of the family therapy. Further, although it did not reach significance, there was a strong suggestion that this strategy of in-home sessions was responsible for the use of less medication in those treated with family therapy.

These studies were all of a first-generation type, that is, they were done by people who designed the treatment and were heavily involved in its delivery. A second-generation study in which the developers of the treatment taught others how to deliver it but did not treat patients themselves has now been completed by the National Institute of Mental Health (NIMH) in a five-site collaborative study. The importance of such second-generation studies for public health purposes is critical: the methodology must be transferable or it can never be used in any sort of general manner. The NIMH study compared an in-home (weekly for the first 3 months, biweekly for the next 6 months, and monthly to complete the first year) intensive behavioral family therapy in conjunction with a monthly multiple family and patient group meeting to monthly family and patient group meetings alone. The study was able to demonstrate a number of issues: first, that the family home-based treatment could be taught to clinicians; second, that families and patients would participate; and third, that those families who did participate in the initial component of the treatment (a 4-hour psychoeducational workshop) had better initial outcomes. The overall outcome of the study, however, showed no differences between the intensive, in-home treatment plus the monthly group meeting and the monthly group meeting by itself. One possible interpretation of these results is that there is a general positive outcome from involving families in a therapy program that respects their needs and that provides them with useful clinical information, but that the ultimate refining of the procedure does not appear to add significantly to the outcome.

Consistent in the principles of family therapy is the establishment of a positive alliance with the family. Families should be provided psychoeducational material about schizophrenia that includes basic, clinically useful information such as identification of early signs of relapse, the role of medication, and anticipated adverse effects of these medications. Families and patients need to learn simple communication skills (e.g., how to make a positive request, how to make a negative request, how to use “I” statements). In addition, simple problem-solving skills (e.g., identification of a problem, listing of possible solutions, selecting the solution, practicing the solution, implementing it, and reviewing the outcome) should also be taught. Finally, helping the family expand its social network is extremely important. Each of these components can be delivered in a neutral context of caring and the results achieved are incontrovertible.

PSYCHIATRIC REHABILITATION

Because the majority of persons with schizophrenia, even those with a favorable response to antipsychotic medications, will have residual symptoms, cognitive impairments, and limited social skills, psychosocial interventions aimed at the functional rehabilitation of the patient have been designed and systematically studied since the 1980s. Largely following the work on persons with physical disabilities, psychiatric rehabilitation uses principles of learning and social systems theories to effect three types of changes: (1) direct improvement of the disability, (2) development of a new skill that circumvents the original impairment, and (3) targeted manipulations of the environment to make it more supportive and to improve functioning.

The common goal of these interventions is to improve the person's social competence in self-care, work, leisure, relationships, and parenting. Improvement in any of these areas contributes to more autonomous functioning in the community. Two broad types of clinical studies have looked at the effects of psychiatric rehabilitation: studies of social skills training and studies of particular systems of delivery of mental health services. Both these have been evaluated in several randomized controlled studies, but the studies differ in their methodological rigor and potential for applicability in the community. The clear advantage for the studies of social skills training is the ability to more clearly interpret the findings in terms of the specific teaching techniques used. Studies of social skills training are limited by questions of its generalization to more naturalistic settings. Conversely, studies of systems of delivery of services offer a better opportunity of rapid applicability in the community, although their specific reason for working is difficult to identify. In the current era of managed care and financial restraint it is particularly important to determine which elements of a package of care are essential and which are superfluous. Therefore studies that use specific learning technologies, which have the potential to be assembled in different systems of delivery depending on the needs of particular patients and the resources available, offer the greatest potential.

SOCIAL SKILLS TRAINING

Social skills have been described as those specific response capabilities necessary for effective social performance. By definition all patients with schizophrenia are, at least during a considerable period of time, impaired in one or more social skills. To what extent these limitations are secondary to the positive symptoms, negative symptoms, and cognitive impairments of schizophrenia is still debated. The severity and persistence of symptoms and cognitive deficits undoubtedly contribute to the

poor social competence. The ‘lost opportunities' to acquire the skills, especially during the crucial developmental years of adolescence and early adulthood when the illness first manifests, could also importantly determine the impaired social competence. Social skills training should be distinguished from the activities in other rehabilitation programs in which the acquisition of skills occur incidentally. Three important social skills models are the *basic social skills model*, the *social problem-solving model*, and the *cognitive remediation model*.

Basic Social Skills Model Also known as the motor skills model, the basic social skills model was developed in the 1970s and has been studied in controlled-randomized clinical trials with schizophrenia patients since the 1980s. Typically, dysfunctional complex social behaviors are identified and broken down into more elementary tasks, which are learned through repeated performance; then the elements are combined into a more complete functional repertoire. A socially withdrawn patient may be taught the set of skills necessary to start a casual conversation with a stranger. The patient may first be videotaped while role-playing a conversation with a confederate; then the therapist provides feedback with the videotape focusing on elementary behaviors: Is there avoidance of eye contact or too intense gazing? Are the answers too short and the speech barely audible? Does the patient ask follow-up questions that denote interest and promote the flow of the conversation? Each elementary behaviors (e.g., contact, speech volume, length of response, questions) are repeated until learned. The therapist may model the behavior. Next, the patient role-plays the integrated social repertoire and finally practices it in a natural setting.

The literature is consistent in that patients with schizophrenia can be taught various social skills that can be retained for up to 12 months. The data on whether the social skills learned will lead to an improvement in other important clinical measures, such as symptom severity and relapse rate, are mixed. In one of the most rigorous clinical trials of social skills training to date, researchers at the University of Pittsburgh compared relapse rates for outpatients with schizophrenia assigned to an individually administered program of social skills training plus antipsychotic medications with a group that only received pharmacotherapy. At 1 year of follow-up, there was a 46 percent rate of relapse in the control group compared to 30 percent in the social skills training group. The difference remained statistically significant in favor of social skills training for up to 21 months but not at the end of the study (24 months). The limited durability of a therapeutic effect in schizophrenia is not unique to social skills training and it should be viewed in the context of the total period of time during which the intervention is applied. For antipsychotic medications too, relapse prevention is closely related to length of exposure to treatment. For psychosocial interventions in general and social skills training in particular, booster sessions or continuous treatment may be required in order to maintain a favorable effect on relapse rates.

Even if schizophrenia patients learn social skills, the extent to which these skills generalize in the patients' natural environment and result in improved social competence is a crucial measure of outcome. Generalization has not been clearly demonstrated for the motor skills model. In part to deal with this limitation, problem-solving techniques have been integrated with the more traditional social skills training model.

Social Problem-Solving Model Developed by researchers at the University of California at Los Angeles, this model uses social learning principles and assumes that impairments in information processing underlie the limited social competence present in the patient with schizophrenia. Like traditional social skills training, complex problem behaviors are identified. Patients can then be assigned to each of five target modules for improvement: (1) medication management, (2) symptom management, (3) recreation, (4) basic conversation, and (5) self-care.

For each of these modules an emphasis is placed on learning, receiving, processing, and sending skills, in the hope that these will increase flexibility, durability, and generalization of the module learned. *Receiving skills* are those skills necessary to appropriately identify social cues. *Processing skills* deal with the context-appropriate interpretation of input information and the generation of the various potential responses. *Sending skills* correspond to the behaviors targeted by the traditional motor skills model. A recent study reported the results of a 2-year study comparing problem-solving group therapy with supportive group therapy for relapse prevention and social adjustment in outpatients with schizophrenia. Each group received the same intensity, frequency, and overall length of psychosocial treatment. There was a small but statistically significant advantage for the experimental intervention in two out of six measures of social adjustment after 2 years. There were no differences in relapse rate. Therefore the benefits of the problem-solving therapy were modest at best. It has been argued that for many patients with schizophrenia deliberately evaluating a social situation in terms of information-processing skills may be particularly difficult and could actually limit the acquisition of social skills. The traditional strategy of simple practice so that overlearned responses can be emitted automatically may be more advantageous. The social problem-solving model will require further evaluation but it offers advantages resulting from its potential for applicability: the modules are clearly structured, manuals are available for patients and therapists, and each module stands independently and can be implemented according to the individual patient's needs. A recent report on this model found it to be more effective in a measure of independent living skills than in a control condition. This effect was maintained even 18 months after completing the intervention.

Cognitive Remediation That patients with schizophrenia have a multiplicity of cognitive impairments is well established. These are most likely not just epiphenomena of symptom severity or medication adverse effects because they are present in various subclinical populations (children at high risk for schizophrenia, nonpsychiatric relatives of schizophrenia patients, and persons with schizophrenia-spectrum [Cluster A] personality disorders). The cognitive impairments are usually generalized, but specific functions like attention, memory, and planning may be more impaired than others. The use of cognitive remediation of schizophrenia is relatively new, and the impaired functions that underlie the generalized deficit, as well as the failure in social competence, have yet to be fully established. Researchers have reasoned that the limitations on the durability and generalization of social skills training may be overcome by improving the impairments in basic cognitive functions before teaching social skills. Studies on cognitive remediation of schizophrenia are few in number. There is some evidence that patients can improve their performance through practice in measures of vigilance and planning. Nevertheless, transfer of learning to another test has not been documented, even within the same cognitive domain (vigilance or planning), let alone showing any evidence of generalization to particular social skills. Probably the most comprehensive hierarchical program, which attempts to teach social skills by building upon learning on elementary cognitive functions, is the integrated psychological treatment for schizophrenia devised by researchers in Switzerland. Patients are seen in a group setting three times a week over 3 months and begin training in card sorting and concept formation using computer games (cognitive differentiation subprogram). This is followed by exercises fostering social problem-solving (social perception and verbal communication subprograms). The final subprograms (social skills and interpersonal problem-solving) resemble the more traditional motor skills model. Although the few controlled studies of integrated psychological treatment in schizophrenia show some modest gains in elementary cognitive functions and some learning in social skills, this preliminary literature is not supportive of the view that improved basic cognitive performance will predict acquisition of social skills. The generalization of integrated psychological treatment to measures of symptomatology and social competence in the community remains to be assessed.

It has been argued that until more is known about the specific cognitive dysfunctions in schizophrenia and the way these might determine higher-order problems in social competence, cognitive remediation may be more successful by focusing on cognitive schemas more closely linked to relevant patterns of psychopathology. Schizophrenia is most likely a heterogeneous disorder. Studies of cognitive psychopathology suggest three clinical syndromes within the disorder: psychomotor poverty, disorganization, and reality-distortion, each with an underlying faulty cognitive style. The psychomotor poverty syndrome may be characterized by a failure to initiate a cognitive set, leading to mental poverty and apathy. The disorganization syndrome is a failure to maintain a cognitive set, leading to distraction and disorganized thinking. Finally, the reality-distortion syndrome is an inability to change cognitive sets, resulting in fixed beliefs and misinterpretation of internal stimuli. It has been suggested that initial training in these cognitive styles for patients selected on the basis of their symptomatology may be more fruitful than remediation of nonspecific elementary cognition and may lead to greater flexibility than traditional social skills training.

These techniques focus on improving faulty cognitive processes. Recently there has been an interest in cognitive-behavioral therapy of schizophrenia, which focuses on the content of the symptoms. Researchers in United Kingdom have applied coping strategy enhancement for residual psychotic symptoms. The goal is to teach coping mechanisms that will distract patients and help them ignore their symptoms, hopefully decreasing their distress. Initial reports suggest a beneficial effect on delusions with loss of effect at 6 months and limited generalizability to other symptoms or social functioning. A different approach, and closer to the original cognitive-behavioral therapy for depression, this modality consists of a gentle but systematic verbal challenge of the delusional belief. This is followed by a behavioral experiment that does not support the delusional belief. The outcome of the experiment (reality testing) reinforces the verbal challenge. This technique may help decrease the severity of delusions. Persistent hallucinations seem particularly resistant to cognitive-behavioral therapy, perhaps because of the recurrence of internally generated stimuli that the patient misattributes to an external source. A recent approach attempts to help patients reattribute the voices to themselves through focusing on the meaning and other characteristics of the hallucinations. These content approaches may offer hope for some patients with persistent delusions or hallucinations. Nevertheless, these studies should be viewed as preliminary and awaiting replication in well-controlled studies with larger samples.

Social skills training has been shown to improve social competence in the laboratory and the clinic. The extent to which this learning translates into better role functioning in the community has yet to be determined. Therapeutic effects have been demonstrated for social skills training in clinical measures like relapse rate, but because of the limited durability, booster or follow-up sessions may be required.

SERVICES DELIVERY SYSTEMS

The period of deinstitutionalization of care for the mentally ill in the United States began in the 1950s and peaked in the 1970s. This massive relocation of patients from state hospitals to the community implied but frequently did not deliver a parallel shifting in delivery of services on a long-term basis. These services not only

included the continued provision of psychiatric treatment to prevent rehospitalization, but the availability of stable and secure housing and systematic efforts to rehabilitate and reintegrate patients into the workplace.

Vocational Rehabilitation Work has been viewed as an important element of the treatment of schizophrenia dating back to the era of the large asylums, which often had farms or other protected settings for patients to work in. With the modern goal of maintaining patients to be as functional and autonomous as possible in the community, various programs to help patients find and maintain jobs have been implemented. Despite these efforts, rates of competitive employment for chronically mentally ill persons have been estimated to be less than 20 percent and are more likely to be lower for patients with schizophrenia. With the current average hospital stay being shorter than 2 weeks, there are practically no hospital-based workshop programs and most vocational rehabilitation takes place in the community. These programs are very heterogeneous but can be subsumed under four models: (1) job clubs, (2) Boston University model, (3) transitional employment, (4) and supported employment.

Job clubs were originally used to help unemployed nonpsychiatric persons to find jobs. This approach focuses on teaching individuals how to look for a job and how to apply for it; there is no actual teaching of job skills. Because past history of competitive employment is the best predictor of future employment, this approach is probably not useful for the majority of patients with schizophrenia who never learned particular job skills.

The Boston University Model is an intensive and individualized program. A patient and a counselor first identify a specific paid job that the patient would like to obtain. Then they both proceed through a systematic review of the skills needed for the job, the skills the patient has, and the resources available to improve these skills. A plan is defined that usually takes, 1 or 2 years to implement. This model may be most helpful for younger, less disabled patients who have a prospect for long-term career choices.

The transitional employment program (the train-and-place model) is exemplified by Fountain House, one of the oldest rehabilitation programs in the United States. Initially, the patient's work aptitudes and preferences are assessed. Next, patients are taught general work habits (e.g., appropriate appearance, keeping hours, asking for clarification, following through). Then patients start working in a sheltered program that is usually owned by the rehabilitation agency, learning more specific skills like typing, filing, janitorial work, or maintenance routines. Once a certain level of competency has been consistently maintained for a period of time, they are placed in a regular job. Many of the most severely disabled patients with schizophrenia are incapable of moving beyond the sheltered workshop level. The transitional process of training, sheltered work, and placement appears to reduce stress related to the demands of employment.

Supported employment is the most recent approach. It attempts to improve the opportunities for competitive employment by referring the patient to a regular job that is intended to be permanent. Unlike in the transitional model, the job identified for the patient is not owned by the rehabilitation agency. The patient's skills and a job that matches these skills are identified and the patient begins to work. The goal is for the patient to develop the necessary skills while working, getting on-site support and training from a work coach. This on-site job training was developed for developmentally disabled individuals who require initial high-intensity services that are later phased out. For persons with schizophrenia some form of continuous long-term on-the-job training may be needed.

Outcome research for these vocational rehabilitation programs is particularly limited by the lack of standardization of the experimental intervention and the difficulty in implementing adequate control treatments. Another limitation is that in these studies patients are not usually differentiated diagnostically, but lumped as chronically mentally ill or psychiatrically disabled. Also, the adequacy of pharmacological treatment is generally assumed. Various vocational outcome measures are used: job performance and satisfaction, earnings, percentage of time employed, and maintenance of a full-time or part-time job or competitive employment. Full-time competitive employment is the most desirable outcome measure. A meta-analysis on 19 controlled studies of various vocational rehabilitation interventions found a 51 percent rate of paid employment in the experimental group compared to 29 percent for the control group, a significant difference. There were additional advantages for vocational rehabilitation in terms of job starts and longer duration of employment. In none of the studies did the outcomes favor the control interventions. Nevertheless there were no differences in terms of competitive employment in any of the studies after the patients were discharged from the programs. The success of these interventions has been mostly to help patients to adapt to a specific transitional or sheltered employment, but they have failed to prepare them for future regular employment.

Results from two recent studies involving supported employment provide a more hopeful outlook. In a quasiexperimental study in New Hampshire researchers compared vocational outcomes in two groups: patients involved in a traditional partial hospitalization program and those assigned to an integrated program of supported employment and intensive case management. During the follow-up year the experimental group significantly increased its rate of competitive employment by 14 percent while there was no improvement in the control group. In another study, researchers in Indiana compared two forms of supported employment programs: one with gradual entry and the other with accelerated involvement in the job. The accelerated-entry patients showed significantly superior outcomes in competitive employment at 1-year follow-up (56 versus 29 percent).

Several vocational rehabilitation studies have also measured other clinically relevant outcomes, like rate of hospitalization, medication compliance, and substance abuse; most of these studies find advantages for the experimental treatment. Nevertheless, a causal relationship cannot be inferred from these studies because they all fail to describe other important clinical interventions and patient characteristics.

In summary, vocational rehabilitation programs by definition enhance job-related activities in chronically mentally ill patients (including persons with schizophrenia), but they do not have significant effects on competitive employment once the patient leaves the program. However, there is reason for optimism with some forms of supported employment.

CASE MANAGEMENT

Patients with schizophrenia are often ill prepared to find and maintain proper use of the multiple services they need in order to function in the community. The providers of these services include psychiatrists, nurses, pharmacists, general practitioners, dentists, psychologists, social workers, vocational and recreational therapists, home supervisors, patient advocates, lawyers, and benefits officers. Case managers function at two ends of a continuum: the broker approach and the intensive case management approach.

At a minimum, case managers function as brokers of services and are contacted by other professionals. Case managers identify a new need for the patient and referring the patient to the provider able to deliver these services. This approach may be sufficient for patients with physical disabilities and for some patients with mental illness of moderate severity. Unfortunately, many patients with schizophrenia lack the level of cognitive and social competence to consistently follow through and get their needs met. The polar opposite of the case-manager-as-broker is exemplified by the Assertive Community Treatment (ACT) program. Originally developed by researchers in Madison, Wisconsin, in the 1970s, this is the most carefully defined, well-documented, and successful program for the delivery of services for persons with chronic mental illness. Patients are assigned to one multidisciplinary team (case manager, psychiatrist, nurse, general physician, etc.). The team has a fixed case load of patients and delivers all services when and where needed by the patient, 24 hours a day, 7 days a week. This is a mobile and intensive intervention that provides treatment, rehabilitation, and support activities. These include home delivery of medications, monitoring of mental and physical health, in vivo social skills training, and frequent contact with family members. There is a high staff-to-patient ratio (1:12, compared to 1:30 in traditional case management models). The original study from Wisconsin followed chronically mentally ill patients assigned to the ACT program and compared them with a group discharged from the hospital to standard community care. After 14 months the ACT group showed significant advantages in rates of hospitalization, sheltered employment, independent living, family burden, with essentially no difference in costs. Unfortunately, the advantages were lost after the patients were discharged from the experimental program; there is no present data on the minimum intensity needed for the program to maintain gains or which special population of patients may require continuous services. There have been several replications of the effectiveness of the ACT program in reducing total number of days in the hospital and increasing patient and family satisfaction. Nevertheless, most studies have failed to document improvement in employment, social functioning, and other measures of quality of life. Because of the comprehensive services provided by the ACT program and the lack of adequate controls, it is unknown whether the reduction in hospitalization is due to improved medication compliance, continuity of caregivers, 24-hour coverage, site of service, intensity of services, therapeutic alliance, or a combination of any of these elements. Neither is it known whether ACT is more cost effective than another high-intensity system that does not use multidisciplinary teams with constant availability. Preliminary results are available from a randomized study from Connecticut that compared the ACT program with a program of high-quality brokered case management (two-thirds of the patients were diagnosed with schizophrenia or schizoaffective disorder). In the control intervention, patients had access to mobile crisis services, supported housing, respite services, vocational programs, clubhouses, and outpatient psychiatric clinics. Case managers were responsible for brokering instead of directly providing any of these services. Results show that after 18 months the control group spent twice as much time in the hospital (14.3 percent versus 7.6 percent) as the ACT group. There was also a significant advantage for the ACT group in terms of percentage of time spent in an unstable living situation (11.6 versus 16.9 percent); data on cost effectiveness is not currently available.

In summary, ACT programs can effectively decrease the risk of rehospitalization for chronically mentally ill patients in general and persons with schizophrenia in particular but the beneficial effects do not extend to measures of social functioning. The issue of cost effectiveness will not be settled until a systematic effort is undertaken to identify the essential elements of the ACT program.

RESIDENTIAL TREATMENT AND HOUSING PROGRAMS

Patients with schizophrenia often need supportive housing. They can sometimes reside with their families, but eventually most patients will need other forms of permanent housing. Since deinstitutionalization, housing options for the chronically mentally ill have used a linear continuum paradigm. According to this view, patients are placed in different housing programs following hospitalization, beginning with the most controlled, supervised, and hospital-like setting, and moving down in a progressive fashion to the least restrictive, regular–household-like settings. These housing programs have received numerous names, but they basically vary depending on the level of staff supervision, the length of stay, number of residents, and whether other services in addition to housing are provided (e.g., vocational rehabilitation or recreational activities). For patients who are at imminent risk of relapse or in the initial stage of decompensation, *crisis care centers* may be particularly helpful. These have a 24-hour nursing staff and are supervised by a psychiatrist. Patients are in a more controlled environment where symptom progression and risks can be assessed and medications delivered; no vocational or other rehabilitative services are provided. Length of stay is usually limited to 30 days and disposition is either to a hospital or to a nonclinical residential type of program. *Transitional half-way houses* provide a supportive environment for patients recently discharged from the hospital who require some limited level of clinical supervision, such as dispensation of medication. By definition, length of stay is limited to a few months and patients are then placed in some form of long-term housing. Persons with schizophrenia who have pervasive disruptive symptoms that interfere with daily living skills or are associated with potentially dangerous behavior may require *long-term group residencies*. These often have 24-hour-a-day on-site supervision, usually with minimal clinical services. Their length of stay is between several months and years and no rehabilitative services are provided. *Cooperative apartments* typically house a small number of patients who do not require on-site supervision. *Nursing homes* are a long-term housing and clinical care option for severely disabled individuals who require daily nursing care. *Boarding homes* are usually remodeled apartment buildings that only provide room and board for persons with some form of disability; there are no clinical or rehabilitative services but there is often some minimal supervision. *Foster care homes* are owned by private citizens who agree to house psychiatricaly disabled persons for a fee; the match between patient and provider is particularly important.

Two other well-known centralized programs which provide housing in addition to various rehabilitative services are the Fairweather Lodge and Fountain House. The Fairweather Lodge was conceived in California in the 1960s with the goal of reducing the revolving-door cycle of chronically mentally ill patients who improved while hospitalized but were unable to remain in the community for long periods of time. As originally conceived, a small group of hospitalized patients is taught a variety of skills for daily living. They are encouraged to work together and are eventually discharged to live in a community lodge that serves the functions of housing, socialization, and work; the lodge frequently operates its own business. The basic philosophy is that patients will help rehabilitate themselves while functioning as a family. Although initial controlled studies found advantages in rehospitalization and employment, these have not been replicated—partly due to the difficulties in implementing the original model. With the current limitations on length of hospital stay, this model may be an option only for a minority of patients.

Fountain House was started in New York in the late 1940s not just as a housing option but as a full rehabilitative program in which patient involvement and self-help are emphasized, with support from staff as needed. One component of the program is the clubhouse, which provides opportunities for socialization while functioning as a transitional workshop; the patients learn clerical, maintenance, and food preparation skills while working. There are no controlled randomized studies on the effectiveness of this approach but some uncontrolled studies have found beneficial effects on employment. A new paradigm on housing for the chronically mentally ill, *supported housing*, aims toward further patient reintegration in the community while minimizing stigmatization. This approach is analogous to the concept of supported employment. Patients are encouraged to live in small groups in regular homes in the community. The basic concept is of housing as a normal living environment, not as a setting for services administered by an agency. Patients are not placed but are encouraged to choose a particular home that suits their needs. Long-term support by staff is available but not on site. It is not yet clear for what group of patients and at which point in the course of the illness supported housing will be most beneficial.

Textbook of Psychiatry

12.10 SCHIZOPHRENIA: INDIVIDUAL PSYCHOTHERAPY

WAYNE S. FENTON, M.D. AND THOMAS H. MCGLASHAN, M.D.

No single treatment can ameliorate the myriad symptoms and disabilities associated with schizophrenia. As articulated in the American Psychiatric Association's *Practice Guidelines for the Treatment of Patients with Schizophrenia*, therapeutic efforts must be comprehensive, multimodal, and empirically titrated to the individual patient's response and progress. While there is at present no cure for schizophrenia, the skillful application of pharmacological, psychotherapeutic, rehabilitative, and community support interventions can limit illness morbidity and mortality, improve patient outcome, and enhance quality of life.

As with individuals with other long-term medical disorders, many patients with schizophrenia will need comprehensive and continuous care over prolonged periods. To the extent that both biological and psychosocial factors are crucial determinants of the course and outcome of schizophrenia, a psychiatrist may be in the best position to coordinate and integrate the various treatments required and provide continuity of care over time.

Each component of a comprehensive treatment plan for a patient with schizophrenia targets specific aspects of the disorder and its common sequelae. Pharmacological interventions target positive, negative, and disorganized symptom domains; mood symptoms; and cognition. Rehabilitation efforts target deficits in self-care, social or vocational skills, and provide structure in the form of someplace to be and something productive to do. Access to appropriate entitlements, treatment services, housing, and social support are the goals of community support programs. Individual psychotherapy addresses the human aspects of adaptation to a serious psychiatric disorder and targets problems such as denial, demoralization, treatment compliance, personal relationships, and self-esteem. Its focus is on understanding the patient's beliefs, attitudes, aspirations, and experiences. The coordination, timing, and titration of all specific treatment elements is informed by this understanding and by an ongoing assessment of individual patient needs that can often best be achieved within a long-term physician-patient relationship.

Individual psychotherapy is defined most broadly as a professional relationship in which the technical expertise of the physician is directed toward promoting the patient's recovery or toward relieving suffering. At a minimum this physician-patient relationship provides the context in which symptoms and disabilities are assessed, consent and collaboration for treatment obtained, and the effects of interventions are evaluated. More ambitious goals, appropriate for selected patients in settings where time and resources allow, can include the exploration of maladaptive patterns of living through careful scrutiny of relationships with others and the therapeutic relationship itself. Most psychotherapy, as actually practiced, falls somewhere in between, requiring from the therapist a broad base of medical and psychological skills. A psychiatrist providing psychotherapy for schizophrenia patients should probably be prepared to give an intramuscular injection one day, interpret transference the next, and give a patient a ride to work on the third.

Some form of individual psychotherapy in combination with pharmacological treatment is the most common care offered to patients with schizophrenia. Psychodynamic and biological conceptions of schizophrenia have yielded the two distinct therapeutic traditions of investigative and supportive psychotherapy. Current practice represents an amalgamation of these approaches that is best described by *flexible psychotherapy*. This approach draws upon perspectives and techniques derived from each of these traditions to accommodate the heterogeneity of schizophrenia and the individuals who suffer from it.

HISTORY

In the early decades of the twentieth century schizophrenia was viewed as an irreversible and untreatable process. “Organic” psychiatry as represented by Emil Kraeplin saw schizophrenic personality disintegration as an inevitable product of neurological deterioration. Sigmund Freud, representing the mainstream of psychoanalysis, considered dementia precox to be a “narcissistic neurosis” where “libido” was directed inward, away from others. As a result, transference and hence analytic treatment was considered impossible. In this context, the diagnosis of dementia precox most often led to therapeutic nihilism and the recommendation of life-long institutional care.

Despite the misgivings of classical adherents to Freud, individual psychotherapy for schizophrenia in the United States originated as a modification of psychoanalysis. Early psychoanalysts such as A.A. Brill advocated an active effort to promote “rapport” and arouse patients' interest in their own malady. He described providing direct advice about work and relationships, visiting a patient at home, providing didactic reading material, and at times frankly labeling false beliefs as delusions. In time, he observed that confidence in and a “passive attachment” to the physician can develop so that the latter might become a bridge between the patient and reality.

Between 1922 and 1930 Harry Stack Sullivan ran a small treatment unit for male schizophrenia patients at Sheppard and Enoch Pratt Hospital in Towson, Maryland. He was influenced by the early psychobiological perspectives of Adolph Meyer and William Allison White, who emphasized that personality was influenced by life events not only in childhood, but over the entire course of development. Based on his intuition that like cures like, Sullivan staffed his unit with sensitive, shy, and introverted male attendants who possessed a natural proclivity and ease of rapport with withdrawn patients. Stressing that patients' difficulties were similar to those of so-called normals, Sullivan promoted the development of closeness or benevolent intimacy in this milieu. He observed that providing an experience of reciprocal trust—which he hypothesized many patients had lacked during important periods of development—could be beneficial by allowing a “validation of all components of personal worth.”

Careful observation of the difficulties his patients had in maintaining relationships led Sullivan to formulate the paradigm of interpersonal psychiatry. He de-emphasized the prevailing psychoanalytic view that personality was formed and behavior motivated by drives pressing for expression from within. Instead, he recast psychopathology as difficulties in living arising largely from personal and social relations, and as personality warps thought to be the lasting residue of earlier unsatisfactory interpersonal experiences. Over a period of years Sullivan elaborated these ideas in a series of seminars at Chestnut Lodge Hospital in Rockville, Maryland, where, under the leadership of Dexter Bullard, a group of psychoanalysts and social scientists interested in the intensive study of schizophrenia assembled during the 1940s. There the influence of interpersonal patterns among patients and between patients and staff were observed to have a powerful impact on patients' psychopathology. Covert tension and disagreement among staff, for example, often appeared to be associated with worsening of patients' psychotic symptoms; likewise, improvement followed when those tensions were resolved. Such observations drew attention to the influence of psychosocial factors on schizophrenia and raised the notion that the disorder might be caused and potentially cured by psychosocial means.

Drawing upon her European psychoanalytic background, her mentorship with Sullivan, and her clinical work with psychotic patients at Chestnut Lodge, Frieda Fromm-Reichmann integrated the available knowledge concerning the intensive psychotherapy of schizophrenia into a relatively comprehensive body of theory and technique. Her seminal work, *Principles of Intensive Psychotherapy*, articulated a modified form of psychoanalysis that was applicable to patients with severe mental illness, including schizophrenia. The ideas embodied in her writings and clinical work also represent the first elaboration of what became known as *intensive psychodynamic psychotherapy*.

The predecessors of ego and self psychology, interpersonal psychiatry and psychodynamic psychotherapy became dominant paradigms in American psychiatry in the 1940s and 1950s and beyond. Their hopeful and humanistic perspectives were adopted by many influential psychiatric treatment centers. Intensive individual psychotherapy came to be viewed as the treatment of choice and at times the only effective treatment for schizophrenia. Its practitioners kept the field's interest focused on severely ill patients during the decades prior to the widespread availability of effective pharmacological treatments. Exposure to a second generation of charismatic teachers and clinicians (e.g., Otto Will, Steve Fleck, Elvin Semrad, and Harold Searles) kindled interest in treating and studying schizophrenia among countless psychiatric residents and trainees throughout the country.

INVESTIGATIVE PSYCHOTHERAPY

Perspectives derived from the tradition of investigative psychotherapy are of value in understanding the psychological aspects of the disorder and in managing commonly encountered difficulties in forming and maintaining a therapeutic relationship. A review of the voluminous clinical literature in this area suggests that differences in language and terminology notwithstanding, a consistent orientation and approach has been articulated. This can be outlined in terms of the nature of investigative psychotherapy, the nature of schizophrenia from the psychotherapist's point of view, elements of the psychotherapeutic situation, general technical interventions, and general technical attitudes.

INVESTIGATIVE PSYCHOTHERAPY

Sullivan defined the psychiatric interview as a two-person transaction, more or less voluntarily initiated on a progressively unfolding expert-client basis. Its purpose is to elucidate the patient's characteristic patterns of living, the revealing of which is assumed to be useful. The psychotherapeutic encounter is an actual interpersonal experience in which the doctor and patient are both participant observers. According to Fromm-Reichmann, the goal of intensive psychotherapy is alleviation of the patient's emotional difficulties and elimination of symptoms. This is accomplished by undertaking a thorough scrutiny of the patient's life history (especially the history of interpersonal relationships), reviewing in close detail the realities of the patient's current relationships and life situation, and understanding the genetic (historical) roots and current ramifications of maladaptive interpersonal patterns as reflected in the doctor-patient relationship and in daily life. Important emotional experiences related to the patient's difficulties are assumed to have been forgotten and their recovery during the therapeutic process is expected. This process is expected to result in the modification of maladaptive interpersonal patterns and personality growth.

Schizophrenia The literature on intensive psychotherapy emphasizes the influence of the environment and learning in the etiology of schizophrenia. Characteristic difficulties in interpersonal relations among schizophrenia patients are said to include a basic mistrust of and expectation of harm from others, marked ambivalence in relationships with endless oscillations between longing for merger based on intolerance of loneliness and withdrawal and isolation based on terror of closeness, weak or absent ego boundaries with resulting difficulty differentiating one's own thoughts and impulses from those of others, the absence of a sense of self often compensated for by an effort to ascertain the expectations of others and mold oneself accordingly (false self) or alternatively to organize in fixed opposition to the wishes of others, a pervasive posture of passivity (things happen to one and others are the cause of all difficulties), fear that strong emotional arousal of any sort (anger, pleasure, wants, desires) will escalate uncontrollably and lead to panic or catastrophe (with compensating constriction and repression of drives or affects and resultant inability to express affects or desires to others), fragmented or idiosyncratic thinking, frequent misinterpretation of the motivation of others, and an antipathy towards reality with intolerance of frustration and withdrawal into fantasy.

Extrapolating from these aspects of schizophrenic psychopathology, most early proponents of intensive psychotherapy postulated real or fantasized negative first experiences between the infant patient and primary caregivers. This was thought to result in a central unconscious conflict described as “that of a small child dependent on a person by whom he feels persecuted and who is, in his opinion, unstable and uncertain,” as described by Lewis Hill. This position represents the patient's conviction concerning the nature of human relationships and it dominates all thoughts, feelings, and behaviors. Regrettably, psychodynamic theorizing regarding the cause of schizophrenia often devolved into blaming the parents for causing their child's illness. Despite the lack of any credible scientific evidence to support these theories, for a period they were widely and uncritically accepted. Now rejected as invalid, psychodynamic etiological explanations of schizophrenia have left a legacy of mistrust between families, patients, and psychiatry. Clinical descriptions deriving from that era, however, continue to be of value in enriching clinicians' understanding of schizophrenia patients' subjective experience, and may allow clinicians to anticipate the impact of life events and important relationships on the patient's course of illness.

A developmental perspective and hierarchical model of the mind is implicit in the clinical theory underlying intensive psychotherapy. Although a variety of specific developmental schemes has been offered, most suggest some version of the following phases in emotional development: (1) autistic phase during the first weeks of life in which the presence of others is not recognized, satisfaction of biological needs is hallucinated, and only undifferentiated states of anxiety or activation and satiation are present; (2) symbiotic phase in which a boundaryless state of bliss is present with an empathic caregiver who can anticipate and fulfill all needs—successful completion of this phase is thought to form the substrate of basic trust; (3) separation-individuation phase beginning with the ability to ambulate, when the image of the good-enough caregiver becomes progressively internalized, allowing a feeling of security during physical separations. Early in this phase experiences of frustration with the caregiver are emotionally separate from experiences of satisfaction and the respective good object and bad object seem like different people. Aggression and anger deriving from frustrations are projected onto and attributed to the bad object. The good-enough caregiver accepts these projections without responding with excessive retaliatory anger or anxiety and thus contains and soothes the frustrated child. These experiences of containment or holding form the basis for children's later capacity to soothe themselves, modulate affect, and become comfortable with emotional arousal. By the end of this phase cognitive and emotional development allow for recognition that the frustrating and satisfying caregiver are indeed the same person (libidinal object constancy), a recognition that forms the basis of seeing others as separate and complex individuals; (4) Oedipal phase, which is the major focus of psychoanalysis with patients who have neuroses. This involves the mastering of triadic relationships, competitive urges, and identifications with the same-gender parent.

Although no writers about intensive psychotherapy consider the schizophrenia patient's mental functioning as equivalent to that of an infant, more primitive adaptive levels of functioning derived from early phases of development are considered to be ever present, hierarchically underlying more sophisticated adaptive levels acquired later in development. During states of psychotic regression, developmentally primitive states of mind are thought of as gaining ascendancy while higher capacities are temporarily lost. Nonetheless, the retention of some nonpsychotic functioning is assumed, however sick the patient is.

Psychotherapeutic Situation: Participants Although the characteristic difficulties of schizophrenia patients have been elaborated at length in the literature, attributes of the optimal psychotherapist are less well defined. Among those cited as important are an interest in and capacity to tolerate intense affect, dependency, confusion, and ambiguous communication. Basic respect for the patient is a prerequisite, especially respect that stems from a conviction that the patient's problems are not too different from one's own. Aloofness, rigidity, and critical pomposity are especially discouraged. Psychotherapists should be flexible, creative, and willing to admit when they are wrong. The match between patient and therapist is thought to be central, but defies easy categorization. Many authors emphasize that a physician working with schizophrenia patients must possess sufficient self-esteem and sources of satisfaction in his or her nonprofessional life to avoid using the patient to meet personal needs for admiration or prestige.

Setting Intensive psychotherapy must be conducted in a setting of mutual safety. Within an organized care setting, the milieu must be ideologically supportive. Frequency of visits can range from one to five per week. Use of the couch and free associations as in psychoanalysis are discouraged as aggravating disorganization and thought disorder. As part of creating the setting for individual psychotherapy, the therapist endeavors to achieve an early consensus with the patient regarding the nature of the latter's problems, the treatment required, and the rules governing therapy.

Process Process elements in the psychotherapy of schizophrenia refer to expectable developments in the doctor-patient relationship as it evolves over time, including transference and countertransference. The management of these is considered central to the therapeutic endeavor. *Transference* broadly refers to the manner in which the perception of others in the present is shaded or distorted by important past relationships. It is thought of as a natural but often unconscious aspect of all human relationships. Examining transference as it develops and unfolds in the doctor-patient relationship is a major task in investigative (as opposed to supportive) psychotherapy—this examination is expected to be useful in allowing patients to better understand their current difficulties and respond more realistically and productively to people in their current life. It should also facilitate the recall of memories that may be accessible only through their recreation in the transference relationship.

In nonpsychotic transferences the patient perceives or responds to the therapist as if the latter resembled some other important figure from the patient's past. The patient retains the capacity to recognize these as misperceptions, to separate real aspects of the therapist from distorted aspects, and to trace the distortions back to their origin in past experiences.

James, a shy and isolated young man with schizophrenia treated as an outpatient with intensive psychotherapy and medication, was able to begin classes at a local college. Many years earlier he had first become ill and was hospitalized a few days after leaving home to attend college far from his family. An avid reader, he had long dreamed of returning to school to study English literature. As the semester progressed James became increasingly self-conscious and despite a good midterm grade began talking about dropping the course. Wishing to see his patient succeed, James' young male therapist agreed to drive him to class first once, then three times a week. To the therapist's surprise, after several weeks John's resentment erupted in a tirade about not wanting to be forced to go to class so his therapist could look good. Discussion led to recollections of the daily struggles James had had when he became afraid to attend class in junior high—at that time his resentment and school refusal had led to physical altercations with his parents at the front door. The therapist pointed out the similarity between John's past and current reactions and noted that while all parents take pride in their children's success, it was doubtful that this was his parent's principal motivation in pushing him to attend school. Patient and therapist realized that at present it had been James' idea to go to class, and that he would have to decide whether or not to continue.

The capacity to recognize earlier experiences as the source of current distortions is often absent or lost in schizophrenia, leading to transference psychosis in which the patient believes or behaves as if the therapist actually is, or is like, some figure from the past.

Frances, a woman in her 20s with paranoid schizophrenia, had been raised in a neighborhood that she claimed was kept safe and orderly by organized criminals. Furious at her family for having committed her several months earlier she claimed to have no psychiatric problems whatsoever, adamantly refused antipsychotic medications, and complained that her family had bribed the police to lock her up. Despite her extensive denial, she attended scheduled outpatient appointments with complete reliability. After several months, however, Frances began accusing the therapist of spreading the rumor that she was a prostitute and having the police follow and harass her. She called the Mayor's office to report that the therapist was taking bribes and, expecting retaliation, left the therapist's office threatening to harm herself. The therapist, who for weeks had adamantly tried to reassure the patient that he was not having the police follow her, found himself needing to obtain their assistance to arrange for the patient's detention and emergency assessment.

Transference is at times an inevitable and unavoidable development in intensive psychotherapy, including transference psychosis. Nonpsychotic transference can usually be resolved with time, support, and interpretation. Psychotic transference is more difficult to remove and a therapeutic relationship must often be developed that can accommodate this distortion while remaining useful to the patient.

Countertransference refers to all the therapist's thoughts and feelings about the patient. Some of these are distortions arising from the therapist's personal past, but others derive largely from current interaction with the patient. Feelings that arise in work with schizophrenia patients can be particularly intense and uncomfortable, and may include discouragement, fear, worthlessness, hatred, contempt, guilt, rage, envy, or lust. In view of this, awareness of countertransference and the ability through introspection to understand its sources are crucial functions for the psychotherapist.

Countertransference can often serve as an important source of information about the patient's state of mind, particularly in patients who are unable to talk.

John was a recently hospitalized, mute, schizophrenia patient. Moments after seating him for an initial psychotherapeutic interview, the therapist found himself feeling trapped and terrified by the sudden recognition that John, with a paranoid glare, was on the verge of assault. After ruling out a run for the door as too risky, the therapist looked at John and asked: “Are you afraid of me?” “Yes,” indicated a perceptibly relieved patient, “I think something bad is going to happen and you're part of it.” “Well, you're scaring the hell out of me,” said the therapist. Now appreciably calmer John said, “I'm sorry,” and a conversation ensued. Some time later John explained that on the day of his arrival he felt he had been brought to the hospital to be executed and expected at any moment to be shot in the head. Parenthetically, the therapist learned to conduct initial assessments of hospitalized patients in a place where help could be more readily obtained if needed.

The therapist's reaction may also serve as a good barometer for understanding how others typically react and respond to the patient:

Mary, a woman in her 30s, complained bitterly to her female therapist about weakness, fatigue, and an inability to function that she steadfastly attributed to her medications. Try as she might, the therapist's efforts to respond to these complaints, by changing medications, offering advice (such as exercise), and reframing the complaints amounted to nothing. Fed up with complaints that she “didn't understand,” the therapist was herself left feeling useless, angry, and very tempted to tell the patient to quit complaining and take some responsibility for herself. The therapist remembered, however, that for the past year Mary had had no contact whatsoever with her sister after the latter told Mary to quit complaining and try to make something of her life. Many of Mary's relationships with friends had ended with recriminations about their lack of sympathy and understanding.

Finally, successful management of countertransference allows the therapist to create a holding or containing relationship with the patient that is postulated to be central to the mutative action of psychotherapy.

Frank, a schizophrenia patient in his early 30s who lived in the community, had enormously ambivalent feelings about his 20-hours-per-week job as a dishwasher at a nearby hotel. Frank often found his interaction with co-workers stressful and was prone to avoid work; he was also plagued by unrelenting guilt about his inability to move up to full-time work on any sustained basis. Frank's father often reinforced this view by telling him that his illness amounted to little more than laziness, and that with will power and a strong character Frank should certainly be able to handle a full-time job. Over a period of years a clear pattern in Frank's illness was detectable: Frank would work part-time and be stable for a period. Driven by his guilt, he would increase his work hours. The stress and overstimulation of the heavier work schedule would lead to an exacerbation of symptoms and finally a fullblown relapse. He would have to quit work altogether for a period, seek a new part-time job, and the cycle would begin anew. During Frank's relapses, his primary symptom was the delusional fear that he would be “damned” and persecuted for his moral weaknesses.

Over years of outpatient psychotherapy, Frank's interactions with his therapist about work (the therapist himself being something of a workaholic) were of great interest. Whenever Frank contemplated missing a day's work (and there were many such times) he would call the therapist at home the evening before for permission, often presenting the flimsiest of excuses and rationales about why he should not work the next day. Receiving these calls late in the evening (when he himself was still working) the therapist often felt the intense urge to tell Frank to shape up, be a man, show some character, and quit acting like a little work would kill him. Recognizing this urge as countertransference (derived in part from Frank's seemingly unconscious effort to recreate his relationship with his father with the therapist, the therapist was largely able to refrain from such moralistic admonishments, discuss matters calmly, and allow Frank to decide on his own about work the next day.

Over a period of years Frank came to realize that his illness was something real rather than a moral weakness. With this realization he was able to accept the fact that for him, full-time work was probably not going to be possible. The frequent relapses ceased and Frank was able to sustain longer periods of stability. The therapist felt that his recognition of countertransference allowed him to “hold” Frank's self-loathing about his work disability and reflect this back to Frank in a more benign manner—without being overly accusatory or moralistic. To the therapist this seemed to be an important factor leading to Frank's more benign and accepting view of his own disabilities.

Transference and countertransference tend to mirror each other at any given time, and over the course of treatment a range of transference and countertransference configurations are traversed. These may recreate earlier developmental epochs. For example, typical configurations can include (1) an autistic relationship in which the patient does not express the slightest interest or even recognize the existence of the therapist—the therapist in turn feels devalued as a nonhuman object; (2) the idealizing, symbiotic interaction in which the therapist is perceived by the patient as an omnipotent, protective, and loving figure and negative feelings are projected onto others outside the dyad; here the therapist is likely to feel that he or she alone can truly understand this patient, whose problems clearly stem from the insensitivities of others; (3) the hostile, paranoid relationship in which the therapist is perceived as a bad object, untrustworthy, engulfing, and intent on harming the patient; here the therapist often feels hatred and rage at the patient's accusations and is tempted to become defensive or retaliatory, thus fulfilling the patient's expectation of others as untrustworthy.

General Technical Interventions The literature on intensive psychotherapy describes categories of interventions that roughly correspond to different phases of therapy. Although these tasks and strategies may be relevant at any point in treatment, they are often ordered sequentially: (1) establishing a relationship with the patient, (2) elucidating the patient's experience in the here and now, (3) tolerating the mobilized transference and countertransference, (4) integrating the patient's experiences into an expanded perspective of the self, and (5) working through. If therapy progresses, the accomplishment of earlier tasks allows greater attention to

be paid to subsequent ones.

Establishing a Relationship With the Patient Because of suspiciousness, disorganization, indifference, or ambivalence about human attachments, establishing a relationship with the schizophrenia patient can be challenging. Analytic strategies of passive neutrality and anonymity can easily be misinterpreted as disinterest or dislike and are generally discouraged. Consistency, straightforwardness, and an active effort to establish rapport are advocated. Within bounds, a reasonable degree of self-disclosure on the therapist's part can help to counter distortions by allowing the patient to get a fix on the therapist as a person. A relationship should be sought on the patient's terms. If the patient initially wants the therapist only to meet some immediate need (e.g., to secure discharge from a hospital or intervene with the patient with family) this is taken as the starting point and viewed positively as a sign that the therapist is seen as potentially useful. At times, engaging in activity (walking or playing a game), finding a neutral topic of common interest (sports, music), or placidly accepting periods of silence will further promote establishing a relationship. Creativity and patience are the only rules.

If the initial encounters are traversed successfully, a background feeling of security and predictability will increasingly characterize the therapy.

> After summoning the police to have Frances detained and committed, her therapist decided that transfer to a new doctor would probably be best: after all, how could this patient ever trust a therapist who, confirming her worst fears, had her picked up by the police? Wanting some closure before transferring the case, the therapist drove to the state hospital where Frances had been committed to visit her. To his surprise, the patient greeted him warmly and thanked the therapist for going out of his way to visit her. With second thoughts about transferring the patient, the therapist agreed that they would meet at his office after Frances's discharge. Discharged from the hospital on long-acting antipsychotic medication, Frances arrived as scheduled for her outpatient appointment. The therapist acknowledged the awkwardness of meeting again at the site of their last acrimonious encounter. Both patient and therapist agreed that avoiding future hospitalizations would be a common goal. Although, if asked, Frances still denied any psychiatric difficulties, she agreed to continue medication to keep her family and the doctors “off her back.”

At times, a more engaging style can promote the establishment of a relationship. Some have advocated active participation or playing with a patient's communications or symptoms as a means of capturing their attention.

> Despite trials of a variety of treatments Tim, a patient in his mid-30s, often contended that he was in continuous and intensive training by “security forces” to unite world nationalities under one government. His therapist suggested he call a summit of world leaders to further this plan. After an extensive discussion that included consideration of the site of such a meeting, logistics, security, and arrangements for translators, Tim cracked a smile; although he continued to be preoccupied with messages he received from “security forces” the world summit became an inside joke between doctor and patient.

Intellectual conversation can obscure important emotional reactions, but may be promoted to further the goal of establishing a relationship; it can also provide a patient whose self esteem has been damaged the opportunity to exercise areas of competence.

> Donna, a 27-year-old woman, experienced an acute psychotic episode during her second year as a graduate student in comparative religion at a first-rate university. While hesitant to discuss the events leading to her hospitalization, she easily discussed the papers she had to complete to secure readmission to the program. Impressed by Donna's vital engagement with the subject and her ability to present it in a compelling manner, for several weeks the therapist took on the role of a uninformed student glad to receive a survey of comparative religion from such a competent teacher. The therapist felt that acknowledging the patient's intellectual ability and expertise in comparative religion made it considerably easier for the patient to later accept the therapist's expertise in medicine and psychiatry.

Elucidating the Patient's Experience Elvin Semrad viewed the three core tasks of psychotherapy as helping the patient acknowledge, bear, and put into perspective feelings and painful life experiences. Acknowledging the patient's feelings and painful experiences in the present becomes particularly pertinent once a relationship has been established. Acknowledging first requires elucidating affects. Strategies for elucidating include listening, narrowing the focus, seeking concrete detail, acknowledging feelings (especially of loss, anger, sadness), and naming or labeling affects. The therapist may act as a comforter, inquisitor, or teacher, conveying to the patient that experiencing feelings will neither overwhelm the patient nor hurt others. Psychotic symptoms, when expressed, are considered to signal an affective reaction to some actual event that patient and doctor do not yet understand. Examining the patient's day-to-day life in detail will allow the therapist to develop a more vivid picture of the patient's difficulties, frustrations, and characteristic reactions to others. The aim is to help the patient better organize and communicate, to guide the patient into sharpened conceptualizations, and to promote tolerance of life experience as it is.

If successful, therapist and patient will share a common language with which to communicate about the latter's difficulties and increasingly the patient will independently report important life events and emotional reactions to them.

> During a therapy hour, John, a patient in his 20s with treatment-resistant schizophrenia reported that under his control, a nuclear attack had just been launched in Europe and that as he and the therapist sat, millions of people were being killed. With single-minded persistence, despite John's evasive disorganization, the therapist attempted to find out what John had been doing that morning before his therapy appointment. The therapist was able to piece together that immediately preceding the “nuclear attack” John had been listening to the radio and another patient on his unit had changed the station without asking. The therapist suggested, and John acknowledged, that this had made John a bit irritated. The therapist suggested that perhaps there was a connection between John's anger at his peer and his current concern with millions being killed. The therapist wondered whether next time something like that happened it would be possible for John to temperately register his protest to his peer. John indicated this was out of the question—he did not want to be tried for murder. The therapist indicated that in his view, a mild protest was quite different from murder.

Tolerating the Mobilized Transferences and Countertransferences Tolerating affects, transference, and countertransference corresponds to Semrad's concept of “bearing” painful feelings that have been acknowledged. Tolerance is achieved first by the therapist and then, through example, by the patient. Here the concept of “holding” or “containment” is relevant and is thought to be central to the mutative effect of psychotherapy. By means of *projective identification* the patient is thought of as putting negatively valenced affects and self-representations into the therapist who, by processing these feelings in a more mature way, contains, holds, or metabolizes them and makes them palliatively available for reinternalization by the patient. More simply stated, patients experience themselves being accepted, negative emotions and all, and learn from the therapist's example to become better able to accept unwanted aspects of themselves. Thus, patients' identification with the therapist and their functioning is seen as a major factor in the therapeutic action of psychotherapy.

> Having exhausted her ability to respond constructively to Mary's unending complaints, the therapist found herself viewing Mary with contempt and derision, comparing her unfavorably to patients with severe physical disabilities who had struggled courageously to accomplish goals despite their disability. Upon reflection, the therapist became vividly aware of the manner in which Mary's view of herself as the victim of other people's insensitivity had become a self-fulfilling prophesy. Mary's inconsolable complaining was so irritating that these accusations, if not true today, would be true tomorrow: the therapist or anyone else who had to deal with Mary would soon find themselves irritated and would run out of patience. Concluding that Mary's own feelings of incompetence and self-hatred had been projected onto her, the therapist found her contempt for Mary tempered by a better understanding of Mary's suffering. The therapist hoped that if this could be conveyed to Mary, the vicious cycle of Mary's turning nearly everyone against her might be interrupted.

Integrating the Patient's Experience into an Expanded Perspective of Self Broadening patients' understanding of themselves and their situation corresponds to the third part of Semrad's triad: helping patients put into perspective their painful affects, life experiences, and maladaptive solutions. According to Sullivan “No one has grave difficulties in living if he has a very good grasp of what is happening to him.” Thus, providing insight is another way in which psychotherapy is thought to be useful, complementing identification with the therapist. Integrating the patient's experience entails a change in therapeutic relationship and enlists interpretation as its major technical tool.

At this phase in therapy the nature and tenor of the therapeutic relationship changes such that the therapist becomes more demanding, frustrating, and insistent on adaptation, reality testing, and health. While remaining supportive, the therapist increasingly confronts defenses, frustrates wishes, and interprets transference. The major task is to accept the patient but to reject the patient's psychosis and maladaptive interpersonal maneuvers. Insight in this context can occur at several depths: (1) as simple recognition of the fact of illness, (2) as knowledge about the nature of the illness (e.g., that hallucinations come from one's own mind, (3) as recognition of the dynamics of the illness (i.e., that symptoms occur in relation to personal difficulties), and (4) as recognition that symptoms solve problems and conflicts. Emotional insight, gained by direct experience in the doctor-patient relationship, is emphasized. These derive from interpretations pointing out the transferential

nature of the patient's feeling towards the doctor, including their origin in the patient's past experience and their inappropriate application in the patient's current everyday life.

The what, how, and when of interpretation stems from an empathic attunement to the patient's tolerance, although certain recommendations recur repeatedly. Most psychotherapists are reluctant to interpret content (particularly sexual) since patients are often flooded with unwanted thoughts and impulses. Rather, interpretations focus on defensive operations, resistances to therapy, and the link between symptoms and everyday stresses. Especially targeted for interpretation are negative transference, aggressive impulses, depressive concerns, and dependency issues, which are often warded away from consciousness because of the patient's fear that their emergence would be overwhelming. Interpretations are presented in a way that is aimed at helping patients learn to formulate interpretations on their own. They are presented as tentative observations in the spirit of mutual inquiry. Short, simple, nontechnical language should be used and the patient is considered the final judge of an interpretation's validity and usefulness.

If traversed successfully, this phase of therapy will leave patients with a more accepting and complex view of themselves as a people capable of experiencing the full range of human emotions. Patients will no longer view all their difficulties as the product of mistreatment at the hands of others, and will assume more responsibility for their own treatment and health. Passivity and indecision will be seen as an active choice, and patients will recognize that continued progress depends on their willingness to attempt new solutions, both inside and outside of treatment.

Working Through With improvement in psychosis and maturation of the patient's nonpsychotic personality, the phase of integrating evolves into the last phase of working through. Patients become better able to help therapists perform their functions and eventually become capable of performing these functions themselves. Patients see their therapists as real, different, and imperfect in their empathy. Each step towards greater independence and autonomy generates separation anxiety and a “two steps forward and one step back” trajectory can be anticipated. Regressions or symptomatic exacerbations recur but should be shorter, less intense, and more readily influenced by interpretation. The end of treatment may be negotiated, but many authors have noted that not uncommonly patients remain attached and may contact the therapist during crucial junctures many years after therapy has ended.

SUPPORTIVE PSYCHOTHERAPY

Goals Supportive psychotherapy has historically been favored by biologically and pharmacologically oriented clinicians. It is firmly grounded in the medical model in which the patient is seen as suffering from an organically based illness that requires treatment from a physician.

As described by Talcot Parsons nearly 50 years ago, the medical model implies essential elements of expected behavior for both the physician and patient. These elements define the physician's and patient's respective roles, relationship, and responsibilities.

The physician's role is characterized by four key qualities: it is (1) universalistic, (2) functionally specific, (3) affectively neutral, and (4) collectivity oriented. The universalistic norm requires the physician to treat all patients alike according to scientific and medical standards. The role is functionally specific in that the physician is seen as a specialist in health and disease who is expected to limit attention to circumscribed areas involving medical matters. Affective neutrality prevents the doctor from entering too sympathetically into the patient's situation, allowing for steadfastness of judgment and the exercise of emotional control. Finally, collectivity-orientation, as opposed to self-orientation, demands that the doctor treat the patient according to the patient's needs and the health standards of the community.

Like the role of the physician, the role of the patient is defined by expected behavior that involves both rights and obligations. First, the person who is ill is exempt from normal social responsibilities and excused from customary obligations so as to attend to the process of getting well. A second right is exemption from responsibility for illness—the illness is not considered the patient's fault and the patient has the right to receive care. At the same time, the patient has the obligation to want to get well, obtain technically competent help, and cooperate with treatment.

In contrast to the ambitious aim of personality change associated with the intensive therapy tradition, the short- and long-term goals of supportive psychotherapy are comparatively modest. These include (1) relief from the immediate crisis or direct reduction of acute disequilibrium, (2) removal of symptoms to premorbid levels, (3) re-establishment of psychic homeostasis through a strengthening of defenses, (4) sealing over psychotic experiences and conflicts, (5) the circumscribed fostering of adaptation, and (6) mobilization and preservation of healthy aspects of the patient to enable optimal functioning and minimize the impact of persistent deficits. Supportive therapy uses the physician-patient relationship to create a background of adequate clinical care that supports the prescription of effective pharmacological interventions. Functional or social recovery, rather than personality change, is the primary aim of treatment.

Techniques The overall technical approach of supportive psychotherapy is one of pragmatism and management in which based on medical and psychiatric expertise, the physician helps the patient interpret and adapt to reality. As such, the therapist employs techniques that include defining reality, offering direct reassurance, giving advice on current problems of living, urging modification of expectations, and actively organizing the environment for patients who cannot do so themselves. To help stabilize the patient's environment the therapist often maintains close contact with the patient's family or other treaters and may intervene on the patient's behalf with family, employers, and social agencies.

Eliciting and tracking symptomatology and targeting symptoms for psychopharmacological intervention is a major focus for the supportive psychotherapist. Psychopathology is interpreted in a medical context as the unwanted emergence of signs of illness. The basic content of psychotherapy focuses on teaching and relearning—the patient is educated regarding the nature of the illness, taught to monitor symptoms, and act promptly to suppress their exacerbation. The therapist fosters positive transference as a benign authority; positive feelings are treated as real and negative transference is avoided. The therapist may become very active in helping the patient learn new ways of adapting and may use or prescribe cognitive, behavioral or social skill training techniques.

Empirical Studies

Efficacy of Individual Psychotherapy In the decades following the introduction of phenothiazines psychiatry became increasingly divided into adherents of the psychodynamic and biological paradigms. Disagreement concerning the value of intensive psychotherapy became a focal point of often acrimonious ideological and scientific debates. Randomized clinical trial methodology unambiguously demonstrated the value of pharmacological interventions in schizophrenia and came to be seen as the optimal standard for evaluating all treatments. In this context, five studies conducted during the 1960s and 1970s attempted to assess the efficacy of various forms of individual psychotherapy compared to treatment programs that did not specifically feature psychotherapy. Although criticized by proponents of intensive psychotherapy on a number of methodological grounds, together the results of these randomized clinical trials provided little or no evidence for the efficacy of psychotherapy as the sole treatment for schizophrenia. Supporting this conclusion were the results of long-term follow-up studies both at Chestnut Lodge, where many of the techniques of intensive individual psychotherapy were developed, and at Columbia's Psychiatric Institute. Exceptions notwithstanding, these studies found that the majority of patients treated with intensive psychotherapy alone remained seriously and chronically ill.

Reflecting the then-extant ideological rivalry between psychodynamically and biologically oriented clinicians, the Boston Psychotherapy Study was designed in the 1970s to address the methodological weaknesses of earlier clinical trials. This study aimed to evaluate the comparative effectiveness of expressive, insight-oriented individual psychotherapy and reality-adaptive, supportive psychotherapy against a backdrop of high-quality inpatient, outpatient, and pharmacological treatment provided to both patient groups. Contrary to the investigator's expectations, neither treatment emerged as clearly superior, although differential effects across outcome domains were noted: reality-adaptive, supportive therapy was preferentially effective in the areas of recidivism and role performance while expressive, insight-oriented therapy exerted a modest preferential effect on ego functions and cognition.

The disappointing results of randomized clinical trials and follow-up studies contributed substantially to a decline in prestige and influence of the psychodynamic paradigm generally, and intensive individual psychotherapy of schizophrenia in particular. An additional challenge came from infant observational research that indicated that infants were far more active, stimulus seeking, and socially oriented from birth than was suggested by earlier psychodynamic theory. Similarly, stages such as the autistic and symbiotic were not observed and the infants' plasticity, resilience, and capacity for adaptation appeared far greater than earlier thought. These findings challenged the validity of psychosocial theories of etiology, at least as articulated by psychodynamic thinkers. Because of these and other factors, individual psychotherapy research and psychological theorizing concerning schizophrenia slowed to a near halt. The biological paradigm decisively gained ascendancy as the most influential in the field.

Reappraisal of Individual Psychotherapy Significant among the findings from the Boston Psychotherapy Study was the degree to which, despite theoretical differences, the actual techniques employed by the expressive, insight-oriented therapy and reality-adaptive, supportive therapists tended to converge. For example,

both theories were found to employ substantial supportive elements. Sobering but significant were the substantial attrition rates for both types of therapy. Although those who remained in therapy continued to accrue benefits, by the end of 1 year more than half (56 percent) and by the end of 2 years more than two-thirds (69 percent) of all patients had unilaterally dropped out of treatment.

Having found few differences in overall outcome between patients treated with expressive, insight-oriented therapy and reality-adaptive supportive therapy, investigators from the Boston Psychotherapy Study searched for common factors in the treatments associated with positive therapeutic change and good outcome. Results indicated that independent of severity of psychopathology, patients able to form a good alliance with the therapist within the first 6 months of treatment were more likely to remain in therapy and to comply with medication. These patients achieved better outcomes at 2 years and used less medication than those who did not form a therapeutic alliance. Looking at therapist activity, these investigators found across both therapies a strong positive correlation between reductions in patient denial of illness and retardation-apathy, and the therapists' demonstration of a sound dynamic understanding and accurate attunement to the patients' underlying concerns. Directive activity was associated with reductions in anxiety and depression.

Rancorous debates concerning the relative value of drugs versus psychotherapy collapsed in the 1980s under the weight of data in opposition to the view that any single treatment is definitive for schizophrenia. Lack of efficacy weighed against a sole reliance on investigative psychotherapy whereas high rates of medication noncompliance, relapse, and persistent dysfunction defined the limits of a narrow medically oriented approach. The historical distinction between supportive and exploratory therapy was no longer salient.

FLEXIBLE PSYCHOTHERAPY

Flexible psychotherapy refers to a broad and pragmatic approach to psychotherapy that relies on a variety of strategies applied flexibly depending on the individual patient's type of schizophrenia and phase of illness. Such an approach might at various times include supportive, directive, educational, investigative, and insight-oriented activity, provided in the context of an ongoing and stable doctor-patient relationship. The quality of this relationship should be characterized by empathy and a sound dynamic understanding of schizophrenia on the part of the physician. Dogmatic or rigid adherence to a single approach applied to all patients is probably the least likely to be of value. As described here in terms of assumptions, clinical tasks, and interventions, flexible psychotherapy approximates how most patients are treated in current practice. A specific form of flexible psychotherapy, *personal therapy*, has recently been sufficiently operationalized to allow for rigorous empirical evaluations.

Flexible Psychotherapy: Assumptions A flexible approach to psychotherapy is based on a revised set of assumptions about the nature of schizophrenia that recognizes the joint contributions of biological, psychological, and social or environmental factors:

1. The stress-diathesis or vulnerability-stress model represents the best available integration of data pertinent to the etiology, course, and outcome of schizophrenia. The model postulates that schizophrenia results from a dynamic interaction between environmental or experiential stress in a person who is vulnerable to react to this stress with schizophrenic symptom formation.

   The vulnerabilities to schizophrenia are likely to be multiple and heterogeneous. Family and twin studies unambiguously indicate a genetic contribution to vulnerability, although a simple Mendelian mode of inheritance is not evident. Epidemiological investigations point to the contribution of acquired, biologically based environmental risk factors such as maternal influenza, Rh incompatibility, maternal starvation, and obstetrical complications. Although a variety of specific vulnerabilities have been identified, none has been shown to be ubiquitous.

   Biologically based vulnerability may be expressed as relatively enduring psychophysiological, cognitive, or behavioral difficulties among subgroups of patients. Most common findings include (1) deficits in information processing and maintaining a steady focus of attention; (2) dysfunctions in psychophysiology suggesting deficits in sensory inhibition and autonomic responsivity; (3) impairments in social competence; and (4) general coping deficits such as overvaluing threat, underappraising abilities, and extensive use of denial.

   The vulnerability to schizophrenia is seen as a relatively enduring proclivity to developing overt clinical symptoms; vulnerability is likely to be manifest as a set of stable traits present premorbidly, at onset, during acute episodes, and remissions. However, vulnerability is not static but is shaped epigenetically over time by environmental influences; a stress sufficient to precipitate relapse at one time, for example, may be less likely to do so at a later point when new coping strategies or better supports have been acquired.
2. The stress side of the vulnerability-stress model postulates that a variety of stressors (internal or external events requiring adaptation) can precipitate the emergence of symptoms in a vulnerable individual. Given biologically based vulnerability, the onset, course, and outcome of an individual's disorder may be shaped largely by interactions between the person and the environment. Among psychosocial factors, stressful life events, cultural milieu (egocentric versus sociocentric), social class, social network size and density, and emotional quality of the living environment have been demonstrated to be associated with the onset or course of schizophrenia.

   The vicissitudes of illness are best understood as a dynamic product of the affected individual's adaptive assets and vulnerabilities interacting over time with various stresses. In a highly vulnerable individual, sufficient stress can precipitate intermediate (prodromal) states of dysfunction that amplify preexisting cognitive, affective-autonomic, and social coping deficits. In the absence of adaptive strategies or environmental supports these interact negatively with the existing stressors to magnify their effect in a downwardly spiraling process that ends in a full-blown clinical syndrome.

   Clinical experience indicates that the stresses associated with illness onset or exacerbation may be highly individualized, rendering generalization about the typical nature of such stresses difficult. Stresses may be primarily biochemical (as in substance abuse), environmental (as in leaving for college, joining the armed services, breaking up with a girlfriend), or social (poverty, unemployment).
3. Schizophrenia is heterogeneous, as are individuals afflicted with it. The clinical diversity of schizophrenia in relation to vulnerabilities and risk factors, age and type of onset, manifest signs and symptoms, longitudinal course, and long-term outcome suggest that the disorder may be heterogeneous in regard to underlying etiology. This heterogeneity may be partially captured by currently available subtyping systems. Paranoid schizophrenia, for example, is associated with good premorbid functioning, late age of onset, many positive symptoms, intermittent illness over the first several years, and a comparatively high likelihood of good outcome despite a higher risk of suicide; the deficit form of schizophrenia is characterized by poor premorbid functioning, earlier onset, severe and enduring negative symptoms, a low risk of suicide, and often persistent life-long disability. However, an etiology-based subtyping that allows for precise longitudinal prediction for individual patients is not available. At a minimum, schizophrenic illnesses of greater and lesser severity and virulence can be identified and the biological vulnerability of individuals may differ.

   Like the illness itself, individuals afflicted with schizophrenia differ substantially in adaptive capacities, intelligence, and instrumental and verbal competence. Furthermore, the degree of social support available to them varies greatly. In general, the greater the level of instrumental skills acquired prior to the onset of illness (work or educational experience, experience with relationships, experience living independently), the better positioned the individual will be to recover or maintain functioning once the illness has become established. For some patients the failure to acquire much in the way of adaptive skills may represent the product of the life-long vulnerability underlying the tendency to the illness. For other patients a particularly virulent form of schizophrenia may catastrophically erode adequate premorbid skills, resulting in substantial permanent disability. Other patients with good premorbid abilities may be left with their skills and competence largely intact after an acute episode.
4. Schizophrenia is often phasic in course. Systematic investigation of longitudinal course has only recently begun and the understanding of illness phases is preliminary. Phases may include (1) prodromal periods, during which a highly individualized constellation of symptoms that represent early manifestation of clinical decompensation emerges; (2) acute or active phases, often associated with the full-blown emergence of positive symptoms superimposed onto pre-existing deficits; (3) subacute, convalescent, or stabilization phases characterized by gradual restoration of some functioning perhaps associated with postpsychotic depression; (4) moratoriums or adaptive plateaus, characterized by a gradual reconstitution of identity, gathering of support, and strengthening of skills; (5) change points or shifts in functioning over a relatively brief period of time, initiated by the patient's own desires or pressure from others and associated with the potential for either quantum improvement or decompensation; (6) end-state or stable plateaus, relatively enduring periods of stability characterized by greater or lesser fixed deficits or chronic levels of positive symptoms.

Flexible Psychotherapy: Clinical Tasks and Technical Strategies To treat schizophrenia the therapist must use a variety of interventions and strategies. The crucial question is which interventions are of potential value for a particular individual at a particular phase of illness. All interventions aim to minimize the effect of vulnerabilities, bolster adaptive capacities, and reduce the extent and impact of stress. The range of therapeutic tasks and associated goals and interventions can be ordered hierarchically. As outlined in Table 12.10-1, different therapeutic tasks are of particular importance during different illness phases. In addition, although some

tasks are clearly relevant for all patients receiving individual treatment; other tasks, particularly those relating to the goals of intensive psychotherapy, are pertinent for only a small subgroup of patients. The strategic rosetta stone here is the therapist's capacity to shift gears, be flexible, and change roles with all patients based on changing circumstances, always keeping in mind the goal of helping the patient accept, learn about, and self-manage what may often be a chronic and devastating illness.

Table 12.10-1 Flexible Psychotherapy: Therapeutic Tasks, Interventions, and Goals

Consideration of the patient's schizophrenia subtype, current and premorbid functioning, and self-defined treatment goals are all relevant to the determination of appropriate treatment tasks. For patients with severe disorganized or deficit forms of schizophrenia, for example, the most humane and practical goal may be establishing a supportive ongoing treatment within a sheltered setting that minimizes stress and provides for basic human needs for an indefinite period. For the majority of patients who reside in the community amidst varying supportive structures, some degree of psychoeducation and rehabilitative tasks should be planned with the aim of minimizing acute relapses and promoting maximal functioning and quality of life. A primary focus on investigative tasks should be reserved for motivated patients who have established a good working relationship with the therapist and exhibit an interest in and ability to make constructive use of such techniques. These patients are likely to have demonstrated good premorbid functioning, intermittent and less severe forms of schizophrenia, minimal residual deficits, and retention of some capacity for self-observation, curiosity, tolerance of frustration, and humor. Attunement to psychological concerns may be particularly important for patients who have a dramatic response to new medications.

The use of multiple treatment modalities creates the need for someone to orchestrate and coordinate them. In many instances a psychiatrist is best at providing individual therapy and continuity of care over a prolonged period. As is true in medicine generally, the quality of the individual doctor-patient relationship is a major factor in the success of the therapeutic endeavor. Thus, a focus on the skillful use of this relationship usefully informs all tasks at all levels. Here, removed from its outmoded etiological assumptions and overly ambitious aims, the substantial clinical knowledge derived from the tradition of investigative psychotherapy can be applied pragmatically in a contemporary context.

Many of the tasks overlap with the concerns and expertise of other service providers; however, all the tasks should be the concern of the individual psychotherapist and a focus for individual psychotherapy. A common mistake made by trainees is to focus on higher-level psychological tasks while ignoring overwhelming difficulties at the level of basic human services. Thus, the necessary first goal of psychotherapy with a homeless person may be direct assistance in finding housing. Although other professionals may be relied upon to accomplish specific tasks, physician-therapists should consider themselves responsible for ensuring the results of these efforts.

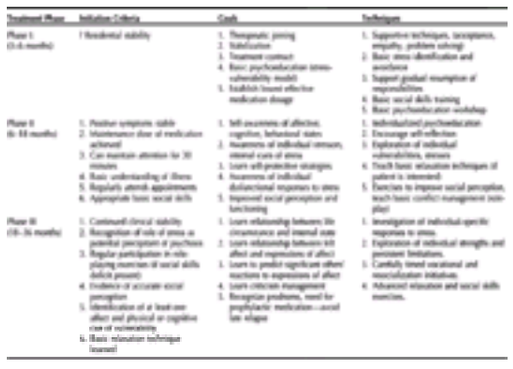
The following general treatment strategies are common to all the specific therapeutic tasks outlined:

1. Evaluation.A thorough evaluation of the patient initiates the treatment process. During medical assessment and stabilization this includes ruling out identifiable physical conditions, assessing competence to consent to treatment and risk, and determining the response of symptoms to short-term pharmacological intervention. Psychosocial assessment inventories available supports and aims to measure the degree to which the patient's adaptive capacities measure up against the stresses and demands of their living environment. Efforts to establish a supportive ongoing treatment test the patient's capacity to trust and rely upon another human being for support and guidance. When applicable, psychoeducational, rehabilitative, and investigative interventions are preceded by an assessment of the patient's cognitive strengths and deficits, allowing interventions to be formulated that match the patient's talents.
2. Continuous reevaluation. The fluid nature of schizophrenia and an individual's adaptation to it over time demands periodic reassessment of course, prognosis, phase of illness, and target problems; as these change, so do treatment goals. Providing concrete support in the form of a ride to work may be helpful early in the effort to promote vocational rehabilitation, but later may promote unwarranted dependency and prolong disability.
3. Timing. The phasic natural history of schizophrenia requires attention to the timing of particular therapeutic tasks. For many patients, in order to minimize stress and forestall relapse, relatively little beyond assessment, stabilization with medication, and establishment of a supportive ongoing treatment should be attempted during the first 6 to 12 months following an acute episode. Once the patient is asymptomatic and shows signs of revitalization, rehabilitation and more complex psychoeducational elements may be gradually introduced.
4. Titration.Treatment interventions should be applied with graded increases of intensity and complexity. Higher-level therapeutic tasks should be attempted and higher levels of work or social functioning expected only after completion and consolidation of earlier gains. Substantial rehabilitation, for example, will rarely be possible until progress has been made in attaining a stable supportive treatment relationship. Similarly, there is evidence that early, active, and ambitious psychologically oriented treatment may be disorganizing or toxic for certain patients. In general, treatment changes should be pursued cautiously, with only one element being modified at a time.
5. Integration with psychopharmacology. Each of these tasks take acute and prophylactic antipsychotic drugs as given for most patients. Control and prevention of psychotic symptoms using the lowest effective dosage of medication is the overall treatment goal. Decisions regarding pharmacological management are often linked to the relative success or failure of accomplishing various psychotherapeutic tasks. Considerable psychoeducation, for example, should be accomplished before attempting maintenance medication dose reduction or the initiation of a targeted (intermittent) medication strategy. Long-acting injectable antipsychotic agents may be useful for patients who are unable to tolerate the daily reminder of illness associated with oral medication or for patients who are unable to maintain a reliable treatment relationship.

Personal Psychotherapy While reflecting clinical practice, flexible psychotherapy has not been formally assessed. Similar in overall outlook to flexible psychotherapy, however, *personal therapy* has recently been developed by Gerry Hogarty and his colleagues at the University of Pittsburgh as a form of individual treatment that is sufficiently operationalized to allow empirical testing. Personal therapy is designed for recently discharged outpatients with chronic or subchronic schizophrenia. Its objective is to enhance personal and social adjustment and forestall late (third-year) relapse. A disorder-specific treatment, it accommodates neuropsychological aspects of schizophrenia and attempts to avoid the adverse effect of poorly timed interventions.

Within a stress-vulnerability model individual-specific stress, often interpersonal, is seen as precipitating affective dysregulation. This loss of control over mood is seen as resulting in poorly reasoned dysfunctional behavior that negatively influences the reciprocal behavior of others in a cycle that may end in relapse. Based on individual patients' needs, personal psychotherapy uses a range of interventions to promote patients' self-awareness and foresight and to equip patients with adaptive strategies that facilitate self-monitoring and self-control of affect.

Personal psychotherapy includes three phases, each with explicitly defined goals and corresponding interventions. The achievement of these goals is carefully assessed before the patient advances to the next level of treatment. Phases of treatment, goals, and operational criteria defining readiness to move to more advanced phases are summarized in Table 12.10-2. Within each phase, the exposure of patients to specific interventions is varied based on individual need. While the therapy was designed to be given over a 3-year time span, patients spend as much time at each level as required to meet advancement criteria and not all patients progress through all three phases. Personal therapy is administered against a backdrop of psychopharmacological treatment that aims to minimize adverse effects by using the lowest medication dose needed to prevent symptom exacerbation.



Treatment Phase	Initiation Criteria	Goals	Techniques
Phase I (1–6 months)	↑ Residential stability	1. Therapeutic joining 2. Stabilization 3. Treatment contract 4. Basic psychoeducation (stress-vulnerability model) 5. Establish lowest effective medication dosage	1. Supportive techniques, (acceptance, empathy, problem solving) 2. Basic stress identification and avoidance 3. Support gradual resumption of responsibilities 4. Basic social skills training 5. Basic psychoeducation workshop
Phase II (6–18 months)	1. Positive symptoms stable 2. Maintenance dose of medication achieved 3. Can maintain attention for 30 minutes 4. Basic understanding of illness 5. Regularly attends appointments 6. Appropriate basic social skills	1. Self-awareness of affective, cognitive, behavioral states 2. Awareness of individual stressors, internal cues of stress 3. Learn self-protective strategies 4. Awareness of individual dysfunctional responses to stress 5. Improved social perception and functioning	1. Individualized psychoeducation 2. Encourage self-reflection 3. Exploration of individual vulnerabilities, stressors 4. Teach basic relaxation techniques (if patient is interested) 5. Exercises to improve social perception, teach basic conflict management (role-play)
Phase III (18–36 months)	1. Continued clinical stability 2. Recognition of role of stress as potential precipitant of psychosis 3. Regular participation in role-playing exercises (if social skills deficit present) 4. Evidence of accurate social perception 5. Identification of at least one affect and physical or cognitive cue of vulnerability 6. Basic relaxation technique learned	1. Learn relationship between life circumstances and internal state 2. Learn relationship between felt affect and expressions of affect 3. Learn to predict significant others' reactions to expressions of affect 4. Learn criticism management 5. Recognize prodrome, need for prophylactic medication—avoid late relapse	1. Investigation of individual-specific responses to stress 2. Exploration of individual strengths and persistent limitations. 3. Carefully timed vocational and resocialization initiatives. 4. Advanced relaxation and social skills exercises.

Table 12.10-2 Personal Therapy: Goals, Techniques, and Criteria for Advancement

Investigators at the University of Pittsburgh have recently completed two 3-year randomized controlled trials of personal therapy for newly discharged patients with schizophrenia and schizoaffective disorders. Patients residing with their families were assigned to supportive therapy, personal therapy, families psychoeducation or management, or a combination of the latter two treatments. Patients living alone, who were generally more disabled, were assigned to personal therapy or supportive therapy.

Results indicated that personal therapy was remarkably well accepted by patients participating in the trials. Over 3 years only 8 percent of patients receiving personal therapy and 23 percent of patients in contrasting treatments, were dropped for noncompliance or administrative reasons. The efficacy of personal therapy in relapse reduction was tied to residential status. Patients receiving personal therapy who were living with family experienced fewer relapses. The more impaired group of patients receiving personal therapy who were living alone experienced a greater relapse rate. Consistent with the clinical dictum that psychologically oriented treatments can be futile or harmful when applied before basic human service needs are addressed, personal therapy patients who relapsed were more likely to have unstable housing and difficulty securing food and clothing.

Independent of relapse reduction, personal therapy produced substantial differential improvements in social adjustment and role performance. Whereas improvements in social adjustment among patients receiving supportive and family therapy reached a plateau at 12 months, the personal adjustment of personal therapy patients continued to improve in the second and third postdischarge years with no evidence of a plateau. Relative to supportive and family therapy, individual psychotherapy was superior in promoting a progressive improvement in psychosocial adjustment.

Results from the Pittsburgh clinical trial of personal psychotherapy provide the first rigorous empirical support for the efficacy of disorder-specific and flexible form of individual psychotherapy as part of an overall treatment plan that includes psychopharmacology, attention to social service needs, and rehabilitation. Although research psychotherapies often have a limited impact on clinical practice, personal therapy is not tightly prescriptive. Rather, it provides a general strategy for ordering clinical work that leaves considerable room for individualization. Some form of individual psychotherapy combined with medication is the most common treatment provided to outpatients with schizophrenia. Personal therapy provides a previously lacking empirically supported framework to guide the provision of usual care.

Targeted Individual Psychotherapies Working within an overall clinical framework that takes the necessity of multidisciplinary and individualized treatment as a starting point, several new individual psychotherapies that target specific problems or subgroups of patients have been developed and tested. These psychotherapies have generally been time-limited and administered as an adjunct to usual long-term care that includes medical management and medication. These illness-phase–specific treatments use circumscribed and measurable goals to target improvements in medication-resistant positive symptoms or treatment compliance.

Elizabeth Kuipers and her colleagues at London's Institute of Psychiatry described the result of a randomized trial of cognitive-behavioral therapy for stabilized schizophrenia outpatients with at least one persistent medication-resistant positive psychotic symptom. The cognitive-behavioral intervention began with active efforts to promote engagement and a therapeutic alliance and later used individually tailored skills training, relaxation, and psychoeducational and exploratory techniques. Over a 9-month trial period, individual therapy recipients had a low dropout rate, expressed high levels of satisfaction with treatment and compared to a standard treatment control group showed a 25 percent reduction in symptom severity as measured by the Brief Psychiatric Rating Scale. Patients rated at baseline as showing some cognitive flexibility about delusions were most likely to benefit from this psychotherapeutic intervention.

Nicholas Tarrier and his colleagues at University of Manchester conducted a randomized trial of intensive cognitive-behavioral therapy twice a week for 10 weeks (20 sessions) as an adjunct to usual care for compliant outpatients with medication-resistant positive psychotic symptoms at a residual phase of illness. To control for nonspecific factors, comparison groups included a generic supportive counseling with routine care and routine care–only group. Compared with routine care alone and routine care with supportive counseling, significant improvement in the severity and number of positive symptoms was found in those treated with cognitive therapy 3 months after treatment. Compared with both treatment groups, patients receiving usual care alone experienced more relapses and days hospitalized.

A brief individual psychotherapy termed compliance therapy has been designed for acutely psychotic patients with chronic illness who have recently been readmitted for an illness relapse. This intervention consists of 4 to 6 cognitive-behaviorally oriented sessions lasting 20 to 60 minutes twice a week administered prior to hospital discharge. The sessions focus on (1) a review of symptoms and treatment adverse effects, (2) the patient's actions and beliefs regarding treatment, and (3) reducing stigma comparing pharmacotherapy to the need for medicine in other physical illnesses and defining drug treatment as a freely chosen strategy to enhance quality of life. In a randomized, controlled trial, Anthony David and his colleagues at the Maudsley Hospital reported that inpatients receiving compliance therapy showed greater postdischarge insight and more observer-rated treatment compliance compared with nonspecific counseling. In addition, survival in the community and social functioning were significantly better in the treatment group over an 18-month follow-up period.

Prodromal Phase Intervention Many investigators have noted in recent studies of first-episode schizophrenia that patients typically experience active psychosis for 12 to 24 months before obtaining treatment. The observation that a longer duration of untreated psychosis is associated with a poorer initial pharmacological treatment response and more severe, chronic disability has rekindled interest in early detection and intervention as potential means to prevent the onset of severe symptoms or positively modify the long-term course of schizophrenia. Specialized early intervention programs have been developed in several countries and include individual therapy and case management techniques modified to meet the needs of patients who may be in the prodromal phase. Although no approach to early intervention has undergone rigorous empirical testing, a cognitive-behavioral focus on assisting the person to adapt to the onset of psychotic illness and its effects on self-concept, identity, and self-esteem has been described by Patrick McGorry. Limiting the damage to personal identity, social networks, and role functioning and promoting recovery and adaptation are treatment goals. Providing treatment in a less stigmatizing general youth center, and targeted use of low-dosage antipsychotic medication is a feature of this treatment. In addition, recognizing that many young people who recover from a prodromal state experience a flight into health and a determination to discontinue medication, therapists remain willing to maintain clinical contact without enforcing medication adherence. In this way medication can be quickly reinstituted if required.

Practical Considerations in Outpatient Assessment When scheduling an initial outpatient visit for a patient with schizophrenia the therapist should set aside sufficient time (11/2 to 2 hours) to conduct a thorough preliminary assessment. If the referral is initiated over the phone by someone other than the patient, it is useful to use the phone contact to obtain a cursory outline of the patient's history and current mental status. Information about symptom severity, current medications, and current and past suicidality and aggression should be sought with the aim of determining whether outpatient evaluation can proceed safely. If preliminary contacts suggest the possibility of a need for hospitalization or other immediate short-term care, specific information about what such care resources the patient is eligible to access should be obtained.

It is common for patients with schizophrenia to arrive for a first appointment accompanied by a family member, case manager, or other caregiver. Following introduction to the patient and those arriving with him or her, an initial assessment interview can be conducted with the patient alone. In this interview the therapist may need to make an active effort to promote the patient's comfort. This can be done by, for example, offering coffee, pointing out the specific place to sit, outlining what will be discussed, and if necessary conducting the assessment interview with a specific set of questions. With the patient's permission, it is then often useful to spend some time alone with the accompanying family member or other caregiver. This interview allows the person accompanying the patient to express specific

concerns or worries in private and can provide important additional information about the patient's situation.

Ideally, the outcome of the initial visit will be a mutually agreed upon plan for further assessment or treatment. This plan should include the frequency and duration of visits, payment, medication regime, and arrangements for the patient and caregivers to reach a physician (or other team member) in the event of a crisis between scheduled appointments. Attention should also be given to practical considerations such as transportation to appointments and how and where prescriptions will be filled. If psychotherapy is recommended, a general statement of its methods and goals may be useful ("We will meet so that we can talk together, better understand your difficulties, and work with you on your medications to improve your situation"). In addition, defining some mutually agreed upon area (problem, concern, goal, medication adverse effects) in which the therapist can be seen as potentially useful to the patient will set the stage for a positive therapeutic relationship.

The frequency and duration of psychotherapy are individualized. Weekly psychotherapy for 45 to 50 minutes is most common in an outpatient setting, but the frequency of visits may be increased during periods of clinical instability or if insight-oriented psychotherapy is prescribed. Less frequent visits of shortened duration (15 to 20 minutes) may be negotiated during periods of stability, for patients who have learned to self-manage their illness, or for those who find contact with a physician aversive, disorganizing, or irrelevant.

In addition to setting the stage for establishing a working relationship with the patient, the physician's management of the initial interview should promote collaboration with the patient's family member, case manager, or other caregiver. Both the patient and the caregiver can be told that the patient's confidentiality will be respected, but should the therapist at any time believe a relapse or other dangerous situation is developing, the help of family and other caregivers will be solicited. The family can be encouraged to contact the physician should they develop concerns and the frequency of future family contacts should be agreed upon. Family or caregiver support is crucial to the outcome of treatment and will most likely be extended to a clinician who is felt to be empathic, responsive to concerns, and available.

Therapists should be cognizant of the fact that suicide is the most common cause of premature death in schizophrenia and that patients with schizophrenia are less prone to spontaneously report suicidality. As a result, the therapist should be active in eliciting suicidal ideation; if not directly asked, patients may not reveal their intent. Several studies have shown that two-thirds or more of schizophrenia patients who commit suicide have seen an apparently unsuspecting clinician within 72 hours of death.

Research indicates that less-disabled patients with few negative symptoms who retain the capacity to experience painful affects and can reflect on the seriousness of their situation are at greatest risk of suicide. Periods following discharge from a hospitalization and loss of an important relationship have been identified as high-risk periods. Providing additional therapeutic support for patients during high-risk periods and monitoring for the emergence of potentially treatable syndromal depression may be reasonable strategies to reduce suicide risk.

Medication Compliance Noncompliance with effective psychopharmacological treatments during both short-term and maintenance therapy is a major cause of morbidity among patients with schizophrenia. When prolonged or repeated, noncompliance contributes to a downwardly spiraling cycle of relapse, recidivism, and deterioration of social and instrumental functioning. Empirical correlates of noncompliance include (1) patient-related factors (greater illness severity or grandiosity, lack of insight, substance abuse comorbidity); (2) medication-related factors (dysphoric medication adverse effects, ineffective or excessively high dosages); (3) environmental factors (inadequate support of supervision, practical barriers); and (4) clinician-related factors (poor therapeutic alliance). Available research underscores the multiplicity of explanations for reduced compliance and highlights the necessity of an individualized assessment. Of particular relevance to psychotherapy are patients' health beliefs and the psychological meanings attached to their illness and its treatment.

Among the psychological meanings associated with medication noncompliance, the following have been described: (1) pervasive denial about having an illness and needing treatment; (2) reactive efforts to regain control of one's life and maintain a sense of self-cohesion by organizing in opposition to the will of others; (3) the concrete equation of taking medication with being ill ("If I need drugs, I must be sick; The higher the dose, the sicker I am; I'll stop being ill if I stop taking drugs"); (4) lack of knowledge or incorrect beliefs about medications (taking drugs is a sign of weakness); (5) paranoid views of medication as being poisonous, controlling, or damaging; (6) secondary gain from psychosis—grandiose delusional gratification, escape from normal expectations and responsibilities; (7) pain and anguish accompanying symptom reduction with its attendant recognition that one has been ill and that the illness is severe; (8) displacement from transference—for example, discontinuing medication as an expression of anger towards one's therapist or family; and (9) an expression of unconscious ambivalence or fear of autonomy—as in discontinuing medication immediately before beginning a new job or rehabilitation program.

The variety of possible factors related to noncompliance point to the need for a broad and flexible approach that applies a range of interventions based on current knowledge of psychopharmacology and sound dynamic understanding of the individual patient. General recommendations for improving compliance in the context of psychotherapy have included: (1) conveying interest and concern about medication by asking specific questions about how much medication is being taken, effects, and adverse effects; (2) assuming many patients will at times take more or less medication and creating a therapeutic environment where such experiments are legitimized and can be talked about; (3) involving patients to the greatest extent possible in their own medication treatment—for example, allowing self-regulation of dosage within limits; (4) arranging for the taking of medication under the supervision of family, friends, or others and enlisting their support for medication; (5) direct praise and support for medication compliance; (6) education in the areas of medication adverse effects, relapse prevention, and the biological basis of major mental illness; (7) promoting self-monitoring through record keeping and other behavioral interventions; (8) attending to and building the therapeutic relationship as a lever to change; and (9) helping the patient experience activities that promote self-esteem and compete with psychosis as sources of gratification. The choice of specific interventions should be based on a differential diagnosis that generates hypotheses regarding which specific factors are operative in the individual patient. When lack of knowledge and cognitive deficit are a major factor in noncompliance, specific cognitive and behavioral procedures have been developed to enhance cognitive mastery and skills attainment. When noncompliance represents the unconscious wish to regress or to act out transference, dynamic exploration and interpretation are required. When severe disorganization is a major factor, arrangements for supervised medication administration may be necessary.

Finally, it must be recognized that some patients who appear to be clear candidates for benefiting from medication will continue to refuse this treatment, despite all efforts. These circumstances typically arouse countertransference reactions that require attention, such as telling the patient to seek treatment elsewhere out of anger or wishing to hurt the patient through abandonment. Another unproductive countertransference is withholding advice or support that might be of use to patients in order to see them learn their lesson by experiencing a full-blown relapse. Allowing the noncompliant patient who leaves treatment against medical advice to do so with dignity can set the stage for greater collaboration should the patient return in the future.

Circumstances requiring the therapist to initiate commitment or involuntary administration of medication also typically evoke powerful countertransference. Following such coercive interventions, the psychotherapist may experience considerable guilt about and fear of the patient. At such a time the therapist is tempted to discontinue all contact and turn the patient over to another clinician, rationalizing that a therapeutic alliance will never again be possible after such heavy-handed acts. Experience demonstrates that such an assessment is usually a distortion that more often serves the needs of the therapist than the patient. Following resolution of such an episode, many patients may express gratitude for the therapist's action, and in hindsight recognize that they were in need of treatment.

The results of empirical research have catalyzed a reformulation of psychotherapeutic techniques. An approach to individual therapy that includes appropriate attention to pharmacological, psychotherapeutic, psychosocial, and rehabilitative interventions titrated to the individual patient's response and progress has been articulated in clinical literature. The introduction of new antipsychotic agents with greater efficacy and fewer adverse effects will raise the functional ceiling previously imposed on many patients who experienced persistent symptoms or disabling adverse effects with first-generation agents. The greater efficacy of new medications creates new opportunities to realize the potential therapeutic synergy of blending multiple interventions into an integrated treatment approach.

SUGGESTED CROSS-REFERENCES

General discussions of the psychotherapies appear in Chapter 30. Various aspects of schizophrenia and its treatments are discussed in the other sections of Chapter 12.

CHAPTER 13. OTHER PSYCHOTIC DISORDERS

13.1 SCHIZOAFFECTIVE DISORDER, SCHIZOPHRENIFORM DISORDER, AND BRIEF PSYCHOTIC DISORDER

JOHN LAURIELLO, M.D., BRENDA R. ERICKSON, M.D., AND SAMUEL J. KEITH, M.D.

There are three disorders in addition to schizophrenia listed in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) in the section "Schizophrenia and Other Psychotic Disorders." The first, schizoaffective disorder, is a complex illness that has changed significantly over time. In its simplest definition, it is presently conceived as an illness with coexisting, but independent, schizophrenic (psychotic) and mood components. Schizoaffective disorder is seen primarily as part of a schizophrenia spectrum rather than an equal hybrid of mood and schizophrenia disorders. Schizophreniform disorder is a diagnosis that assumes another will replace it after 6 months. Most cases of schizophreniform disorder progress to either schizophrenia or schizoaffective disorder, with some cases rediagnosed as a non–schizophrenia spectrum illness (i.e., schizotypal or schizoid personality disorders), while a few resolve completely. Finally, the diagnosis brief psychotic disorder describes an impairment in reality testing that lasts at least 1 day, but less than 1 month. All three disorders have a psychotic component, are often misunderstood, are incorrectly applied, and are not as well studied as schizophrenia, bipolar I disorder, or major depressive disorder.

SCHIZOAFFECTIVE DISORDER

As the end of the century nears great strides have been made in clarifying the diagnostic criteria for many psychiatric illnesses. However, patients often do not fall neatly into set illness criteria. There are several approaches to dealing with such patients. One is to diagnose the patient with two distinct illnesses and treat those illnesses as separate problems. Another possibility is to consider that the patient has a primary illness and symptoms of a second illness that are not as important and might even resolve when the primary illness is treated. A third approach considers that the patient suffers from a distinct blended illness with its own history, diagnosis, and treatment. This last approach best represents the current orthodoxy in the diagnosis and treatment of patients with the DSM-IV diagnosis of schizoaffective disorder. Unfortunately, this approach is not easily applied, often making the diagnosis confusing and convoluted.

History At the beginning of this century, patients with mental illness were grouped together as suffering from the common illness insanity. With the work of Emil Kraepelin, and Eugene Bleuler, distinct diagnostic groups began to emerge. Kraepelin was able to distinguish an unremitting, dementing illness in young patients that became known as schizophrenia, which he contrasted with an episodic illness of affect now known as bipolar I disorder. However, there were patients who did not fit neatly into either category. Bleuler believed that the presence of any symptoms of schizophrenia even when there was an affective component was still schizophrenia. Patients with mixed features of schizophrenia and affective (mood) disorder were first described by George Kirby and August Hoch in the early part of the century. In 1933, Jacob Kasanin introduced the term "schizoaffective psychosis" to describe a group of patients who had symptoms of both affective and schizophrenic illnesses. While he is credited with introducing the term, on subsequent review of these patients, all would now meet the diagnosis of a pure mood disorder. Nevertheless, the term schizoaffective disorder has survived albeit in several different contexts.

Comparative Nosology One of the difficulties in using a diagnosis that depends on not being another diagnosis is that both depend on changes in the other. Schizoaffective disorder is affected by any changes in the diagnostic criteria of schizophrenia, affective disorder, or both. As psychotic affective disorders and schizophrenia have been better distinguished, those who fall through the "diagnostic cracks" have become clearer. In the second edition of DSM (DSM-II) schizoaffective disorder was a subtype of schizophrenia and denoted patients who had any mood symptoms while meeting the criteria for schizophrenia. In contrast, the Research Diagnostic Criteria (RDC) for schizoaffective disorder allowed as few as one symptom of schizophrenia in a patient who met the criteria for a full affective disorder. The third edition of DSM (DSM-III), influenced by studies in the United States and Great Britain, narrowed the diagnosis of schizophrenia and expanded the diagnosis of bipolar disorder. It allowed symptoms of schizophrenia to coexist with a mood disorder as long as these schizophrenic symptoms did not remain when the mood disorder resolved. Moreover, mood-incongruent psychotic symptoms could now exist in bipolar disorder. Finally, schizoaffective disorder moved from its schizophrenia subtype place to stand alone as a "psychotic disorder not elsewhere classified." The revised third edition of DSM (DSM-III-R) expanded this notion by inserting the criterion that a patient with schizoaffective disorder must meet the criteria for schizophrenia for at least 2 weeks independent of any mood syndrome.

DSM-IV has retained most of the DSM-III-R criteria but has stricter diagnostic criteria for schizophrenia. Patients must meet the symptoms of schizophrenia for at least 1 month as opposed to the previous 1-week criterion. Schizoaffective disorder is now listed in the section "Schizophrenia and Other Psychotic Disorders." The 10th revision of *International Statistical Classification of Diseases and Related Problems* (ICD-10) essentially describes the same disorder. The ICD-10 schizoaffective disorders describe single as well as recurrent episodes. Subtypes include manic, depressed, and mixed types. Mixed type includes a cyclic schizophrenia and a mixed schizophrenic-mood psychosis.

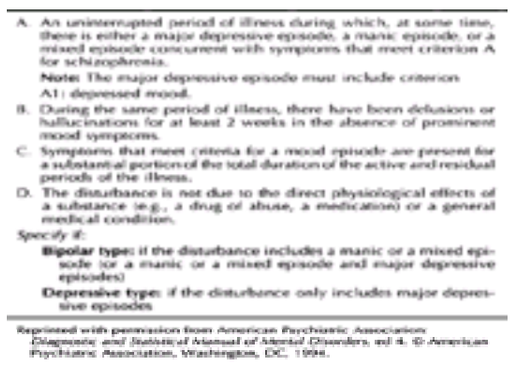
Epidemiology There is no psychiatric epidemiological study of the incidence or prevalence of schizoaffective disorder in a general population. Even if there were such studies, older reports might not be useful, because the diagnosis (and therefore the incidence and prevalence) would have changed over time. Prevalence rates for consecutive patients diagnosed in a psychiatric treatment setting are available. These numbers range from 2 to 29 percent, a potentially significant cohort requiring treatment. Several lines of evidence support the idea that one might expect an increased prevalence of schizoaffective disorder in women. Women have a higher prevalence of major depressive disorder than men do, and women with schizophrenia express more affective symptoms than men with schizophrenia do. In family studies of patients with schizoaffective disorder, relatives of females with schizoaffective disorder have a higher rate of schizophrenia and depressive disorders than do relatives of males with schizoaffective disorder.

Etiology It is difficult to determine a cause of a disease that has changed so much over time. One might conjecture that the etiology of schizoaffective disorder as currently defined might be similar to the etiology of schizophrenia. Thus etiological theories of schizoaffective disorder would include some genetic and environmental causation. Molecular genetic studies of schizoaffective disorder have lagged behind recent studies of the genetics of schizophrenia and bipolar I disorder. Available family studies have reported that families of schizoaffective probands have significantly higher rates of relatives with mood disorder than families of schizophrenia probands. Similarly, these schizoaffective probands have more psychotic symptoms than families of mood disorder probands. The results of these family studies have argued that schizoaffective disorder is a unique disorder, separate from schizophrenia and mood disorders.

Possible environmental causes of schizoaffective disorder are similar to those of schizophrenia, including in utero insult (including malnutrition and viral causes) and obstetrical complications. One hypothesis considers schizophrenia to be a developmental and progressing disorder that can be seen in the development of brain dysmorphology. This includes less cortical gray matter and more fluid and fluid-filled spaces; however, no definitive study of patients with DSM-IV schizoaffective disorder has been done. One might assume that schizoaffective patients would have similar brain abnormalities, because the disorder mimics many aspects of schizophrenia.

For nearly a half century the prevailing etiologic theory of schizophrenia was the dopamine hypothesis. In its simplest description it postulates that the underlying abnormality is excess dopamine in areas of the brain, leading to psychosis. Thus, successful treatment with antipsychotics is due to their dopamine-blocking properties. With the successful use of clozapine (Clozaril) and other serotonin-dopamine antagonists, the dopamine hypothesis has been amended. Currently, a critical balance between the neurotransmitters dopamine and serotonin is believed to be important for treating schizophrenia. At the same time it is accepted that there are abnormalities of serotonin and norepinephrine in mood disorders. These theories are particularly interesting when considering underlying causes of schizoaffective disorder. Possibly this balance of dopamine and serotonin is particularly affected in schizoaffective disorder, leading to chronic psychosis and intermittent but substantial mood alterations.

Diagnostic and Clinical Features DSM-IV diagnostic criteria are provided in Table 13.1-1.



A. An uninterrupted period of illness during which, at some time, there is either a major depressive episode, a manic episode, or a mixed episode concurrent with symptoms that meet criterion A for schizophrenia.
   Note: The major depressive episode must include criterion A1: depressed mood.
B. During the same period of illness, there have been delusions or hallucinations for at least 2 weeks in the absence of prominent mood symptoms.
C. Symptoms that meet criteria for a mood episode are present for a substantial portion of the total duration of the active and residual periods of the illness.
D. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Specify if:

Bipolar type: if the disturbance includes a manic or a mixed episode (or a manic or a mixed episode and major depressive episodes)

Depressive type: if the disturbance only includes major depressive episodes

Table 13.1-1 DSM-IV Diagnostic Criteria for Schizoaffective Disorder

These criteria are a product of several revisions that have sought to clarify several diagnoses including schizophrenia, bipolar disorder, and major depressive disorder. It was hoped that improving these diagnoses would make schizoaffective disorder begin to stand out apart from them. However, the diagnostic criteria still leave much to interpretation. The diagnostician must accurately diagnose the affective illness, making sure it meets the criteria of either a manic or depressive episode but also determining the exact length of each episode (not always an easy or possible task). The length of each episode is critical for two reasons. First, to meet the B criterion (psychotic symptoms in the absence of the mood syndrome) one has to know when the affective episode ends and the psychosis continues. Second, to meet criterion C the length of all mood episodes must be combined and compared with the total length of the illness. If the mood component is present for a substantial portion of the total illness, then that criterion is met. Calculating the total length of the episodes can be difficult, and it does not help that the term “substantial portion” is not defined. In practice, most clinicians look for the mood component to be 15 to 20 percent of the total illness. Patients who have one full manic episode lasting 2 months but who have suffered from symptoms of schizophrenia for 10 years do not meet the criteria for schizoaffective disorder. Instead, the diagnosis would be a mood episode superimposed on schizophrenia. It is unclear whether the bipolar or depressive type specifiers are helpful, although they may direct treatment options. These subtypes are often confused with earlier subtypes (schizophrenic versus affective type) thought to have implications in course and prognosis. As with most psychiatric diagnoses, schizoaffective disorder should not be used if the symptoms are caused by substance abuse or a secondary medical condition.

The ICD-10 diagnostic criteria for schizoaffective disorder are listed in Table 13.1-2.

Table 13.1-2 ICD-10 Diagnostic Criteria for Schizoaffective Disorders

Ms. A.D. was a 29-year-old white unmarried woman, with a 10-year history of schizoaffective disorder bipolar type. She was first hospitalized after child protection took her son away for alleged child abuse. When the patient was interviewed at that time, she was described as dressed like a “gypsy” with heavy makeup and pressured speech. She told the treatment team her son had been abused by his father, a well-known rock star. During this time she was stabilized on lithium (Eskalith) and haloperidol (Haldol). A.D.'s manic symptoms resolved, but her belief that she was a rock star's girlfriend remained. Since that first hospitalization she has lost custody of her son. She remains delusional about the child's famous father, and in addition, she believes people are out to get her. She has had three distinct episodes of mania during which she needs little sleep and has racing thoughts and pressured speech. She has been intermittently compliant with medications and is currently receiving haloperidol in a long-acting form. In the 10 years of her illness she has never been free of her delusions. She has not been able to work and receives federal disability assistance.

Differential Diagnosis The psychiatric differential diagnosis includes all the possibilities usually considered for mood disorders and for schizophrenia

In any differential diagnosis of psychotic disorders a complete medical workup should be performed to rule out organic causes of the symptoms. A history of substance use with or without a positive toxicology screening test may indicate a substance-induced disorder. Preexisting medical conditions, their treatment, or both may cause psychotic and mood disorders. Any suspicion of a neurological abnormality warrants consideration of a brain scan to rule out anatomical pathology and an electroencephalogram (EEG) to determine any possible seizure disorders (e.g., temporal lobe epilepsy). Psychotic disorder due to seizure disorder is more common than that seen in the general population. It tends to be characterized by paranoia, hallucinations, and ideas of reference. Epileptic patients with psychosis are believed to have a better level of function than patients with schizophrenic spectrum disorders. Better control of the seizures can reduce the psychosis.

The same hypothetical case is used in the 3 cases below with different outcomes to illustrate the diagnostic decision.

Mrs. B. was a 32-year-old married woman with three children. She reported being relatively happy and free of illness until the birth of her third child. She had the usual “baby blues” that resolved after the first month. When her third child was 14 months old, she began to have trouble sleeping, and her husband noticed that she was sometimes irritable and at other times euphoric. She began to talk rapidly and call family members at all hours of the night. One night her husband received a phone call that his wife was in the county jail. She had secretly left the house, gone to a local bar, and instigated a fight with a female patron. The police thought she was acting wildly and suspected some sort of intoxicant. She was taken to the local psychiatric clinic where a urine toxicology screen was negative. She was admitted to the hospital and treated with the benzodiazepine, lorazepam (Ativan), and the mood stabilizer lithium, and after 2 weeks was completely asymptomatic.

Her diagnosis is bipolar I disorder, manic type.

Discussion The patient suffered from an elevated and euphoric mood alone. She did not exhibit any symptoms of schizophrenia and was appropriately treated with a benzodiazepine, lorazepam, to calm her and long-term treatment with a mood stabilizer, lithium. This patient might have future episodes with hallucinations, delusions, or both. These psychotic symptoms may or may not be congruent with her mood state (e.g., a patient who is depressed and has the delusion of being a terrible person who has committed a crime and deserves to suffer and be punished). However, the psychotic symptom might also be very incongruent with the mood. The critical distinction for this patient was that the psychotic symptom existed only during the mood episode. Conceptually, the psychosis was fueled by the mood. Correct the mood and there is no fuel for the psychosis and it also disappears.

Mrs. S. was a 32-year-old married woman with three children. She reports that she has been relatively happy and free of illness until the birth of her third child. She had the usual “baby blues” that resolved after the first month. When her third child was 14 months old she began to have trouble sleeping and her husband noticed that she was becoming increasingly isolated and not able to take care of her children. One night her husband received a phone call that his wife was in the county jail. She had secretly left the house, gone to a local bar and instigated a fight with a female patron. The police thought she was acting wildly and suspected some sort of intoxicant. She was taken to the local psychiatric clinic where a urine toxicology screen was negative. At that time she told the staff that she was sure someone was using her social security number and consuming the benefits she would need when she was older. She had gone to the bar because a man's voice had told her that the person who was using her benefits was there. This voice had been talking to her for over a year and often commented on her looks and actions. The patient was admitted to the hospital, treated with the antipsychotic risperidone (Risperdal), and after 2 weeks of treatment was completely asymptomatic.

Her diagnosis is schizophrenia, paranoid type.

Discussion The patient's primary symptoms were delusions and hallucinations without any accompanying mood abnormality. They were of sufficient severity and duration to give her a diagnosis of the paranoid type of schizophrenia, and she was appropriately treated with an antipsychotic agent. Patients suffering from schizophrenia often have both depressive and euphoric symptoms. A common mistake is assuming that a schizophrenic patient presenting with a full range of affect is a patient with schizoaffective disorder. The presence of euphoria or demoralization alone does not meet the criteria for diagnosis of schizoaffective disorder. Patients must both meet the appropriate criteria for the affective disorder and have the affective disorder for a substantial portion of their chronic illness. That said, a patient with schizophrenia suffering from subsyndromal demoralization or disinhibited behavior might benefit from an antidepressant or mood stabilizer, respectively.

Mrs. S.A. was a 32-year-old married woman with three children. She reports that she has been relatively happy and free of illness until the birth of her third child. She had the usual “baby blues” that resolved after the first month. When her third child was 14 months old she began to have trouble sleeping and her husband noticed that she was becoming increasingly irritable, euphoric, isolated and not able to take care of her children. One night her husband received a phone call that his wife was in the county jail. She had secretly left the house, gone to a local bar and instigated a fight with a female patron. The police thought she was acting wildly and suspected some sort of intoxicant. She was taken to the local psychiatric clinic where a urine toxicology screen was negative. At that time she told the staff that she was sure there was someone using her social security number and consuming the benefits she would need when she was older. She also described herself as being one of the 10 smartest people in the world and was sure that the treatment team did not understand her because of their incompetence and she asked to be seen by the head of the hospital. The patient was treated with the antipsychotic risperidone and the mood stabilizer lithium and was completely asymptomatic after 2 weeks of treatment. A year later her husband brought her back to the psychiatric hospital. He reported she had been doing well and was compliant with her medication, which was now lithium carbonate alone. Her mood has been unremarkable, but in the last month she again began to say that someone had stolen her social security benefits. On interview she was calm and cooperative although a little guarded. She reluctantly admitted that the man's voice had returned recently. Risperidone was added back to her regimen, and after 2 weeks she returned to her usual self.

Her diagnosis is schizoaffective disorder, bipolar type.

Discussion The third case (above) displayed symptoms of both a mania and a delusion. She was appropriately treated with an antipsychotic agent and a mood stabilizer. If the vignette had ended there, one might conclude that she had a manic episode with psychotic features. However, she had an exacerbation a year later. This time her mood was totally normal but her delusions and hallucinations returned. She is restarted on the antipsychotic since it appears the mood stabilizer alone was insufficient. It was very appropriate in this circumstance to first taper the patient off the antipsychotic and try the patient on a mood stabilizer alone, aware of the long-term risks of antipsychotics. However, having had the delusional episode while on the mood stabilizer most likely portends a need for intermittent or maintenance antipsychotic treatment.

These 3 women, while having historical details in common, illustrate the differences between a pure mood disorder, schizophrenia, and schizoaffective disorder.

Course and Prognosis Considering the uncertainty and evolving diagnosis of schizoaffective disorder, determining the long-term course and prognosis is difficult. Given the definition of the diagnosis, one might expect patients with schizoaffective disorder to have either a course similar to an episodic mood disorder, a chronic schizophrenic course, or some intermediate outcome. It has been presumed that an increasing presence of schizophrenic symptoms predicted worse prognosis. Studies using RDC criteria showed that after 1 year patients with schizoaffective disorder had different outcomes depending on whether their predominant symptoms were affective (better prognosis) or schizophrenic (worse prognosis). With the narrower definition of DSM-III-R and DSM-IV, all patients had to have an independent schizophrenic component to meet the diagnosis of schizoaffective disorder. One study that followed patients diagnosed with DSM-III-R schizoaffective disorder for 8 years found that the outcomes of these patients more closely resembled schizophrenia than a mood disorder with psychotic features.

Treatment There are several extensive reviews of the treatment of schizoaffective disorder, but critical evaluation of the results of these studies is not easy. Because the operational definition of schizoaffective disorder has shifted over the last 30 years, comparing or pooling studies is impossible. The efficacy and selection of treatment for a patient under the broader (more mood disorder inclusive) DSM-II criteria may differ from that of the patient diagnosed with the narrower DSM-III-R criteria. However, there are some general recommendations for treatment. The principle rule is to treat the patient's symptoms, not the diagnostic label.

Mood Stabilizers Mood stabilizers are a mainstay of treatment for bipolar disorders and would be expected to be important in the treatment of patients with schizoaffective disorder. Few studies have examined the efficacy of mood stabilizers in schizoaffective disorder, in contrast to the extensive studies of lithium, valproate (Depakote), and to a lesser extent carbamazepine (Tegretol) in bipolar I disorder. A recent study that compared lithium with carbamazepine showed superiority for carbamazepine for schizoaffective disorder, depressive type, but no difference in the two agents for the bipolar type. In practice however, these medications are used extensively alone, in combination with each other, or with an antipsychotic agent. In manic episodes, schizoaffective patients should be treated aggresively with dosages of a mood stabilizer in the middle to high therapeutic blood concentration range. As the patient enters a maintenance phase the dosage can be reduced to low to middle range to avoid adverse effects and potential effects on organ systems (e.g., thyroid and kidney) and to improve ease of use and compliance. Laboratory monitoring of plasma drug concentrations and periodic screening of thyroid, kidney, and hematological functioning should be performed. As in all cases of intractable mania, the use of electroconvulsive therapy (ECT) should be considered.

Psychosis or akathisia must be distinguished from a manic episode. For a psychotic agitation, an antipsychotic agent (often with a benzodiazepine) is indicated. In akathisia, numerous studies have shown that reducing the antipsychotic agent dosage or using benzodiazepine or a b-adrenergic receptor antagonist are helpful.

Antidepressants By definition many schizoaffective patients suffer from major depressive episodes. Treatment with antidepressants mirrors treatment of bipolar depression. Care should be taken not to precipitate a cycle of rapid switches from depression to mania with the antidepressant. The choice of antidepressant should take into account previous antidepressant successes or failures. Selective serotonin reuptake inhibitors (e.g., fluoxetine [Prozac] and sertraline [Zoloft]) are often used as first-line agents because they have less effect on cardiac status and have a favorable overdose profile. However, agitated or insomniac patients may benefit from a tricyclic antidepressant. As in all cases of depression, use of ECT should be considered.

It is very important to try to distinguish psychosis, akinetic syndromes, and primary negative symptoms from depression. Again, psychosis should be adequately treated with an antipsychotic agent. Suspected akinetic treatment can be improved by lowering the dosage of antipsychotic agent, treating with an anticholinergic agent, or switching to a serotonin-dopamine antagonist like clozapine (Clozaril), risperidone, olanzapine (Zyprexa), or quetiapine (Seroquel). Negative symptoms are often difficult to tease out. While there are no definitive studies, these symptoms may improve with the use of serotonin-dopamine antagonists.

Antipsychotic Agents As mentioned above, antipsychotic agents are important in the treatment of schizoaffective disorder. The introduction of chlorpromazine in the 1950s showed antipsychotic agents that block the action of the neurotransmitter dopamine are effective in the treatment of psychosis. Therefore it is not surprising that these compounds are effective in treating the psychotic symptoms that plague patients with schizoaffective disorder. What is not as clear is whether they alone can control both the schizophrenic and the affective symptoms. Because of the complexity and mixed nature of the illness pharmaceutical companies have generally avoided separate studies of antipsychotic agents, with schizoaffective patients. As medications were approved for use in schizophrenia, they were almost immediately used for patients with schizoaffective disorder. With the advent of combined serotonin-dopamine blocking agents, more schizoaffective patients are being recruited for efficacy and safety trials of new antipsychotic agents.

The introduction of the serotonin-dopamine antagonist holds promise for patients with schizophrenia and schizoaffective disorder. While much more data exist on clozapine efficacy in patients with schizophrenia, a few studies have described either comparable or greater efficacy with schizoaffective patients. There may be

several reasons why patients diagnosed with schizoaffective disorder respond favorably to clozapine. First, clozapine has been shown to be superior in treating positive symptoms of schizophrenia and therefore the positive symptoms of schizoaffective disorder. Second, akinetic syndromes that can mimic depressive syndromes are greatly reduced with clozapine use. Third, some evidence indicates that clozapine may have mood-stabilizing properties. This hypothesis is based on several studies showing good results using clozapine in patients with difficult cases of bipolar disorder. Data for risperidone, olanzapine, and quetiapine in treating schizoaffective disorder are minimal. One such study showed superiority of haloperidol and amitriptyline over risperidone in a group of psychotic patients (including schizoaffective disorder patients) with depressive symptoms.

Psychosocial Treatment Considering the present notion that schizoaffective disorder as specified in DSM-IV closely resembles schizophrenia, one can assume that psychosocial treatment of schizoaffective disorder should mimic that of psychosocial treatment of schizophrenia. Therefore, patients should benefit from a combination of family therapy, social skills training, and cognitive rehabilitation. Because the psychiatric field has had difficulty deciding the exact diagnosis and prognosis of schizoaffective disorder, this uncertainty must be explained to the patient. Historically, patients and families have been told that schizoaffective illness has a better prognosis than schizophrenia, but this may no longer be true. Patients and their families must contend with an evolving diagnosis; they may be told the patient is suffering from a treatable mood disorder at first and later told that it is a severe psychotic disorder. The range of symptoms can be quite large as patients contend with both ongoing psychosis and varying mood states. It can be very difficult for family members to keep up with the changing nature and needs of these patients. Medication regimens can be more complicated, with multiple medications frequent, and psychopharmacological education is important. However it is often difficult to explain to patients and their families that new medication treatments have been tested in affective and schizophrenic disorders but not schizoaffective disorder.

SCHIZOPHRENIFORM DISORDER

History Gabriel Langfeldt, first used the term *schizophreniform* in 1939, at the University Psychiatric Clinic in Oslo, Norway. As originally used, this diagnosis relied on a tradition of Scandinavian psychiatry, which had identified a condition that had relatively brief and self-contained psychotic intervals. Patients recovered well and had affective and sometimes hysterical components to their illness, and the diagnosis was used to distinguish a group considered to have little relation to true schizophrenia.

Comparative Nosology In contrast to this rather specific role for schizophreniform disorder, the current DSM-IV diagnosis has relatively little to do with the origin of the term and much more to do with the tradition of Kraepelinian schizophrenia as a chronic illness. Prior to the DSM-IV revision of this diagnostic entity, DSM-III and DSM-III-R had used this diagnosis as a “schizophrenia-in-waiting” diagnosis, with the only difference between the two diagnoses being whether the illness had lasted a total of 6 months including psychotic, prodromal, and residual symptoms. Under the DSM-III and DSM-III-R systems, the psychotic phase of the illness needed to last only 1 week, and less if treated successfully. The remainder of the 6-month-duration criteria for schizophrenia comprised residual or prodromal symptoms. Patients who had an insidious onset with prodromal symptoms preceding the onset of psychotic symptoms by at least 6 months would be given a diagnosis of schizophrenia as soon as the psychotic symptoms lasted 1 week. Those who had limited prodromal symptoms or who had sudden onset of psychosis as the first sign of illness, however, would not be diagnosed as having schizophrenia until the total period of illness reached 6 months. During what for many was a waiting period, the diagnosis of schizophreniform disorder would be used. Because of the relatively brief period of psychosis required (1 week) on the one hand and the similarity with schizophrenia on the other, this category formerly consisted of patients with potentially many types of psychoses—brief reactive psychosis, “schizophrenia-in-waiting,” and true schizophreniform disorder. Unfortunately, the true schizophreniform disorder would be difficult to sort out from this diagnostic system, and relative to the other categories it is probably quite rare, although potentially important as a time-limited psychotic illness that returns to baseline functioning without residual symptoms.

The revisions of DSM-IV have made one of the above overlaps less likely—the one with brief reactive psychosis. To separate these two disorders diagnostically, the DSM-IV diagnosis for schizophreniform disorder requires a month of psychotic symptoms rather than 1 week. Further, brief reactive psychosis has changed to brief psychotic disorder because the diagnostic criteria reaction-to-a-stressor was considered too ubiquitous—but DSM-IV includes the concept as a specifier. From the other side, the diagnosis of schizophreniform has moved much closer to its parent diagnosis of schizophrenia with the requirement for 1 month of psychotic symptoms. Although no data are currently available on the course of schizophreniform illness, the requirement for a greater duration of psychotic illness will probably make it less likely that a given patient will recover before 6 months of total illness comprising both psychotic symptoms and residual or prodromal symptoms (now referred to as attenuated symptoms) is reached.

This category now looks exactly like schizophrenia with an unanticipated full recovery before 6 months. Some data suggest that those who indeed do recover before 6 months have better 5- and 10-year outcomes. Whether this represents a separate disorder category or merely one end of a distribution of outcomes in schizophrenia is yet to be determined. There will always be the unusual patient who appears to have schizophrenia but recovers completely. They are exceedingly rare. Further, this category of illness continues to be severely hampered by a lack of research, and indeed the changing criteria for diagnosis makes it difficult to focus on this “moving target.” Most data will continue to be anecdotal. ICD-10 does not have a designated schizophreniform disorder, although the concept is included in several categories. The diagnosis acute schizophrenia-like psychotic disorder describes a disorder that would otherwise be considered schizophrenia but with symptoms lasting less than 1 month. If the symptoms persist past the month, the ICD-10 diagnosis of schizophrenia should be used. There is also a subclassification for a schizophreniform psychosis manic or depressed type under “schizoaffective disorders”; however, according to DSM-IV, schizophreniform disorder is subsumed order ICD-10's category of other schizophrenia.

Another reason for having this diagnostic category is that it avoids having to use the term *schizophrenia* with all of its negative connotations early in the diagnostic formulation. Many families require considerable time to reconcile the future of their family member. A gradual introduction to the concept of schizophreniform disorder, with a waiting period during which the family can more realistically orient itself and learn about the illnesses in the schizophrenia spectrum may prove helpful to some. Further, because of the negative connotation of schizophrenia and the stigma currently attached to it, a diagnostic system that avoids a false-positive diagnosis of schizophrenia is desirable. A 6-month duration of illness prior to making the diagnosis of schizophrenia will eliminate virtually all false-positive diagnoses.

As noted above, schizophreniform disorder shares an overlap with schizophrenia with two exceptions: the duration of illness is from 1 to 6 months and social or occupational dysfunction is not required to meet the diagnosis, although it may occur at some point in the illness. Given the requirement of 1 month of psychotic symptoms, however, it seems quite unlikely that a person's social and occupational functioning would not be disrupted. DSM-IV describes two possible conditions for this diagnosis: (1) when a person has recovered within the 6-month period (the “pure” form of schizophreniform disorder) and (2) when a person has not had the illness long enough (6 months) to meet the diagnosis of schizophrenia. For this latter condition, the term “provisional” is used. A guide for clinicians is given as a part of the diagnosis, which should be qualified by the presence or absence of good prognostic signs. The following are listed, and two are required for the qualifier of good prognosis: (1) rapid onset of psychotic symptoms, (2) confusion at the peak of psychotic symptomatology, (3) good premorbid social and occupational functioning, and (4) maintenance of a range of affect.

As with most psychiatric diagnoses, schizophreniform disorder should not be used if substance abuse or a secondary medical condition causes the symptoms.

Epidemiology Because of the significant change in the diagnostic criteria for schizophreniform disorder in DSM-IV, there are currently no epidemiological data from community samples. The risks of drawing from treatment samples are well known in terms of the variability introduced by clinic type, socioeducational variables, urban/rural factors, and even treatment philosophy. The elegance of the Epidemiologic Catchment Area (ECA) study with its five sites, using census track data collection, is not likely to be repeated in the near future, and its data were derived using DSM-III criteria. The significant changes from that period would include changing from 1 week of psychotic symptoms to 1 month, adding the concept of “provisional” diagnosis, and adding the good prognostic signs. Clearly, lengthening the requirement for psychotic symptoms was the most significant change, because it eliminated what most certainly were many cases of brief psychotic disorder. The data from the ECA study indicate a lifetime prevalence of 0.2 percent and a 1-year prevalence of 0.1 percent. Even with inclusion of cases of brief psychosis, this is a relatively small category. One could extrapolate that with the further stringency of DSM-IV, the category would become even smaller.

Etiology Because of the change in the duration of illness, most persons who fall in this category will have underlying pathologies similar to those with schizophrenia. This will certainly be true for those who carry this diagnosis provisionally while waiting for the 6-month time period to elapse before changing the diagnosis to schizophrenia. There has been ample speculation about whether “acute” schizophrenia (rapid onset, good premorbid functioning) differs from insidious-onset schizophrenia in anything more than severity of such factors as negative symptoms. A rapid and complete response to a treatment intervention may eventually help to differentiate those in this category from standard antipsychotic nonresponders. The concept that the heterogeneity of the underlying biology may be responsible for differential treatment response is not new, but it has been given increasing credibility with the advent of the serotonin-dopamine antagonists (clozapine, risperidone, olanzapine, and quetiapine). It is now probably safe to say that any set of biological, neurophysiological, psychologic or other tests will find this group of patients looking much more closely like schizophrenia than any other category. In fact, the abnormalities consistent with schizophrenia may already be present in schizophreniform disorder. One such abnormality, decreased gray matter volume, has been seen in MRI studies but to a lesser extent than in patients with chronic

schizophrenia. The cause of pure schizophreniform disorder will probably not be known for a long time, because a patient group that small will be hard to study.

Diagnostic and Clinical Features The DSM-IV criteria for schizophreniform are listed in Table 13.1-3. Schizophreniform disorder in its typical presentation is a rapid-onset psychotic disorder without a significant prodrome. Hallucinations, delusions, or both will be present; negative symptoms of alogia and avolition may be present. Affect may be flattened, which is seen as a poor prognostic sign. Speech may be grossly disorganized and confused, and behavior may be disorganized or catatonic. The symptoms of psychosis, the negative symptoms, and those affecting speech and behavior will last at least 1 month but may last longer. The patient's degree of perplexity about what is happening should be assessed, as this is a differentiating prognostic sign.

A. Criteria A, D, and E of schizophrenia are met.
B. An episode of the disorder (including prodromal, active, and residual phases) lasts at least 1 month but less than 6 months. (When the diagnosis must be made without waiting for recovery, it should be qualified as "provisional.")

Specify if:
Without good prognostic features
With good prognostic features as evidenced by two (or more) of the following:
(1) onset of prominent psychotic symptoms within 4 weeks of the first noticeable change in usual behavior or functioning
(2) confusion or perplexity at the height of the psychotic episode
(3) good premorbid social and occupational functioning
(4) absence of blunted or flat affect

Table 13.1-3 DSM-IV Diagnostic Criteria for Schizophreniform Disorder

Although the above is the typical presentation, a picture exactly resembling that of schizophrenia may also occur. In that case, the onset may be insidious, premorbid functioning may have been poor, and affect is quite blunted. The only differentiation from schizophrenia for this type of presentation will be duration of the total episode of illness. When it has lasted 6 months, the diagnosis becomes schizophrenia. In making the diagnosis in the case with insidious onset, the “attenuated symptoms” of the acute episode may have lasted for some time. If they have been present for at least 5 months and then the acute episode lasts 1 month, the diagnosis of schizophrenia is appropriate, without a prior diagnosis of schizophreniform disorder.

In the typical form of the disorder, the patient returns to baseline functioning by the end of 6 months. Theoretically, repeated episodes of schizophreniform illness are possible, each lasting less than 6 months, but rarely is functioning not lost with repeated episodes of this severe illness, and schizophrenia is a more likely consideration.

Ms. L.J. was a 29-year-old Hispanic second daughter of an intact and stable family. She completed high school without problems and was described as outgoing and friendly. She considered college but opted to work. She spent several years as factory worker and had decided to go back to school and become a teacher. Five months ago she had a sudden “awareness” that God was present and filling the souls of people around her. She became acutely distressed when she realized God was not going to “touch her.” Her family was quite surprised and alarmed by her sudden change in behavior. She was brought to the local emergency room. While she occasionally drank alcohol and had smoked marijuana in the past, the family did not suspect a substance abuse problem. Toxicology screening in the emergency room was negative for substances. She was admitted to the hospital for evaluation. She told the psychiatrist that she felt she had done something wrong and that was why God had abandoned her. She also reported that she felt people on the ward were reading her mind. She was particularly concerned that her critical thoughts about others could be heard and then these angry people would attack her. L.J. was stabilized on haloperidol then switched to risperidone because of side effects. A family meeting was held to discuss her problems. At that time, the psychiatrist recommended a wait-and-see approach. The psychiatrist told the family and patient to follow up with an outpatient doctor and remain on the medication if the outpatient psychiatrist recommended it. Two months after her admission she no longer was distressed by her religious concerns. However, she still felt people could read her mind. Three months after her admission she no longer felt that people could read her mind, and she had returned to her community college. A month later, she stopped taking her antipsychotic agent because she felt she didn't need it. Two weeks ago her family brought her to the emergency room because she was again talking about God and “hiding” from people who could read her thoughts. She initially refused medications but resumed taking them, with some improvement of her psychosis. A family meeting was held to discuss the return of her psychosis and the fact that she may eventually be diagnosed with schizophrenia.

Differential Diagnosis Although the major differential diagnoses are with brief psychotic disorder and schizophrenia, the rapid onset of acute psychosis may be the most important diagnostic point in a patient's course of illness. The clinician should focus on the prior 6 months, taking a detailed history of occupational and social functioning, the pattern of onset, the presence or absence of mood changes, alcohol and substance abuse, and other illness and prescriptive medication. Of special interest will be any family history of psychiatric illness, mood disorders or schizophrenia-like illnesses in particular. A recent study showed a high prevalence of personality disorders after recovery from the psychosis. One could hypothesize that the personality disorder predisposes one to psychosis especially when under stress.

A complete physical examination is always indicated with the presentation of a psychotic illness. Suggestions of endocrinologic involvement, such as thyroid functioning, should be followed up with laboratory studies. If substance abuse is suspected, however remote a possibility, a toxicology screening test should be performed. Changes in sensorium and the rapid onset of symptoms should raise clinical suspicion of substance toxicity. Alcohol may be involved in a number of ways. Certainly, alcohol withdrawal and the onset of delirium may be associated with psychotic symptoms. Further, alcohol abuse leads to unreliable medication taking, even of prescribed medications, which can lead to psychotic features.

The separation of mood disorders with psychotic features from a rapid-onset schizophreniform disorder may be difficult and tests the clinician's skills. Negative symptoms such as alogia, avolition, and blunted affect may be difficult to distinguish from the loss of interest and pleasure seen with major depressive episodes. Appetite, sleep, and other neurovegetative symptoms may also occur with both. The presence of the psychotic features of the illness, in the absence of these mood features, will assist the clinician in making the diagnosis of schizophreniform disorder, but this may take time to evolve.

To differentiate from brief psychotic disorder, a time cutoff has been established, more than 1 day but less than 1 month. During this period, the diagnosis must be brief psychotic disorder. In diagnostic systems prior to DSM-IV, the presence or absence of a stressor was used to differentiate these two conditions further, but it is no longer used in the nosology, except as a descriptor or modifier. Differentiation is based solely on the time line.

Course and Prognosis The course of schizophreniform disorder is for the most part defined in the criteria. It is a psychotic illness lasting more than 1 month and less than 6 months. The real issue is what happens to persons with this illness over time. Most estimates of progression to schizophrenia range between 60 and 80 percent. What happens to the other 20 to 40 percent is currently not known. Some will have a second or third episode during which they will deteriorate into a more chronic condition of schizophrenia. A few, however, may have only this single episode and then are able to continue on with their lives. While this is clearly the outcome desired by all clinicians and family members, it is probably a rare occurrence and should not be held out as likely.

The prognostic features used to characterize the illness are listed above. Their presence will, indeed, be useful in suggesting some likelihood of a favorable outcome. Clinical experience, however, tempers the confidence in these predictors, as many patients with all four of the descriptors have a deteriorating course and outcome.

Treatment Although no available studies have directly addressed the treatment of schizophreniform disorder, the approach should be that for any psychotic disorder of recent onset. The most important initial evaluation is safety, both for the patient and the patient's environment.

Safety Assessment of safety or danger is a complex series of probabilities, not certainties. The best predictor is, of course, past behavior. Someone suffering from the sudden onset of psychosis may not have any past history if this is the first episode. If so, any evidence of prior violence must be seriously considered in forming the initial treatment plan. The evaluation of predictability and hostile affect becomes critical in deciding whether hospitalization is necessary. With someone suffering from an acute psychotic disorder who shows any signs of hostility, anger, and confusion or has a history of explosive or violent activity, hospitalization should be an important consideration. In the absence of these features, hospitalization may be a consideration if the environment itself, usually the family, cannot comfortably

ensure that the treatment plan can be carried out in a safe, stress-reducing manner. For most families this will not be possible.

Inpatient Treatment Plan The inpatient unit is usually a significant part of the initial treatment plan. In addition to pharmacological management, the unit program and philosophy are critical ingredients in helping to stabilize the patient as rapidly as possible. An environment that is critical, intrusive, and overinvolved, with a multistimulus approach to the patient has negative impact on psychosis-prone patients. With this in mind, the patient should not necessarily be required to attend group meetings, therapeutic community, or orientation but should rather be approached in a one-on-one manner with time-limited interactions. Communication should be direct and simple, and the program should be structured with relatively little free time. Visitors should be oriented to this same principle and should be encouraged to visit one at a time.

Outpatient Treatment Plan The patient who has begun to recover from an acute psychotic episode will continue to need a comfortable environment with considerable structured activity. Complex communications and interactions should be kept to a minimum early, although introduction of some simple group work in an attempt to normalize socialization may be carefully planned. Gradual resumption of activities should be attempted one at a time, with mastery achieved before the introduction of new activities. In the case of a student, for example, it would be much better to begin with one course and succeed than with a full course load that would most likely lead to failure. Incremental progress is the goal, and it should extend well beyond the 6 months required for diagnosis.

Role of the Family There is no more significant factor in the successful outcome of a patient with acute onset psychosis than family involvement in the treatment. As reviewed elsewhere, the data are compelling that a clinical treatment program that enlists the family in a positive clinical alliance does better than one that does not, regardless of the other treatment modalities being used. There is no more consistent finding in outcome studies of the late 1980s and 1990s than the positive outcomes found in programs that work with families. In general, most of these programs begin with some form of educational program about schizophrenia, the importance of medication, the expectations of families, and the identification of early signs of impending relapse. Some of the programs have worked elaborately with patients and their families with behavioral paradigms, others have worked with monthly group interactions involving multiple patients and their families. For many of these families this introduction to working as a member of the treatment team enlists them into a long-term positive relationship with the treatment program. For others, it gives them the skills needed to participate in the rehabilitation process. This positive alliance will serve the program, the patient, and the family well. It opens lines of communication and takes a major step toward ensuring that the patient will receive the best monitoring and most appropriate treatment available. Active involvement of a family support group, such as the local chapter of the Alliance for the Mentally Ill, is often quite useful as well. Frequently, however, families experiencing their first episode of psychosis in a family member find association with a group of people who have family members with chronic illnesses to be too threatening. They may wish to believe that their family member will recover, and certainly for those who have true schizophreniform disorder, this will be true.
