Diagnosis and Clinical Features Traditionally the diagnosis of Huntington's disease was made in the context of a positive family history and the onset of characteristic symptoms, and was usually confirmed by noting caudate atrophy on MRI. Now, definitive diagnosis can be made before the onset of symptoms and even in utero, via genetic testing for the number of trinucleotide repeats in IT-15. Clinical features are dominated by motor, cognitive, and psychiatric disturbances. Motor symptoms are classically choreiform, with gradual onset and marked progression. Other motor symptoms, including parkinsonism, myoclonus, dystonia, dysarthria, and tics are also observed. In early-onset Huntington's disease, parkinsonism, ataxia, seizures, and dementia are characteristic. The motor abnormalities frequently result in falls with head trauma and aspiration caused by dysphagia. On neurological examination primitive reflexes are found.

Psychiatric Features A variety of cognitive changes have been noted in patients with Huntington's disease, and are commonly present early in the course. According to DSM-IV the “essential feature of dementia due to Huntington's disease is the presence of a dementia that is judged to be the direct pathophysiological consequence of Huntington's disease.” Huntington's disease has been described as a prototypical subcortical dementia, although the validity of this concept of cortical and subcortical dementias has been debated. Typically, rather than symptoms of cortical dementias (agnosia, apraxia, and poor comprehension), Huntington's disease is characterized by abnormalities in problemsolving, insight, judgment, abstraction, attention, and motivation. Memory problems include difficulties involving retrieval. Language impairment is usually characterized by dysarthria and perseveration.

Psychiatric presentation depends to some extent on age at onset, which is typically the third or fourth decade. Symptom onset can also be seen in childhood and early adolescence or as late as after age 50. Earlier onset is usually accompanied by depression and characterological manifestations, including apathy, irritability, and emotional lability. Mood disorders affect about 30 percent of patients, and typically develop well before the onset of the movement disorder. The most common mood disorder is major depression, although mania is also seen in up to 10 percent of cases. Suicide, a complication of depression, affects about 6 percent of patients with Huntington's disease, which is four to six times higher than in the general population. Psychosis has been reported in 6 to 25 percent of patients with Huntington's disease. Hallucinations and paranoid delusions are most frequent and can develop prior to the onset of motor symptoms.

Pathology and Laboratory Examination Early in the course of Huntington's disease reduced metabolism is seen in the caudate nucleus and the putamen. Later, as symptoms develop, the classic reduction and disappearance of the head of the caudate is seen. On neuropathological examination atrophy is found in the caudate nucleus and the putamen, with the frontal and occipital cortex being variably affected. Tissue loss is observed less frequently in the globus pallidus, substantia nigra, and thalamus. On microscopic examination, loss of medium-sized spiny GABAergic neurons is most prominent, while some sparing of interneurons, such as those containing somatostatin, is observed. Some postmortem and PET studies suggest that D_1 and D_2 receptors are both reduced to similar degrees, suggesting that both striatonigral and striatopallidal pathways are involved in the neurodegeneration. The enkephalin-containing neurons of the striatopallidal pathway may be the first to die, perhaps accounting for the initial presentation with chorea. Loss of this pathway should lead to relative overactivation of the D_1-mediated direct pathway. In early-onset cases, both pathways may be equally affected, leading to predominant parkinsonian symptoms.

Differential Diagnosis The differential diagnosis of Huntington's disease has been simplified by the identification of the mutant gene. The primary challenge for the clinician is thus to know when to order the test. A family history of Huntington's disease in the face of new-onset movement disorder, psychological changes, or cognitive problems should lead one to the diagnosis. For adopted persons, the diagnosis of Huntington's disease must be entertained for new-onset movement disorders. A list of other disorders that also produce chorea and dyskinesia is provided in Table 2.6-2.

Table 2.6-2 Differential Diagnosis of Chorea/Dyskinesia

Course and Prognosis The course of Huntington's disease is relentlessly progressive with increasing cognitive deficits and neurological dysfunction. Typically, patients survive 10 to 15 years after the first clinical manifestations. Death results from head trauma, cachexia and attendant pneumonia, or suicide. There is no cure and the illness is uniformly fatal. Age of onset and progression appears to be strongly correlated with the number of trinucleotide repeats. Patients with 47 or more repeats have an earlier age of onset and more rapid deterioration of both neurological and cognitive function.

Treatment There is no currently accepted treatment that will ameliorate or limit the progressive neuronal degeneration that ultimately leads to the demise of patients with Huntington's disease. Trials of antioxidants, such as idebenone, have not produced significant results, although larger studies are needed. Fetal striatal tissue transplants are currently in development and may offer some hope in the future. Symptomatic relief for chorea can be obtained with neuroleptics, such as haloperidol (Haldol) and risperidone (Risperdal). Cholinergic agonists have not been particularly helpful for treatment of chorea, although trials of newer drugs such as tacrine (Cognex) that cross the blood-brain barrier more easily have not been published.

Treatment of secondary psychiatric symptoms is similar, for the most part, to that of primary disorders. Depression can be treated reasonably well with antidepressants; manic symptoms are more easily controlled with anticonvulsants than with lithium. Psychotic symptoms may not respond as well to neuroleptics as

do primary psychoses. Agitation and other behavioral abnormalities that frequently accompany dementing illnesses can be managed by standard psychiatric interventions.

B.W., aged 41, was admitted to a forensic unit for his first psychiatric hospitalization for court-ordered competency evaluation after assaulting his ex-wife. He was a vague historian. He lost his full-time position as a carpenter 3 years before admission, but was evasive regarding the circumstances. He acknowleged previous treatment with neuroleptics for paranoid ideation, but duration of treatment was unknown. The patient reported a history on the paternal side of "some kind of mental disorder," which resulted in the institutionalization of several relatives, but he had no additional information. Outpatient records revealed that increasingly explosive behavior led to a diagnosis of antisocial personality disorder when the patient was in his mid-30s. The admitting psychiatrist observed choreiform movements of the limbs and trunk, and referred the patient for MRI (Fig. 2.6-3) to distinguish between a diagnosis of tardive dyskinesia versus Huntington's disease. This case exemplifies the diagnostic dilemma that arises when a patient presents with psychiatric symptoms, is placed on neuroleptics, and develops a movement disorder. The psychiatrist was alerted to the possibility of a neurodegenerative disorder by the constellation of severe familial psychiatric illness, the patient's apparently unremarkable premorbid history until he was in his 30s, and the choreiform movements, deoxyribonucleic acid (DNA) testing was not yet available; however, the MRI scan (Fig. 2.5-2) was virtually pathognomonic for Huntington's disease.

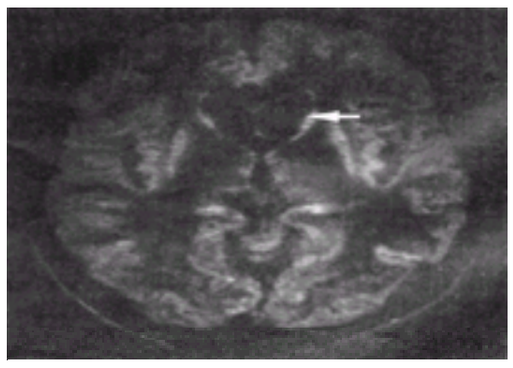

FIGURE 2.6-3 MRI of patient in case report of Huntington's disease (see text). White arrow delineates atrophic head of caudate, with characteristic "butterfly" appearance of the anterior horns of the lateral ventricles. (Courtesy of Steven S. Wolf, M.D.)

NEUROLEPTIC-INDUCED TARDIVE DYSKINESIA

Tardive dyskinesia is a movement disorder that develops during the course of long-term treatment with neuroleptic agents. It is characterized primarily by choreiform and athetotic movements; dystonia, tics, and parkinsonism are also seen. The onset of tardive dyskinesia is typically delayed, with symptoms first appearing only after years of treatment. Because tardive dyskinesia can be disfiguring, persistent, and even permanent, it has been a major limiting factor in the use of antipsychotic medications. Recently, the introduction of clozapine (Clozaril) in the United States has offered hope that tardive dyskinesia may be avoided. Clozapine is a unique, "atypical" neuroleptic that does not appear to cause tardive dyskinesia. Unfortunately, its use has been severely restricted because of its other side effects, the most serious of which is agranulocytosis. Clozapine-induced agranulocytosis has caused a number of fatalities; its use in the United States is now contingent on weekly white blood cell counts. Since the introduction of clozapine and the recognition of its unusual features, intensive efforts have been directed at developing clozapine-like medications that do not cause agranulocytosis. It is hoped that the emerging generation of putative atypical antipsychotics, such as risperidone, olanzapine, and sertindole will, like clozapine, have a reduced liability to produce tardive dyskinesia.

Definition The research criteria for neuroleptic-induced tardive dyskinesia require choreiform, athetoid, or rhythmic involuntary movements to develop in association with use of neuroleptic agents for at least 3 months, persist for at least 4 weeks, and not be attributable to another disorder.

Epidemiology Although estimates vary widely, the best studies suggest that tardive dyskinesia affects about 20 to 30 percent of patients treated with long-term neuroleptic medications. About 5 percent of patients develop tardive dyskinesia for each year they remain on these drugs. A number of variables have been associated with increased liability for developing tardive dyskinesia, including increased age, a diagnosis of mood disorder, brain damage, dosage and duration of treatment, and number of drug-free periods. Sex is often mentioned as a factor, but results from many studies are often confounded by other variables, such as age, and dosage of the neuroleptic drug. Nevertheless, older women seem to be more susceptible to developing tardive dyskinesia. The incidence of tardive dyskinesia during long-term treatment with the newer, putatively atypical agents, such as risperidone, olanzapine, and sertindole, is not known.

Etiology By definition, tardive dyskinesia is caused by chronic exposure to neuroleptic medications (i.e., drugs that potently inhibit D_2 receptors). Neuroleptic drugs do not produce tardive dyskinesia in all exposed persons, however, which means that substantial differences in liability exist. The additional factors that predispose persons to tardive dyskinesia suggest that a number of neurobiological processes may be involved. For example, the association of tardive dyskinesia with cortical brain damage implies that altered corticostriatal input could play a role. The possible reduced liability to tardive dyskinesia associated with atypical agents—the serotonin-dopamine agonists—implies that serotonin may play a role. Finally, the appearance of tardive dyskinesia-like movements in drug-naive patients with schizophrenia raises questions of whether the tardive dyskinesia-inducing processes are fundamental to the neurobiology of this illness.

Diagnosis and Clinical Features The diagnosis of tardive dyskinesia is made by excluding other organic causes of hyperkinetic movement disorders. In general, patients who present with mild to moderate choreo-athetotic symptoms during long-term treatment with neuroleptic drugs will invariably be diagnosed as having tardive dyskinesia. The yield of extensive medical evaluations on such patients is very low, and it is unclear whether this is cost effective. However, a neurological examination and family history are easily obtained and represent a reasonable initial workup. Additional laboratory testing can be considered, particularly for patients with moderate to severe symptoms, functional impairment, marked dystonic features, significant asymmetry, medical complications, or rapid progression. Such presentations sometimes indicate an underlying neurological disorder. A reasonable laboratory screening battery for such cases would include blood cell count (to look for acanthocytes), thyroid indices, liver function tests, electrolytes, renal function tests, antinuclear antibodies and lupus erythematosus preparation, rapid plasma reagin (RPR), serum copper and ceruloplasmin, and pregnancy test (where appropriate). Additional testing for suspicious cases would also include slit lamp examination of the eyes, MRI of the brain, and electroencephalogram (EEG).

Neurological Features Tardive dyskinesia is characterized by chorea and athetosis. The distribution of these movements tends to fall into two areas: (1) the oral, buccal, and facial regions, and (2) the neck, trunk, and extremities. Some authors have proposed that orofacial and limb-truncal distributions may have different underlying neurobiological correlates. Frequently, patients have symptoms both in orofacial regions and in the extremities. Dystonia is a second type of movement abnormality frequently seen in tardive dyskinesia, when it predominates, it is referred to as *tardive dystonia.* Dystonic symptoms usually affect the neck and hands, but can involve other regions as well. Other types of movement abnormalities can be part of the tardive dyskinesia syndrome; these include akathisia, tics, and even parkinsonism. Patients with tardive dyskinesia also have more neurological soft signs as compared to patients without tardive dyskinesia. The motor symptoms of tardive dyskinesia should be routinely looked for using the Abnormal Involuntary Movement Scale (AIMS) examination, or one similar to it, in all patients treated with long-term neuroleptic agents.

Psychiatric Features Patients with tardive dyskinesia tend to demonstrate a number of neuropsychiatric features as compared to patients without tardive dyskinesia. These differences include more negative symptoms (i.e., alogia, avolition, and affective flattening), more prominent ventricular enlargement, and greater deficits in neuropsychological testing. Such patients may be more likely to develop tardive dyskinesia. It has been argued, for example, that patients with schizophrenia have deficits in cortical function from a variety of different regions (e.g., frontal and temporal regions). Patients with more severe cortical deficits may be more likely to develop tardive dyskinesia because of changes in subcortical function that are secondary to cortical abnormalities. Another possibility is that the constellation of negative symptoms, cognitive deficits, and ventriculomegaly is related to tardive dyskinesia itself.

Pathology and Laboratory Examination No characteristic feature is noted in laboratory evaluations of tardive dyskinesia. A variety of postmortem studies have suggested alterations in GABAergic neurons in several basal ganglia structures, but these findings are experimental and have no diagnostic value. Neuroimaging studies have suggested a slight increase in ventricular volume in patients with tardive dyskinesia, but not all studies have found this.

Differential Diagnosis Neuroleptic-induced tardive dyskinesia must be distinguished from other hyperkinetic movement disorders such as are described in Table 2.6-2. Other causes should be sought when symptoms preceded treatment with neuroleptics or if other neurological signs are evident. Moreover, neuroleptic-induced tardive dyskinesia may coexist with other neuropathology.

Course and Prognosis Once tardive dyskinesia appears, it is thought that symptoms are not relentlessly progressive but seem to plateau in severity; however, clear documentation of this is limited. Experts typically recommend discontinuing neuroleptics if possible, but this is usually very difficult. Patients probably have a greater chance of complete remission if they stay off neuroleptics, but increases in relapse and even suicide complicate this therapeutic option. The symptoms of those who remain on neuroleptics will wax and wane over the course of years. Marked progression in severity appears to be relatively uncommon. When severe tardive dyskinesia occurs, it is thought to develop fairly quickly over the course of months. Severe tardive dyskinesia is seen in a fairly low percentage of the population, estimated to be 5 to 7 percent in some studies. Extreme cases, which are even more uncommon, can lead to a variety of complications. These include disfigurement, marked weight loss, respiratory distress (from diaphragmatic involvement), and difficulties with walking, eating, and even sitting. Death has been reported from aspiration and general cachexia. Prognosis may be improved by switching patients to atypical neuroleptics, although studies in this area are scarce. Clozapine, in particular, is clearly associated with a dramatically reduced incidence of tardive dyskinesia. Switching patients with moderate to severe tardive dyskinesia to clozapine may therefore improve their chances of remission, although this has not been clearly documented.

Treatment Treatment options abound, largely because of their fairly low efficacy. The development of a new class of putative atypical, clozapine-like agents is sure to have an impact on how tardive dyskinesia is dealt with. Many practitioners are switching patients to risperidone, olanzapine, or clozapine with the hope of improving chances of remission. It is too early to say whether the currently available atypical neuroleptics are effective in suppressing tardive dyskinesia symptoms or improving long-term outcome. A number of other medications have been used to suppress moderate to severe symptoms. These include benzodiazepines (particularly clonazepam [Klonopin]), clonidine (Catapres), propranolol (Inderal), vitamin E, reserpine (Diupres), and calcium channel inhibitors. The selection of suppressive agents depends on carefully weighing the benefits and risks for individual patients.

TOURETTE'S DISORDER

Introduction Tourette's disorder occupies a unique position in the field of neuropsychiatry. Although often classified as a neurological movement disorder, Tourette's disorder is characterized by abrupt movements and vocalizations, or tics, usually performed in response to compelling urges. The phenomenology of tics sets them apart from the majority of movement disorders, in which the abnormalities of movement are strictly involuntary. Moreover, obsessive-compulsive symptoms are intimately linked with Tourette's disorder, and other forms of psychopathology are frequently comorbid. For these reasons individuals with Tourette's disorder may seek treatment from neurologists or psychiatrists; thus, Tourette's disorder clearly bridges these two disciplines and may be considered a model neuropsychiatric disorder.

Definition Criteria for Tourette's disorder are provided in DSM-IV (see Table 42-1) and include the core features of multiple motor tics and one or more vocal tics, not necessarily concurrent, usually occurring in bouts throughout the day, and persisting for at least 1 year. Further, symptoms should appear by age 18, must cause marked distress or impairment in some important aspect of daily life, and must not be attributable to a substance or a general medical condition. Other proposed criteria are less stringent and include individuals with symptoms regardless of degree of impairment of social-occupational function.

Epidemiology and Etiology Once considered rare, Tourette's disorder is now recognized as a relatively common disorder. Although an accurate prevalence rate has not been established, an earlier figure of 0.5 per 1000 is likely to be a significant underestimation. Tourette's disorder has been identified in all major cultural and racial groups, and is three to four times more common in males than in females. Georges Gilles de la Tourette provided the first comprehensive description of the condition that bears his name in 1885, yet its etiology remains elusive over a hundred years later. High concordance rates for Tourette's disorder within monozygotic twin pairs (approximately 75 percent) clearly suggests a strong genetic burden, although the lack of complete concordance and existence of sporadic cases also implies a contributory role for nongenetic factors. Multiple family members may be afflicted with either Tourette's disorder, chronic motor or vocal tic disorder, obsessive-compulsive behaviors, or combinations thereof. Thus, Tourette's disorder may simply be the most pronounced manifestation of a group of related tic disorders, ranging from transient tic disorder at one end of the spectrum to Tourette's disorder at the other end, which share a common genetic substrate. Most evidence points to a major autosomal-dominant gene for these tic spectrum disorders, with penetrance ranging from approximately 70 percent in females to 99 percent for males. Despite overwhelming evidence of a genetic substrate, attempts to identify a major gene effect by linkage analysis have excluded a significant portion of the genome and a number of candidate genes. Multicenter studies are also adopting methodologies other than linkage analysis to address the genetic contribution to Tourette's disorder.

Clinical Features Tics usually first appear in childhood (mean age of onset is 7 years), with motor tics most often predating vocal tics. Motor tics may range from simple eye blinks, grimaces, neck jerking, or shoulder shrugs to complex tics consisting of touching, stamping the feet, squatting, smelling objects, echopraxia (imitation), or copropraxia (obscene gesturing). Similarly, vocal tics range from simple utterances such as throat clearing, sniffing, humming, grunting, or barking, to complex vocal tics, including blurting out words or phrases, echolalia (repeating the words of others), palilalia (repeating one's own words), or coprolalia (obscenities or socially inappropriate language). The latter has lent a certain notoriety to Tourette's disorder, although it appears in 20 percent or less of patients, a figure that may prove to be an overestimation as milder cases of Tourette's disorder are diagnosed. Coprolalia is rare in Japan compared with Western countries, which suggests a significant cultural influence upon the manifestation of these complex tics. Tics of all types characteristically disappear during concentration on a task or enjoyable activity and exacerbate with stress, boredom, or excitement. Another common feature is that tics can often be suppressed for variable periods of time, usually associated with mounting inner tension until the tics are released.

Psychiatric Features Beginning with the early historical accounts, reports of associated psychopathology in Tourette's disorder have been both numerous and contentious, some suggesting no specific links and others implicating a host of allied psychopathology. The most frequently encountered symptoms include obsessive-compulsive behaviors, hyperactivity, depression, and anxiety. Learning disabilities and self-injurious, oppositional, aggressive, and antisocial behaviors have all been reported. Vulnerability to depression and anxiety may be a consequence of the chronic, socially stigmatizing nature of the disorder for many patients. Overall neuropsychological test performance is unremarkable in patients with Tourette's disorder, although subtle deficits in visual-motor skills have been noted. There is no evidence of progressive deterioration in cognitive function.

OBSESSIVE-COMPULSIVE BEHAVIORS Complex tics may be difficult to distinguish from obsessive-compulsive behaviors; it has been argued that the distinction is merely one of degree. Typical symptoms include smelling or touching rituals, need for symmetry, checking behaviors, and obsessive thoughts of aggressive or sexual acts. Certainly, there is a close link between obsessive-compulsive symptoms and Tourette's disorder; the prevalence of obsessive-compulsive disorder is much higher in patients with Tourette's disorder than in the general population—estimates vary, but an estimate approaching 50 percent is typical. However, studies of patients with comorbid obsessive-compulsive disorder and Tourette's disorder suggest some differences from obsessive-compulsive disorder without associated tic disorder. Obsession with symmetry, “just right” phenomena (the need to perform a behavior repetitively until it feels just right), and certain rituals such as tapping, touching, and counting, are more common in patients with obsessive-compulsive disorder and Tourette's disorder, whereas pure obsessive-compulsive disorder patients have more contamination fears and cleaning rituals. Compulsive behaviors in Tourette's disorder are more frequently driven by a need for completeness or perfection, whereas compulsions in pure obsessive-compulsive disorder are more commonly driven by a sense of fear, dread, or worry. These observations have raised suspicions that obsessive-compulsive disorder might be a heterogeneous condition, one subtype being especially prevalent in Tourette's disorder patients. Twin, family, and complex segregation analysis studies also support the proposition that some obsessive-compulsive behaviors are in fact an alternative clinical manifestion of the Tourette's disorder gene.

ATTENTION-DEFICIT/HYPERACTIVITY DISORDER Frequently comorbid with Tourette's syndrome, attention-deficit/hyperactivity disorder has a prevelance of 20 to 90 percent within clinic populations. However, the relationship between the two conditions is unclear and a common genetic substrate appears unlikely. Like obsessive-compulsive disorder, attention-deficit/hyperactivity disorder may be genetically heterogeneous and one form might represent part of the Tourette's syndrome diathesis.

Pathology and Laboratory Examination Like other movement disorders, Tourette's syndrome has long been suspected to involve pathology within the basal ganglia; however, neuropathological and biochemical studies have been small in number and inconclusive. Progress has recently been made with the creation of a consortium of academic centers to systematically collect and examine postmortem specimens. Evidence of subtle structural pathology was found in several recent MRI volumetric studies, revealing decreased size or alteration of the normal asymmetries of the basal ganglia. Among identical twins with Tourette's syndrome lower birth weight is associated with greater tic severity in most cases, indicating that prenatal events may influence the eventual severity of the condition. The dopaminergic system has also been implicated by the observed response of Tourette's syndrome symptoms to D_2 receptor antagonists, such as haloperidol (Haldol),

and the frequent exacerbation of symptoms by dopamine-stimulating agents, such as methylphenidate (Ritalin). Thus, it has been proposed that increased dopamine-receptor sensitivity, triggered perhaps by some prenatal event, may modulate clinical expression of the Tourette's syndrome diathesis. In vivo neuroimaging studies have failed to find an alteration in D_2 receptors in Tourette's syndrome patients compared to normal control subjects. However, a recent SPECT study of identical twins discordant for Tourette's disorder severity revealed a small but significant increase in binding of ^{123}I-iodobenzamide (a D_2-receptor antagonist) in the more affected twin of each pair. Differences in binding between twins almost completely predicted differences in tic severity, thus supporting the dopamine-receptor supersensitivity hypothesis. Elevations in the striatal dopamine transporter have also been detected in postmortem samples and by SPECT. All these studies were based on small samples and require larger scale replication. A post-infectious hypothesis for the pathophysiology of some cases of Tourette's disorder and related disorders has been proposed, based on descriptions of obsessive-compulsive symptoms in Sydenham's chorea, a sequela of untreated group A b-hemolytic streptococcal infection, and observation of new-onset tics after recent streptococcal infection. It is hypothesized that such infection may trigger an autoimmune response with antibodies directed against neurons in the basal ganglia. Studies are in progress to characterize antineuronal antibodies in Tourette's disorder. Preliminary reports have also described increased expression of a B lymphocyte surface antigen, highly associated with rheumatic fever, in children with Tourette's disorder, suggesting a potential susceptibility marker, at least in some individuals. Currently, there are no diagnostic neuroimaging, blood, or cerebrospinal fluid assays useful in establishing a diagnosis of Tourette's disorder.

Differential Diagnosis Tourette's disorder may be differentiated from other hyperkinetic movement disorders by the history of both motor and vocal tics and in the absence of other CNS symptoms, pathology, or exposure to neuroleptics or stimulants. Inquiry will frequently reveal a premonitory “irresistible urge.”

Course and Prognosis Over time, specific tics often disappear, only to be replaced by new tics in different locations; however, in about two thirds of individuals the trend is towards a gradual reduction in symptom severity as the individual enters adulthood, although only a minority of patients will experience a complete remission.

Treatment Treatment begins with education of the patient, family, and teachers about the condition. This will often suffice when Tourette's syndrome symptoms are mild. For more severe cases, and those with associated symptoms of obsessive-compulsive disorder or attention-deficit/hyperactivity disorder, pharmacological intervention may be required. Low doses of neuroleptics, particularly haloperidol and pimozide (Orap), have been used successfully for tic suppression, with adequate control achieved in up to 70 percent of patients. Most recently, risperidone has been tried with promising results. However, all the usual risks attendant to antipsychotic use for other neuropsychiatric disorders exist here as well. Clonidine (Catapres) has also proved modestly beneficial although less effective than the antipsychotic agents. Other agents, such as clonazepam (Klonopin), may help a smaller number of patients. Concomitant obsessive-compulsive disorder is treated with typical antiobsessional agents, such as clomipramine (Anafranil), fluoxetine (Prozac) or fluvoxamine (Luvox). Use of sympathomimetics such as methylphenidate (Ritalin) for concomitant attention-deficit/hyperactivity disorder may exacerbate tics or precipitate the first symptoms of a tic disorder; however, some patients may tolerate stimulant medications without worsening of tics, or only temporary exacerbation.

M.S. developed eye blinking and grimacing at age 4, followed soon thereafter by excessive throat clearing. He was initially treated for allergies. His symptoms evolved into abrupt exhalation tics, neck jerks, and touching tics, with the compulsion to perform the same maneuver with the opposite hand “to even things up.” He could briefly suppress the tics, but at the expense of mounting inner tension to release them. He also reported checking rituals (repetitively checking the knobs of the washing machine, checking to be sure appliances were unplugged, checking door locks), but was not severely bothered by them. His symptoms frequently vanished in physicians' offices, leading to consideration of a psychogenic basis. Other children mimicked and ostracized him and by adolescence he experienced periods of depressed mood and panic attacks. At the age of 32 the possibility of Tourette's disorder was raised by a friend who had seen a daytime television talk show on the subject. A professional referral was made and Tourette's disorder was diagnosed. It was noted that M.S.'s father had had facial grimacing and peculiar “mannerisms,” as did a paternal uncle. The patient elected not to take medication but benefited from education about Tourette's disorder and participation in a local Tourette's disorder support group. His function improved and he was able to attain a degree in engineering while working full time. This case is typical of many patients who remain undiagnosed or are misdiagnosed for years, further compounding a stressful situation. Clinicians may be misled by the suppressibility to suspect that the condition is under pure voluntary control, and exacerbation under stress may lead to suspicion that the symptoms have an emotional or neurotic basis. Some clinicians erroneously believe that motor and vocal tics must be present together, or that coprolalia is required for the diagnosis. Tourette's disorder has recently received widespread attention in the media, which may eventually lead a patient to the proper diagnosis, 30 years after symptom onset as in this case.

SUGGESTED CROSS-REFERENCES

Neuroimaging is discussed in Section 1.16, Section 2.13, and Section 51.2f. Cognitive disorders are discussed in Chapter 10, mood disorders in Chapter 14, obsessive-compulsive disorder in Chapter 15, attention-deficit/hyperactivity disorder in Section 51.3e. Psychotherapies are discussed in Chapter 30 and biological therapies in Chapter 31.

2.7 NEUROPSYCHIATRIC ASPECTS OF MULTIPLE SCLEROSIS AND OTHER DEMYELINATING DISORDERS

WILLIAM W. BEATTY, PH.D., AND ROBERT H. PAUL, PH.D.

Myelin is a specialized extension of the central nervous system (CNS) oligodendrocyte plasma membrane. Composed of about 70 percent lipid and 30 percent protein, the known function of myelin is to make saltatory conduction possible. If damage to the myelin surrounding a nerve is limited, propagation of action potentials will be slowed; more extensive damage may result in conduction block. Because myelinated axons carry important components of the sensory inputs to the brain (e.g., the optic nerves and tracts), the motor outputs from the brain (e.g., the corticospinal tracts), as well as communications within the brain (e.g., in the corpus callosum), the symptoms of demyelination vary greatly from one patient to another.

A large number of CNS disorders can affect the integrity of the white matter (myelin). These include traumatic brain injury, especially closed head injury, vascular disorders, especially Binswanger's disease, infectious diseases such as acquired immune deficiency syndrome (AIDS); exposure to various neurotoxins such as alcohol or volatile inhalants; various inherited disorders of lipid metabolism (e.g., the leukodystrophies); and multiple sclerosis.

Because the disorders that affect the white matter vary greatly in their etiology and epidemiology, there are marked differences in their neurological, cognitive, and psychiatric consequences. However, white matter disorders share two common features: (1) they are rarely focal; instead there are usually multiple sites of injury to the CNS and, (2) there are enormous differences from one patient to another in the mixture of neurological, cognitive, and psychiatric effects of white matter diseases.

MULTIPLE SCLEROSIS

History and Epidemiology Multiple sclerosis, the most common demyelinating disease, affects 250,000 to 350,000 persons in the United States. Jean-Martin Charcot, the French physician who made pioneering contributions to both neurology and psychiatry, provided a remarkably accurate description of the major neurological, cognitive, and psychiatric features of multiple sclerosis. Charcot realized that multiple sclerosis is often characterized by exacerbations in which old neurological symptoms worsen and new symptoms appear, followed by periods of remission in which symptoms abate, sometimes to the point of complete recovery. Because neuropathological studies revealed the presence of multiple lesions distributed throughout the white matter of the CNS, the name *multiple* or *disseminated sclerosis* was applied. To distinguish multiple sclerosis from other conditions with similar symptomatology, the clinical diagnosis requires evidence (radiological or by examination or history) of at least two distinct episodes of neurological impairment that cannot be explained by a single CNS lesion.

Multiple sclerosis affects about twice as many women as men and is most prevalent among whites of northern European descent. Prevalence also increases with increasing distance from the equator. The latitude of birth and childhood residence rather than of adult residence seems more important for determining risk of developing the disease.

About 85 percent of cases of multiple sclerosis are diagnosed between age 20 and 50; however, with more widespread availability of magnetic resonance imaging (MRI), a small but increasing number of cases among children and teenagers are being reported.

MRI has greatly increased the precision of diagnosing multiple sclerosis. MRI can reveal evidence of lesions that are disseminated in space, even when clinical evidence to identify multiple distinct episodes separately in time is lacking. However, the white matter changes (Fig. 2.7-1) observed on MRI scans are not specific to multiple sclerosis. Similar changes occur in other neurological conditions and to some extent in the general population, especially the elderly. Consequently, MRI, even if evidence of lesions is found in the optic nerves, long tracts of the spinal cord, or periventricular white matter (the most frequent sites of multiple sclerosis lesions) is only suggestive. Confirmation of the diagnosis by clinical and other laboratory measures is essential. The most useful laboratory tests are visual or somatosensory evoked potentials and analysis of g-globulin and myelin basic protein in the cerebrospinal fluid. In multiple sclerosis patients sensory evoked potentials are slowed or absent and g-globulin and myelin basic protein levels are elevated, especially during an exacerbation. As with MRI, none of these laboratory measures is specific for multiple sclerosis and not all multiple sclerosis patients show any or all of these changes.

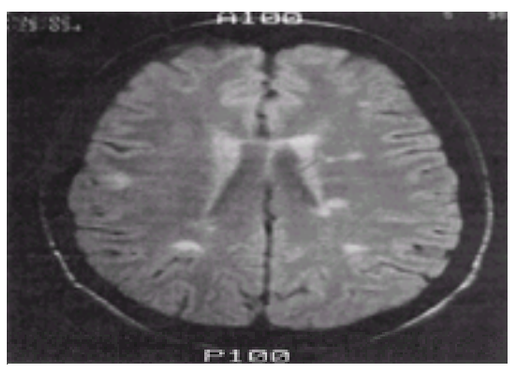

FIGURE 2.7-1 T2-weighted axial MRI scan from a 30-year-old female patient with multiple sclerosis. Many areas of increased signal intensity, which appear white, are scattered throughout the white matter, which appears gray. This is the typical appearance of multiple sclerosis lesions on MRI. (Courtesy of Don Wilson, M.D.)

The course of multiple sclerosis is just as variable and unpredictable as the presenting symptoms. In addition to the *relapsing-remitting* type in which relapses (exacerbations) that can affect sensory or motor systems alternate with periods of remission in which recovery to nearly premorbid functioning occurs, there are three other forms or subtypes of the disease. In the *benign* form, relapses are infrequent, affect mostly sensory functions, and show almost complete recovery between attacks. In the *chronic progressive/secondary progressive type* there is either a slowly deteriorating course from disease onset (chronic progressive) or a relapsing-remitting course with incomplete recovery after exacerbations (secondary progressive). In the *primary-progressive* type there is a steadily and often rapidly worsening course from the onset of the disease. The modest reduction in average life expectancy of multiple sclerosis patients as a whole is mainly accounted for by patients with this disease type. There is some evidence that the distribution of lesions is different in the primary-progressive type than in other forms of the disease, but there is no good evidence that diagnostic type (other than primary-progressive), even if assigned according to operational criteria, is of much value in predicting the future disease course or level of functional impairment of individual patients. One reason why this is so is that it is not uncommon for patients whose disease has initially followed a true relapsing-remitting course (i.e., full recovery after exacerbations) to enter a period of slow decline. Also, patients with chronic progressive multiple sclerosis may enter periods of stability in which further functional losses do not occur; such periods may last for months or years.

The consequence is that most multiple sclerosis patients experience a great deal of uncertainty about both the short-term and long-term courses of their disease.

Etiology and Mechanism of Demyelination Multiple sclerosis is now widely accepted to be an autoimmune disorder in which T lymphocytes (and a few B lymphocytes) invade the CNS and attack the myelin. The details of initiation and termination of the attack are still unknown, but there is considerable evidence that the proinflammatory cytokines, interleukin-1 (IL-1), tumor necrosis factor, and interferon gamma play an important role. Other regulatory cytokines such as interferon beta

(IFN-b) may counteract the effects of the proinflammatory interferons.

Research in this area is progressing rapidly, aided by the availability of a useful animal model. Experimental allergic encephalomyelitis is produced by autoimmunizing animals against myelin basic protein. Animals with encephalomyelitis exhibit the motor symptoms and demyelination typical of human multiple sclerosis.

The final pathway of myelin breakdown in the CNS involves splitting the tightly compacted membrane lamellae and enzymatic attack of the myelin proteins and lipids. The proteolytic and lipolytic enzymes may invade the CNS from the blood through gaps in the blood-brain barrier, be secreted by inflammatory cells, or originate from lysosomes from macrophages, microglia, or astrocytes at the target site in the CNS. The consequence is the formation of a lesion (plaque) as shown in Figure 2.7-2 and Figure 2.7-3.

FIGURE 2.7-2 Two cuts in the axial plane from the formalin-fixed brain of a 38-year-old man with multiple sclerosis who died of sepsis secondary to a urinary tract infection. Several areas of demyelination are visible as gray areas within the white matter. (Courtesy of Roger Brumback, M.D.)

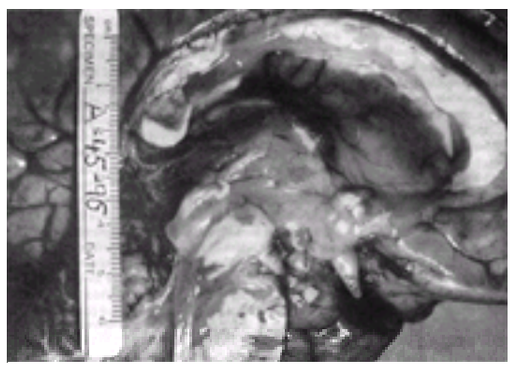

FIGURE 2.7-3 Midsaggital section through the brain of the same patient as in Figure 2.7-2. Extensive demyelination of the corpus callosum is evident that is complete in the posterior part of the body of that structure. Note that demyelination of the ventral part of the corpus callosum is more extensive, reflecting the predilection of multiple sclerosis lesions to involve periventricular regions. (Courtesy of Roger Brumback, M.D.)

Plaques may be immunologically active, characterized by cuffs of lymphocytes and macrophages, or immunologically silent in terms of inflammation. MRI technology has developed to the point where it is possible to distinguish active lesions from older inactive lesions, which are comprised of astrocytes. This permits in vivo monitoring of disease activity.

Susceptibility to multiple sclerosis seems to be influenced by a genetic factor or factors because concordance rates for the disease are about 30 percent for identical twins compared to 2 percent for fraternal twins or siblings of the same sex. Several potential markers have been proposed, but no specific gene has been identified. Based on the twin studies it is clear that any genetic influence is likely to affect susceptibility to multiple sclerosis, while also interacting with other factors.

Since the time of Charcot the possibility that exposure to stressful events might precipitate the initial episodes of multiple sclerosis or trigger exacerbations has attracted considerable interest. The idea is plausible because multiple sclerosis patients are especially susceptible to the debilitating effects of heat. Further, in multiple sclerosis, like other neurological diseases, symptoms may worsen during times of minor infection. Addressing the first question (i.e., that stress provokes the initial multiple sclerosis attack) requires a retrospective design that is subject to recall bias. Moreover, there are difficulties in establishing the time of disease onset, in defining and measuring stressful experiences, and in selecting an appropriate comparison group. Several older as well as two recent studies published since 1980 have reported that patients with multiple sclerosis recalled experiencing more stressful events than matched controls in the period (up to 2 years) before disease onset.

Determining if a relationship between stress and exacerbations exists is potentially more feasible because a prospective design can be used. In general, no study has found that patients who exhibited exacerbations were exposed to more stress than those who did not experience exacerbations and that periods of increased exposure to stress preceded exacerbations. Despite the absence of empirical evidence to support a link between stress and the onset of multiple sclerosis or the triggering of exacerbations, it is fair to say that many patients and health professionals believe such an association exists.

Psychiatric Features Psychiatric disturbance in multiple sclerosis patients has been consistently reported since Charcot's initial description of the disease. In his seminal work Charcot noted that depression, pathological laughter, and “stupid indifference” were psychiatric symptoms characteristic of multiple sclerosis. Current research continues to identify the presence of these and similar psychiatric disorders in the multiple sclerosis population.

Most reported prevalence rates of depression in multiple sclerosis range from 45 to 62 percent. This variability probably results from the use of assessment techniques that differ qualitatively. Studies that assess depression in multiple sclerosis using symptom inventories (e.g., the Beck Depression Inventory) typically report high prevalence rates. However, these studies probably overestimate the prevalence of depression because many symptom inventories inadvertently assess physical and cognitive symptoms of multiple sclerosis (e.g., fatigue, memory disturbances). In support of this contention, studies have shown that when multiple sclerosis patients are assessed using structured clinical interviews or symptom inventories that exclude nonmood items the prevalence of depression drops substantially. This does not imply, however, that depression is uncommon in multiple sclerosis patients. Even the most conservative prevalence estimates report rates of depression that are higher than those typically found in the general population.

The cause of depression in multiple sclerosis remains unclear. Typically, depression in multiple sclerosis is believed to represent either a primary manifestation of the disease caused by cerebral involvement, or a psychological reaction to living with a debilitating and chronic illness; research does not support a genetic basis for depression in multiple sclerosis.

Several lines of evidence indicate that depression in multiple sclerosis patients results from cerebral demyelination. First, multiple sclerosis patients report high rates of depression when compared to other populations of patients with chronic illnesses. Second, cerebral involvement is more closely related to depression in multiple sclerosis than is spinal cord involvement. Third, depression in multiple sclerosis is unrelated to neurological status (i.e., disease duration, course, and severity of disability), and to degree of cognitive impairment.

It should be noted, however, that most studies cited as evidence for a biological basis of depression in multiple sclerosis have assessed depression with symptom inventories, which might estimate the prevalence of depression inaccurately. Further, measures of patients' perceptions regarding their disabilities are notably lacking from most studies. This is an important limitation because, depending on the patient, multiple sclerosis-induced cognitive impairment might be more distressing than

physical disability.

Reactive explanations for depression in multiple sclerosis are based on the theory of learned helplessness, which states that depression may develop when people are confronted with aversive situations that are unpredictable or uncontrollable. Because multiple sclerosis patients have limited control over the course of their illness and the disease affects them both physically and cognitively, learned helplessness theory is a plausible explanation for the depression that occurs in multiple sclerosis. The validity of this explanation is supported by the finding that patients' degree of social support significantly predicts their mental health status.

Early studies investigating psychiatric disturbance in multiple sclerosis reported high prevalence rates of pathological laughter and crying, but more recent studies have not confirmed this finding. Pathological laughter and crying in multiple sclerosis is phenomenologically similar to pseudobulbar palsy, a disorder that results from damage, usually bilateral, to fiber tracts connecting the cortex to subcortical forebrain structures. In pseudobulbar palsy, the behavioral expression of a mood state is incongruent with the patient's cognitions; for example, a person might cry uncontrollably, yet deny feeling sad.

Contemporary reviews of multiple sclerosis psychopathology have considered “stupid indifference” to be similar to *la belle indifférence*, a feature that is usually associated with conversion disorder. Patients with *la belle indifférence* fail to appreciate the significance of their impairments. Psychodynamic theories contend that *la belle indifférence* represents patients' denial or repression of their illness. From a neurological perspective, however, *la belle indifférence* is similar to *anosodiaphoria*, a condition in which patients with cerebral injuries are unconcerned about their neurological deficits. Because multiple sclerosis usually affects cerebral tissue, anosodiaphoria is probably a more accurate account of “stupid indifference” in multiple sclerosis than is *la belle indifférence.* Anosodiaphoric multiple sclerosis patients (often referred to as *euphoric* patients) are typically described as “content and comfortable” despite having serious physical and mental disabilities. The prevalence of anosodiaphoria in multiple sclerosis is uncertain, but research suggests that most patients are aware of their disabilities. MRI studies in patients who do not express anosodiaphoria have shown that it is related to the extent of lesion involvement in the frontal lobes.

Epidemiological studies have found that multiple sclerosis patients are twice as likely as healthy controls to have bipolar I disorder. Although the cause of this comorbidity has not been definitively determined, some evidence indicates that both disorders might have a shared genetic basis. For example, in one study family histories of bipolar I disorder were investigated in three groups of multiple sclerosis patients: (1) patients with bipolar I disorder, (2) patients with depression or mania, and (3) patients with no psychiatric disturbance. Results of the study indicated that family histories of both multiple sclerosis and bipolar I disorder were more common in patients with bipolar I disorder than either of the other two groups.

Fatigue Fatigue is one of the most common and debilitating symptoms of multiple sclerosis. Surveys have shown that more than 80 percent of multiple sclerosis patients report experiencing fatigue on a daily basis. Although most studies have focused on physical fatigue, evidence suggests that cognitive fatigue might also be problematic for some individuals.

Symptoms of fatigue in multiple sclerosis patients tend to worsen as the day progresses, making late afternoon a particularly difficult time of day. Heat, physical exertion, and stress also exacerbate the severity of fatigue in multiple sclerosis. Because of the nature of fatigue in multiple sclerosis many patients must complete activities early in the day and avoid some events altogether. For these reasons, it is not surprising that many patients consider fatigue to be the most disabling symptom of their disease.

The cause of fatigue in multiple sclerosis is unknown. Although fatigue is a common symptom of depression, studies have shown that fatigue in multiple sclerosis is qualitatively distinct from the fatigue that is characteristic of mood disorders. Results from several studies indicate that fatigue is more common in multiple sclerosis patients with greater physical disability and a progressive disease course; however, some patients present with fatigue as the initial symptom of the disease. MRI studies have recently shown that fatigue in multiple sclerosis is associated with greater lesion volume in the brainstem and midbrain. In addition, fatigue in multiple sclerosis has been shown to be inversely related to pineal gland calcification, which implies that fatigue in multiple sclerosis might result from altered melatonin secretion.

Cognitive Impairment Charcot accurately described three of the major aspects of cognitive impairment that affect some multiple sclerosis patients—poor memory, poor abstracting, and slowed information processing. Yet as recently as 1982, even research neurologists believed that these impairments were uncommon and confined to multiple sclerosis patients with severe physical disabilities. More recent research indicates that 40 to 65 percent of multiple sclerosis patients will exhibit some kind of cognitive deficit on neuropsychological testing. Further, simple screening tests like the Mini Mental State Exam are insensitive to the cognitive impairments most common in multiple sclerosis. Likewise, measures of neurological impairment (e.g., the widely used Expanded Disability Status Scale) or disease duration are not useful predictors of the cognitive status of individual patients. Mild neurocognitive disorder may be evident after the first exacerbation (i.e., before the clinical criteria for diagnosis are fulfilled).

Intelligence More than 35 years ago it was reported that men who developed multiple sclerosis while in military service showed a drop of 13.5 I.Q. points over a period of about 4 years. Subsequent longitudinal studies that lacked the advantage of premorbid data observed much smaller declines or even modest increases in I.Q. over intervals of 1 to 3 years. Because most multiple sclerosis patients referred for neuropsychological evaluation perform within normal limits on standard I.Q. tests, many concluded that I.Q. was unaffected in multiple sclerosis. More recent work indicates that, on average, multiple sclerosis patients scored somewhat lower than demographically matched controls on verbal I.Q. and significantly lower on performance I.Q. The difference between verbal and performance I.Q. probably arises because the performance tests are timed whereas the verbal tests generally are not. Hence, the performance tests require both speed and accuracy whereas the verbal tests emphasize accuracy. In general, verbal I.Q. is only slightly affected in multiple sclerosis and patients with very low scores are likely to exhibit global impairments on other cognitive tests.

Language Language is also well preserved in multiple sclerosis. Aphasia, agraphia, and alexia are extremely rare, although problems of speech production (hypophonia, dysarthria) are common. Most patients perform normally on tests of confrontation naming; patients with significant naming impairments are likely to exhibit deficits on several other cognitive tests. By contrast, impairments on verbal fluency tests, which require the subject to generate words that begin with a particular letter or exemplars of a certain category, are typically observed in patients with multiple sclerosis. Although verbal fluency tests are often considered language tests, it is probably better to think of them as measures of speed of access to established knowledge about words.

Attention and Information Processing The status of attention in multiple sclerosis patients is unclear. Many studies have reported significant attentional impairments in multiple sclerosis; however, other studies have not found similar results. Whether or not multiple sclerosis patients exhibit attentional deficits is partly determined by the type of attention tested. For example, multiple sclerosis patients typically perform within the normal range on attention tests that require automatic processing (e.g., recognition of letters). On more demanding attention tests, such as those that require working memory (i.e., controlled processing tasks), multiple sclerosis patients have been found to perform significantly worse than controls, but deficits are not consistently observed on all tasks. For example, only half of the published studies that have examined controlled processing in multiple sclerosis with the Wechsler Adult Intelligent Scale-Revised (WAIS-R) Digit Span subtest have found multiple sclerosis patients to perform significantly worse than healthy controls.

Deficits are more consistently observed on tests that require multiple sclerosis patients to focus on two or more stimuli simultaneously (i.e., divided-attention tasks). Many studies have shown that multiple sclerosis patients perform significantly worse than controls on the Paced Auditory Serial Addition Task, which requires subjects to add digits to numbers previously given. Similar deficits are observed on tests of comparable difficulty (e.g., the Stroop test, which requires subjects to state aloud as quickly as possible the color of the ink in which the name of a color is printed).

Information-processing speed is also impaired in multiple sclerosis patients. One of the most commonly employed instruments to examine information-processing speed in multiple sclerosis is the Symbol Digit Modalities Test, a verbal analogue of the Digit Symbol subtest of the WAIS-R. On this task, subjects orally substitute numbers for symbols according to a key that is kept in the subject's view. Performance on this task depends on how quickly subjects can make the correct substitutions in a specified time period. Studies that have investigated information-processing efficiency with this task have consistently reported that multiple sclerosis patients perform significantly worse than healthy controls.

Memory Impairments in memory are the most extensively studied of the cognitive deficits that accompany multiple sclerosis. Memory difficulties also constitute the class of cognitive dysfunction that multiple sclerosis patients most often complain about. Problems in concentration are a close second, and the two deficits may be closely linked. Modern neuropsychological theory makes distinctions between several different types of memory and the empirical evidence indicates that certain forms of memory are much more likely to be affected by multiple sclerosis than others.

Explicit memory tests involve conscious recollection of specific events or more general knowledge acquired in the recent or distant past. Examples include reciting a

list of words, recalling the name of a famous person when shown a photograph, or naming the high school that one attended. On implicit memory tests, subjects can display evidence of retention without conscious awareness. For example, patients with amnesia from diencephalic or temporal lobe injury learn new motor skills normally, but are unable to remember having performed the tasks previously.

Memory tests may include tasks designed to study learning and memory for information acquired after the onset of disease *(anterograde memory)* or for information acquired before disease onset (*remote* or *retrograde memory*). There are an enormous variety of tests devised to study anterograde memory. Examples of explicit memory tests include word and picture lists, short stories, and production of drawings of forms or shapes that were previously copied. Anterograde implicit memory tests include learning new motor skills and various priming tasks. On priming tests, exposure to stimuli alters the speed or accuracy of subsequent responses, but subjects do not appear to consciously recollect the original exposure. Remote memory is usually tested by asking subjects to identify pictures of people who were famous in the past, to recall past public events, or to answer structured questions about episodes or events that occurred during various periods in their own lives. There are no standard tests for remote implicit memory.

Anterograde memory tests are also classified in terms of the length of the retention interval. For present purposes, *immediate memory* will refer to tests on which the retention interval is 0 to 60 seconds in length; *recent memory* will refer to retention intervals that are longer than 60 seconds. In the research literature *short-term memory* and *working memory* are approximately synonymous with *immediate memory*, and *long-term memory* means roughly the same as *recent memory.*

IMMEDIATE MEMORY The most widely used measure of immediate memory is the Digit Span test from the WAIS-R, which is also a measure of attention and concentration. The test is comprised of two subtests: *Digits Forward* (subjects are read a string of digits that they attempt to recite in order) is a relatively pure measure of attention and immediate memory; *Digits Backwards* (subjects attempt to recite the list of digits in reverse order) also requires manipulation of information in memory.

The performance of multiple sclerosis patients on the Digit Span test has been inconsistent from study to study, with mild deficits being the most common finding. The most likely explanation for the conflicting results is the heterogeneity of the samples studied. However, illness variables cannot account for the inconsistencies in results because deficits have been reported for patients with very mild physical disabilities and intact performance has been exhibited by more severely disabled patients.

On other tests of immediate memory, deficits by multiple sclerosis patients have been observed consistently. These tests have the common property of requiring subjects to divide their attention between the items to be remembered and some other task.

RECENT MEMORY When groups of multiple sclerosis patients are asked to recall information presented minutes, hours, or days earlier, impairments are generally evident. Comparable deficits have been observed using a variety of verbal stimuli including short prose passages, associated word pairs, and lists of words as well as nonverbal stimuli such as figures and the location of stimuli in spatial arrays. On multi-trial learning tests deficits are usually evident on the first trial. The deficits that are readily apparent when memory is tested by recall methods are less clear when recognition methods are employed.

REMOTE MEMORY The most common clinical test of remote memory requires subjects to recite the names of recent heads of state beginning with the current office holder and working backward in time. On this test (the *presidents test* in the United States) multiple sclerosis patients perform as well as demographically matched controls. However, on tests requiring identification of famous persons from photographs or recall of past public events multiple sclerosis showed consistent impairments that were equally severe for all past decades. Less severe impairments for recognition memory of the same information were also seen.

Such tests of remote memory require display of knowledge that is assumed to be widely shared among members of a culture. However, on these tests it is impossible to tell if a failed item was ever known by an individual patient. Tests of autobiographical memory circumvent this problem because they tap information that was certainly known by all subjects. Recent research indicates that multiple sclerosis patients exhibit mild impairments in autobiographical memory; however, their deficits are so modest that they are almost certainly clinically insignificant. The existence of small deficits that extend back into childhood memories indicates that the impairments seen on other tests are probably real deficits in remote memory.

IMPLICIT MEMORY The little information that is available indicates that implicit memory is intact in multiple sclerosis patients. This is true for motor-skill learning and several priming paradigms.

AWARENESS OF MEMORY DEFICITS Clinical experience suggests that some patients with multiple sclerosis are aware of their impairments in memory and adopt effective strategies for minimizing the impact of these difficulties in their everyday lives. Other patients with equally serious impairments are either unaware of their memory deficits or deny their existence.

Metamemory is a term that refers to knowledge of one's own memory. Experimental studies of metamemory require subjects to predict their own ability to recall or recognize newly acquired information or items of general knowledge. Subjects' predictions are then compared to their performances on memory tests. Thus, it is possible for a patient to exhibit impaired memory, but accurate (or inaccurate) metamemory. It is also possible for a patient with normal memory to show impaired (or intact) metamemory.

Studies of metamemory in multiple sclerosis indicate that the severity of cognitive impairment and the type of memory task influences the accuracy of patients' metamemory performances. For anterograde memory tests, patients with deficits in both memory and problem solving showed the largest deficits in metamemory; these patients overestimated their actual memory performance by more than 50 percent. Less serious metamemory deficits were shown by multiple sclerosis patients with either memory or problem-solving impairments; patients without either deficit were as accurate as controls in forecasting their anterograde memory performance. Although the subgroups of multiple sclerosis patients varied in the accuracy of performance on the tests of general knowledge, regardless of the extent of their cognitive impairments all patient groups could identify which items they would recognize as accurately as normal controls.

MODELS OF MEMORY DYSFUNCTION The anterograde memory deficits associated with multiple sclerosis have usually been attributed to patients' difficulties in retrieving information that has been encoded and stored. Support for this idea comes from the usual finding that memory impairments are more conspicuous on recall than on recognition tests, the absence of a temporal gradient of retrograde amnesia on remote memory tests, consistent deficits on verbal fluency tests, and evidence that fundamental mechanisms such as use of imagery and the capacity to encode verbal stimuli semantically are intact. Studies using the *selective reminding* technique provide direct evidence that the major problem in verbal memory for multiple sclerosis patients is an inability to retrieve information from long-term storage consistently.

An alternative explanation maintains that the verbal memory impairment in multiple sclerosis patients is simply a failure to learn the information adequately. When multiple sclerosis patients were given additional trials to bring their performance up to the level of controls, there was no deficit in delayed recall.

Both these theories are based on studies that compared multiple sclerosis patients to demographically matched controls, a tactic that ignores the heterogeneity of multiple sclerosis patients. When the statistical technique of cluster analysis is applied, quite a different picture emerges. In a recent study using the Selective Reminding technique about 25 percent of the multiple sclerosis patients had no memory deficits at all; another 25 percent had severe memory deficits that resembled those of patients with amnesia. The remaining patients on average showed patterns of performance consistent with the theory that retrieval failure was the major source of their memory problems. However, closer examination of individual patient profiles revealed that only 2 of 51 patients with mild memory deficits met stringent operational criteria for retrieval failure. The acquisition deficit hypothesis fared only a little better: 4 patients out of 51 met stringent operational criteria for acquisition failure.

As a practical matter, the embarrassment of these theories is of little consequence. Patients with an amnestic-like pattern are also likely to suffer impairments in a number of other cognitive domains. Attempts at memory rehabilitation by compensatory techniques are less likely to succeed with these individuals. Patients with milder memory deficits are also less likely to have global cognitive impairments and are more likely to learn to circumvent their memory problems.

Problem Solving Patients with multiple sclerosis exhibit a consistent pattern of deficits on both verbal and nonverbal tests of abstraction and problem solving. Measures that reveal deficits include the Category Test and the Wisconsin Card Sorting Test, two standard measures widely used in clinical neuropsychology, as well as in several experimental tasks. Analysis of patterns of errors, especially on the Wisconsin Card Sorting Test, has emphasized the importance of perseverative responding (i.e., inability to abandon incorrect hypotheses) in the problem-solving impairment. However, multiple sclerosis patients also exhibit deficits on problem-solving tasks on which perseverations do not occur. Thus, difficulties in forming concepts, an impairment described by Charcot, seem to be the most general

source of problem-solving difficulties.

Visual Processing Tasks Patients with multiple sclerosis are often mildly impaired in judging the orientation of lines, discriminating faces, and comprehending emotions conveyed by facial expressions. These deficits are commonly observed on the Performance scale of the WAIS-R, which emphasizes visual processing. There is no convincing evidence that any of these impairments reflect anything more than sensory or motor disturbances.

Impact on Work and Social Functions Surveys of multiple sclerosis patients in North America and Europe indicate that as many as 80 percent retire from gainful employment prematurely. Physical impairment and susceptibility to fatigue are obvious factors that contribute to premature retirement, but cognitive impairment, especially deficits in anterograde memory and information-processing speed, is an important and independent predictor of early retirement. Because the age of onset of the disease is early and the impact on life expectancy is slight, premature retirement caused by multiple sclerosis imposes a significant financial burden on patients and society.

Like any chronic disease, multiple sclerosis also places many burdens on spouses and families. These include loss of income, loss of partnership, and increased responsibilities for providing care to the patient and parental supervision of children. Although patients' physical limitations are usually obvious to family members, their susceptibility to fatigue and the cognitive and emotional difficulties that often accompany the disease may not be properly comprehended by family members. Each of these disease features has been thoroughly documented in the research literature, yet physicians and other professionals who care for multiple sclerosis patients often do not take the time to ensure that family members understand the array of changes that can accompany multiple sclerosis. Lack of understanding by family members may lead them to misattribute forgetfulness or chronic tiredness to deliberate attempts by multiple sclerosis patients to avoid responsibility or to solicit undeserved attention.

Screening for Cognitive Impairment Cognitive impairments can occur very early in the course of multiple sclerosis and contribute significantly to a multiple sclerosis patient retiring prematurely from the work force. In an ideal world all patients with multiple sclerosis would have regular neuropsychological evaluations to detect cognitive impairments early when compensatory strategies might be most likely to be effective. However, a complete neuropsychological evaluation is expensive and 25 to 40 percent of multiple sclerosis patients do not have cognitive impairments that are severe enough to impair their ability to function in everyday life.

Since 1992, several brief screening examinations that have high sensitivity and specificity for detecting cognitive impairments in multiple sclerosis patients have been developed. One of these batteries can be easily administered and scored by personnel with little or no formal training in neuropsychological testing. The proper use of a cognitive screening examination is similar to any medical screening test: to determine which patients should receive more extensive and more expensive diagnostic procedures. More widespread use of screening tests should lead to more efficient use of neuropsychological resources, reserving these relatively expensive tools for patients who are most likely to benefit from a complete assessment of cognitive function.

Mary D. (not her real name) was a 36-year-old woman who worked as a psychiatrist at an urban medical school when she volunteered as a subject in one of the authors' studies. Her first symptom (blurred vision) had occurred 12 years earlier while she was a medical student. Subsequently, she developed numbness and weakness and was diagnosed with multiple sclerosis 4 years later. Her symptoms remained fairly mild and relapses were infrequent throughout medical school, two residencies, and the first few years as an academic psychiatrist. However, Mary D. noticed that her increasing memory problems were compromising the quality of her work. Specifically, after seeing several patients consecutively, she could not remember important details of the interviews and she feared that she was confusing information about one patient with that of another. She volunteered as a research subject in a project on cognition in MS, in part to determine whether her suspicions about her own memory loss were valid.

During neuropsychological testing, which included a 2-hour battery of measures known to be sensitive to the impairments often seen in multiple sclerosis, Mary D. exhibited only mild walking difficulties, normal vision, and essentially no depression. In addition to memory problems, she complained of fatigue for which she was taking fluoxetine (Prozac) and amantadine (Symmetrel).

Testing revealed clear deficits in both verbal and nonverbal memory, information-processing speed, and abstraction problem solving; other cognitive functions were within normal limits.

As a result of the testing, Mary D. made a minor change in her professional life. She insisted that a 10-minute break be imposed between patients seen in her practice. This allowed her to dictate initial notes about each interview, circumventing her memory difficulties. At this writing (3 years after testing), Mary D. continues to work full time as a psychiatrist, although she left the medical school to take a more lucrative position in the private sector.

Mary D.'s case is noteworthy because she has been able to perform an intellectually demanding job capably despite deficits in three cognitive domains. It might be argued that the neuropsychological tests that she failed are irrelevant to job performance, but this is unlikely because the same memory and speed of information-processing tests she performed poorly on were significant predictors of employment status in the larger group of multiple sclerosis patients in the study in which she participated. Her mild sensory and motor symptoms no doubt made it easier for her to continue to work, but she experienced the considerable fatigue that is common in multiple sclerosis.

Three other factors seem important. First, she liked her job and was highly motivated to continue working; second, she suspected her cognitive deficits and accepted the test results as confirmation and an indication of the need to modify her work schedule in order to accommodate her deficits; third, she had the power to make the necessary adjustments in the way she conducted her work in order to circumvent her cognitive limitations.

Mary D.'s case illustrates what can happen and what health professionals could help to happen more frequently. What is needed is an appraisal of patients' capabilities as well as their deficits, an analysis of requirements of their jobs, and the possibility that each patient's job could be reconfigured or done in a different way. The nature of work in developed countries has changed enormously since Charcot first described multiple sclerosis. At that time most jobs required physical strength or fine-motor skill to execute highly overlearned responses. Memory and the ability to process information quickly were not very important for job performance, which may explain why neurology almost “forgot” that multiple sclerosis causes cognitive impairments for more than 100 years. Today the relative importance of cognitive abilities for employment success is clearly greater than it was 100 or even 25 years ago. The wide availability of computers and the increasing interest of many businesses in developing programs in which employees do most of their work at home offer enormous opportunities for allowing patients with multiple sclerosis (and other chronic conditions) to maintain employment.

Multiple Sclerosis as Subcortical Dementia Several authorities have suggested that multiple sclerosis gives rise to a pattern of cognitive and emotional deficits typical of the subcortical dementias associated with disorders like Huntington's disease. Consistent with this idea, many multiple sclerosis patients display cognitive deficits in processing information quickly, solving novel problems, visuospatial skills, and anterograde memory recall, and have personality and mood disturbances. The agnosias, apraxias, and aphasias often observed in cortical dementias such as dementia of the Alzheimer's type rarely occur in multiple sclerosis; as noted earlier, multiple sclerosis patients sometimes perform poorly on tests of confrontation naming. Such patients are likely to exhibit deficits in other cognitive domains, but they rarely show unusual difficulties in finding words to communicate in ordinary conversation.

Although these considerations can be taken to support the idea that multiple sclerosis gives rise to a form of subcortical dementia, in reality the situation is more complicated. First, while group studies depict a pattern of impairments and strengths that is prototypical of subcortical dementia, only a small proportion of patients, considered as individuals, meet suggested criteria for subcortical dementia (e.g., deficits in three or more different cognitive domains); many patients show no cognitive impairments at all. Second, as the case of Mary D. demonstrates, some multiple sclerosis patients who meet operational criteria for subcortical dementia can make minor adjustments to compensate for their deficiencies and lead relatively normal and productive lives.

The concept that multiple sclerosis can give rise to a form of subcortical dementia can be seen as a template to plan the initial evaluation of a patient; in this way the concept has some utility for clinicians. Any other application of the concept is likely to lead to misleading and potentially harmful inferences.

Progression of Cognitive and Emotional Deficits In numerous cross-sectional studies the correlations between disease duration and cognitive performance, when adjusted for chronological age, are uniformly low in size and often statistically nonsignificant. Longitudinal data are sparse, but the available information indicates that there are no meaningful declines in average performance of multiple sclerosis patients on neuropsychological tests over study periods of 1 to 3 years. The exception to this generalization is for tests that have a large sensory or motor component on which performance tends to decline with time.

The implications of these findings for cognitive rehabilitation of multiple sclerosis patients are clearly positive, because gains from therapy would not be cancelled by

progressive cognitive deterioration as occurs in dementia of the Alzheimer's type. Undoubtedly, some multiple sclerosis patients do experience significant cognitive decline, but at present there is no way to identify these patients.

Even less is known about the possible progression of emotional disturbances such as depression in multiple sclerosis. Again, cross-sectional studies do not reveal simple relationships between disease duration (or disability status) and measures of depression or aspects of psychological distress.

Neuroimaging Correlates Structural MRI, which revolutionized the clinical diagnosis of multiple sclerosis, continues to be the main research tool to examine correlates of cognitive impairment and to monitor the CNS effects of new pharmacological treatments.

Various measures have been employed to evaluate overall brain disturbance. The earlier studies used neuroradiological ratings of atrophy, lesion size, and extent of ventricular enlargement. More recent work measures total lesion area or volume or the area of certain structures that are often affected in multiple sclerosis, such as the corpus callosum. Regardless of the anatomical measure used, patients with greater brain disturbance perform more poorly on a variety of cognitive measures.

More specific relationships have also been reported. Studies of patients who received surgical section of the corpus callosum to control medically intractable seizures perform poorly on a variety of tasks that require transfer of information between the two cerebral hemispheres. In multiple sclerosis patients, the degree of impairment on tasks that require interhemispheric transfer is positively correlated with the extent of atrophy of the corpus callosum, but not with other anatomical measures such as total lesion area.

The Wisconsin Card Sorting Test is a problem-solving task that is known to be sensitive to focal lesions of the frontal lobes and to diffuse cerebral injury; as a group, multiple sclerosis patients display impairment on this test. However, there is great variability within the multiple sclerosis group and many patients perform normally. Recently, it has been shown that multiple sclerosis patients who performed poorly on the Wisconsin Card Sorting Test had significantly larger lesions in the white matter of the frontal lobes than patients who performed normally. There were no differences in total lesion load between the frontal and posterior groups.

These results encourage the view that it will be possible to establish more specific brain-behavior relationships and possibly to predict patterns of cognitive impairment. Functional neuroimaging would be an obvious way to approach this problem, but to date few studies with multiple sclerosis patients have been reported. None has employed an activation paradigm of the sort that has proved so powerful in studying neuroimaging correlates of cognitive processes in normal subjects.

Fewer studies have examined neuroimaging correlates of psychiatric disturbance in multiple sclerosis, but one study described a correlation between depression and the extent of lesions in the temporal lobes.

Treatment Because multiple sclerosis patients may exhibit a bewildering variety of physical symptoms, they often receive numerous medications to alleviate these conditions. If patients also require drugs to relieve psychiatric disorders, the possibility of drug interactions should be carefully considered.

Physical Symptoms Spasticity is a common problem in multiple sclerosis. Baclofen is most commonly prescribed, but various benzodiazepines, especially clonazepam (Klonopin) are also administered. Various other drugs such as cyclobenzaprine (Flexeril) are used less often.

Urinary incontinence is also common in multiple sclerosis. Peripherally active anticholinergics such as oxybutynin (Ditropan) are typically prescribed. For chronic pain, opiates are usually given with varying success.

Fatigue Amantadine and pemoline (Cylert) are given for the relief of fatigue. Amantadine was shown to be effective for some patients in a recent clinical trial, but pemoline was no more effective than placebo. Some physicians regularly prescribe corticosteroids to alleviate fatigue and elevate mood. Corticosteroids have an established role in reducing inflammation and shortening the duration of relapses in multiple sclerosis, but long-term administration of these drugs must be questioned on several grounds. Corticosteroids have unpredictable and occasionally dramatic effects on mood and behavior and increase susceptibility to hip fracture in multiple sclerosis patients.

Psychiatric Symptoms Despite the high prevalence of psychiatric disturbance in multiple sclerosis patients, few controlled studies have focused primarily on treatment-related issues. Although some authors have cautioned that multiple sclerosis patients might not respond to traditional pharmacotherapy or psychotherapy because of the demyelination process of the disease, no empirical studies have supported these claims. The few available studies have found that MS patients respond to traditional psychiatric therapy as well as other patient populations do.

Depression in patients who have multiple sclerosis has been found to respond to cognitive therapy, cognitive-behavior therapy, and group psychotherapy. Studies have shown that psychotherapy benefits patients and their families by helping them cope with the unpredictable and variable nature of the disease. For example, educating patients about their disease and providing them with strategies to facilitate continued employment and social involvement tends to reduces stress and helps patients adjust to living with a chronic illness.

Pharmacological treatments have also demonstrated efficacy in managing depression in multiple sclerosis. Specifically, tricyclic medications such as amitriptyline (Elavil), nortriptyline (Pamelor), and desipramine (Norpramin) have produced good clinical results, although the anticholinergic adverse effects of these drugs may limit their utility. Some authors have suggested that imipramine might be most appropriate for depressed multiple sclerosis patients who also experience bladder-control difficulties. The selective serotonin reuptake inhibitors (specifically sertraline [Zoloft] and fluoxetine) have also been shown to effectively treat depression in multiple sclerosis.

Pathological laughter and crying can usually be managed successfully with amitriptyline. Patients who fail to respond to amitriptyline might improve following a trial of levodopa (Larodopa). Multiple sclerosis patients with bipolar I disorder have been found to respond well to lithium treatment.

Drugs That May Affect the Course of the Disease Two synthetic analogues of natural human interferon beta have recently become available for the treatment of relapsing-remitting multiple sclerosis. Interferon beta-1b (Betaseron) reduced the frequency of relapses, and blocked the increase in lesion load as measured by serial MRI; over a 5-year trial, patients receiving this preparation tended to show smaller increases in disability, but the trend was not statistically significant.

Interferon beta-1a (Avonex) reduced the proportion of multiple sclerosis patients whose disability status progressed to a predetermined level, suggesting that interferon beta-1a slowed the course of the disease.

A slightly different form of interferon beta-1a (Rebif) is approved in Europe and Canada and is under review in the United States. This form reduced relapse rate, slowed progression of disability, and reduced total lesion load on MRI.

The most common adverse effects of all three drugs are local irritation at the injection site and flu-like symptoms, which usually disappear in a few months. Some patients experience increases in depression or chronic fatigue while taking interferon beta-1b. These adverse effects have not been reported for the interferon-1a forms, but experience with them is more limited than with interferon beta 1a.

Interferon beta has a number of immunomodulating actions that could contribute to its therapeutic action. Among the more interesting possibilities are the inhibition of interferon gamma from activated lymphocytes and the inhibition of production of tumor necrosis factor by macrophages. Both interferon gamma and tumor necrosis factor are hypothesized to play roles in demyelination. Once considered a potential therapy, interferon gamma is now known to worsen disease symptoms.

The fourth new drug, glatiramer (Copaxone), was formerly called copolymer 1. The drug is the acetate salt of synthetic polypeptides composed of four amino acids: L-alanine, L-glutamic acid, L-lysine, and L-tyrosine. Copaxone moderately reduced relapse rate and disability progression.

The effects, if any, of these four drugs on cognitive functions in multiple sclerosis are not known. Similarly, there is no evidence at present that any of the many other drugs given to multiple sclerosis patients worsens (or improves) cognitive functions at the doses utilized. However, strongly anticholinergic antidepressant medications such as amitriptyline and many of the benzodiazapines can impair anterograde memory at therapeutic doses. There are numerous other effective medications without these adverse effects so the problem of iatrogenic memory impairment can usually be avoided.

OTHER DEMYELINATING DISORDERS

In addition to common conditions such as traumatic brain injury that directly damage the white matter there are a number of rare genetic diseases that affect the integrity of myelin. Most of these disorders exhibit an autosomal recessive or X-linked pattern of inheritance and involve genes that control the production of enzymes that influence the synthesis or assembly of the lipids and proteins that comprise the myelin sheath. These reactions, including the production of the catalytic enzymes, occur in multiple steps. Depending on the stage of the biochemical chain that is affected by the gene defect, the enzyme may be completely absent, present in reduced concentration, or present in normal concentration with reduced activity. The nature of the change in enzyme function determines the age of onset of the disease and, to some extent, the pattern of neurological, cognitive, and psychiatric symptoms.

The *gangliosidoses* result from alterations in the enzyme hexosaminase A. Complete absence leads to *Tay-Sachs disease*, which begins in early infancy as a severe neurodegenerative disorder that progresses to death in several years. Less severe enzyme deficits are associated with onset in adolescence as in *Sandhoff's disease*, which often presents as bipolar I disorder with later development of neurological symptoms.

Neuronal ceroid lipofuscinosis is associated with motor dysfunction including facial dyskinesias as well as progressive dementia with personality changes. The name applied to this disorder depends upon the age of onset. In early infancy, it is called *Haltia-Santavuori disease*, but with adult onset it is called *Kufs disease.*

Another group of metabolic disorders includes *metachromatic leukodystrophy, adrenoleukodystrophy, globoid cell leukodystrophy* , and *Hurler syndrome.* These disorders may first appear in childhood, adolescence, or early adulthood. Psychiatric and cognitive symptoms are often prominent early and the progression of these symptoms is highly variable.

Diagnosis of these conditions is improving rapidly. Already there are clinical tests that are specific for some of the implicated enzymes; rapid advances in the molecular biology of the human nervous system will undoubtedly yield additional tests of high sensitivity and specificity.

Until recently, treatment for these genetic storage diseases has been mostly supportive and palliative. A recent review of more than 200 patients who received bone marrow transplantation for metachromatic leukodystrophy, globoid cell leukodystrophy, adrenoleukodystrophy, or Hurler syndrome indicated significant improvement in survival, performance on neuropsychological tests, MRI and spectroscopic measures of brain structure and metabolism, and quality of life. In contrast, the nutritional treatment for adrenoleukodystrophy portrayed in the recent motion picture, *Lorenzo's Oil*, has not proved generally effective.

2.8 NEUROPSYCHIATRIC ASPECTS OF HIV INFECTION AND AIDS

IGOR GRANT, M.D., F.R.C.P.(C), AND J. HAMPTON ATKINSON, JR., M.D.

Acquired immune deficiency syndrome (AIDS) is a lethal neuromedical disorder associated with infection by viruses of the *Retroviridae* class known as *human immunodeficiency viruses* (HIV). Although the central feature of HIV infection involves gradual collapse of the body's ability to mount an appropriate cell-mediated immune response, with attendant medical complications, neuropsychiatric phenomena can also be prominent. These phenomena can be considered under three major headings: neurobiological, psychobiological, and psychosocial. This section provides an overview of the biomedicine of HIV infection, followed by a comprehensive discussion of the neuropsychiatric complications.

HIV INFECTION

Acquired immune deficiency results from infection with human immunodeficiency viruses, of which two are currently known— HIV-1 and HIV-2. Globally, the vast majority of AIDS cases result from HIV-1 infection, whereas AIDS secondary to HIV-2 appears to be confined primarily to a region in West Africa. There may be other subtypes of HIV, which are now classified as HIV-O.

The critical events in HIV-1 disease are associated with infection of a subset of lymphocytes known as the *T4 (helper)* or *cluster designation 4 positive (CD4+) lymphocytes.* CD4+ cells play a central role in cell-mediated immunity and coordinate other critical immune events. Steady depletion of CD4+ cell numbers throughout the course of HIV-1 disease leads to a catastrophic collapse of cell-mediated immunity, as well as to immune dysregulation. In turn, these events lead to death from overwhelming infections, neoplasms, or wasting syndrome.

HIV-1 HIV-1 belongs to the family of retroviruses. Other retroviruses include human pathogens, such as HIV-2, and human T-cell leukemia viruses (HTLV). Pathogenic retroviruses have also been identified in several animal species, including simian immunodeficiency virus (SIV) in macaques, chimpanzee virus, sooty mangabey virus, African green monkey virus, and mandrill virus. Among other animals, there are retroviral infections of sheep (visna virus), goats (caprine arthritis encephalitis virus), horses (equine infectious anemia virus), cats (feline immunodeficiency virus [FIV]), and cows (bovine visna).

Retroviruses have several features in common. First, they tend to be transmitted sexually and by vertical transmission (mother-fetus). Second, they tend to produce disease in the immune and central nervous systems. Third, the time from infection to the development of clinical disease can be protracted. And fourth, the immune response that is mounted by the host appears to be ineffective in preventing disease progression or eliminating the virus.

It is generally believed that HIV-1 arose from some common viral ancestor that itself may have been a retrovirus infecting animals. However, only HIV-2 has strong genetic similarity to an animal retrovirus, the sooty mangabey virus. It is interesting that both HIV-2 and the sooty mangabey are found in West Africa, where those monkeys are commonly eaten by people. The closest animal virus relative of HIV-1 at present may be the chimpanzee virus isolated from animals in Gabon.

There are many genetic strains of HIV-1. At present, these are classified into two major groups, *M* and *O.* Most disease is attributed to M subtypes, of which there are ten (A to J). The B subtype predominates in North America, western Europe, and Australia and New Zealand; the A and D types are prevalent in Africa; the C and E types are common in Southeast Asia. This marked genetic variability of HIV-1 poses challenges to developing universally effective vaccines.

Epidemiology At the end of 1997, more than 600,000 cases of AIDS were reported (including almost 400,000 deaths). Initially a disease primarily of men, women comprised 16 percent of AIDS cases by 1997. The proportion of African-Americans with AIDS is rising in the United States. For example, although approximately 12 percent of the U.S. population is African-American, approximately 36 percent of AIDS cases reported by the end of 1997 were among African-Americans. Minority women have been especially impacted. In the United States, African-American women accounted for 56 percent of AIDS cases reported in women by the end of 1997.

Worldwide, the World Health Organization in 1997 estimated that 29.4 million adults and 1.1 million children under the age of 15 were living with HIV-1 infection, and that 16,000 people became infected each day. Over 30 million people have developed HIV infection since the epidemic began; approximately 90 percent of these infections occurred in developing countries, with 65 percent in sub-Saharan Africa and 20 percent in Southeast Asia. It has been estimated that 11.7 million people have now died from HIV-associated illnesses worldwide. Based on current trends, estimates of the number of persons likely to be infected by the year 2000 have ranged from 40 million to over 100 million. The scope of the problem is therefore highly significant, especially in developing countries.

Mode of Transmission The modes of transmission include heterosexual and homosexual intercourse, vertical transmission from infected mother to fetus or newborn, and instrumental transmission, which involves introduction of HIV-contaminated fluids or materials into the body by means of needles, blood products, or various medical accidents. Receptive fellatio involving ejaculation of HIV-infected semen is another potential mode, but the actual risk is not known. Kissing is not considered a risk unless there is extensive oral disease with open sores. (Because this chapter concerns infection with HIV-1, not HIV-2, the term *HIV* is used to refer to HIV-1–related phenomena.) Worldwide the sexual mode of transmission is the most important, with homosexual sex accounting for the majority of cases in North America, Europe, and the Antipodes, heterosexual transmission being the most common in Africa and Asia, and both patterns occurring in South America.

In North America there appears to be a steady shift in risk patterns. Although the incidence of AIDS associated with homosexual transmission has stabilized or even declined somewhat, the incidence of cases related to heterosexual transmission and injection drug use continues to rise. In the period from 1988 to 1995, the proportion of AIDS cases attributable to injection drug use rose from approximately 15 to 23 percent, and that attributable to heterosexual contact grew from approximately 5 to 18 percent. About 50 percent of women with AIDS acquire HIV either directly or indirectly through injection drug use (i.e., either through being injection drug users themselves, or from having sex with a man who is an injection drug user).

These various data suggest that clinicians in the future will be treating increasing numbers of HIV-infected persons who have acquired their disease through injection drug use, heterosexual transmission, or some combination of these two, and that the rates among women, Hispanics, and blacks will continue to rise.

Process of HIV Infection The cellular and viral dynamics of HIV infection are not fully understood. In order to become infective, once HIV gains entry to the body either through disruption in the mucous membranes or directly by injection, it must enter cells that can support its replication. Entry into cells generally requires that the host cell express the CD4 receptor as well as a co-receptor, in the form of a chemokine receptor. *Chemokines* are proteins secreted by many types of cells in response to inflammatory triggers. They induce leukocyte migration and may be involved in other aspects of host defense against infection, and in the pathophysiology of inflammatory diseases. Over 40 chemokines and more than a dozen chemokine receptors have been identified. Two chemokine receptors—CCR5 and CXCR4—are known to be important for HIV entry into cells. CCR5 is expressed by monocyte-macrophage cells, CXC4 by T cells, and both are found on dendritic cells of lymph nodes. Fusion of HIV with the host cell membrane requires the presence of these chemokine receptors. In their absence, viral attachment can occur,

but fusion and viral entry are blocked. Interestingly, a small proportion of people have a genetic variation that alters the molecular structure of CCR5 so that it is not expressed on the cell surface; such individuals appear to be resistant to infection with HIV.

Once HIV fuses with a host cell membrane, it becomes uncoated and viral ribonucleic acid (RNA) and proteins are released into the cell. HIV reverse transcriptase then creates a deoxyribonucleic acid (DNA) copy of viral RNA. Viral DNA enters the nucleus of the host cell, where it is spliced into the host DNA and is termed a *provirus.* The proviral DNA then directs the formation of messenger RNA (mRNA) in a process called *transcription.* The mRNA enters the cell cytoplasm where it harnesses the protein-making machinery to generate new viral proteins and enzymes in a process termed *translation.* These proteins then accumulate inside the cell membrane and ultimately bud off as a new viral particle. However, the virus is not yet infectious, because the large viral polyproteins have not yet been cleaved into functional units. This cleavage involves the viral enzyme protease. Once the polyproteins are properly clipped, the new virion becomes a fully infectious HIV particle. Understanding the mechanisms of viral attachment, entry, and replication has been crucial to the development of new antiretroviral drugs.

Once infection is established, an extremely active process ensues wherein infected cells constantly release new virions into tissue compartments and the circulation, followed by the body's response to clear these viruses. It is now thought that several billion new virus particles may be generated daily with millions of CD4 cells destroyed every day, being replaced by comparable numbers of new cells generated by the host. The half-life of virus in the circulation is thought to be 6 hours, while that of productively infected CD4 lymphocytes is probably 1.6 days. These CD4 cells are the main reservoirs of virus, but other cells and tissue compartments participate as well. For example, some HIV is harbored by longer-lived cells of the macrophage line; it is also known that viruses are sequestered in the dendritic follicular cells of lymph nodes and microglia in the brain.

The early period of infection may be characterized by high plasma viral load and increasing efforts by the host's immune system to clear the virus. In the typical case, an equilibrium is established wherein viral load drops, but remains detectable. The period between initial exposure and this equilibrium state (approximately 6 months) is termed the *phase of primary infection.*

Clinical Picture HIV can be detected in blood, cerebrospinal fluid (CSF), lymph nodes, and other tissues shortly after infection. Antibodies to various HIV constituents typically appear after 3 to 12 weeks via a process called *seroconversion.*

Seroconversion occurring 3 months or more after exposure has been reported, but appears to be quite rare. Antibodies to HIV can be detected with the enzyme-linked immunoabsorbent assay (ELISA), an inexpensive procedure that is universally available, highly sensitive, and reasonably specific. However, because false-positive test results occasionally occur, confirmation must always be made through Western blot analysis before a person is notified that he or she is seropositive.

During the period of seroconversion, perhaps one half to two thirds of infected persons experience a seroconversion illness, which may resemble the flu. The symptoms include low-grade fever, myalgia, headache, fatigue, gastrointestinal upset, and a skin rash. Rarely, neurological complications can occur at that point, which may include aseptic meningitis, encephalopathy, or acute demyelinating neuropathy (Guillain-Barré syndrome).

Following the period of primary infection, there typically follows an asymptomatic period that may continue for many years, until medical complications develop that permit the diagnosis of AIDS. During the protracted asymptomatic stage (which in North America has a median duration of 10 years), there is typically a steady depletion of the CD4+ lymphocyte number from a preinfection level of approximately 1000 per mm_3 or more to a level of 200 per mm_3 or less. The likelihood of AIDS-defining complications increases markedly when CD4+ cells drop to below 200 per mm_3. Why some people develop AIDS within a few years whereas some others remain nonprogressors for 15 or more years is not known. Some reports have noted that nonprogressors have higher numbers of cytotoxic T lymphocytes and increased neutralizing antibodies, suggesting a better immune response; other data indicate that nonprogressors may be infected with less pathogenic strains of HIV.

Prior to the development of opportunistic infections or other complications, many HIV-infected persons develop *persistent generalized lymphadenopathy.* The prognostic significance is unclear, and it should not be assumed that persons with this condition are necessarily more advanced in HIV illness than other asymptomatic persons.

In North America and Europe the most common complication leading to the diagnosis of frank AIDS (other than drop in CD4 cell count below 200) is pneumonia caused by the protozoan *Pneumocystis carinii.* Patients present with chronic nonproductive cough and dyspnea, and they may develop hypoxemia. Diagnosis usually requires fiberoptic bronchoscopy with alveolar lavage, from which specimens can be suitably stained for the *Pneumocystis* organism. Treatment is with trimethoprim-sulfamethoxazole (Bactrim, Septra) or pentamidine (Pentam, Nebupent). In the United States it is now commonplace to initiate prophylactic treatment for *Pneumocystis* in those with CD4 cell count below 200.

Other common infections that herald the onset of AIDS include tuberculosis, candidiasis, and repeated herpes zoster. Additional complications include Kaposi's sarcoma (linked to human herpesvirus-8 [HHV-8] infection) and oral hairy leukoplakia.

Later AIDS-related events, signifying more profound immunodeficiency, include cytomegalovirus (CMV) infection (including CMV retinitis and gastroenteritis), various atypical infections (e.g., *Mycobacterium avium intracellulare*), as well as lymphomas and a severe wasting syndrome (which may be caused by various infections or by HIV itself).

DIAGNOSIS

CDC Classification System The Centers for Disease Control has developed a classification system for HIV infection comprised of two dimensions: history of clinical conditions and degree of immunosuppression. HIV-related clinical conditions are subdivided into three categories. *Category A* represents patients who have remained medically asymptomatic or have had only a transient illness at seroconversion or persisting lymphadenopathy. *Category B* identifies those patients with more serious HIV-related conditions (minor opportunistic infections). Lastly, *Category C* is indicative of patients who have had more serious AIDS-defining illnesses such as *Pneumocystis carinii* pneumonia. These classifications are currently all-absorbing, such that patients who develop the relevant symptoms but then recover do not revert to a less advanced classification.

The second dimension is degree of immunocompromise. This is based on the individual's CD4+ T-lymphocyte cell count per microliter of blood. Patients with CD4 counts greater than 500 are the healthiest, and fall into *Category 1.* Those with CD4 cell counts from 200 to 499 are in *Category 2*, and patients with CD4 counts below 200 are in *Category 3.* AIDS is diagnosed in those with CD4 <200, a Category C complication, or both (Table 2.8-1).

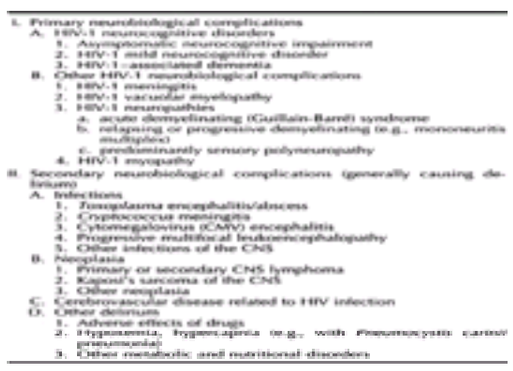
CD4+ Cell Count Categories	Clinical Categories: A Asymptomatic or Lymphadenopathy	B Symptomatic, but not A or C Conditions	C AIDS-Indicator Conditions
1. >500/mm^3	A-1	B-1	**C-1**
2. 200–499/mm^3	A-2	B-2	**C-2**
3. <200/mm^3	**A-3**	**B-3**	**C-3**

Bold entry means CDC 1993 AIDS indicator conditions (A-3, B-3, C-1, C-2, C-3).

Table 2.8-1 CDC 1993 Classification System for HIV Infection

Neurobiological Aspects of HIV Infection The neurobiological complications of HIV infection can be either *primary* or *secondary.* The primary neurobiological complications are those that can be attributed directly to HIV infection of the central nervous system or to immunopathological events (e.g., autoimmune phenomena) precipitated by HIV infection. Secondary neurobiological complications include infections and neoplasms facilitated by the immunodeficiency state, cerebrovascular

complications, and toxic states produced either by HIV-associated medical illnesses (e.g., hypoxemia due to *Pneumocystis* pneumonia) or by toxic effects of various therapeutic agents (e.g., myopathy due to zidovudine [Retrovir]). Some of the more common complications are listed in Table 2.8-2.



I. Primary neurobiological complications
  A. HIV-1 neurocognitive disorders
    1. Asymptomatic neurocognitive impairment
    2. HIV-1 mild neurocognitive disorder
    3. HIV-1–associated dementia
  B. Other HIV-1 neurobiological complications
    1. HIV-1 meningitis
    2. HIV-1 vacuolar myelopathy
    3. HIV-1 neuropathies
      a. acute demyelinating (Guillain-Barré) syndrome
      b. relapsing or progressive demyelinating (e.g., mononeuritis multiplex)
      c. predominantly sensory polyneuropathy
    4. HIV-1 myopathy
II. Secondary neurobiological complications (generally causing delirium)
  A. Infections
    1. Toxoplasma encephalitis/abscess
    2. Cryptococcus meningitis
    3. Cytomegalovirus (CMV) encephalitis
    4. Progressive multifocal leukoencephalopathy
    5. Other infections of the CNS
  B. Neoplasia
    1. Primary or secondary CNS lymphoma
    2. Kaposi's sarcoma of the CNS
    3. Other neoplasia
  C. Cerebrovascular disease related to HIV infection
  D. Other delirium
    1. Adverse effects of drugs
    2. Hypoxemia, hypercapnia (e.g., with *Pneumocystis carinii* pneumonia)
    3. Other metabolic and nutritional disorders

Table 2.8-2 Neurobiological Complications of HIV-1 Infection

HIV-Associated Neurocognitive Disorders From a psychiatric perspective the most important of the primary neurobiological complications are the HIV-associated neurocognitive disorders. The cardinal feature of these disorders is impairment in cognitive functioning; associated features include motor slowing or incoordination and, sometimes, mood disturbances.

Classification and Diagnostic Criteria There has been considerable confusion about the occurrence and features of the neurocognitive disorders, primarily because precise diagnostic criteria were not established until recently. For example, one of the earliest terms was *HIV encephalopathy*, a designation derived from early pathological studies that noted the presence of encephalitic features in the brains of many patients dying with AIDS. Another term was *AIDS dementia complex*, which suggested a constellation of cognitive, motor, and affective-behavioral complications. Many clinicians and investigators tended to use this designation somewhat indiscriminately—not bearing in mind, for instance, that the term *dementia* connotes severe disability. As a consequence of this inexact terminology clinicians failed to recognize milder cognitive disorders or were reluctant to diagnose patients for fear of stigmatizing them with the label of AIDS dementia complex. Richard Price and Bruce Brew provided a framework for staging AIDS dementia complex into five levels of severity, including a subclinical stage; however, it is preferable that the neurocognitive complications be classed as two syndromes differing in level of severity: *HIV-associated dementia* and the *HIV-associated mild neurocognitive disorder.*

The diagnostic criteria for the two syndromes, as used in this section, are presented in Table 2.8-3. The principal differentiating point between dementia and mild neurocognitive disorder is the extent to which the cognitive disorder interferes with a person's day-to-day functioning. Thus, a diagnosis of dementia is reserved for severe cognitive disorders that interfere substantially with work, home life, and social activities. On the other hand, mild neurocognitive disorder can be diagnosed if cognitive deficits that do not interfere in a major way with life functioning are reliably identified. Some people manifest mild neuropsychological deficits that are entirely subclinical (i.e., there is no documented interference in day-to-day functioning). Because such deficits do not reach the threshold for being termed a disorder, the term *asymptomatic neurocognitive impairment* may be used (Table 2.8-2).

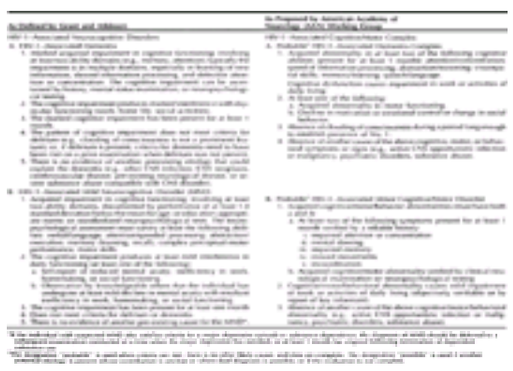


Table 2.8-3 HIV-1–Associated Cognitive Disorders

These definitions of HIV-associated dementia and HIV-associated mild neurocognitive disorder are conceptually similar to the nomenclature proposed by the American Academy of Neurology (AAN) AIDS Task Force. The definition of HIV-associated dementia differs from the AAN's HIV–1–associated dementia complex in not requiring a disturbance in either motor functioning or motivation, emotional control, or social behavior in addition to the cognitive deficit. Also, the emphasis is on marked cognitive disturbance and marked interference in daily functioning as key criteria for dementia. Mild neurocognitive disorder differs from the comparable AAN HIV–1–associated minor cognitive/motor disorder in specifying neuropsychological criteria for establishing the cognitive disorder. The purpose is to avoid inappropriately labeling persons as impaired without hard data. Like the criteria for dementia, the critical symptoms and signs are restricted to the cognitive sphere. Thus, the definitions used in this section reflect what are believed to be the central features of the disorders—cognitive impairment.

MILD NEUROCOGNITIVE DISORDER

Signs and Symptoms A person experiencing mild neurocognitive disorder associated with HIV infection will typically have some difficulty concentrating, may experience unusual fatigability when engaged in demanding mental tasks, may feel subjectively slowed down, and may notice difficulty in remembering. Such persons may say that they are not as sharp or as quick as they once were.

Such a set of presenting complaints, especially in younger individuals who may be struggling to accept their seropositive status, may lead the clinician to conclude that anxiety, depression, or hypochondriasis are responsible. Although affective features are occasionally the best explanation for such complaints, that is not generally the case. Rather, comprehensive neuropsychological testing may reveal that the individual does indeed have difficulties with speeded information processing, divided attention, and sustained effortful processing as well as deficiencies in learning and recalling new information.

Some individuals with mild neurocognitive disorder also have difficulties with tasks involving problem solving and abstract reasoning, and there may also be slowing of simple motor performance (e.g., speed of finger tapping). Verbal skills are less affected, although there may be some decrement in fluency (e.g., quickly reciting as many animals as possible or as many words beginning with a particular letter as possible).

These neuropsychological findings, which emphasize attentional problems, slowing of information processing, and deficiencies in learning, are reminiscent of neuropsychological patterns seen in patients with so-called subcortical dementias (e.g., Huntington's disease and Parkinson's disease). Fine-grained analysis of memory breakdown in HIV-infected persons also confirms a subcortical pattern. For example, persons with HIV-associated cognitive disorders have difficulty recalling words from a list but do not make intrusion errors (i.e., confabulatory responses) the way patients with cortical dementias (e.g., dementia of the Alzheimer's type) tend to do. Neuropsychological features that suggest selective involvement of subcortical structures are consistent with neuropathological findings. It is important to stress that these mild neurocognitive deficits occur independently of depression, anxiety, and other non-HIV sources of cognitive deficit.

Associated Features There are no laboratory findings specific to mild neurocognitive disorder. For example, the CD4+ lymphocyte number tends at most to be very weakly related to the severity of cognitive disturbance. However, the rate of CD4 decline over time may be related to rate of cognitive deterioration. Other immunological indicators (e.g., serum b_2-microglobulin) also relate only weakly to neuropsychological performance. Cerebrospinal fluid studies may reveal increased

mononuclear cell number, protein elevation, mild elevation in b 2-microglobulin, and some increase in quinolinic acid (QA), a putative excitotoxin. HIV RNA can often be detected in CSF using sensitive techniques (polymerase chain reaction [PCR]). There is some evidence that viral load in CSF, but not in plasma, is correlated with severity of neuropsychological impairment, especially in AIDS patients.

Neurological examination tends to be unremarkable; occasionally there may be frontal release signs (e.g., glabella response), but such findings also occur in those without mild neurocognitive disorder.

Structural brain imaging (e.g., computed tomography [CT] scanning, magnetic resonance imaging [MRI]) tends to be noncontributory. Dynamic brain imaging (e.g., single photon emission computed tomography [SPECT]) can reveal reduction in the uptake of tracer substances, but once again the relationship between reduced uptake and neuropsychometric findings is not strong.

The results of electrophysiological studies are often completely normal, although there may be evidence of slowing of central conduction time as indicated by slowed latencies of median nerve or tibial nerve somatosensory evoked potentials. Event-related potentials are typically normal. Disturbance in smooth-pursuit eye movement has occasionally been noted.

HIV-ASSOCIATED DEMENTIA

Signs and Symptoms As might be expected, the cognitive abnormalities in persons with dementia are more profound and more generalized than in patients with mild neurocognitive disorder. Patients report severe forgetfulness, difficulty concentrating, problems with naming and word finding, marked mental slowness, and disorientation. Bedside mental status examination may initially show only modest abnormality (e.g., Mini-Mental State Examination [MMSE] scores in the mid-20s). Nevertheless, comprehensive neuropsychological testing usually reveals marked impairment in speeded information processing, attention, abstracting ability, complex perceptual motor skills, learning of new information, and recall.

As the dementia progresses, the patient may become more apathetic, severely disoriented, and frankly confused and may have difficulty with independent living. Some patients become markedly irritable or labile in mood. Periods of delirium, often related to intercurrent medical events or treatment, may be superimposed on the progressive dementing picture. A small proportion of patients with dementia develop psychotic symptoms that typically have a paranoid flavor and are accompanied by auditory and visual hallucinations.

Associated Features Frank neurological findings are typical in HIV-associated dementia, including presence of frontal release signs, exaggerated deep tendon reflexes, disturbed smooth pursuit eye movement, incoordination, and motor weakness; the latter two findings tend to be worse in the lower than in the upper limbs. In advanced dementia, the patient may become mute and unresponsive and may develop urinary and fecal incontinence. The dementing disorder may be complicated by other neurological syndromes, such as sensory neuropathy and myelopathy.

Neuroradiological examination usually reveals cerebral atrophy (dilation of sulci and ventricles; Fig. 2.8-1 and Fig. 2.8-2 compare normal brain with brain that has atrophy). There may be lucencies in the white matter on CT scanning, and MRI may reveal abnormal areas of high signal, especially on T2-weighted images. Those parenchymal abnormalities may range from multifocal punctate abnormalities to larger confluent areas of abnormal signal. Figure 2.8-2,Figure 2.8-3, and Fig. 2.8-4 provide examples of such patterns.

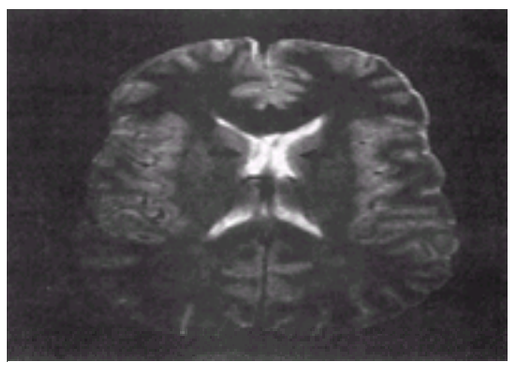

FIGURE 2.8-1 Normal MRI from a 35-year-old man with HIV infection. This T2-weighted axial section shows lateral ventricles of normal size (solid arrows) and no enlargement of sulci. (Courtesy of John R. Hesselink, M.D.)

FIGURE 2.8-2 This axial T2-weighted image reveals moderate enlargement of ventricles (solid arrows) consistent with moderate central parenchymal volume loss in a man in his late 30s with AIDS. There are also several small (open arrows) and large patches of increased signal, the latter situated periventricularly around the frontal and occipital horns of the lateral ventricles (curved open arrows). The hyperintensities are consistent with HIV encephalitis, but could also represent another infectious etiology. (Courtesy of John R. Hesselink, M.D.)

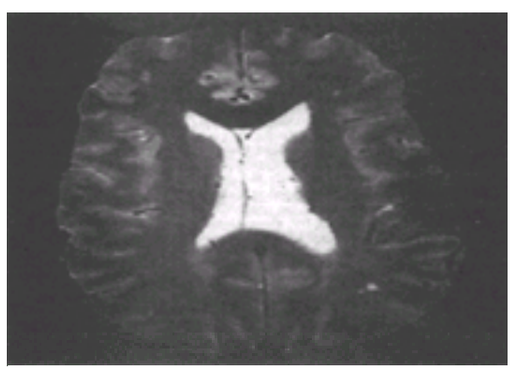

FIGURE 2.8-3 This T2-weighted axial image from a 40-year-old man with HIV infection demonstrates scattered punctate high-signal abnormalities (solid arrows). (Courtesy of John R. Hesselink, M.D.)

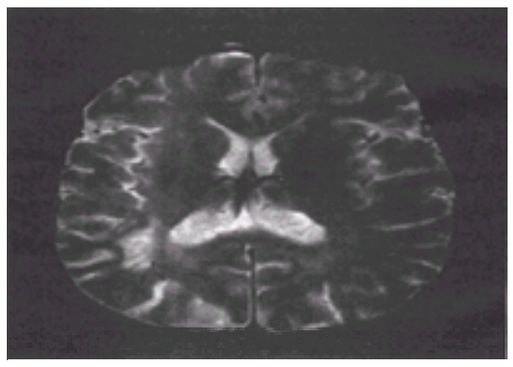

FIGURE 2.8-4 This axial T2-weighted image from a 48-year-old man with AIDS reveals a confluent area of high signal, consistent with HIV encephalitis in the right posterotemporal region (curved arrow). (Courtesy of John R. Hesselink, M.D.)

Dynamic brain imaging (e.g., positron emission tomography [PET]) may reveal increased uptake of 18-fluorodeoxyglucose (FDG) at onset of dementia, especially in the subcortical gray structures; as the dementia progresses, the metabolic abnormality tends to subside and may be replaced with hypometabolism. Studies with magnetic resonance spectroscopy have detected reduction in *N*-acetylaspartate, a putative neuronal marker, suggesting damage to or loss of neurons.

Electrophysiological abnormalities are common at this stage, and they may include slowing (and rarely, spike discharges) on the electroencephalogram (EEG), slowing of latencies on evoked potential studies, and abnormalities in event-related potentials. Ophthalmological examination will often reveal cotton wool spots in the retina, indicating small areas of infarction. Eye movements tend to be grossly ataxic.

Laboratory findings associated with dementia include very low CD4 numbers (not an invariable association), high serum and CSF b $_2$-microglobulin, increased CSF neopterin, and increased CSF quinolinic acid. Increasing CSF viral load is related to severity of dementia.

Neuropathology In the first few years after AIDS was first defined as a clinical entity, it was speculated that neuropsychiatric complications might result from CMV encephalitis. In the mid-1980s, however, it became clear that HIV itself frequently invaded the central nervous system (CNS), with specific neuropathological results.

On microscopic examination, the characteristic neuropathological changes in the brains of those dying from HIV-associated dementia include myelin pallor, microglial nodules, multinucleated giant cells, perivascular infiltrates, and foci of demyelination. Typical inflammatory changes are minimal or absent. Figure 2.8-5 and Figure 2.8-6 are photomicrographs illustrating some of those changes. Although the neuropathology can be widespread, it is typically concentrated in subcortical gray and deep white matter.

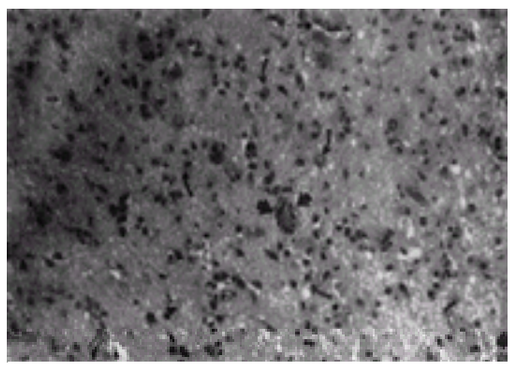

FIGURE 2.8-5 Neuropathology of HIV. This section illustrates two common findings: multinucleated giant cells (one such indicated by two straight arrows) and infiltration by mononuclear macrophages (curved arrows). (From an immunoperoxidase-stained paraffin-embedded section of brain tissue. Original magnification ×300.) (Courtesy of Clayton A. Wiley, M.D., Ph.D.)

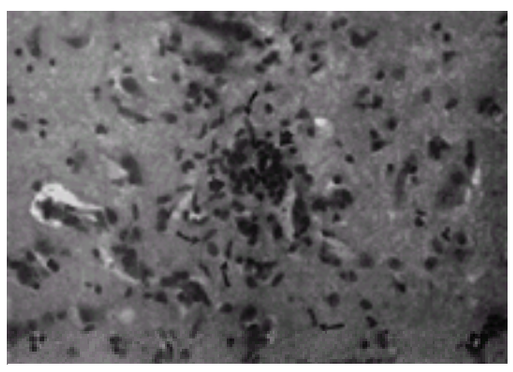

FIGURE 2.8-6 Neuropathology of HIV. This section illustrates a microglial nodule, frequently noted (along with multinucleated giant cells) in brains of persons dying with HIV-1-associated dementia. The nodule (indicated by two straight arrows) is filled with and surrounded by microglia, which are mononuclear cells with elongated nuclei (curved arrows). (From a hematoxylin- and eosin-stained paraffin-embedded section of brain tissue. Original magnification ×600.) (Courtesy of Clayton A. Wiley, M.D., Ph.D.)

Immunocytochemical or molecular biological studies on the brains of patients dying with presumed HIV-associated dementia usually demonstrate infection of the CNS by HIV-1. As detection techniques have improved, so has the likelihood of detecting HIV in the brain. For example, introduction of the PCR-technique to amplify viral products has facilitated more frequent and more widespread identification of HIV in the brain than was possible through immunocytochemical or *in situ* hybridization approaches.

Considerable effort has been devoted to cellular localization of HIV in the brain. It appears that cells of the macrophage-microglia line are principally infected. There have been no confirmed reports of productive HIV infection of neurons or astroglia; several unconfirmed reports suggest that oligodendroglia may occasionally be infected.

Although HIV is not found in neurons, neuronal loss can occur in the neocortex and deep gray structures. Furthermore, there is evidence that neurons can be damaged in HIV encephalitis. Figure 2.8-7 shows neurons that have lost their dendritic spines and others with abnormal vacuolation. Those observations raise questions about the mechanisms of CNS damage in HIV infection.

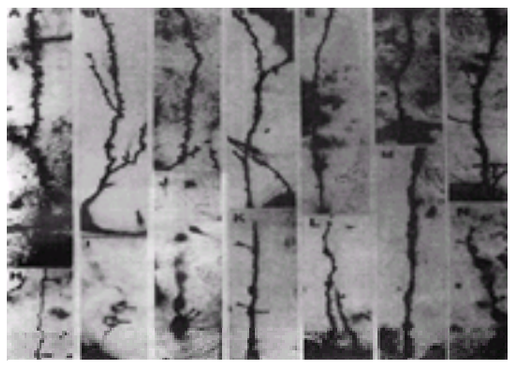

FIGURE 2.8-7 Comparative morphology of different Golgi impregnated dendritic segments in control **(A - C)** and HIV encephalopathy (HIVE) **(D - N)** frontal cortex. Medial **(A)**, proximal **(B)**, and distal **(C)** apical segments in control tissues showed abundant spines. Proximal (**D** and **E**), middle **(F)**, and distal **(G)** apical segments in HIVE cases showed decreased number of spines. **H**, typical varicosities (*arrowheads*) observed in neuritic processes of HIVE cases. **I**, vacuolated (*arrows*) apical dendrite in HIVE. **J**, vacuolated dendritic segment with occasional spines (*arrowheads*). Middle **(K)** and distal **(L)** dendritic segments were swollen throughout their length; occasional spines (arrowheads) and abnormal spines (arrow) were present. **M**, extensively distorted apical dendrite. **N**, dendrite with segmented dilatations (*stars*) and a few abnormal spines (*arrowheads*) were observed. (Magnification ×495.) (Reprinted with permission from Masliah E, Ge N, Morey M, DeTeresa RM, Terry RD, Wiley CA: Cortical dendritic pathology in HIV encephalitis. Lab Invest *66:*288, 1992.)

Pathogenesis Much recent research on neuro-AIDS has focused on possible mechanisms underlying neuronal injury in HIV infection. The macrophage microglia cells play a central role in current concepts of neuropathogenesis. It has been proposed that there are two stages of HIV infection of brain macrophages. The first stage involves binding of HIV to the cell, leading to virus internalization. During this stage, the macrophage may release toxins or stimulate other cells to do so. In the second stage HIV is integrated into the macrophage genome, leading to active viral reproduction accompanied by heightened macrophage activation. During this stage the macrophage responds in an excessive manner to secondary activators, which can include the brain's own cellular regulatory system, other infectious organisms, cytokines produced by other immune cells, and viral envelope glycoprotein gp120. Activated in this manner, macrophages are thought to produce a variety of neurotoxins including glutamate-like molecules, cytokines, free radicals, and arachidonic acid. Whereas several theories of neuropathogenesis vary in certain details, the general consensus is that neuronal injury in AIDS involves overactivation of channels permeable to calcium, including voltage-dependent channels and those operated by *N*-methyl-D-aspartate (NMDA) receptors. Indeed, the final common pathway of neuronal injury in AIDS has been found to resemble the mechanism of damage in stroke, trauma, epilepsy, neuropathic pain, and several neurodegenerative diseases. The theory is that neurotoxins activate NMDA receptors, thereby leading to influx of calcium, which in turn causes the neuron to release glutamate. The glutamate excites other neurons, causing further calcium influx and leading ultimately to cellular injury and death.

Course and Prognosis The prevalence of mild neurocognitive disorder increases with disease progression. For example, approximately 50 percent of patients diagnosed with AIDS have either asymptomatic neuropsychological impairment or mild neurocognitive disorder. Among patients who have no medical symptoms or who have early medical symptoms of insufficient severity to merit the diagnosis of AIDS, the rate of mild neurocognitive disorder is highly variable. Some investigators have found no increases in this disorder among asymptomatic seropositive persons compared to suitably matched controls; other studies have reported that subtle cognitive changes do occur in the early and middle phases of disease. Twenty to 30 percent of such asymptomatic or early symptomatic persons will have either mild neurocognitive impairment or mild neurocognitive disorder.

It is not known whether mild neurocognitive disorder predisposes patients to the development of frank dementia. In one series, a 2-year follow-up indicated that neuropsychological assessment at entry was not predictive of later dementia, but that neuropsychological worsening in a 6-month period was.

Given what is known thus far it is probably prudent for the clinician to consider that mild neurocognitive disorder can complicate the early natural history of HIV infection in some individuals. Therefore, those presenting with cognitive complaints or experiencing behavioral abnormalities should undergo comprehensive neuropsychological testing, neurological examination, and, as indicated, brain imaging studies.

Dementia occurs almost exclusively in more advanced AIDS. Although there have been some reports of dementia as the first presenting feature of AIDS, it is an uncommon initial finding. The exact prevalence of dementia among AIDS patients is not clearly known. Estimates in the earlier literature ranged from 15 to 66 percent of more advanced cases; the current data suggest a prevalence of 4 to 7 percent of those with AIDS. There is a general impression that the incidence of frank dementia has declined substantially in the last several years with the general availability of antiretroviral therapy.

The prognosis of asymptomatic neurocognitive impairment and mild neurocognitive disorder is not known. At present, they appear to be long-term stable conditions or only very slowly progressive. The advent of frank dementia is a poor prognostic sign. In one series about three quarters of the patients died within 6 months of developing frank dementia; presence of mild neurocognitive disorder is also associated with earlier time to death.

Other Primary Neurobiological Disorders Although the cognitive disorders are arguably the most important of the primary HIV-associated neurobiological conditions, there are several others of which the clinician needs to be aware.

Meningitis At about the time of seroconversion, a small proportion of individuals experience symptoms of meningeal irritation, usually in the context of a seroconversion illness (fever, achiness, weakness, other flulike symptoms). Symptoms may include photophobia, headache, and neck stiffness; very rarely, a more floridly encephalitic picture evolves with confusion and clouding of consciousness.

Periseroconversion meningoencephalitis is typically self-limited, although a few patients develop a chronic aseptic meningitis syndrome, with chronic headaches lasting many months. Such headaches may respond to low doses (e.g., 25 to 50 mg) of amitriptyline (Elavil) or nortriptyline (Aventyl, Pamelor).

Vacuolar Myelopathy Vacuolar myelopathy is probably the second most prevalent and serious primary HIV-related CNS complication. It is a disorder that occurs typically in later stages of the disease, with a prevalence of 20 to 30 percent in AIDS patients. Subclinical spinal cord disease probably exists in a much higher proportion of infected persons, in perhaps 50 percent of patients with AIDS and in a variable proportion of asymptomatic carriers.

The presenting features are spastic paraparesis, a predominantly posterior column sensory loss (i.e., greater loss of vibration and proprioception versus other sensory loss), which may lead to bowel and bladder incontinence. Sometimes the myelopathy coexists with dementia, although the two conditions are thought to differ in etiopathogenesis. For example, whereas HIV is typically detected in the CNS of HIV encephalitis cases, there is less evidence for productive HIV infection in relation to the demyelinating and gliotic lesions found in myelopathy. Furthermore, the myelopathy does not seem to respond favorably to zidovudine.

Neuropathies Acute demyelinating neuropathies can occasionally develop early in the course of illness, such as at the time of seroconversion. A generalized form of acute demyelinating neuropathy is the HIV-associated Guillain-Barré syndrome. Presenting features include a rapidly evolving symmetrical paralysis with variable sensory signs, often beginning in the lower limbs. Although the syndrome is an uncommon complication of HIV infection, it is evident that HIV serotesting is an important aspect of the differential diagnosis of Guillain-Barré syndrome, especially in younger males.

Although the acute demyelinating neuropathies that occur in the early stages of HIV disease tend to be self-limiting, other more persistent kinds of neuropathy can occur during the middle and later phases. These include a predominantly sensory polyneuropathy characterized by onset of numbness, tingling, burning, or pain in a primarily distal and relatively symmetrical distribution. Symptoms are especially common in the feet and include painful sensations and contact sensitivity without motor involvement.

The prevalence of these disorders is not well understood, although it has been estimated that 10 percent of asymptomatic carriers and about a third of patients with AIDS experience sensory neuropathy. Zidovudine treatment is only sometimes effective. Low doses of noradrenergic antidepressant medications, such as desipramine (Norpramin), nortriptyline, or amitriptyline less than 50 mg, and carbamazepine (Tegretol) are useful in suppressing symptoms.

Patients with more advanced immunodeficiency can also experience chronic progressive or relapsing inflammatory demyelinating polyneuropathies, of which mononeuritis multiplex may be a variant. The various neuropathies may also be complicated by a primary myopathy, which has been associated with HIV infection.

Secondary Neurobiological Complications The most important secondary neurobiological complications of HIV infection are brain infection by *Toxoplasma gondii, Cryptococcus neoformans*, primary CNS lymphoma, and delirium secondary to metabolic derangements or pharmacological toxicity.

Toxoplasmosis Toxoplasmosis is the most prevalent cause of space-occupying brain lesions in AIDS. The disease represents reactivation of a highly prevalent pre-existing infection by the protozoan *T. gondii* in the setting of advanced immunosuppression. It is seen almost exclusively in patients with fewer than 200 CD4+ T lymphocytes per microliter. Cerebral toxoplasmosis typically presents with seizure or focal neurological disturbances, such as hemiparesis, in combination with subacute or acute changes in mental status. MRI brain scanning reveals single or multiple lesions of high-signal intensity on T2-weighted images (Fig. 2.8-8). The lesions enhance with administration of gadolinium or another contrast agent. In an AIDS patient with a positive serological test for toxoplasma and a contrast-enhancing cerebral mass lesion, empiric treatment with pyrimethamine (Daraprin) and sulfadiazine (Microsulfon) is indicated, and will typically produce both clinical and radiographic improvement in 7 to 14 days. The prior probability of toxoplasmosis is markedly diminished, however, in patients whose toxoplasma serology is negative, or in those who have been taking a sulfa antibiotic reliably. Under these circumstances, a brain biopsy may be obtained to diagnose other potential causes, principally primary CNS lymphoma. Since the widespread use of trimethoprim-sulfamethoxazole for prophylaxis against pneumocystic pneumonia in patients with CD4+ lymphocytes <200 in the United States, the incidence of cerebral toxoplasmosis has dropped considerably.

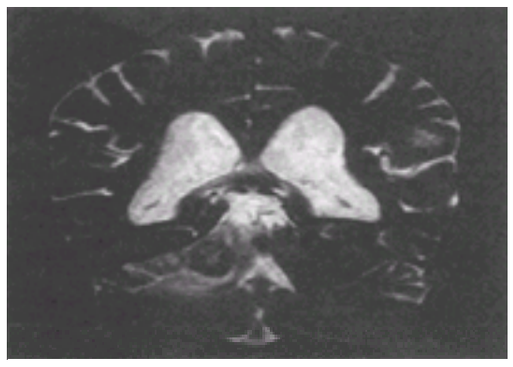

FIGURE 2.8-8 This coronal T2-weighted image from a 49-year-old man demonstrates a right cerebellar hemispheric mass, which was determined to be due to Toxoplasma infection. This scan also reveals brain atrophy with moderate enlargement of the lateral ventricles and increased fluid in the sulci (fluid is white on this T2-weighted image). (Courtesy of John R. Hesselink, M.D.)

Cryptococcus Meningitis *C. neoformans* is a yeast capable of infecting the meninges and brain of immunocompromised persons; perhaps 10 percent of persons with AIDS develop this serious complication. The presenting features are fever with meningeal signs (headache, neck stiffness, nausea, and delirium). On examination, there may be signs of cranial nerve involvement and papilledema. CT and routine MRI scan are sometimes unremarkable, although evidence of meningeal involvement may be seen on MRI enhanced with gadolinium, which is helpful in visualizing areas of blood-brain barrier permeability.

Although there is generally a favorable response to specific treatment, which combines amphotericin B (Fungizone) and flucytosine (Ancobon), relapse is common and early death is a frequent outcome. As with toxoplasmosis, initial treatment needs to be followed by lifelong suppressive therapy with agents such as fluconazole (Diflucan) or amphotericin B; treatment with the latter entails placement of an indwelling catheter since it is given intravenously.

Cytomegalovirus (CMV) Encephalitis Herpes viruses can produce encephalitis in immunocompromised persons. CMV commonly coinfects the brain in late-stage AIDS. If encephalitis develops, it can present with fever, rapidly progressive delirium leading to obtundation, and seizures. The condition may be difficult to distinguish from HIV-associated dementia, although the MRI brain scan, if positive, may show typical areas of periventricular and subependymal abnormal signal. Genciclovir and foscarnet (Foscavir) are virustatic, but long-term efficacy has yet to be established. By enhancing the return of immune function, protease inhibitors appear to be lowering the prevalence of CMV disease in the CNS.

Progressive Multifocal Leukoencephalopathy Many healthy persons are asymptomatic carriers of papovaviruses (human papilloma or wart viruses), but in the setting of severe immunodeficiency these viruses can produce a catastrophic encephalopathy. The patient may present with multifocal neurological signs, including hemiparesis, language disturbance, gait difficulty, and a progressive delirium.

CT scanning may show zones of subcortical lucency, and MRI scan may reveal patchy areas of high signal in the subcortical white matter (Fig. 2.8-9). Historically, the disease progresses rapidly to death but reports of stabilization and marked improvements in clinical neurological status in patients with progressive multifocal leukoencephalopathy have appeared since the introduction of highly active combination antiretroviral therapies.

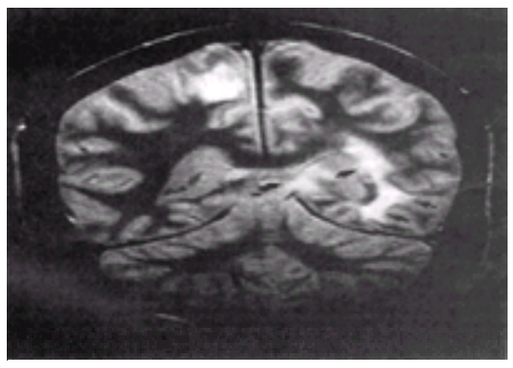

FIGURE 2.8-9 This coronal MRI taken from a 48-year-old HIV positive man with AIDS demonstrates a hyperintensity in the subcortical white matter in the left parietal lobe due to progressive multifocal leukoencephalopathy (PML) (arrows). From other images it was observed that the lesions were multifocal, extending from frontal to occipital lobes, and involving the basal ganglia. (Courtesy of John R. Hesselink, M.D.)

Lymphoma AIDS is probably the most common condition associated with primary lymphoma of the CNS. These B-cell lesions tend to arise multifocally and produce a slowly deteriorating neurocognitive disorder that may at first be confused with HIV-associated dementia, but later progresses to multifocal signs and signs of increased intracranial pressure. On MRI, lymphoma is difficult to differentiate from toxoplasmosis; increased uptake of thallium-201 on SPECT is more common in lymphoma than toxoplasmosis. Brain biopsy is usually required to make a firm diagnosis (Fig. 2.8-10). Many clinicians empirically treat for toxoplasmosis and reserve invasive diagnostic procedures until such treatment clearly fails. There is no effective treatment for the lymphoma although radiation therapy can reduce intracranial pressure.

Delirium Delirium exists when a patient experiences rapidly evolving cognitive decline, especially in the areas of attention, learning and remembering new information, and orientation with reduced or fluctuating alertness (clouding of consciousness). Although intrinsic disorders (i.e., infections, neoplasms, and so on) are common causes, delirium can also reflect metabolic derangements or pharmacological toxicity.

Epidemiology The prevalence and incidence of delirium in HIV illness are unknown, although delirium (along with adjustment disorder) is generally one f the most frequent diagnoses made by psychiatric consultation services when evaluating hospitalized HIV patients. It is likely that delirium is as underdiagnosed and undertreated in HIV units and in general surgical and medical wards.

As treatments for advanced HIV disease have improved, an increasing number of patients who otherwise would have been hospitalized are now being managed in ambulatory settings. Therefore, physicians working in outpatient clinics and in private consultation offices need to maintain a high index of suspicion to the possible emergence of delirium in symptomatic HIV patients, regardless of the setting.

Etiology The combination of systemic illness, neurocognitive impairment, and multiple medications with CNS effects place the person with symptomatic HIV disease at high risk for delirium. Therapeutic agents likely to be associated with delirium are described in Table 2.8-4. Particularly noteworthy are those agents with anticholinergic properties, such as amitriptyline and chlorpromazine (Thorazine), along with antiemetic agents (scopolamine, prochlorperazine [Compazine], antihistamines, and benzodiazepines. Opportunistic or other infections, metabolic factors (hypoxemia, hypercarbia, electrolyte imbalances, hypoglycemia), hepatic and renal dysfunction, surgical intervention, and psychoactive substance use and withdrawal states can all contribute to likelihood of delirium.

Table 2.8-4 Neuropsychiatric Side Effects of Therapeutic Drugs for HIV

Pneumocystis pneumonia can be complicated by hypoxemia, which can lead to clouding of consciousness. Similarly, delirium has occasionally been reported as a complication of zidovudine and ganciclovir. Other causes of delirium in late-stage AIDS include severe nutritional deficiencies (e.g., vitamin B_{12}) and electrolyte imbalance (e.g., hyponatremia).

Diagnosis and Clinical Features Both hyperactive (vigilant) and hypoactive (withdrawn) deliria occur. Detecting the essential features of delirium, including impairment of sustaining and shifting attention, disorganized thinking, altered level of alertness, increased or reduced psychomotor activity, and memory impairment requires careful interviewing and discipline on the part of the examiner, who may be conducting an assessment in a busy medical unit, or who may be distracted by the patient's flamboyant, delusional, or hallucinatory symptomatology. In outpatient settings deliria may be even more difficult to detect, based on incipient or subtle presentations or on an interviewer's lower index of suspicion. Detecting delirium is crucial because it is a medical emergency requiring prompt assessment for potentially lethal conditions (e.g., opportunistic brain infection, tumor, or cerebrovascular events).

Differential Diagnosis The differential diagnosis includes substance intoxication delirium, substance withdrawal delirium, and delirium due to a general medical condition; deliria can also be imposed on dementia. The standard neuromedical workup for deliria should be pursued, along with toxicology screening and brain imaging (MRI or CT), if possible.

Course and Prognosis The course and prognosis of deliria in the HIV-positive patient appear to mimic the course and prognosis of other medical illnesses. There is a prodromal phase, which may be brief or of several days' duration, an acute phase, when the diagnosis is made, and then either rather prompt resolution or a more persisting subacute phase, which may last for several days or weeks. Excess morbidity from delirium beyond its neuromedical etiology may result from suicide, injury while fleeing delusional dangers, or assault based on paranoid perception of caretakers. If delirium is associated with an underlying HIV dementia, the prognosis may be especially poor.

PSYCHOBIOLOGICAL ASPECTS OF HIV INFECTION

The fundamental premise of modern psychiatry is that emotional life and behaviors have biological underpinnings that develop and are shaped within a broader social context. Perhaps that interplay is nowhere more evident than in the psychobiology of HIV infection. The HIV pandemic in Western industrialized nations now includes both the initial risk groups (homosexual men and injection drug users), growing number of women, and adolescents; the pandemic crosses diverse ethnic and socioeconomic strata. Further, dramatic medical advances have begun to alter the natural history of the illness from one of accelerating deterioration to a more chronic course resembling that of chronic cardiac and neurological diseases. The changing face of the HIV pandemic suggests that the role of clinical psychiatry must expand to encompass new populations and to adapt to changing neuromedical aspects of illness. The psychiatrist involved in the care of HIV-infected patients will be asked to address patients' premorbid psychiatric disorder and as well as new-onset emotional distress, which may complicate a patient's response to infection, disease, and treatment.

Etiology Figure 2.8-11 illustrates several models for understanding the origin of psychiatric conditions observed in the course of infection and illness from HIV. The transition model proposes that adverse psychological phenomena (e.g., adjustment disorders, mood disorders, anxiety disorders) may be anticipated at key points, such as discovery of seroconversion, initiation of antiretroviral treatment, onset of physical symptoms, advance in HIV illness stage, and HIV-related bereavement, and that they reflect a breakdown in coping capacities in the face of HIV.

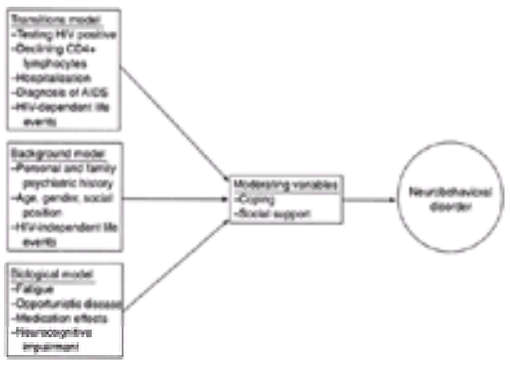

FIGURE 2.8-11 Models for understanding neurobehavioral conditions in HIV infection and illness.

The biological model suggests that HIV involvement of the CNS may be associated directly with depressive or manic syndromes or psychotic phenomena. Patients may respond to their awareness of HIV-associated neurocognitive decline with psychological distress, or the neurocognitive decline itself may increase the likelihood of such symptoms.

A third conceptualization, which may have been underestimated, is the so-called background model. It emphasizes that a psychiatric disorder that preceded the HIV epidemic may emerge during the course of an HIV illness for reasons not directly associated with HIV transitions; this model takes note of evidence from several medical illness populations that stressful life events not directly attributable to the medical condition may determine the level of emotional distress more strongly than do illness-related events. In sum, there is more to HIV psychiatry than HIV.

Social Factors No other epidemic of the twentieth century has been associated with as much social stigmatization and political debate as has HIV. Fear of HIV and AIDS is widespread in the general community (including among many medical and mental health caregivers) and is based on concerns about contagion as well as on bias. Although there is evidence of increased tolerance, the practical consequences of infection still include loss of employment, denial of medical benefits or life insurance, and derailment of career aspirations. Clinicians treating HIV-infected persons must be careful not to underestimate these social phenomena and their impact on individual patients, and they should be willing to examine their own fears and biases about HIV and their own mortality.

Apart from the effects of society's response to HIV, several studies suggest that the patient's immediate social support is a key moderator of the effects of illness and of life events on mood and function. Regardless of stage, HIV-seropositive persons with satisfying and stable social support, especially those who cope actively with those life events, will be significantly less distressed than those with unsatisfying or inconsistent support.

Psychological Factors In Western industrialized nations the two major groups that have been at highest risk for infection with HIV—homosexual men and intravenous drug users—may be at elevated risk for psychological difficulties that precede the date of infection. In failing to take a careful history, a psychiatrist can make the error of ascribing to HIV infection and its consequences psychological disorders that may have little direct relation to the infection as such.

A series of studies comparing the lifetime prevalence of diagnosable psychiatric disorders between seronegative homosexual and heterosexual men matched for age and social position suggest there may be more syndromal disorders in homosexual men than in heterosexual men. The lifetime prevalence of major depressive disorder in seronegative homosexual men ranged from 30 to 35 percent compared to the expected rates of about 3 percent from the Epidemiologic Catchment Area (ECA) surveys of community controls similar in age. Similarly, the lifetime prevalence of alcohol use disorders ranged from 25 to 40 percent compared to expected rates of 15 to 20 percent in epidemiological surveys. As for nonalcohol substance-related disorders (excluding intravenous drug abuse), lifetime rates in the cohorts of homosexual men ranged from 20 to almost 40 percent, whereas data from the ECA studies suggest expected rates of around 10 percent for men similar in age.

Inferences about biological predisposition and recurrent disorder must be tempered by the realization that in the majority of cases mood disorders first occurred in the context of disclosure or conflict over sexual orientation, and that the use of alcohol or other drugs may be prevalent among homosexual men as a way of coping with stigmatization. Nevertheless, little is known at present about the interaction of HIV and psychiatric history, and careful clinical follow-up for recurrence is an important research question and a prudent clinical approach.

For individuals with injection drug use disorders, studies preceding the HIV epidemic indicated high lifetime rates of personality disorders, anxiety disorders, and mood disorders. Elevated lifetime rates of antisocial personality disorder (ranging from 25 to over 50 percent), phobias (10 percent), and major depressive disorder (20 to 25 percent), are reported, with even higher rates being noted in persons who have multiple drug use disorders or who have both an alcohol use disorder and another substance-related disorder. Apart from formal psychiatric disorder, personality inventories such as the Minnesota Multiphasic Personality Inventory-2 (MMPI-2) have revealed persisting symptoms of depression, anxiety, low self-esteem, and ego boundary disturbances among individuals with substance-related disorders.

In general, across all risk groups, women and persons of minority ethnicity are among the fastest-growing HIV risk groups. There is concern that these groups may also be at increased risk for emotional distress, given the potential socioeconomic disadvantages and the stigmatization of being female, homosexual, and of racial or ethnic minority. More research is needed to address the needs of those populations. Vulnerability to emotional distress (anxiety and depressive symptoms) appears to be associated with a personal or family psychiatric history, perception of low social support, use of passive and avoidant coping approaches, and the experience of stressful life events apart from HIV seropositivity itself, along with the demographic characteristics of youth, low education, and unemployment. HIV-seropositive persons with hemophilia without identifiable vulnerability factors show comparable levels of emotional adaptation. Those with any one risk factor were at greater risk of distress whereas those with multiple risk factors comprised the most distressed group.

Understanding background assets and vulnerabilities affords the clinician more diverse opportunities to treat psychiatric adjustment, to enhance coping capacity, to retain or provide social support, and to make a more meaningful contribution than would be possible if one's view were restricted to treating HIV-related issues alone.

TRANSITION POINTS IN HIV SYNDROMES

Seroconversion and Serotesting Phenomena The point of testing seropositive is associated with many of the same responses described for other life-threatening illness: shock, anger, anxiety, guilt, and denial. Fear of disclosure of serostatus, of loss of control, of abandonment by family and friends, of the inability to work, of medical expenses, and of pain may be evident. Anger may be directed at friends, family, lovers, physicians, and other caregivers. Loss of self-esteem and self-blame are common, as is regret or guilt over lifestyle (e.g., drug use). Conflicts about trusting and relying on physicians and others may emerge. The reality of death may be confronted. Psychological issues surrounding seroconversion continue throughout the course of infection and adaptation to illness.

The CDC guidelines recommend routine HIV testing in hospitals and clinics when seroprevalence exceeds 1 percent. The validity of this recommendation has been debated, but voluntary testing is generally advocated on the grounds that behavioral interventions are the only immediately available prevention strategies against HIV transmission, and that effective medical therapies are available for HIV-associated disease. Further, some psychiatric disorders (e.g., bipolar I, disorder, alcohol use disorders, severe personality disorders) are believed to confer increased risk for HIV because of their association with poor impulse control, impaired assessment of risk, the bartering of sex for illicit drugs, and other factors. General guidelines for voluntary HIV testing and counseling are described in Table 2.8-5.

1. Discuss meaning of a positive result and clarify distortions (e.g., the test detects exposure to the AIDS virus; it is not a test for AIDS).
2. Discuss the meaning of a negative result (e.g., seroconversion requires time, recent high-risk behavior may necessitate follow-up testing).
3. Be available to discuss the patient's fears and concerns (unrealistic fears may require appropriate psychological intervention).
4. Discuss why the test is necessary. (Not all patients will admit to high-risk behaviors.)
5. Explore the patient's potential reactions to a positive result (e.g., "I'll kill myself if I'm positive"). Take appropriate necessary steps to intervene in a potentially catastrophic reaction.
6. Explore past reactions to severe stresses.
7. Discuss the confidentiality issues relevant to the testing situation (e.g., is it an anonymous or nonanonymous setting?). Inform the patient of other possible testing options where the counseling and testing can be done completely anonymously (e.g., where the result is not made a permanent part of a hospital chart). Discuss who has access to the test results.
8. Discuss with the patient how being seropositive can potentially affect social status (e.g., health and life insurance coverage, employment, housing).
9. Explore high-risk behaviors and recommend risk-reducing interventions.
10. Document discussions in chart.
11. Allow the patient time to ask questions.

Adapted from Rogers RR, Ciesla JA, Denicoff KI, Akhtar AR: Laboratory and Diagnostic Testing in Psychiatry. American Psychiatric Press, Washington, DC, 1989.

Table 2.8-5 Pretest HIV Counseling

Contrary to what one might predict, studies using standardized questionnaires and rating scales suggest that symptoms of depression and anxiety are usually only moderately elevated from baseline in groups of individuals examined before and immediately after HIV antibody test results are announced, and the symptoms generally return to slightly below immediate pretesting levels within 3 months. Initial concerns about widespread suicidal ideation or suicide attempts following testing positive for HIV have been unfounded. The most prevalent psychiatric disorder in this phase is an adjustment disorder with depressed or anxious features, the prevalence of which has been as high as 20 percent in some samples. Estimates of the prevalence of psychiatric disorder in response to seroconversion are speculative for several reasons—it is unknown whether distress or psychiatric mood disorder contributed to the acquisition of HIV or led to a request for serotesting or whether the setting or the positive test result brought about the psychiatric disorder.

Physically Asymptomatic, Early Symptomatic, and Later Phases Psychologically, the physically asymptomatic person must balance the likelihood of a foreshortened life expectancy with the fact of living in the present, evaluating plans for the future, and confronting the need for medical follow-up. Individuals with plasma HIV RNA at £10,000 copies per mL and a CD4+ lymphocyte count of <500 are candidates for early aggressive combination antiretroviral therapy. Ambivalence or skepticism about treatment, lack of concern about HIV, and doubts about the need for medications in the absence of symptoms may be evident.

Most studies consisting of samples of homosexual men indicate that levels of anxious and depressed moods are similar across physically asymptomatic seropositive men and seronegative at-risk controls. Some investigations indicate that on an annual basis over 20 percent of seropositive individuals experience episodic anxiety symptoms lasting at least 1 month, compared with negligible rates among community low-risk controls. In early-stage illness complaints of fatigue and insomnia are likely to reflect underlying major depressive disorder. As persons become medically more symptomatic, distress may increase. There is some evidence that patients with more advanced symptoms may be more distressed, perhaps related to the progression of their AIDS or fears of transition to frank AIDS. Physical symptoms of HIV disease (e.g., loss of appetite, autonomic arousal) may increase as depressed mood deepens.

In general, patients who are younger, socioeconomically disadvantaged, or with reduced levels of social support (e.g., the “closeted” homosexual person or undisclosed drug-using individual) are most likely to experience greater psychological distress. Beyond that, the perception of physical symptoms—regardless of HIV status or CDC stage—(e.g., lymphadenopathy, skin rash, cough, fever, sore throat) appears to be strongly associated with psychological distress. Even when signs of disease cannot be documented, the patient's conviction about bodily complaints helps to determine psychological distress.

If syndromic diagnoses (as contrasted with self-report of psychological symptoms) are considered, rates of current psychiatric disorder are similar across physically asymptomatic and mildly symptomatic persons and do not differ markedly from rates in seronegative at-risk controls (such as homosexual men). The current rate of an adjustment disorder is approximately 5 percent, as is the rate of major anxiety disorder (generalized anxiety disorder or panic disorder). The point prevalence of major depressive disorder is about 8 percent, which is similar to rates found in other chronic medical illness, outpatients with end-stage renal disease, or patients with insulin-dependent diabetes mellitus. Current diagnoses of an alcohol-related disorder (in non–drug-abusing risk samples) are usually in line with the expected community rates.

As the biology of illness asserts itself forcefully, the picture may change, and in frank AIDS or in hospitalized patients higher rates of psychiatric disorder (especially depression) have been detected. Most of those data were collected early in the epidemic. It is unclear if such rates would still pertain given the prevailing therapeutic advances, the ability to maintain better overall health among those living with AIDS, and the possibilities that antiretroviral treatment may forestall neurocognitive decline. In any event, these rates presently are similar to the rates found in patients hospitalized with non-HIV medical disease.

Psychosis and manic states arising de novo are uncommon in HIV illness, but when such syndromes occur, they are usually in the context of neurocognitive disorder and frank AIDS. Psychosis and manic conditions may be associated with early mortality. Other biological psychiatric disorders encountered in later-phase illness include deliria and dementia. To these causes must be added iatrogenic phenomena from treatment, as described in Table 2.8-5.

OTHER PSYCHIATRIC DISORDERS

Adjustment Disorders

Epidemiology, Etiology, Diagnosis, and Course There are no studies yet that predict rates of adjustment disorder and attempt to link them to transition points in HIV illness or to intercurrent non-HIV events. The rates of adjustment disorder with depressed, anxious, or mixed features vary widely according to the population studied. For example, in cohorts of military personnel who have undergone mandatory testing and who are examined shortly after being informed of serostatus, rates of an adjustment disorder approach 15 to 20 percent. On the other hand, studies of men who have known their serostatus for at least 1 year after voluntary testing reveal negligible rates of adjustment disorder even though these men may be dealing with HIV staging or treatment concerns. The clinical course of these HIV-related adjustment disorders is usually benign and responsive to education and support.

ANXIETY DISORDERS

Epidemiology The rates of the major anxiety disorders, panic disorder, obsessive-compulsive disorder, and generalized anxiety disorder appear to have lifetime prevalences and current prevalences within the range expected from epidemiological studies (e.g., 1 to 2 percent).

Etiology Preoccupation with HIV can be the manifest content of panic and of obsessive-compulsive disorders or the probable latent source of generalized anxiety disorder. There is no systematic evidence that anxiety disorder due to HIV disease occurs in the context of HIV infection of the brain.

Diagnosis, Clinical Features, and Differential Diagnosis The diagnosis and clinical features of the major anxiety disorders are usually straightforward, and in many cases a history of anxiety may precede the likely time of infection. The differential diagnosis must include HIV-related and non–HIV-related endocrinological disorders and concurrent cardiopulmonary disorders, anemia associated with HIV, intoxication and withdrawal syndromes, and major depressive disorder.

Course and Prognosis Almost no data are available, but the course and outlook do not in general seem to deviate from that expected in non-HIV samples.

MOOD DISORDERS

Major Depressive Disorder

Epidemiology The lifetime prevalence of major depressive disorder among men with homosexual or injection drug use risk factors is estimated to range between 25 and 35 percent, with some studies suggesting that in the majority of cases the first episode of major depressive disorder preceded the likely date of seroconversion. The point prevalence of major depressive disorder has generally been in the range of 4 to 8 percent for seropositive homosexual or bisexual men, with rates being similar across medically asymptomatic seropositive and moderately symptomatic persons; there may well be an increase in frank AIDS. The point prevalence in

women injection drug users approaches 15 to 30 percent across all stages of disease. Some early estimates based on chart review suggested that 40 percent of hospitalized individuals with frank AIDS (more advanced disease) may meet criteria for major depressive disorder.

Etiology It is not yet determined whether HIV itself increases the likelihood of major depressive disorder beyond the expected increases found in other chronic diseases. HIV infection can be associated with anergic-apathetic-fatigue states, presumably mediated by release of somnogenic lymphokines. Decline of immunocompetence as reflected by lower CD4+ lymphocyte count is not itself associated with mood disorder. The relative etiological weight of illness factors (e.g., initiating antiretroviral therapy, noting the onset of constitutional symptoms, diagnosis of frank AIDS) and other factors, such as adverse life events independent of HIV infection or pre-existing mood disorder, are being explored in prospective studies. Previous mood disorder, substance use disorder, and neurocognitive impairment are thought to predict subsequent depressive episodes.

Diagnosis and Clinical Features The diagnosis of major depressive disorder is rather straightforward provided that the patient has few medical symptoms and generally well-preserved cognitive capacities. As the illness progresses, somatic symptoms of disease (e.g., fatigue, weight loss, insomnia) or of neurocognitive impairment (e.g., slow thinking, diminished powers of concentration, or forgetfulness) may complicate diagnosis. In the presence of somatic symptoms, the diagnosis of major depressive disorder should not be made unless there are prominent symptoms in such areas as pervasive sadness, diminished interest or pleasure, feeling of worthlessness or guilt, indecisiveness, and morbid preoccupation with death. In particular, diminished activity based on fatigue must be discriminated from withdrawal due to lack of interest or pleasure. The interviewer must be careful to distinguish a true sense of worthlessness from one of disappointment at not being able to perform at full capacity; persisting guilty rumination must likewise be distinguished from episodic guilt associated with drug use or from having a sexually transmitted disease, and from regret over lost opportunity. In terms of evaluating thoughts of death, which might be expected to occur in individuals with HIV illness, the level of morbid preoccupation and a change of focus from usual thoughts or attitudes about death must be assessed. Because many HIV-positive persons have considered suicide at some point in the illness, the interviewer must note whether suicidal ideation is held out as a plan potentially to use at some future date as a way of maintaining control, or if it represents a self-destructiveness indicative of depression, based on a morbid sense of failure, worthlessness, or past transgressions.

Differential Diagnosis The differential diagnosis includes mood disorder (depressed) due to a non-HIV medical condition, early delirium, HIV-associated neurocognitive disorders, and apathetic-anergic syndromes. Since establishing the diagnosis can be difficult in advanced illness, it is important to combine meticulous neuromedical evaluation, psychiatric interviewing, and neuropsychological assessment. Electroencephalography may help to identify a delirium and is especially useful if baseline recordings are available for comparison. Evaluation may reveal more than one disorder concurrently, and treatment will generally be directed sequentially at the most prominent symptoms.

Cognitive complaints of mental slowing and lack of concentration can be part of a depressive picture or evidence of neurocognitive disorder. In physically asymptomatic stages, cognitive complaints are especially likely to reflect depressed mood rather than cognitive impairment. Conversely, persons with mild neurocognitive disorder documented by neuropsychological testing do not have markedly high rates of mood disorder. Therefore, the full evaluation of cognitive complaints requires both detailed mood assessment and neuropsychological testing.

Course and Prognosis The annual risk of an episode is from 10 to 20 percent; the majority of cases may be classified as mild to moderate in severity. The course of individual episodes is variable and is similar to that found in major depressive disorder in psychiatric populations: most persons have infrequent, widely spaced episodes whereas a few have frequent episodes. The usual prognosis is for remission either spontaneously or with treatment, although a more chronic course will ensue in a significant minority of cases. In some studies the persistence of depressive symptoms is associated with a heightened risk of mortality from AIDS.

Mania Mood disorders with manic features, with or without hallucinations, delusions, or a disorder of thought process can complicate any stage of HIV infection, but most commonly occur in late-stage disease complicated by neurocognitive impairment.

Epidemiology Precise estimates of prevalence or incidence are not available but may approach 1 percent. Some evidence suggests the rate in AIDS is up to ten times the general population rates.

Etiology In non–HIV-infected patients, mood disorders with manic features are noted to occur at therapeutic dosages of many medications and in a wide variety of neurological conditions, such as cerebrovascular disorder, meningitis, and tumor, and these sources can also be causative in HIV illness. Steroids, zidovudine, and ganciclovir are the most frequently reported iatrogenic causes. There are two typical onsets of mania in HIV. Manic states with onset early in HIV are associated with personal or family history of bipolar I disorder. Manic syndromes in persons without previous personal or family history of mood disorder usually have their onset late in the course of HIV illness and have a higher prevalence of comorbid dementia; in these cases the etiology is presumed to be related to the pathophysiology of HIV infection of the CNS.

Diagnosis and Clinical Features Cases may first have a period of days or weeks of change in personality (e.g., become pompous, belittling, and sexually inappropriate) and then progress into a fuller manic picture. The mood disturbance is generally elevated, with associated grandiosity. Diminished need for sleep, loquaciousness, teeming thoughts, and unrealistic personal or financial plans may appear. Irritability may be prominent in AIDS. In early-stage disease the neuromedical evaluation is generally unremarkable apart from findings expected for HIV disease, but personal and family histories of mood disorder are evident. In cases first appearing in the context of AIDS, personal and family histories are usually unremarkable but there is clinical dementia or neurocognitive impairment.

Differential Diagnosis Differential diagnosis includes brief psychotic disorders, the substance-related disorders, bipolar I disorder, neuromedical causes of mania, an evolving delirium, or manic symptoms that herald HIV-associated psychosis or dementia. Brief psychotic disorder is distinguished by hallucination, delusions, and bizarre or disordered thinking. Substance-related disorders can be distinguished by history and toxicology screen; bipolar I disorder may be suspected if there is prior personal or family history of mood disorder. Discontinuation of suspect medication and medical assessment may reveal iatrogenic or neurological sources.

Psychotic Disorders Psychotic symptoms are usually later-stage complications of HIV infection. They require immediate medical and neurological evaluation and often require management with antipsychotic medications. Whereas psychotic symptoms can obviously occur in deliria or can reflect neurological or primary psychiatric disorder or iatrogenic origins, there is also considerable interest in new-onset psychosis, wherein these etiologies do not seem to be present (e.g., psychotic disorder due to HIV disease).

Epidemiology Prevalence estimates vary widely depending on methodology: large-scale surveys find a prevalence of new-onset psychosis at less than 0.5 percent whereas chart review methods find frequencies ranging from 3 to 15 percent in persons for whom obvious causes (e.g., delirium) have been excluded. Thus, psychotic symptoms may be uncommon but not rare in HIV-infected populations.

Etiology Beyond known causes of psychosis (delirium; substance-related disorders; neurological vascular disease, opportunistic infection, or neoplasm; and iatrogenic causes) several theories have been offered to explain new-onset psychosis in which no known cause can be identified: these include direct effects of HIV on the brain; other CNS viruses, such as cytomegalovirus or human herpes virus; coinfection with two or more viruses; or brief psychotic disorder.

Diagnosis and Clinical Features The clinical presentation in new-onset psychosis is extremely variable. The most prevalent symptom seems to be delusions (occurring in almost 90 percent of cases in some series) with persecutory, grandiose, or somatic components. Persecutory themes can be quite elaborate, with patients proclaiming messianic themes or believing that they have been accorded superhuman powers by God. Somatic delusions may include being shot through with electricity or lasers. Delusions of thought insertion, thought broadcasting, and of passivity and control are also described. Most patients experience auditory hallucinations, with perhaps one half of those also experiencing visual hallucinations. A majority of series also report disorders of thought process, including looseness of associations or frankly disorganized thinking. Disturbances of mood commonly coexist, with anxiety being the most prevalent symptom, followed by depressed mood, euphoria, or irritability, and mixed depressed and euphoric states. Lability, flatness, and inappropriate laughter or anger are also described; bizarre behavior is commonplace. There are reports of persons eating dirt to conquer their fear of germs, and one patient painted himself and his entire apartment, including furniture and appliances, with green paint in an effort to “celebrate life.”

Bedside examination reveals impairment in memory or other cognitive functions in perhaps one third of patients; more comprehensive and formal neuropsychological assessment would be likely to detect neurocognitive difficulties in a larger proportion of cases, but many psychotic individuals are unable to complete such examinations.

Neurological findings are infrequent and nonspecific, usually consisting of ataxia, mild increases in motor tone, hyperreflexia, and tremor, but bizarre grimacing and posturing can also be present. Cerebrospinal fluid is generally unremarkable except for the mild pleocytosis common to HIV infection. Diffuse cortical slowing has

been reported in about one half of patients on whom an EEG was performed. CT and MR scans reveal nonspecific cerebral atrophy in about one half of cases; rarely, focal abnormalities are evident, suggesting tumor, opportunistic infection, or vascular etiology.

Differential Diagnosis The differential diagnosis includes brief psychotic disorder, major depressive disorder (with psychotic features), schizophrenia, psychoactive substance-related disorders, and iatrogenic causes (Table 2.8-4), cerebrovascular disorder, CNS neoplasm, and opportunistic infection (e.g., cryptococcosis, toxoplasmosis, human herpesvirus). The history and basic laboratory evaluation (e.g., toxicology screening) will usually make psychiatric etiologies clear. A thorough neuromedical assessment must be performed in order to rule out a remediable neurological cause.

Course and Prognosis The course and prognosis are highly variable and depend partly on whether specific complicating conditions coexist. For example, concurrent dementia due to HIV disease indicates a poor prognosis. Here the course may be one of rapid deterioration, with death within 6 months or less. However, when neurocognitive abnormalities are not detected or are mild, individuals have been followed for up to 2 years in a stable, treated course. Nevertheless, there is some evidence that death occurs earlier in those experiencing psychosis than in nonpsychotic patients who have similarly advanced HIV disease. In the short term, prognosis with regard to symptom control is quite favorable, with most patients responding to low-dosage regimens of antipsychotic medications.

SUBSTANCE-RELATED DISORDERS

Epidemiology If injection drug users are excluded (for whom, by definition, lifetime prevalence of substance use disorders is 100 percent), the lifetime rates in the major risk group—homosexual and bisexual men—range from 20 to over 40 percent. While some studies show higher current (previous 1 to 6 months) rates of substance-related disorders among seropositive homosexual and isexual persons compared with those expected from community samples, others show roughly comparable or only slightly higher rates.

Substance abuse can influence the likelihood of HIV transmission in at least two ways. First, sharing of infected needles (“works”) by intravenous drug users can result in direct entry of HIV into the bloodstream. Second, even among noninjection drug users, intoxication can increase the likelihood of having sex with multiple partners, reduce the use of condoms, and, because of altered pain perception, increase the likelihood of traumatic anal intercourse. Thus, even though those at risk for HIV exposure may not abuse substances significantly more, the implications of such use may be drastically different.

Etiology The etiology of substance abuse in those at risk for HIV infection is no better understood than it is for substance abuse generally. It has been speculated that at least among homosexual and bisexual persons the developmental stresses of establishing an alternate sexual identity and of negotiating that identity within the context of family expectations and stigmatization by society may contribute to substance use as a way of mastering distress.

Course and Prognosis Several prospective studies are currently under way that will provide much-needed systematic data about the natural history of alcohol and nonalcohol substance-related disorders in various risk groups, as well as among HIV-infected persons. Studies of HIV-positive homosexual and bisexual men suggest that most incident alcohol and other substance use disorders are relapses of conditions whose original onset preceded the likely date of seroconversion. Furthermore, seropositive and seronegative homosexual and bisexual men are equally likely to experience an episode of the disorder within the follow-up period. Incident rates are generally less than 5 percent, annually, despite markedly elevated lifetime histories of substance-related disorder. It may be that within homosexual and bisexual communities the emphasis on health promotion and education about the adverse health consequences of alcohol and other drugs of abuse has had a positive effect. These preliminary data also suggest that the stress of HIV infection or of the threat of infection does not necessarily lead to an increased risk of developing an alcohol or nonalcohol substance-related disorder.

The course of substance use disorder and that of HIV may intersect, with important prognostic implications. For example, stimulants may accelerate HIV replication, especially in the CNS. These drugs (e.g., amphetamines and cocaine) may produce brain injury by vascular injury and ischemia, and by increasing dopamine and glutamatergic transmission, leading to cytotoxic injury and death of selected neurons. It is reasonable then to expect that persons with stimulant-use behavior and HIV infection would show very high rates of cognitive impairment; however, surprisingly few studies have been conducted to address this question. Rates of cognitive impairment in individuals who contracted HIV infection through injection drug use are reported to be similar to those of subjects who are infected through sexual contact. The rate and frequency of cognitive symptoms do not appear to be increased with chronic substance abuse, nor does evidence suggest that injection drug users have shorter survival or shorter time for progression to AIDS. Nevertheless, important questions remain. One of these concern possible effects of both chronic neurocognitive impairment and ongoing drug abuse on adherence to prescribed antiretroviral drug treatments. Also, because neurocognitive impairment increases risk for early death in HIV-infected people who are not substance users, additional impairment resulting from ongoing substance abuse may further influence the course of the disease.

Standard psychological therapies developed in working with patients with heart disease, cancer, or other life-threatening illnesses are generally applicable to the patient with HIV illness. Potential roles for the psychiatrist in the seroconversion and serotesting phase are to discuss the basic medical and psychological meanings of seropositivity, to help the person decide who should be informed of risk factors and serostatus, as well as the manner in which such disclosure should take place, to manage anxious or depressive symptoms, and to assist in developing a follow-up plan for HIV education and treatment, including self-help groups and safe sex practices. Many authorities believe that it is best to bring up issues of power of attorney for health care and custody of children earlier in the course of the disease rather than later. In later phases the clinician can assist in addressing issues brought up by monitoring changes in HIV RNA viral load, CD4+ lymphocyte count, watching for symptoms, and adherence to treatment, and by maintaining morale. It is appropriate to discuss treatment alternatives and issues of adapting to health change, and to address mortality and aggressiveness of end-stage care.

Prevention Efforts at primary prevention to stem the spread of the disease have been successful in some arenas but not in others. In industrialized countries, for example, screening procedures for blood banks have largely eliminated transfusion and blood-product–related spread. Public education efforts may also have altered sexual practices in some at-risk subgroups (e.g., certain homosexual and bisexual men).

Unfortunately, such efforts have been slow to evolve and have not yet been applied to the vast majority of at-risk persons. That there are difficulties in modifying the kinds of behaviors leading to HIV transmission should not come as a surprise to psychiatrists. One is dealing, generally speaking, with a biologically driven behavior (sex) that is highly motivated and strongly pleasurable, and is trying to balance that against risks that are often perceived as not highly imminent and whose consequences appear only many years later. With respect to drug abuse, behavior governed by anticipation of immediate pleasure or a sense of calm among individuals with impulsive and risk-taking habits, who may lack self-esteem and a sense of future, is difficult to modify through any conventional educational approach.

Compounding these individually determined resistances is the fractured attitude of society about issues such as sexuality, birth control, and drug abuse. Condoms may be safe and effective, but U.S. society has had difficulty implementing even this relatively simple preventive measure because of its reluctance to discuss sexuality and the specifics of modes of transmission explicitly in schools and in the media. Ambivalence about sexuality and decisions to put philosophical objections to birth control ahead of preventing the spread of a fatal disease compromise prevention efforts.

Nevertheless, evidence continues to accumulate that, if properly implemented and supported, certain techniques do lower the likelihood of HIV transmission. The elements of prevention programs that are currently thought to be efficacious were reviewed and described in the February 11 to 13, 1997 National Institute of Health (NIH) consensus statement. It presents evidence for efficacy of programs directed at men who have sex with men, adult women at risk for sexual transmission, serodiscordant couples, adolescents, and injecting drug users. For example, a program combining information on HIV transmission, with a focus on developing a responsible attitude both to self and others, including necessary skills training in negotiation of safer sex, and coupled with access to condoms, has resulted in a substantial reduction in new cases of HIV in military recruits in Thailand. It is important to note that, beyond being grounded in state-of-the-art notions of behavioral science, this program received strong unambivalent support from authorities. In contrast, in the United States, despite numerous reports and opinions from learned panels, including the NIH consensus panel, to the effect that needle exchange programs can reduce HIV transmission in injection drug users, there has been little political will to implement such programs; indeed, some jurisdictions have actually moved to criminalize such prevention efforts.

Postexposure Prophylaxis Prompt initiation of antiretroviral therapy following accidental exposure to HIV by needle stick or similar accidents can reduce the likelihood of an infection actually developing by about 80 percent. The average risk of infection from percutaneous injury is about 0.3 percent. While the seriousness of the exposure (e.g., amount of inoculum) needs to be weighed against the risks of antiretroviral therapy, most authorities recommend combination treatment with zidovudine 200 mg three times a day and lamivudine (Epivir) 150 mg two times a day for 4 weeks for all but the most trivial exposures. If the source of exposure was an AIDS patient or one with a high viral load, a protease inhibitor (e.g., indinavir [Crixivan] 800 mg three times a day can be added). Such prophylactic treatment is accompanied by monitoring for plasma viral load as well as for serostatus.

The matter of postexposure prophylaxis for cases other than accidental exposure or rape remains controversial. The risk of infection from vaginal intercourse is estimated at 0.05 to 0.15 percent, from receptive anal intercourse, 0.08 to 0.32 percent, and approximately 0.7 percent from using contaminated injection drug equipment. Treatment, as for accidental occupational exposure, can be initiated within 72 hours of exposure with zidovudine and lamivudine. However, because of costs involved and risks of developing resistant HIV strains, postexposure treatment may not be indicated for those who clearly intend to re-expose themselves by repeated high-risk behavior.

Treatment A growing list of agents that act at different points in viral replication has raised for the first time the hope that HIV might be permanently suppressed or actually eradicated from the body. At the time of this writing, the active agents were in two general classes: the reverse transcriptase inhibitors and the protease inhibitors. The reverse transcriptase inhibitors are further subdivided into the nucleoside reverse transcriptase inhibitor group and the nonnucleoside reverse transcriptase inhibitors. Table 2.8-6 lists the currently available agents in each of these three categories.

Generic Name	Trade Name	Usual Abbreviation
Nucleoside Reverse Transcriptase Inhibitors		
Zidovudine	Retrovir	AZT or ZDV
Didanosine	Videx	ddI
Zalcitabine	Hivid	ddC
Stavudine	Zerit	d4T
Lamivudine	Epivir	3TC
Abacavir	Ziagen	
Non-nucleoside Reverse Transcriptase Inhibitors		
Nevirapine	Viramune	
Delavirdine	Rescriptor	
Efavirenz	Sustiva	
Protease Inhibitors		
Saquinavir	Invirase	
Ritonavir	Norvir	
Indinavir	Crixivan	
Nelfinavir	Viracept	

Table 2.8-6 Antiretroviral Agents

Although the indications for initiating antiretroviral therapy have not been fully resolved at the time of this writing, the International AIDS Society-USA Panel (1997) recommended that therapy be initiated for individuals with plasma HIV RNA levels greater than 5000 to 10,000 copies per mL, regardless of CD4 cell count. The panel further recommended that all persons with detectable HIV in plasma (the nominal level of detection is in the range of 200 to 400 copies per mL) be provided such treatment on request. The Panel cautioned, however, that at present such treatment must be lifelong, is complex, requires strenuous effort at adherence, and results in many adverse effects ranging from unpleasant to serious. Complete and informed involvement on the part of the patient is essential because viral resistance to the various compounds can develop quickly even after brief periods of nonadherence. For these reasons, some physicians and patients may decide not to initiate antiretroviral therapy immediately and may prefer to follow the patient closely for any changes in plasma viral load.

Currently it is recommended that treatment be initiated with triple therapy, that is, a combination of two reverse transcriptase inhibitors plus one protease inhibitor. Three agents are recommended because an individual with a plasma viral load of 20,000 copies per mL is likely to harbor all possible resistant genotypes of HIV that can result from one- or two-point mutations. Thus, even the use of two agents leaves the distinct possibility that a few resistant strains will escape, leading to treatment failure. The likelihood that an infected person will harbor HIV genotypes with three independent mutants is very low; thus, triple therapy should be initiated where possible.

In choosing specific drug combinations, clinicians take into account both the mode of action of specific agents, and their drug-drug interactions. For example, zidovudine and lamivudine are both reverse transcriptase inhibitors; however, zidovudine appears to work best in actively replicating cells whereas lamivudine is most active in resting infected cells. Furthermore, zidovudine penetrates into the central nervous system; however, the penetration of lamivudine is low.

The goal of therapy is to maintain plasma viral load at an undetectable level. By early 1998 patients could expect to have to take treatment indefinitely. Indications for changing treatment include upswing in plasma viral load, toxic effect, intolerance, and nonadherence.

The antiretroviral agents have many adverse effects, too numerous to describe. Of importance to psychiatrists is that protease inhibitors are metabolized by the hepatic cytochrome P-450 oxidase system, and can therefore increase levels of certain psychotropic drugs that are similarly metabolized. These include bupropion (Wellbutrin), meperidine (Demerol), various benzodiazepines, and selective serotonin reuptake inhibitors (SSRIs). Therefore, prescribing psychotropic drugs to persons taking protease inhibitors must be done with caution.

In addition to the new nucleoside reverse transcriptase inhibitor, nonnucleoside reverse transcriptase inhibitors, and protease inhibitor agents that may soon become available, other classes of drugs are under investigation. These include agents that interfere with HIV cell binding and fusion, the action of HIV integrase, drugs that interfere with certain HIV genes such as *gag*, among others.

Beyond treatment directed specifically against HIV, many interventions are available to prevent and treat various complications of immunodeficiency caused by opportunistic viral, bacterial, fungal, and protozoan infections. There has been a substantial increase, both in survival and in quality of life, resulting from early diagnosis and treatment of these opportunistic conditions.

The use of combination antiretroviral regimens, combined with more specific treatments of complications, has prolonged the survival of asymptomatic as well as symptomatic HIV-infected persons. However, despite progress in maintaining patients longer and in better states of health, the ultimate outcome is still uncertain; that is, it is unclear at present whether any HIV-infected person can expect to escape developing AIDS and ultimately dying. HIV-infected persons are keenly aware of this prognosis and their concern sometimes takes the form of psychiatric disturbances. These phenomena, along with the primary and secondary neurocognitive complications related to HIV infection, are discussed next.

The introduction of potent antiretroviral drug combinations, and the development of sensitive quantitative assays of HIV RNA concentrations, has begun to revolutionize the treatment of HIV cognitive disorders as it has done for systemic disease. There is hope that measuring the viral load in CSF will be a window into brain infection and a guide for monitoring response to therapy.

Elevated concentrations of HIV RNA in CSF are associated with neurocognitive impairment in AIDS. High-dosage zidovudine monotherapy can ameliorate HIV-associated neurocognitive impairment, perhaps in part because of its good penetration of the blood-brain barrier. Since the introduction of protease inhibitors and combination antiretroviral therapy, zidovudine monotherapy is no longer an option for treatment; nevertheless, it remains an important component of combination regimens. Protease inhibitor drugs are not able to cross the blood-brain barrier in therapeutic amounts and therefore might not be expected to be effective in treating neurocognitive disorders. Nevertheless, combination of these drugs with other first-generation agents like zidovudine appears to prevent or even reverse the progression of these disorders. Clinical improvement both in terms of enhanced performance on standardized neuropsychological testing, and improvement in the pattern and severity of white matter signal abnormalities detected on MRI scans, can be seen within 2 to 3 months of beginning therapy. Perhaps one out of every three affected patients will show clinically significant improvement in neurocognitive function. It is not clear how protease inhibitors could arrest or even reverse HIV-associated neurocognitive impairment. It may be that a markedly reduced viral load no longer triggers the production of neurotoxic cytokines, excitatory neurotransmitters, and inflammatory agents by the immune system.

Novel treatments may also be useful. Neuronal excitotoxicity, mediated through the activation of glutamatergic receptors by the HIV envelope protein gp120, is a potentially important mechanism by which brain dysfunction might occur in HIV infection. Memantine is an open-channel antagonist of NMDA-type glutamate receptors that is generally well tolerated. It is currently being studied as a treatment for dementia in a large Phase III placebo-controlled clinical trial. On the theory that an agent that could dislodge gp120 from neural receptor sites might be promising, an octapeptide called *d-ala-peptide-t-amide (peptide t)* has been used in Phase II clinical trials. Compared to placebo, peptide t was associated with neuropsychological improvement in cognitively impaired individuals (with CD4 counts <200), and a reduced likelihood of progression of impairment on 6-month follow-up. Calcium channel inhibitors, which theoretically appeared useful, have not proven successful.

The remaining forms of treatment are principally supportive. The most important step is to exclude other potentially treatable conditions, such as secondary infections or neoplasia, metabolic abnormalities with low-grade delirium, or other psychiatric disorders (e.g., major depressive disorder). Once the diagnosis is clear, then the usual supportive measures for neurocognitively impaired persons should be employed. These include identifying areas of cognitive strength and deficit, reducing emphasis on areas that are now impaired (e.g., divided attention, speeded processing), emphasizing efforts to maintain good orientation and reality testing, and avoiding medications that may further compromise cognitive function, in particular, benzodiazepine drugs. If they need to be used, such medications should be at lower-than-usual doses. Additionally, antidepressant and antipsychotic agents, if indicated, may also have to be prescribed in much lower dosages (e.g., at 25 percent of the usual recommended dosage).

PSYCHOTHERAPY

Approaches Major psychodynamic themes for HIV-infected patients involve self-blame, self-esteem, and issues regarding death. The psychiatrist can help patients deal with feelings of guilt regarding behaviors that contributed to infection or AIDS. Some HIV and AIDS patients feel that they are being punished. Difficult health care decisions, such as whether to initiate or continue taking antiretroviral medication and terminal care and life-support systems, should be explored, and here denial of illness may be evident. Major practical themes involve employment, medical benefits, life insurance, career plans, dating and sex, and relationships with families and friends. The entire range of psychotherapeutic approaches may be appropriate for patients with HIV-related disorders. Both individual therapy and group therapy can be effective. Individual therapy may be either short-term or long-term and may be supportive, cognitive, behavioral, or psychodynamic. Group therapy techniques can range from psychodynamic to completely supportive in nature.

At the time of testing positive the HIV-infected person is almost immediately faced with questions about disclosing his or her serostatus. Most counselors suggest that recently infected individuals withhold disclosure to others until they feel well-enough informed about HIV and its treatment, and ready to answer questions that may arise. This readiness includes feeling informed enough to answer questions that others may ask in relation to their own safety, to differences between HIV and AIDS, to stage of disease and lifespan. A patient's readiness to accept the emotional consequences of disclosure—such as another's fury and rejection—must also be anticipated. In brief the HIV-infected person must assess not only his or her readiness, but the readiness of others to hear the announcement of seropositivity. Among the fears that must be confronted is the individual's concern that once serostatus has been revealed, he or she has lost control of who next knows of their seroconversion. In deciding whether or not to tell others the patient must address their sense of betrayal if they are not told. The same issues apply to the person's work environment. As a practical matter the individual may need to decide whether to tell a trusted colleague in case of a job-related accident that might put others at risk of infection. Similarly, parents must decide when or whether to tell their children. Some parents want to tell very young children as soon as possible, while other parents prefer to withhold this information until their child's teenage years, for fear of “taking away their childhood.” The question of custody of children after the parent's death will need to be considered. The same question of timing will arise about when to tell children that they are seropositive. The parent must balance fears that telling the child's school will lead to discrimination while guarding their child's and others' safety should there be an accident.

The psychiatrist may have a special role regarding HIV treatment. The advent of protease inhibitors, and the promise of additional increasingly effective therapies, has brought hopes of a “cure” to patients and physicians alike. Even patients who have failed one or more rounds of combination therapies may find that family, friends, and physicians continue to be optimistic. The psychiatrist may be the only “safe” person to whom the patient can express discouragement, weariness, fear of treatment failure, and fury or guilt for not being able to tolerate successful therapy or for not responding to regimens that have benefited others. The psychiatrist also may be the only one confronting unrealistic expectations of cure, or assumption that safer sex practices are no longer relevant. Paradoxically, the therapeutic task also may be to examine the patient's reaction to a reprieve from certain death—the so-called second life agenda.

Direct counseling regarding substance use and its potential adverse effects on the HIV-infected patient's health is indicated. Specific treatments for particular substance-related disorders should be initiated if necessary for the total well-being of the patient.

Support Systems The gay community has provided a significant support system for HIV-infected people, particularly homosexual and bisexual persons. Public education campaigns within this community have resulted in significant (more than 50 percent) reductions in the highest-risk sexual practices. Individuals are likely to practice safe sex if they know guidelines for safe sex, have access to a support group that reinforces such practices, are in a steady relationship, and have a close relationship with a person with AIDS. Unfortunately, injection drug users have been difficult to reach, but locating HIV treatment clinics in methadone (Dolophine) treatment settings and other innovative outreach efforts are in progress. Involving injection drug users in prevention efforts is particularly important because they are a major reservoir from which the virus spreads to women, heterosexual men, and children. The paradoxical effect of highly effective antiretroviral therapies may be to increase rates of high-risk sex and injection drug users, based on the belief that a cure is available or that undetectable viral load renders the person noninfectious.

Assessment The assessment of HIV-infected patients should include a complete sexual and substance-use history, a psychiatric history, and an evaluation of the support systems available to the patient. The clinician must understand the patient's history with regard to sexual orientation and substance use, and the patient must feel that the therapist is not judging past or present behaviors. A sense of trust and empathy can often be fostered by the therapist's asking specific, well-informed, and straightforward questions about the homosexual or substance-using culture. The therapist must also determine the patient's knowledge about HIV and AIDS.

Therapist-Related Issues Countertransference issues and the burnout of therapists who treat many HIV-infected patients are two key issues to evaluate on a regular basis. Therapists must acknowledge to themselves their predetermined attitudes toward sexual orientation and substance use so that those attitudes do not interfere with the treatment of the patient. Issues regarding the therapist's own sexual identity, past behaviors, and eventual death may also give rise to countertransference issues. For some psychotherapists who have practices with many HIV-infected patients, professional burnout can begin to inpair their effectiveness. Some studies have found that seeing many HIV-infected patients in a short period of time seems to be more stressful to therapists than seeing a smaller number of HIV-infected patients over a long period of time.

Involvement of Significant Others The patient's family, lover, and close friends are often important allies in treatment. The patient's spouse or lover may have guilt feelings about possibly having infected the patient or may experience anger at the patient for possibly infecting him or her. The involvement of members of the patient's support group can help the therapist assess the patient's cognitive function and can also aid in planning financial and living arrangements for the patient. The patient's significant others may themselves benefit from the attention of the therapist in helping them cope with the illness and the impending loss of a friend or family member.

Psychopharmacological Treatment The psychopharmacological treatment of patients with HIV infection is safe and effective, providing one keeps in mind the guidelines on dosing and drug interactions developed for the use of psychotropic drugs in the medically ill and the elderly. Psychotropic drugs have no known adverse effects on immunological functions.

INTERACTIONS OF PSYCHOTROPIC DRUGS AND ANTIRETROVIRAL DRUGS

Protease inhibitors are metabolized by the cytochrome p-450 oxidase system, primarily by the 3a 3/4 isoform, and secondarily by the 2D6 system. Obviously these pathways are shared by many psychotropic drugs. The clinical relevance of this potential for drug interactions has not been well studied. Drug manufacturers of the protease inhibitors have as a first step listed many psychotropic drugs as relatively or absolutely contraindicated in combination with protease inhibitors, which may be an overstatement. Because these presumptive drug interactions have not been systematically studied, it would be unfortunate to deny patients entire classes of potentially safe and beneficial psychotropic drug interventions. For now the most sensible policy is to be aware of the likely major drug-drug interactions, to monitor patients for treatment-emergent adverse effects and, wherever possible, for plasma psychotropic concentrations. The most likely interactions are as follows. All protease inhibitors will increase psychotropic drug concentrations if the major route of metabolism of the psychotropic agent is the 3 cytochrome P450 (CYP) CYP 3A system. If the CYP 2D6 system is the primary route of metabolism (e.g., tricyclic medications, SSRIs), ritonavir (Norvir) will specifically inhibit their metabolism. Thus the protease inhibitors may inhibit the metabolism of many antidepressants and antipsychotic agents as well as benzodiazepines. For example, plasma concentrations of alprazolam (Xanax), midazolam (Versed), triazolam (Halcion), and zolpidem (Ambien), may be increased and dosage reduction and careful monitoring may be required to prevent oversedation or other toxic effects. Protease inhibitors have been reported to increase concentrations of bupropion, nefazodone (Serzone), and fluoxetine (Prozac) to toxic levels, and to increase desipramine plasma concentrations by 100 to 150 percent. Drug interactions with antipsychotic agents are less well studied, but here ritonavir particularly may increase concentrations. Concentrations of methadone and meperidine are also reported to be elevated. Additionally, concentrations of some drugs of abuse such as methylenedioxymethamphetamine (MDMA) may be increased. In turn, protease inhibitors may induce the metabolism of valproate (Depakene) and of lorazepam (Ativan) and lead to lower plasma concentrations.

Some psychotropic medications may induce metabolism of protease inhibitors. Carbamazepine and phenobarbital may reduce serum concentrations of protease

inhibitors. The clinical relevance of this potential interaction is not clear, but use of an alternate mood stabilizer may be indicated. Interactions with lithium (Eskalith) and gabapentin (Neurontin) have not been reported.

Finally, psychotropic drugs may reduce the metabolism of some protease inhibitors, with an increase of protease inhibitor adverse effects; this has been reported with nefazodone and fluoxetine.

ANXIETY DISORDERS

Symptomatic anxiety that does not meet criteria for a formal diagnosis in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) is perhaps the most prevalent anxiety state. It may arise episodically or become a chronic feature of preoccupation with physical symptoms or illness. The decision to treat episodes of acute anxiety rests on whether it appears to interfere with daily functioning or quality of life. Restlessness, anxiousness, or inability to concentrate that impair one's usual social relationships or functioning for a week or more may indicate a need for psychological or pharmacological therapy. Nonpharmacological treatments may be tried first, including supportive psychotherapy or the use of stress and anxiety management approaches, such as relaxation training, education, and assisting in accessing various social services.

Psychopharmacological treatment is usually brief, lasting no more than 2 to 6 weeks, based on the view that most episodes of anxiety will remit within that time. For physically asymptomatic seropositive patients, the usual choice is an intermediate or long-acting benzodiazepine (e.g., diazepam [Valium] at 20 to 40 mg a day, or lorazepam at 0.5 mg every 8 hours). For individuals with more physically symptomatic disease, many clinicians recommend the use of agents with short to intermediate half-lives and no active metabolites, such as oxazepam (Serax) at 10 mg every 6 hours, or lorazepam at 0.5 mg every 8 hours.

In general, evidence of a therapeutic effect should be expected within 1 week of starting treatment. Failure to improve means that the diagnosis should be reconsidered and that major depressive disorder or substance-related disorder should be included in the differential diagnosis. Chronic anxiety states may be difficult to distinguish from hypochondriasis centered on HIV concerns; the latter tends to be treatment resistant and extremely difficult to manage even with combined psychotherapeutic and pharmacological approaches because obsessional or paranoid character structure may underlie symptomatology. In any event, a small proportion of patients may require maintenance therapy with anxiolytic agents.

For patients with recent histories of alcohol or nonalcohol substance-related disorders, the use of benzodiazepines may not be desirable. Buspirone (BuSpar) or hydroxyzine (Vistaril) are safe and effective, with low initial starting dosages and slow increases for individuals who are physically sicker. The delayed onset of therapeutic effect makes buspirone less suitable for cases of acute severe anxiety.

Occasionally obsessive-compulsive disorders are evident, with HIV infection or AIDS being the focus of rumination and ritualistic behavior. The differential diagnosis should include major depressive disorder. There are reports of such patients responding well to standard antidepressant therapy, such as imipramine (Tofranil) or desipramine (Norpramin). Serotonin reuptake inhibitors (e.g., fluoxetine, fluvoxamine [Luvox], sertraline [Zoloft], paroxetine [Paxil], or clomipramine [Anafranil]) are also effective; however, there is little experience with these agents in seropositive persons; however, fluoxetine was well tolerated in standard dosages in one group.

Similarly, panic disorder in physically asymptomatic or more symptomatic phases responds to standard therapy, which includes education, cognitive therapy, and pharmacological intervention (e.g., with desipramine). Starting doses of benzodiazepines or cyclic antidepressant agents in physically symptomatic persons are as low as one third of those used for physically healthy individuals, and doses should be increased cautiously.

MAJOR DEPRESSIVE DISORDER

Treatment of a major depressive episode in the physically asymptomatic patient with HIV disease is rather straightforward. Clinical experience and a limited number of investigational trials indicate that the usual therapeutic doses of standard agents are generally safe and effective in physically asymptomatic or moderately symptomatic persons, although there are almost no data on maintenance treatment and longterm follow-up. First-generation tricyclic agents with low anticholinergic and other adverse effects (e.g., desipramine), can be used. Most clinicians prefer selective serotonin reuptake inhibitors such as fluoxetine, sertraline, or paroxetine because of their more favorable adverse-effect profiles.

In more advanced HIV disease, starting dosages are usually about one fourth to one half of that in the customary psychiatric patient (e.g., fluoxetine at 5 to 10 mg daily or nortriptyline at 10 mg daily). The most prevalent adverse effects are the same as in non-HIV samples although it is noted that up to 25 percent of outpatients with frank AIDS will experience the severe adverse effects of tricyclics. HIV-infected persons are at increased risk of seizure disorder related to HIV or to opportunistic infection or neoplasm, and caution should be used with bupropion because seizures and confusional states can occur at daily dosage greater than 200 mg or if the individual doses are taken less than 6 hours apart.

Physically asymptomatic patients may show the best rates of response to medication, and there are reports of somewhat reduced efficacy in patients with frank AIDS, suggesting that overall health factors may influence response to therapy. That reduced efficacy in later-stage illness is consistent with reports of a response rate of around 40 percent in hospitalized, non-HIV medically ill patients with major depressive disorder. The possibility of more limited efficacy in later-stage disease has also been related to loss of social support and to the psychological burden of advancing physical illness.

Physically ill patients with major depressive disorder who are unable to tolerate or do not respond to cyclic antidepressant regimens may respond to psychostimulants, such as methylphenidate (Ritalin), dextroamphetamine (Dexedrine), or pemoline (Cylert). Another advantage of these agents is their rapid onset of action, measured in days as compared to weeks for conventional antidepressant agents. The usual starting dose for dextroamphetamine (Dexedrine) is 5 to 10 mg daily in a divided dose in the morning and early afternoon, with increases daily or every other day up to 20 to 30 mg a day. Some authorities prefer methylphenidate because dextroamphetamine may produce severe tremor or a persisting movement disorder in later-stage patients. Previous histories of stimulant or intravenous drug abuse, seizure disorder, opportunistic CNS disease, cardiac arrhythmias, or hypertension are considered relative contraindications to treatment with psychostimulants.

Intramuscular injections of testosterone cypionate (Depo–Testosterone), up to 400 mg biweekly for 8 weeks, have been shown in open label trials to be effective for major depressive disorder as well as for fatigue-anergia syndromes. Responses have been marked even in individuals with late-stage disease. Adverse effects have included irritability, hair loss, fatigue, tension, and breast tenderness, but in most cases these are reported to diminish without change in dosage.

Electroconvulsive therapy (ECT) is effective in patients whose depression requires urgent treatment, in those who have not responded to pharmacological therapies, or in those having major depressive disorder with psychotic features. With judicious use good outcomes may be expected even in persons with neurocognitive impairment, much in the same way that elderly patients with dementia and major depressive disorder respond. Neurological examination and brain imaging are necessary to rule out opportunistic brain disease and increased intracranial pressure before commencing ECT.

DELIRIUM, DEMENTIA, AND OTHER COGNITIVE DISORDERS

Delirium Symptoms of delirium in HIV illness can be effectively managed with low dosages of either low-potency antipsychotic agents, such as chlorpromazine at 10 to 25 mg once to three times daily, or with high-potency agents, such as haloperidol (Haldol) at 0.25 mg to 5 mg once to three times daily, or with atypical serotonin-dopamine agonists, including risperidone (Risperdal) at 0.5 mg to 2 mg daily, or olanzapine (Zyprexa) at 10 mg daily. There may well be an increased incidence of extrapyramidal symptoms associated with high-potency typical agents in advanced HIV illness, and patients with underlying HIV-associated dementia appear to be at highest risk for medication-induced movement disorders. For patients who do not respond to low-dosage oral therapy, excellent results have been reported with intravenous haloperidol given in individual boluses ranging from up to 2 to 10 mg every hour, or in extreme instances, up to 150 mg haloperidol daily. Some clinicians have also had good results with a combination of intravenous haloperidol and lorazepam, with an average daily intravenous dose of less than 50 mg of haloperidol and 10 mg of lorazepam. In general, no serious adverse effects have been noted with those more aggressive intravenous regimens, although nearly one half of the patients treated may have extrapyramidal symptoms.

Benzodiazepines alone (e.g., lorazepam) do not appear to be effective in delirious states, and they may accentuate confusion.

HIV-Associated Dementia and Mild Neurocognitive Disorder Treatment of neurocognitive impairment in HIV should ideally be both psychological and pharmacological. The patient should be informed of the strengths and the liabilities detected on neuropsychological testing and be advised of simple coping

measures, such as keeping to a routine, doing one thing at a time, and reducing external stimuli. The patient's safety is a priority, and friends, family, and service organizations should be enlisted to assist with caretaking.

Antiretroviral treatments are the drugs of choice for HIV-associated cognitive impairment. Although it is not established that antiretrovirals must penetrate well into the CNS in order to be effective, it is wise to try to include those known to cross the blood-brain barrier in such regimens. Of the currently available antiretrovirals the nucleoside reverse transcriptase inhibitors zidovudine and stavudine (Zerit) as well as the nonnucleoside reverse transcriptase inhibitor nevirapine (Viramune) show reasonable concentrations in CSF. In general, the reverse transcriptase drugs do not cross the blood-brain barrier.

Although some clinicians advocate the use of psychostimulants to improve attention, concentration, and psychomotor activity, most observations are based on data from uncontrolled studies. The one controlled study of methylphenidate did not show it to be superior to placebo. Clinicians who report positive experience with stimulants recommend methylphenidate at 2.5 to 5 mg twice a day, with breakfast and lunch, with slow increases up to 20 mg a day. Some have reported that good results can be maintained for many months, although doses may need to be increased. The relative psychiatric and medical contraindications for psychostimulant treatment apply, as discussed in reference to treatment of major depressive disorder.

Studies are currently in progress to determine if aggressive combination antiretroviral therapy can lower CSF viral load as well as improve cognitive functioning.

Fatigue-Anergia States Fatigue-anergia-apathy syndromes can also complicate advanced disease in its middle and later stages. These syndromes are not necessarily accompanied by significant depressive symptomatology or marked neurocognitive impairment. While release of various lymphokines (e.g., tumor necrosis factor, various interleukins) may be primarily responsible, some have suggested that there is a psychodynamic component—a conservation-withdrawal response in the face of loss of control. Beyond ensuring optimal nutrition and medical management, simple measures, such as encouragement and support, allowing a patient to participate in treatment decisions, and providing activities outside the hospital room, can be helpful, with a response usually occurring within 1 week. Psychostimulants at dosages used for patients with neurocognitive disorder (e.g., methylphenidate at 10 to 20 mg daily) have achieved gratifying results in other groups of patients, but there are no controlled studies available. Here too the usual contraindications for psychostimulant treatment should be considered. Testosterone cypionate 400 mg intramuscularly every 2 weeks has been shown to be effective in crossover studies, with increases in energy, motivation, and activity; adverse effects of irritability, tension, and hair loss are mild and transient.

OTHER CONDITIONS

Psychosis Symptoms of HIV psychosis respond well to antipsychotic medications. Although no comparative studies have yet been published comparing atypical and typical antipsychotic agents, these newer medications may become the drugs of first choice, based on adverse effects profiles (e.g., risperidone, olanzapine). Dosing for atypical antipsychotic drugs can be at one half (or less) the dosages used for acute psychoses in psychiatric patients.

For first-generation antipsychotic medications the usual therapeutic dose is one tenth to one third of that used for most acute psychoses in psychiatric settings, with the mean daily dose being about 150 mg in chlorpromazine equivalents (e.g., 1 to 10 mg daily of haloperidol or fluphenazine [Prolixin]). The latency of response is similar to that observed in the functional psychoses, with the majority of improvement said to occur within the first 6 weeks of therapy. It is unclear why lower-dose regimens are adequate, but that may be related to pharmacokinetic changes associated with chronic disease, or to HIV-associated damage to subcortical limbic or basal ganglia structures.

The latter phenomenon has also been thought to explain the sensitivity of patients with HIV-associated psychosis to extrapyramidal adverse effects. Movement disorders attributable to subcortical damage can appear in HIV-infected persons not taking antipsychotic medications, and they include myoclonus, paroxysmal dystonia, parkinsonian features, essential tremors, hemiballism, and hemichorea. In one study, thioridazine and haloperidol were equally effective, but thioridazine produced fewer intolerable extrapyramidal adverse effects. In general, these effects can be managed with low doses of benztropine (Cogentin), at 1 to 3 mg daily, although some authorities suggest substituting amantadine (Symmetrel) at 50 to 100 mg twice daily to avoid the anticholinergic properties of benztropine.

Neuroleptic Malignant Syndrome It is thought that AIDS patients generally and those with HIV-associated dementia in particular may be at increased risk for the most serious adverse effect of antipsychotic drugs, the neuroleptic malignant syndrome. This condition may present itself with subtle signs, and the diagnosis should be considered in any patient on antipsychotic drugs who develops rigidity, akinesia, mutism, lethargy, fever, autonomic instability, and increased creatine phosphokinase (CPK) activity. Neuroleptic malignant syndrome may be particularly associated with high-potency agents. Treatment is directed toward discontinuing the antipsychotic drug and instituting supportive care.

Manic States For immediate control of manic excitement up to 10 mg of clonazepam (Klonopin) daily is effective in many instances. If psychotic features are present, low doses of antipsychotic agents, such as risperidone at 0.5 to 2 mg daily, olanzapine up to 10 mg daily, chlorpromazine at 25 to 150 mg daily, or haloperidol at 0.5 to 5 mg daily, may be employed. For longer-term management lithium is effective but may not be as well tolerated as is carbamazepine and valproate (depakene). For example, in some studies lithium and antipsychotic medications are poorly tolerated by individuals with HIV-associated neurocognitive disorders, especially if brain MRI abnormalities are present (e.g., atrophy) whereas valproate (dosage range 750 to 1750 mg daily; plasma concentration >50 µg per mL) is fully successful. Good control is usually possible within 7 days, and treatment gains have been maintained for up to 4-year follow-up. Lithium has been used to treat patients who develop manic syndromes as an adverse effect of zidovudine, with good control of symptoms, which allows a patient to continue antiretroviral therapy. It may be that valproic acid and carbamazepine would be effective in these iatrogenic manias.

In HIV-infected patients treated with lithium for the control of bipolar I disorder care must be taken to monitor lithium concentrations closely, especially if the patient has significant gastrointestinal disturbances (e.g., vomiting and diarrhea) that may affect lithium absorption and excretion. Carbamazepine may reduce serum concentrations of protease inhibitors, and these agents themselves may lower valproate concentrations.

HIV and the Chronically Mentally Ill In metropolitan areas at the center of the AIDS epidemic, the prevalence of HIV seropositivity among patients admitted to general psychiatric hospitals may exceed 10 percent, and it is believed that HIV serotesting is underused by many physicians treating the chronically mentally ill. Individuals with schizophrenia, bipolar I disorder, or other chronic mental disorders are believed to be at increased risk for HIV acquisition and transmission, based on impulsiveness, difficulty in perceiving risk, and comorbidities, such as concurrent intravenous drug use and unsafe sexual practices. HIV education programs specifically tailored to the needs of patients with chronic mental disorders are currently being developed.

Legal Considerations: HIV Testing, Informed Consent, and Disclosure Written informed consent must be obtained from the person before testing for antibodies to HIV. Given an appropriate rationale, such as the need to provide the best possible care or to safeguard the health of others, permission is rarely denied. Although statutes vary in different jurisdictions, permission to test may be obtained from the patient's attorney-in-fact or closest available relative if the patient is incapable of giving informed consent, so long as the testing is aimed at offering the most appropriate care.

The need to protect potential sexual contacts of patients who are known to be seropositive or at high risk of HIV seropositivity may arise. Physicians and staff have the obligation to offer education to seropositive patients about acquisition and transmission of HIV and techniques to reduce transmission. In psychiatric inpatient settings the staff is obligated to protect the health of others by monitoring and, as necessary, restricting the privileges of patients known to be HIV-seropositive who are engaging or attempting to engage in high-risk (sexual) activity while hospitalized. It is generally agreed that the physician has the ethical right (but not the legal requirement) to disclose HIV seropositivity against the patient's wishes in order to safeguard the health of other selected persons. Spouses, sexual partners, and other high-risk contacts (e.g., those who share needles with the patient) may be informed, but in most jurisdictions the physician is not permitted to directly identify the seropositive person in question. In all cases the physician is obligated to tell the patient that his or her sexual contacts or other high-risk partners are being notified (Table 2.8-7 and Table 2.8-8).

1. Interpretation of test result:
   Clarify distortion (e.g., "'A negative test still means you could contract the virus at a future time; it does not mean you are immune from AIDS'").
   Ask questions about the patient's level of understanding and emotional reaction to the test result.
2. Recommendations for prevention of transmission (careful discussion of high-risk behaviors and guidelines for prevention of transmission).
3. Recommendations on the follow-up of sexual partners and needle contacts.
4. If test result is positive, recommendations against donating blood, sperm, or organs and against sharing razors and anything else that may have blood on it.
5. Referral for appropriate medical and psychological support. Activate supports available to patient (e.g., family, friends, community services).

Table 2.8-7 Posttest HIV Counseling

Table 2.8-8 Physician Responsibilities Regarding Partner Notification

Worried Well A small group of persons, described as the "worried well," remain convinced that they have the symptoms of HIV infection despite repeated negative serological testings. Those patients present with anxiety-based physical symptoms (fatigue, diaphoresis, myalgia, sore throat, and perception of enlarged lymph nodes) and ruminate on images of HIV disease, on past risky sexual practices, and on their potential threat to current lovers or family. They may exhibit compulsive checking of their skin for lesions of Kaposi's sarcoma (such as counting moles or freckles), compulsive washing of items they believe are contaminated, such as clothes, and repeated questioning and physical scrutiny of partners for signs of HIV disease. Such individuals may travel from physician to physician seeking someone who supports their perceptions. The majority seem to qualify for a major psychiatric disorder, including major depressive disorder, delusional disorder, obsessive-compulsive disorder, or hypochondriasis. Treatment usually consists of a combination of appropriate psychopharmacological intervention for the primary psychiatric diagnosis, along with education about anxiety-based symptoms, exploration of distress related to life circumstances that might amplify physical symptoms, and self-monitoring of rituals.

Suicide Studies based on coroners' reports suggest that patients with advanced HIV disease have a thirtyfold risk of committing suicide compared to seronegative persons matched for age and social position. Some survey reports indicate that seronegative persons who are in a high-risk group for HIV infection, as well as seropositive persons at all stages of HIV infection, have an elevated lifetime prevalence of suicidal ideation and suicide attempt compared with community controls. It is important to note that both sources of data suggest that psychiatric disorder is strongly implicated in suicide, attempted suicide, and suicidal ideation. Psychological autopsies from coroners' cases have identified psychiatric histories in almost 50 percent of cases. Suicide attempt and suicidal ideation are correlated with histories of major depressive disorder or substance-related disorders, and in over half of cases these suicidal behaviors commenced before the likely date of seroconversion. Conflicts about sexual preference may be associated with suicide attempts by adolescents. This, together with the increase in HIV infection in adolescents, may place HIV-infected youths at particularly high risk. Suicide rates in women are not noted to be elevated, but the epidemic is now just starting to affect large numbers of women, and their greater vulnerability to major depressive disorder may mean that women are at risk. Advances in therapy may heighten hope and reduce the risk of suicide. However, those whose hopes are first raised but who then do not respond to or cannot tolerate these agents may require psychotherapeutic intervention. Thus, while debate over the distinction between suicide and the right to choose death or to refuse unwanted treatment are important issues, it is imperative that persons expressing suicidal behaviors or ideas be examined for a major psychiatric disorder and be offered appropriate treatment.

Bereavement Persons in social communities representing the high-risk groups for HIV infection are subject to repeated bereavement. Indeed, some surveys find that almost one of three homosexual men has suffered the loss of two or more members of his social network during the preceding 12 months, as compared to none of a heterosexual lower-risk comparison group. Furthermore, it has been noted that approximately 20 percent of these bereaved persons can be characterized as carrying unresolved grief (i.e., a persisting experience of grief for the deceased, difficulty with adjustment to the loss, and an inability to discuss the loss without distress). Persons with unresolved grief have been found to report more depressive and anxious symptoms than those with resolved grief (or those without loss), and they also demonstrate significantly higher lifetime histories of alcohol and other psychoactive substance-related disorders. In one study seropositive men were more likely than seronegative high-risk men to report unresolved grief, although there were no differences in grief resolution between physically symptomatic and physically asymptomatic seropositive persons. Given the association of grief with depression, and the possible psychological consequences of unresolved grief, clinicians should routinely inquire into their patients' history of bereavement and loss, especially because some may be experiencing multiple bereavements. The ultimate impact of bereavements on adaptation to illness, compliance with medical treatment, and adherence to safer sexual practices and health outcome is unknown.

Sleep Disorders Decreased sleep quality, difficulty falling asleep, fragmented nighttime sleep, and early-morning awakenings seem to increase as immune function and CD4+ lymphocyte counts diminish, and they may affect a substantial proportion of persons with AIDS. The reports of increased sleep difficulty in men with later-stage disease seem to be independent of zidovudine therapy or of psychological distress. Some have proposed that alterations in sleep architecture, such as increases in slow-wave sleep, may be an early marker of CNS involvement in HIV-infected persons. The therapeutic approach has generally been limited to symptomatic treatment with nonbenzodiazepine agents used as hypnotics, such as trazodone (Desyrel).

Pain Syndromes Pain probably remains the most underrecognized and undertreated symptom in HIV disease, as it is in other life-threatening illnesses, such as cancer. Undertreatment of pain is especially prevalent in injection drug users. The etiology and pathogenesis of pain in HIV-related disorders is just beginning to be understood. Psychiatric disorders may complicate persisting pain, and, because no one specialty addresses pain syndromes, patient care is often fragmented between anesthesiologists, neurologists, internists, and psychiatrists.

Neuropathic pain related to HIV usually presents as a persisting, painful sensorimotor neuropathy with dysesthesia, stocking-glove sensory loss, diminished distal reflexes, and distal weakness. Similarly postherpetic neuralgia (herpes zoster radiculitis) may involve pain of the face or trunk. Treatment of neuropathic pain syndromes is usually with low-dosage tricyclic antidepressant agents, such as desipramine or nortriptyline at 10 to 25 mg a day. The typical steady-state dosage is 50 mg a day, although some patients require higher amounts (75 to 100 mg daily). A response will often ensue within 1 to 2 weeks, but 4 to 6 weeks of treatment may be necessary before response occurs or another tricyclic agent is chosen. In general, tricyclic antidepressants probably are more effective than SSRIs for chronic neuropathic pain. Opioid analgesics are also effective. Anticonvulsants, such as phenytoin (Dilantin) or carbamazepine, at usual therapeutic concentrations required for seizure management, may also be effective. Postherpetic neuralgia may also be treated with topical capsaicin (Dolorac) and may also respond to clonazepam at 1 to 5 mg daily.

Chronic headache may appear as a residual symptom from acute aseptic meningitis in seroconversion illness or as an effect of zidovudine (which may persist after drug discontinuation). It is known that imipramine, desipramine, amitriptyline and nortriptyline can be effective in treating migraine and mixed migraine-tension headache syndromes in non-HIV populations, and there is speculation that persisting headache following aseptic meningitis may also respond to low-dosage regimens of these agents (e.g., nortriptyline or desipramine at 10 to 25 mg daily with increases up to 75 mg).

Among the rheumatological disorders are arthralgias, myalgias, and arthritides involving large joints of the leg. HIV-related arthralgias may respond to nonsteroidal

anti-inflammatory agents, although acetaminophen (Tylenol) should be avoided because it may diminish the metabolism of zidovudine. HIV may also be associated with a polymyositis, which involves pain, weakness, and elevated CPK, along with changes on electromyography indicating a myopathic process. Long-term administration of zidovudine may also produce a myositis that persists when the medication is discontinued. Psychopharmacological interventions are not of demonstrated efficacy in these states.

Multidisciplinary pain treatment approaches, which employ coordinated efforts of experts in various disciplines, may be as useful in chronic HIV-related pain as they are in chronic, non-HIV pain syndromes. Such approaches employ education about the nature of persisting pain, activity scheduling, self-monitoring and relaxation training, and cognitive therapies to reduce disability related to pain.

Finally, studies of acute postoperative pain and chronic cancer pain generally indicate that for those conditions in which opiate analgesia is indicated, those medications are often underprescribed or irrationally prescribed, in subtherapeutic doses at too extended an interval. The clinician should always be alert to that possibility in advanced HIV disease.

SPECIAL ISSUES

Children and Adolescents In approximately 30 percent of cases, infants born to untreated seropositive mothers will themselves seroconvert within the first 18 months of life, presumably from infection in utero by vertical transmission from the mother; there are some indications that breast feeding is also a risk factor. Antiretroviral treatment during pregnancy dramatically reduces the risk of transmission.

Few data are available describing the neuropsychological or clinical psychiatric findings in children with asymptomatic or mildly symptomatic infection. The predominant feature of AIDS in children consists of a developmental delay evident in infancy and progressive cognitive impairment in older children. The majority of physically symptomatic HIV-positive children evidence a developmental delay, and almost all of those are reported to have CNS dysfunction. Developmental delays are usually most evident in fine and gross motor skills and speech, and school-aged children with frank AIDS may have intellectual abilities in the mildly to severely retarded range.

The course of illness is variable, ranging from static and persisting deficits to rapid decline, with many children showing a steadily deteriorating course. The group of children most at risk for HIV infection is presently the same group most at risk for developmental delay from environmental factors, such as poor nutrition, prolonged hospitalization, and understimulation. Added to those factors must be the impact of the mother's HIV illness on caretaking.

Standard treatment for developmental delay is promptly to institute a program of rehabilitation and enrichment. All seropositive infants and children should be considered for treatment. The verbal and play psychotherapies developed for children with developmental delays and mental retardation from non-HIV sources are also thought to be applicable for children infected with HIV.

Adolescents are one of the fastest-growing risk groups, and runaways, homosexual and bisexual youths, drug-using adolescents, and sexually abused adolescents are thought to be at particularly high risk. Most of the major psychiatric syndromes reported in adults with HIV have been described in adolescents, including major depressive disorder, delirium, and anxiety and psychotic syndromes. There is intense current interest in the efficacy of educational interventions for promoting behavior change and safer sexual practices among adolescents, using peer counseling, mass media, family, and school-based interventions. The longer-term efficacy of those programs is being evaluated.

HIV infection touches every member of the family. One partner's fear of discussing his or her seropositive status with a spouse out of fear of rage and abandonment may lead to attempts to isolate the knowledge and disguise the illness. Parents may be reluctant to disclose their seropositivity or their child's serostatus to members of the extended family because of concerns over rejection and condemnation. Individual members of the family or the entire family may deny the illness of the mother or child. A parent or other family member may express guilt as anger toward the seropositive child, or the child may become the displaced focus for other family conflicts. Conjoint and family therapy interventions are often indicated, but therapy must frequently be directed toward supporting the children's primary caretaker.

Women and HIV Women, especially those of minority ethnicity, are a fast-growing risk group for HIV. Most women infected with HIV are injection drug users or partners of drug users who have become infected by heterosexual intercourse. Studies from partners of injection drug users indicate high concurrent rates of substance-related disorders, major depressive disorder (up to 20 to 25 percent), and severe personality disorders.

The cross-sectional psychiatric findings in HIV-seropositive women may depend greatly on risk group or mode of acquisition. Prospective studies are urgently needed to describe the physical, neuropsychological, and psychological course of HIV infection in women.

In earlier phases of the epidemic physicians frequently suggested that pregnancy be avoided or terminated because of its immunosuppressant effects, and the likelihood of maternal fetal transmission. However, advent of potent new therapy opens the possibility of a safer pregnancy. As of late 1998, one of the most prevalent dilemmas involves pregnancy in the severely immunocompromised woman with CD4 lymphocyte count <200. Because pregnancy may further reduce immune capacity there is enhanced risk of serious opportunistic infections as well as danger to the developing fetus from the aggressive treatment of such infections. Women who are not severely immunocompromised (e.g., CD4 lymphocyte count <200) may face another dilemma: if the woman's partner is also seropositive she risks being infected by novel strains of HIV. Because recommendations in this arena are evolving so rapidly, specialized referral and family planning counseling are usually needed.

SUGGESTED CROSS-REFERENCES

Some of the specific syndromes associated with HIV infection are discussed in Chapter 10 on delirium, dementia, and other cognitive disorders; in Chapter 11 on substance-related disorders; in Chapter 12 on schizophrenia; in Chapter 13 on other psychotic disorders; in Chapter 14 on mood disorders; in Chapter 15 on anxiety disorders; and in Chapter 19 on human sexuality. Treatment of specific disorders is reviewed in Chapter 30 on psychotherapies and in Chapter 31 on biological therapies. Detailed information on neuropsychological assessment is provided in Chapter 7 on diagnosis and psychiatry, specifically in Section 7.4 on neuropsychological and intellectual assessment of adults, and Section 7.5 on neuropsychological and intellectual assessment of children. Additional topics in neuropsychiatry are treated in Chapter 2 on neuropsychiatry and behavior neurology. Discussion of neuroimaging is provided in Section 1.15 and Section 1.16 on neuroimaging in clinical practice. Detailed discussion of life adversity and immunity are treated in Section 25.9 on stress and psychiatry and Section 25.10 on behavior and immunity.

2.9 NEUROPSYCHIATRIC ASPECTS OF OTHER INFECTIOUS DISEASES

BRIAN ANTHONY FALLON, M.D., M.P.H.

Ever since the link between severe neuropsychiatric disorders and infectious disease was established in the early 1900s by the identification of the cause of syphilis, questions have been asked about the role of other infectious organisms in the etiology of neuropsychiatric disorders. At times the link between an infectious agent and a neuropsychiatric disorder is obvious, as in the case of neurosyphilis, the viral influenza outbreak of the 1920s, and the current human immunodeficiency virus (HIV) and Lyme disease epidemics. At other times the link is less clear but strongly suspected, as has been true for chronic fatigue syndrome or in the search for bacterial or viral etiologies of obsessive-compulsive and psychotic disorders. Psychopathology may emerge as a result of direct invasion of the central nervous system (CNS) by neurotropic agents or by an indirect host-determined cellular, humoral, or cytokine immune response to infectious organisms that inadvertently damages host tissue. In its effort to protect, the immune response may thereby provoke neuropsychiatric disorders.

This section focuses on selected infectious diseases other than HIV disease that invade the CNS and that have been directly associated with neuropsychiatric syndromes. Particular attention will be paid to the neuropsychiatric aspects of Lyme disease because it has spread rapidly since the 1970s in various parts of the world and has been associated with a plethora of neuropsychological and neurobehavioral problems in both children and adults. In addition, the concluding portion of this section will briefly address a few areas of recent investigation on the overlap of infectious disease and neuropsychiatry.

SPIROCHETAL DISEASES

Under the umbrella of the order of spirochetes are three agents that are known to invade the CNS. These include borrelia, treponema, and leptospira. Borrelia, which require an arthropod vector and a mammalian or bird reservoir, are commonly known to cause relapsing fever and Lyme disease. Treponema, which are spread person to person and do not use an arthropod vector, are the spirochetes responsible for syphilis. Leptospira, which are spread by contaminated water, are the agents of Weil's disease, which can have CNS manifestations.

Lyme Disease Lyme disease (Lyme borreliosis), transmitted by the bite of an infected Ixodes tick, can cause a vast array of neuropsychiatric disorders, ranging from mild mood changes to psychosis and severe memory loss. Lyme disease has been reported throughout the United States and in many countries throughout the world. The causative agent of Lyme disease, *Borrelia burgdorferi*, is initially inoculated into the skin by an infected tick, typically inducing a local rash, known as *erythema migrans*, which is reported by approximately two thirds of infected patients. Rapidly disseminated by the bloodstream through the body, *B. burgdorferi* has been found in the CNS as soon as 3 weeks after initial skin infection. Known to be neurotropic, *B. burgdorferi* may reside in the cerebrospinal fluid (CSF) or adhere to glial cells or other brain tissue. Like its spirochetal counterpart, *Treponema pallidum, B. burgdorferi* may remain latent, causing illness months to years later. Partly because of this latency in disease expression, patients may be unable to recall the initial tick bite or rash. Antigenic variability, which refers to the ability to express different surface antigens and to thus evade the immune response, is a feature of borrelial organisms that *B. burgdorferi* shares.

Diagnosis The epidemiological surveillance criteria for the diagnosis of Lyme disease in the United States require a history of exposure to an area endemic for Lyme disease and either a physician-diagnosed erythema migrans rash or serological evidence of exposure to *B. burgdorferi* and at least one of the following three clinical features: (1) arthritis; (2) neurologic symptoms (cranial or peripheral neuropathy, meningitis, encephalomyelitis, or encephalitis with evidence of intrathecal antibody production); or (3) cardiac conduction defects. Although useful for epidemiological monitoring, these criteria are unduly restrictive and should not be used for clinical purposes, because these criteria exclude patients who might have Lyme disease, such as seropositive patients who have diffuse arthralgias but not frank arthritis or patients who have encephalopathy without objective CSF abnormalities. Further complicating the diagnosis is the unreliability of the serologic tests. False-positive results might result because of cross-reactivity with other spirochetal organisms. False-negative results may occur because the patient is tested too soon after infection and before an appropriate antibody response is mounted or because the patient's immune response has been abrogated as can occur when a patient is given antibiotic shortly after initial infection. It is not uncommon for a patient with Lyme disease to have negative or equivocal test results in one laboratory, but positive ones in another or for a patient to have negative test results initially but positive ones several months later after antibiotic treatment has been initiated. For these reasons a rational approach to the diagnosis of Lyme disease must be based upon the primary clinical presentation, followed by the supportive evidence of laboratory test results. Laboratory tests that can be helpful include indirect tests such as the enzyme-linked immunosorbent assay (ELISA) and Western blot analysis and direct tests such as the polymerase chain reaction (PCR) assay for borrelial deoxyribonucleic acid (DNA) or antigen detection assay. When Lyme disease is suspected, the clinician should order both an ELISA and a Western blot, as some patients may have a negative ELISA result but a positive Western blot result. Bands of particular significance on the Western blot include the ones identified by the Centers for Disease Control as being most frequent and specific, as well as the 31kD (OspA) and 34 kD (OspB) bands. Although highly specific for *B. burgdorferi* DNA, the PCR assay has low sensitivity. Although laboratory testing is a valuable component of the diagnostic assessment, negative test results cannot be used to exclude Lyme disease in a patient with typical clinical features and a history of exposure to a Lyme disease endemic area.

Clinical Features The erythema migrans rash is the hallmark feature of early Lyme disease; antibiotic treatment at this stage often results in cure. Although typically the rash has a bull's eye, rounded appearance, it may also have a triangular, elongated, or other shape. Because patients may not recall seeing the rash, the flu-like symptoms that often occur shortly after the rash may be ignored, only to be followed several months to years later by the emergence of a multisystem disease affecting the joints, the heart, the eyes, and the peripheral or central nervous system; 15 to 40 percent of patients may have neurologic signs as their presenting feature. Headaches may be followed by meningitis, cranial neuritis, motor or sensory radiculitis, or an encephalitis characterized by mood lability and disturbances of memory or sleep. Although suggestive of Lyme disease, Bell's palsy may occur in only 5 to 10 percent of a sample of patients with neurologic Lyme disease. Symptoms of radiculoneuropathy or peripheral nerve involvement include sharp stabbing or deep boring pains that may radiate from the spine into an extremity of the trunk; areas of numbness, burning, or tingling; weakness; and fasciculations. In later stages of Lyme disease a minority of patients may develop a chronic meningoencephalomyelitis characterized by somnolence, confusion, poor concentration, impaired memory, myoclonus, apraxia, ataxia, paraparesis, dysarthria, dysphasia, seizures, or bladder abnormalities. Some of these patients may be misdiagnosed as having multiple sclerosis because of a relapsing and remitting course and the concurrence of spinal motor signs, ataxia, bladder dysfunction, and, less often, optic neuritis.

The profile of neuropsychiatric Lyme disease typically includes disturbances of cognition and mood. On formal neuropsychological testing, more than 50 percent of patients with chronic neurologic Lyme disease will show impairment in short-term memory, processing speed, or attention. This cognitive impairment, although worsened by marked pain or mood disorders, exists independently of the physical symptoms or the severity of concurrent depression. Typical cognitive symptoms include word-finding problems, word-substitutions, new-onset dyslexia, transient episodes of geographic disorientation, marked inattention and distractibility, difficulty with organization, and the sensation that one's brain is in a fog. Less commonly, the severity of the cognitive disturbance causes a global impairment, suggestive of a new-onset dementia.

Although the full spectrum of psychiatric disorders has been associated with *B. burgdorferi* infection, by far the most frequent are disturbances of mood, characterized by irritability, mood swings, and sleep loss. The majority of controlled studies in which patients with Lyme disease are compared to healthy controls or to patients with other illnesses reveal that depression occurs more frequently in the group with Lyme disease. Children with neurological Lyme disease typically present with complaints of headaches as the most common symptom, followed by behavioral, cognitive, or mood disturbance as the next most prevalent symptom. Behavioral problems include falling asleep in class, agitation, and poor school performance; common cognitive problems include attentional and short-term memory and visospatial deficits; common mood problems include irritability and new-onset anxiety. Other less common neuropsychiatric aspects associated with Lyme disease in adults and children include panic attacks, transient paranoia, illusions or hallucinations (visual, olfactory, auditory), anorexia, depersonalization, violent outbursts, obsessive-compulsive disorder, agitated mania, hyperacute sensitivity to light or sound, and what appears to be personality change. Because of the multisystem involvement in Lyme disease and the frequent concurrence of anxiety and depression, patients may be mistakenly diagnosed as having a primary psychiatric or a

somatoform disorder before Lyme disease is even considered. If Lyme disease is considered but serological tests are equivocal despite the presence of a clinical profile typical of Lyme disease, the somatoform label may once again be mistakenly applied.

A 22-year-old previously healthy college graduate in his first few months of law school developed joint and muscle pains. A medical workup was negative, but the symptoms persisted and worsened, accompanied by fatigue so severe that he was unable to go to class or to study. Referral to a psychiatrist resulted in treatment with a selective serotonin reuptake inhibitor (SSRI) for possible depression without much benefit. Further medical workup revealed a positive result for Lyme disease ELISA with an equivocal Western blot analysis result. The diagnosis of probable Lyme disease was made and the patient was given a 6-week course of oral antibiotics, with a marked improvement in symptoms. Over the following 4 months his prior symptoms returned accompanied by headaches, word-finding problems, paresthesias, shooting and stabbing pains, and hypersensitivity to light and sound. Several consulting doctors gave conflicting opinions, with some firmly stating that this could not be persistent Lyme disease as it had been adequately treated and others stating that persistent infection was indeed possible and that additional treatment with antibiotics was warranted. The Lyme tests remained equivocal and a brain magnetic resonance imaging (MRI) revealed no abnormalities. Three additional months of oral antibiotics resulted in some improvement of arthritic symptoms, but the fatigue and cognitive problems remained. Several months later, the patient developed paranoid delusions followed by a manic episode for which he was hospitalized. Without further testing such as a spinal tap or electroencephalogram (EEG), his doctors dismissed Lyme disease as a possible cause for his new-onset mania. The patient was discharged on antipsychotic agents and lithium, with only a partial improvement in his mood lability. An outpatient internist then checked the patient's spinal fluid, which showed white blood count of 7 × 109 per liter 7 (white blood count [WBC]) and evidence of *B. burgdorferi* antibodies in both his serum and cerebral spinal fluid (CSF). The diagnosis of neuroborreliosis was made and the patient was placed on a 3-month course of intravenous antibiotics. Although the mood lability, mania, and cognitive problems dramatically resolved with long-term antibiotic treatment, 3 years later the patient had not yet returned to school because of problems with persistent fatigue. At that point, because a PCR assay of his plasma was positive for Lyme disease and a brain single photon emission computed tomography (SPECT) scan revealed global heterogeneous hypoperfusion, the patient was once again treated with antibiotics.

This case highlights the diagnostic difficulties of Lyme disease: the confusion triggered by equivocal results on serological tests, the need to consider *B. burgdorferi* as the cause for new-onset mania, the inadequate response to standard psychiatric medications, the initially robust but subsequently partial response to antibiotic regimens, and the persistence of the DNA of the organism despite aggressive antibiotic therapy.

Tests for CNS Lyme Disease Examination of the CSF is crucial to rule out other possible causes of CNS disease and to identify the presence of Lyme meningitis or encephalitis. In early neurologic Lyme disease, a spinal tap may reveal lymphocytic pleocytosis, mildly increased protein, and, in some cases, an elevated immunoglobulin G (IgG) index or the presence of oligoclonal bands. In later-stage neurological Lyme disease, however, the CSF may appear normal. MRI studies may reveal punctate white matter lesions on T2-weighted images, suggestive of a demyelinating disorder such as multiple sclerosis. EEG studies are generally normal, although diffuse slowing or epileptiform discharges may be seen. SPECT and positron emission tomography (PET) studies may be particularly helpful in late-stage Lyme disease. Recent reports indicate that many patients with Lyme encephalopathy have a pattern of either global or heterogeneous hypoperfusion, which in some cases improves after antibiotic treatment (Fig. 2.9-1). Given the difficulties facing the clinician attempting to determine whether the fatigue, mood lability, and cognitive tracking problems are caused by primary depression or by an underlying systemic disease, functional imaging studies are a valuable tool to assist in the differential diagnosis.

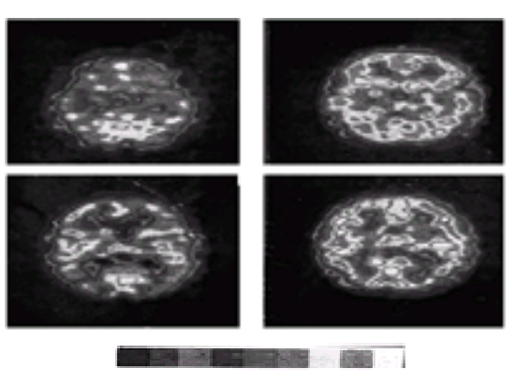

FIGURE 2.9-1 Transverse views obtained with Technetium-99m HMPAO SPECT. The two views on the left are of the brain of an adolescent with Lyme encephalopathy and demonstrate moderate heterogeneous hypoperfusion. The views on the right are of the brain of an adolescent without encephalopathy and demonstrate a normally perfused scan. The color spectrum scale, from purple to white, represents low to normal perfusion. (See color Plate 2.)

Differential Diagnosis In considering the diagnosis of Lyme disease, it is important to ask the patient about exposure to a Lyme disease-endemic area, history of a tick bite or unusual rash, and the presence of multisystemic involvement. Called the “new great imitator” (after the original great imitator, syphilis), the broad spectrum of atypical neurological manifestations of Lyme disease include strokes, Guillain-Barré syndrome, cerebellar syndromes, seizures, pseudotumor-like syndrome in children, spastic paraparesis, multiple–sclerosis–like illnesses, and progressive dementias. Similarly, other diseases that may look like neuropsychiatric Lyme disease need to be excluded, such as major depression with somatic preoccupation, panic disorder, systemic lupus erythematosus or other connective tissue diseases, chronic fatigue syndrome, endocrinological disorders, vitamin deficiencies, other infectious illnesses, vascular dementias, and other neurodegenerative disorders.

Treatment For early Lyme disease without CNS involvement, 3 to 4 weeks of oral doxycycline (Vibramycin) (100 mg twice a day), amoxicillin (Amoxil) (500 mg three times a day), or cefuroxime (Ceftin) (500 mg twice a day) is recommended. For Lyme disease with CNS involvement, an initial course of 4 to 6 weeks of intravenous ceftriaxone (Rocephin) (2 grams/day) or cefotaxime (Claforan) (2 grams/8 hours) is recommended. Symptoms may worsen during the first week of antibiotic treatment, much like the Jarisch-Herxheimer reaction during the treatment of syphilis. For patients who relapse, longer and repeated courses of antibiotics are often helpful. Failure to treat Lyme disease early in its course or for a sufficiently long duration may lead to a chronic illness characterized by persistent waxing and waning neuropsychiatric disturbances, arthralgias, myalgias, sensory-hyperacuities, and severe fatigue. In some patients these symptoms reflect the effects of persistent infection while in others the symptoms may reflect a residual postinfectious syndrome. Because the laboratory tests for chronic Lyme disease are not sufficiently reliable to document the presence or absence of persistent infection, decisions regarding treatment should be based primarily upon the physician's clinical judgment. Given the emerging literature that indicates that *B. burgdorferi* is capable of remarkable persistence in the human host despite standard courses of antibiotic treatment and clinical reports documenting improvement in chronic Lyme disease among some patients treated with long courses of antibiotics, many community physicians are now willing to treat such patients more aggressively. Other physicians, wary of the risks associated with long-term antibiotic treatment, choose not to treat these patients. Until well-controlled studies are conducted of patients with chronic symptoms, the debate on the proper antibiotic treatment for chronic Lyme disease will continue. A vaccine for Lyme disease was introduced in 1999; however, it is only effective in about 50 to 75 percent of cases.

Neurosyphilis The cause of syphilis, *Treponema pallidum*, was identified in 1905. Because of the cognitive loss and neuropsychiatric disturbances associated with tertiary neurosyphilis, these patients accounted for 5 to 15 percent of psychiatric hospital admissions and were diagnosed as having general paresis, general paralysis of the insane, or dementia paralytica. With penicillin treatment of primary and secondary syphilis, neurosyphilis is now an uncommon cause of hospital admissions.

Primary syphilis is manifest by a syphilitic ulcer, the chancre, at the site of inoculation. Secondary syphilis, a result of hematogenous dissemination of the spirochete, is characterized by flu-like symptoms followed by a skin rash, generalized lymphadenopathy, and mucosal lesions. Left untreated, both primary and secondary syphilis resolve on their own, after which the patient enters a latent period during which infection is present but clinical symptoms are not manifest. After months to years, about one third of patients with untreated latent syphilis develop tertiary syphilis that affects the brain or heart. As in neuroborreliosis, invasion of the CNS by *Treponema pallidum* occurs early in the disease and may be asymptomatic for months to years prior to clinical expression.

Clinical neurosyphilis can be divided into four types: syphilitic meningitis, meningovascular syphilis, parenchymatous neurosyphilis, and gummatous neurosyphilis. Syphilitic meningitis, the result of direct meningeal inflammation, rarely has focal findings. Meningovascular syphilis results from the ischemic changes caused by proliferative endarteritis, resulting in permanent CNS damage. In parenchymatous neurosyphilis (general paresis or tabes dorsalis), which generally starts 10 to 20 years after infection, there is direct neural destruction resulting in diminished neuron concentration, demyelination, and gliosis (Fig. 2.9-2). In gummatous

neurosyphilis, the mass effect causes neurological symptoms.

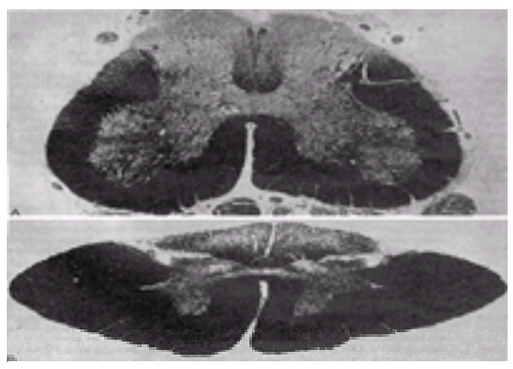

FIGURE 2.9-2 Tabes dorsalis. Degeneration of the posterior column in the sacral and thoracic cord (myelin sheath stain). Reprinted with permission from Merritt HH, Adams RD, Solomon HC: *Neurosyphilis*. Oxford University Press, New York, 1946.)

General paresis often starts with subtle cognitive and emotional changes, such as problems with concentration and irritability; if untreated, it can lead to memory loss, confabulation, anomia, apraxia, or pseudobulbar palsy. The disease may mimic any other psychiatric disorders as well. Half of the patients with neurosyphilis will manifest dementia of whom one quarter will have prominent psychiatric manifestations such as depression, paranoia, psychosis, or mania. A worsening of symptoms during the first 24 hours after the initiation of antibiotic treatment has been termed the *Jarisch-Herxheimer reaction*; in rare cases, psychosis may emerge shortly after antibiotics are started. With disease progression there is loss of muscle tone and fine motor control and seizures, spasticity, and eventually paralysis and death occur. Focal neurological findings are rare, consistent with the generalized pathophysiology. Tabes dorsalis on the other hand develops somewhat later than general paresis, 15 to 20 years after infection, and causes a more characteristic clinical picture of lancinating pains, attacks of abdominal pain, and paresthesias. Because of progressive loss of proprioception and sensation, patients compensate by walking with a broad-based, shuffling gait. Unlike patients with general paresis, not all patients with tabes will have CSF abnormalities.

Tests *T. pallidum* is difficult to demonstrate in the CSF and difficult to culture. Although PCR techniques are being developed to detect the genetic material of the spirochete, this method is currently only available in research laboratories. Clinicians must rely upon serological tests in the context of a careful history and physical examination. Serological tests for syphilis include the nontreponemal Veneral Disease Research Laboratory (VDRI) and rapid plasma reagin (RPR) tests and, for confirmatory purposes, the fluorescent treponemal antibody-absorption (FTA-ABS) test. CSF studies are useful to confirm the diagnosis of neurosyphilis if clinical findings are suggestive, to diagnose asymptomatic involvement so that treatment can be started, and to follow treatment efficacy. These CSF studies are limited by the low specificity of the typical abnormalities of elevated protein, g-globulin, and leukocyte count and the low sensitivity (but high specificity) of the VDRL test. The CSF FTA-ABS test on the other hand is thought to have excellent sensitivity but less specificity than the CSF VDRL test. Neuroradiological studies of neurosyphilis report the presence of cortical atrophy, most commonly affecting the frontal and temporal lobes.

Treatment The goal in clinical neurosyphilis is to reverse the manifestations or arrest the disease progression, although in some patients antibiotic therapy may not be able to achieve these goals. Standard courses consist of intravenous aqueous penicillin G, 12 to 24 million units daily in divided doses at 4-hour intervals for 2 weeks, or intramuscular weekly injections of 2.4 to 4.8 million units of penicillin G benzathine for 3 weeks or intramuscular injections of 2.4 million units of penicillin G procaine four times daily for 2 weeks. The likelihood of marked improvement for patients with general paresis is less than that for patients with syphilitic meningitis or meningovascular syphilis, reflecting the pathological process, which in the former is irreversible neuron damage and in the latter is CNS inflammation. During the first year after treatment, the serum and CSF should be regularly monitored for the reemergence of reactivity so that treatment can be reinitiated if necessary. Certain conditions, such as comorbid HIV infection, may place patients at greater risk for persistence of treponemal infection after antibiotic treatment. However, most neurosyphilis patients, when treated, will show improvement in the cognitive, psychiatric, and functional domains.

NON-HIV VIRAL INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

Numerous viruses are invasive and neurotropic, with the extent of consequent neuronal dysfunction varying widely depending upon the virulence of the virus and the immunological response of the host. This section will focus upon agents known to cause striking neuropsychiatric diseases: herpes simplex, rabies, measles, and subacute sclerosing panencephalitis; Table 2.9-1 presents other infectious causes of neuropsychiatric disorders.

Bacterial Infections
Acute
Haemophilus, meningococcus, pneumococcus
Subacute
Brucellosis, "Group A Beta Hemolytic Streptococcus" leptospirosis, Lyme disease, syphilis, tuberculosis, Whipple's disease
Fungal Infections
Coccidioidomycosis, cryptococcosis, histoplasmosis, *Candida*
Parasitic Infections
Cysticercosis, malaria, toxoplasmosis
Prions
Creutzfeldt-Jakob disease, fatal familial insomnia, Kuru
Viral Infections
Arbovirus, coxsackievirus, cytomegalovirus, enterovirus, Epstein-Barr virus, Flavivirus, herpes simplex virus, human immunodeficiency virus, influenza virus, lymphocytic choriomeningitis virus, measles virus, mumps virus, papovavirus, poliovirus, rabies virus, rubella, togavirus

Table 2.9-1 Selected Infectious Causes of Neuropsychiatric Disorders

Herpes Viruses Included under the spectrum of herpesviruses are human herpesvirus 1 (HHV-1), that is, herpes simplex virus 1; HHV-2, that is, herpes simplex virus 2, varicella-zoster virus, Epstein-Barr virus (EBV), cytomegalovirus (CMV), HHV-6, HHV-7, and Kaposi's sarcoma herpesvirus.

Herpes Simplex Herpes simplex encephalitis is a dramatic disorder, characterized by the abrupt onset of fever, personality change, and headaches, followed by cognitive changes and focal neurological signs, such as aphasia, visual field deficits, hemiparesis, or partial seizures. Although focality is an important feature of herpes simplex encephalitis, other viruses, such as the LaCrosse virus or the nonpolio enteroviruses, may also cause focal signs. Neurobehavioral aspects of herpes simplex encephalitis such as hallucinations, memory loss, or behavioral disturbances may be the primary clinical feature, a consequence of the predilection of the virus for the temporal lobes. Although the course of illness is typically rapidly progressive, resulting in refractory seizures, coma, and death within 2 weeks, occasionally the progression may be slower with varied neuropsychiatric features.

HSV-1 is usually transmitted orally entering the CNS through sensory nerves, particularly the trigeminal ganglia. HSV-2 is transmitted genitally and may seed the sacral ganglia or disseminate hematogenously. Herpes simplex viruses typically produce a lytic infection with neuronal necrosis and tissue destruction, and intranuclear inclusion bodies in the neurons and glia. Patients who survive herpes simplex encephalitis may exhibit postencephalitic symptoms, such as amnesia, aphasia, and less commonly, the Klüver-Bucy syndrome or dementia.

Routine serological studies are of little value in suspected herpes simplex encephalitis. The CSF usually demonstrates leukocytosis (approximately 100 cells/mm ^{3}), a moderate protein elevation, and a normal or depressed glucose content. PCR analysis of the CSF to detect HSV DNA is at present the diagnostic procedure of choice because the PCR assay has high sensitivity and specificity. Recent studies indicate that approximately 80 percent of patients with biopsy-proven herpes simplex encephalitis will have focal EEG abnormalities consisting of slowing or repetitive epileptiform discharges in the frontotemporal area. MRI studies in early stages of herpes simplex encephalitis may reveal T2 prolongation in the insular cortex and cingulate gyrus. SPECT or PET imaging may show reduced blood flow in the

orbitofrontal and temporal regions. Brain biopsy can be helpful in cases that are difficult to diagnose, although the complication rate is approximately 3 percent.

If untreated, 40 to 70 percent of patients with herpes simplex encephalitis will die. Antiviral therapies include acyclovir (zovirax) and vidarbine (Vira-A); however, even with acyclovir treatment fewer than 40 percent of patients survive with minimal or no sequelae (Fig. 2.9-3).

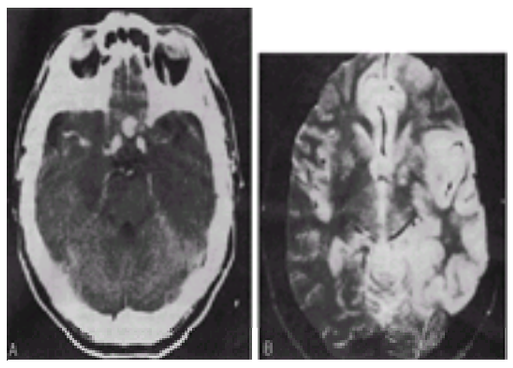

FIGURE 2.9-3 Herpes encephalitis. **A**, Contrast-enhanced axial CT scan shows diffuse decreased density of the left temporal lobe with minimal hypodensity of the medial right temporal lobe. An abnormal CT scan is usually not seen until day 6 to 7 after the onset of manifestations. Eventually, a majority of scans show gyral enhancement in the sylvian fissure area. These findings should raise the suspicion of an underlying infectious lesion such as herpes, early infarction from emboli or vasculitis, or metastatic tumors. **B**, T2-weighted axial MRI scan shows diffuse increased signal intensity along the left temporal lobe cortex as well as the posteromedial left temporal lobe. Both medial frontal lobes are involved as well. An abnormal MRI scan is usually seen by day 1 or 2 after the onset of manifestations. The patient was treated for herpes encephalitis and responded to acyclovir therapy. (Reprinted with permission from Jubelt B, Miller JR: Viral infections. In *Meritt's Textbook of Neurology*, ed 9, LP Rowland, editor. Williams & Wilkins, Baltimore, 1995.)

Epstein-Barr Virus Most adults have evidence of past exposure to EBV, with approximately 50 percent seropositivity among children over age 5. Infection in childhood is generally mild, whereas in adolescence and young adulthood it may result in infectious mononucleosis or, rarely, a fulminant life-threatening disease. EBV enters the body by infecting oral mucosal epithelial cells. The clinical symptoms of infectious mononucleosis of sore throat, headache, malaise, and fatigue are largely a result of the vigorous cellular immune response to EBV infection rather than direct cytotoxic effects. Significant neurological complications of EBV infection are rare, occurring in less than 0.5 percent of cases of infectious mononucleosis.

EBV encephalitis occurs usually within 1 to 3 weeks after the onset of clinical infectious mononucleosis. Patients with EBV encephalitis may present with cerebellar ataxia, personality changes, psychosis, transient global amnesia, perceptual distortions of size and space, focal neurological findings, seizures, or coma. EEG usually reveals generalized slowing with occasional sharp-wave activity. The diagnosis of an EBV neuropsychiatric syndrome requires an appropriate clinical history in the setting of serological evidence of acute or, rarely, chronic active infection. In cases of EBV encephalitis commonly there is a lymphocytic pleocytosis (atypical lymphocytes are particularly suggestive) with elevated protein. In most cases EBV encephalitis is self-limited, with recovery occurring within weeks to months; rarely, acute EBV infection may result in a relapsing or chronic encephalitis. Treatment is generally supportive.

Other Herpes Viruses With herpes zoster, neuropsychiatric complications occur most frequently in immunocompromised patients, resulting in encephalitis, myelitis, or leukoencephalitis. With CMV infection, encephalitis may also occur because CMV is tropic for the CNS; however, only in rare exceptions has CMV encephalitis occurred in non–HIV-infected immunocompromised individuals.

Rabies Although most cases of human rabies occur after animal bites, other sources of rabies infection include aerosols (risk for spelunkers) and person-to-person transmission following corneal transplants. The virus replicates locally at the site of inoculation and subsequently spreads to the CNS by retrograde axonal transport, infecting the lower areas of the brain most prominently, particularly the limbic system, hippocampus, brainstem, and cerebellum. Limbic system involvement may result in aberrant sexual behavior and behavioral dyscontrol, whereas brainstem involvement typically results in alterations of body temperature and respiratory control. The site and amount of inoculation is associated with morbidity. For example, multiple dog bites to the face may result in a 60 percent mortality rate without prophylactic intervention whereas multiple bites to the hand are associated with lower mortality rates of about 15 percent. The incubation period prior to symptomatic expression ranges from a few days to several years. Once symptoms emerge, the course is rapidly fatal. Most patients get the furious form characterized by agitation, hallucinations, odd behaviors, extreme excitability, and in some cases, hydrophobia. Diagnosis is based on the history of an animal bite in a patient with unexplained encephalitis that has been confirmed by the demonstration of rabies antigen on a skin biopsy of the patient or from a putatively infected animal. There is no treatment for rabies virus infection. Disease prevention is critical, aided by preexposure vaccination in high-risk individuals and postexposure prophylaxis with rabies immunoglobulin and rabies vaccine (Fig. 2.9-4).

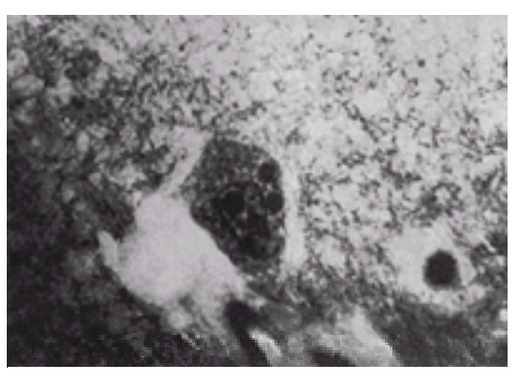

FIGURE 2.9-4 Rabies. Inclusion bodies (Negri bodies) in cytoplasm of ganglion cell of cerebral cortex. (Reprinted with permission from Jubelt B, Miller JR: Viral infections. In *Merritt's Textbook of Neurology*, ed 9, LP Rowland, editor. Williams & Wilkins, Baltimore, 1995.)

Subacute Sclerosing Panencephalitis Subacute sclerosing panencephalitis is a very rare slow infection with measles virus that causes progressive inflammation and sclerosis of the brain. Primarily affecting children and young adults, the rate of subacute sclerosing panencephalitis decreased markedly after 1960 as a result of widespread measles vaccination, with a current rate in the United States of only 1 per 100 million people per year. The onset generally occurs 7 to 12 years after measles and is subtle, characterized by gradual changes in behavior and school performance. Neuropsychological testing may demonstrate reduced overall intelligence and problems with reading, writing, and visuospatial processing. Neuropsychiatric symptoms may include hallucinations, apraxia, agnosia, and Balint's syndrome (optic ataxia, simultanagnosia, and sticky fixation). Repetitive myoclonic jerks are common, at times accompanied by movement disorders and cerebellar ataxia. In advanced stages, dementia, mutism, cortical blindness, optic atrophy, stupor, coma, and death occur. The usual course of the illness is 1 to 3 years, with rare patients surviving up to 10 years.

Serological testing may reveal unusually high titers of antibodies to measles virus. CSF studies typically show high measles antibody titers and a greatly elevated gamma globulin fraction with oligoclonal bands in a CSF with slightly elevated protein concentrations. EEG studies are essential, particularly in the myoclonic stage, when they reveal high-amplitude bilateral and stereotyped complexes that repeat every 3 to 5 seconds. MRI studies may reveal enlarged ventricles and diffuse brain atrophy, with multifocal low-density white matter lesions and lucent areas in the basal ganglia. PET and SPECT studies may reveal early subcortical hypermetabolism followed by global cortical and subcortical hypometabolism.

No treatments are known to reverse the disease, although slightly prolonged survival has been reported with isoprinosine (Inosiplex) and with intraventricular or

intrathecal injections of interferon-a.

Progressive Multifocal Leukoencephalopathy This disease affects immunocompromised subjects and is a progressive infection of oligodendroglial cells with the JC papovavirus. Typically the onset is abrupt with focal neurological or neuropsychological signs and the course is almost invariably fatal within 2 to 4 months. Definitive diagnosis requires a brain biopsy. Neuroimaging studies reveal multifocal areas of high signal intensity in the white matter. Functional imaging with PET or SPECT may reveal a heterogeneous pattern of reduced metabolic activity and perfusion.

SUBACUTE SPONGIFORM ENCEPHALOPATHIES

Included in this group are Creutzfeldt-Jakob disease; *kuru*, a dementing disease of three New Guinea tribes that is most likely spread by ritual cannibalism; *Gerstmann-Straüssler syndrome*, a familial disorder characterized by dementia and ataxia; and *fatal familial insomnia*, a disorder causing disturbances of sleep and of motor, autonomic, and endocrine function. These disorders are all slow infections caused by a transmissible agent not yet clearly described that may be a prion, a virino or an atypical virus. Prions are proteinaceous agents devoid of nucleic acid that are crucial in the pathogenesis of the spongiform encephalopathies. A virino is a small molecule (probably a nucleic acid) associated with a host protein. Characteristic of the neuropathology of these disorders is the neuronal vacuolation that leads to spongy degeneration of the cerebral cortical gray matter.

Creutzfeldt-Jakob Disease Invariably fatal, this transmissible, rapidly progressive disorder occurs mainly in middle age or older and is manifest early on by fatigue, flu-like symptoms, and mild cognitive impairment or focal findings such as aphasia or apraxia. Subsequent psychiatric manifestations include mood lability, anxiety, euphoria, depression, delusions, hallucinations, or marked personality changes. Progression of disease occurs over months leading to dementia, akinetic mutism, coma, and death. Other common neurological findings are generalized startle myoclonus, cortical blindness, and extrapyramidal and cerebellar signs.

The rates of Creutzfeldt-Jakob disease range from 0.25 to 2 cases per million persons a year worldwide. The infectious agent self-replicates and can be transmitted to humans by inoculation with infected tissues and sometimes by ingestion in food. Iatrogenic transmission has been reported via transplantation of contaminated cornea or to children via contaminated supplies of human growth hormone. Household contacts are not at greater risk than the general population, unless there is direct inoculation. Because of an epidemic of a newly recognized prion disease, bovine spongiform encephalopathy (mad cow disease), among cattle in the United Kingdom and because of the unexpected recent emergence of cases of an atypical form of Creutzfeldt-Jakob disease among teenagers in the United Kingdom, fears exist that transmission to humans may have occurred as a result of eating infected meat (Fig. 2.9-5).

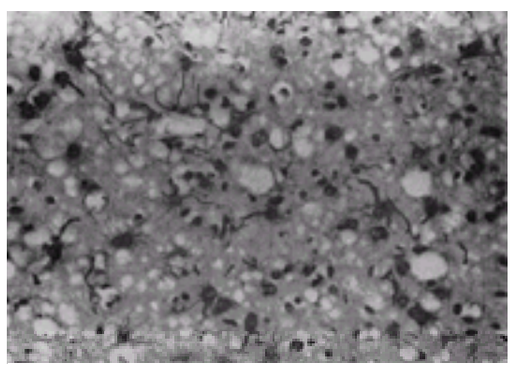

FIGURE 2.9-5 Creutzfeldt-Jakob disease. Section from cortex showing status spongiosis of the neuropil, loss of neurons, and prominent astrocytosis. (PTAH stain × 120). (Reprinted with permission from Jubelt B, Miller JR: Viral infections. In *Merritt's Textbook of Neurology*, ed 9, LP Rowland, editor. Williams & Wilkins, Baltimore, 1995.)

Diagnosis requires pathological examination of the cortex, which reveals the classic triad of spongiform vacuolation, loss of neurons, and glial cell proliferation. Genetic susceptibility is a factor in disease risk, indicated by a common polymorphism of the human prion protein. An immunoassay for Creutzfeldt-Jakob disease in the CSF is currently under development, showing promise in supporting the diagnosis of Creutzfeldt-Jakob disease in patients with dementia. EEG abnormalities, although not specific for Creutzfeldt-Jakob disease, are present in nearly all patients: a slow and irregular background rhythm with periodic complex discharges. Computed tomography (CT) and MRI studies may reveal cortical atrophy later in the course of disease; SPECT and PET reveal heterogeneously decreased uptake throughout the cortex. There is no known treatment for Creutzfeldt-Jakob disease.

OTHER INFECTIOUS CAUSES OF NEUROPSYCHIATRIC DISORDERS

A variety of bacterial, mycoplasmal, fungal, and parasitic infections can cause neuropsychiatric disturbances as a result of a chronic meningitis or sequelae from an acute infection (Table 2.9-1).

EMERGING AREAS OF INVESTIGATION

Chronic Fatigue Syndrome Chronic fatigue syndrome, more commonly referred to as *myalgic encephalomyelitis* in the United Kingdom and Canada, is a multisystem syndrome characterized by 6 months or more of severe, debilitating fatigue, often accompanied by myalgia, headaches, pharyngitis, low-grade fever, cognitive complaints, gastrointestinal symptoms, and tender lymph nodes. The search for an infectious cause of chronic fatigue syndrome has been active because of the high percentage of patients who report abrupt onset after a severe flu-like illness. In the mid-1980s chronic fatigue syndrome was linked to infection with Epstein-Barr virus. After EBV was shown in controlled studies to have no specific role in the etiology of chronic fatigue syndrome, reports have linked chronic fatigue syndrome to a variety of other agents, including enteroviruses, retroviruses, and new lymphotropic herpesviruses but these reports have not been consistently replicated in well-designed studies. Certain organisms, however, such as *B. burgdorferi* (which causes Lyme disease), can result in a chronic fatigue syndrome-like picture; however, most cases of CFS are not linked to Lyme disease. Evidence of immune dysregulation has been frequently reported among patients with chronic fatigue syndrome, but the data are not consistent across studies nor are they reflective of illness severity. Various studies have found high rates (15 to 54 percent) of depressive disorders among patients with chronic fatigue syndrome. In addition, recent research has shown that patients who are most likely to be plagued by persistent fatigue after an acute viral illness are patients with preexisting or comorbid psychiatric problems. However, other research has shown that the cognitive impairment in chronic fatigue syndrome exists even in the absence of preexisting or comorbid psychiatric disorders, thus leading to the conclusion that psychiatric disorders alone cannot account for chronic fatigue syndrome. At present, chronic fatigue syndrome is best conceptualized as a heterogeneous syndrome of uncertain etiology, most likely involving an interplay of psychiatric, infectious, neuroendocrine, and immunological factors.

Group A b-Hemolytic Streptococci Poststreptococcal autoimmunity has been postulated to be a cause of certain types of childhood-onset obsessive-compulsive disorders and Tourette's disorder based on the observation that children who develop Sydenham's chorea are often observed to have tics or obsessive-compulsive symptoms prior to the onset of the chorea. These *pediatric autoimmune neuropsychiatric disorders* are characterized by abrupt and dramatic symptom exacerbations that are temporally related to group A b-hemolytic streptococcal infections. Recent research has identified a genetic marker in pediatric autoimmune neuropsychiatric disorders that has previously been shown to be both highly specific and sensitive in identifying individuals with rheumatic fever. In one study 85 percent of children who developed streptococcal-related obsessive-compulsive disorder or tics and 89 percent of children with Sydenham's chorea carried the D8/17 monoclonal antibody marker on DR+ cells in the peripheral circulation, whereas only 17 percent of healthy controls carried this marker. Investigations are currently underway to determine whether treatments that modulate the immune response (e.g., intravenous g-globulin or plasmapheresis) are effective in eliminating obsessive-compulsive disorder and tic disorders among children with pediatric autoimmune neuropsychiatric disorders.

Borna Disease Virus Borna disease virus (BDV) is a small neurotropic ribonucleic acid (RNA) virus that infects various domestic animal species, causing disturbances in behavior and cognition and, rarely, death. Researchers have found that BDV targets cells of the limbic system in animals and compromises their neuronal function without causing direct damage. BDV has recently been linked to a wide array of neuropsychiatric disorders in humans. Evidence suggestive of BDV infection in humans has been accumulating from several research centers. One research group recently identified serum antibodies to BDV in 9.6 percent of 416 people with schizophrenia, major depressive disorders, bipolar I disorder, and other neuropsychiatric disease whereas these serum antibodies were found in only 1.5

percent of 203 healthy controls. Reverse transcriptase-PCR identified BDV RNA sequences in 13 of a subset of 26 psychiatric patients but in none of 23 healthy controls. Other reports have identified BDV antibodies in 6.8 percent of patients with psychiatric illnesses versus 3 percent of surgical controls. These studies represent provocative preliminary findings that suggest a possible role for BDV in a subset of human neuropsychiatric diseases; well-controlled microbiological and epidemiological studies are needed to determine the significance of these reports.

SUGGESTED CROSS-REFERENCES

Acquired immune deficiency syndrome is discussed in Section 2.8; interactions of the immune system and the CNS are discussed in Section 1.12; neuropsychological testing is discussed in Section 7.4; and neuroimaging is discussed in Section 2.13. Obsessive-compulsive disorder and schizophrenia are discussed in Chapter 15 and Chapter 12, respectively.

2.10 NEUROPSYCHIATRIC ASPECTS OF HEADACHE

KATHLEEN RIES MERIKANGAS, PH.D., AND JAMES R. MERIKANGAS, M.D.

Headache is one of the most common human afflictions. It is the condition that most often leads people to seek medical advice. Ten percent of all people report that headache leads to impairment in their daily life. It has dramatic impact on occupational and social disability and the use of health services. Despite substantial research efforts, the etiology of headache syndromes remains poorly understood. Because headache is commonly associated with psychiatric syndromes, psychiatrists are often consulted for the evaluation and treatment of people suffering from headache. The purpose of this chapter is to: (1) provide an overview of the current diagnostic nomenclature for the most common headache syndromes, (2) describe the clinical and laboratory examination necessary for making a diagnosis of headache, and (3) summarize current treatment strategies for the major headache syndromes.

DEFINITIONS

The International Headache Society (IHS) introduced a new headache classification system in 1988 (Table 2.10-1) in order to provide specific operational criteria for the major types of headache and to facilitate international standardization of the diagnostic nomenclature for headache syndromes. This classification system consists of a classification scheme and diagnostic criteria as well as guidelines for differential diagnosis. The criteria are intended to be applied to classify headache subtypes based on information obtained from a history, a physical and neurological examination, and appropriate laboratory investigations. This system has no category for “psychosomatic” or “psychogenic” headache because there has never been a valid demonstration that mental illness or life stress causes headaches. The most frequent primary headache syndromes are *migraine, tension-type headache*, and *cluster headache.* The other headache subtypes described in the IHS system are secondary to a variety of acute and chronic conditions. For a thorough clinical evaluation of headache it is essential to perform a differential diagnosis of the multiple causes of headache.

1. Migraine
2. Tension-type headache
3. Cluster headache and chronic paroxysmal hemicrania
4. Miscellaneous headaches unassociated with structural lesions
5. Headache associated with head trauma
6. Headache associated with vascular disorder
7. Headache associated with nonvascular intracranial disorder
8. Headache associated with substances or their withdrawal
9. Headache associated with noncephalic infection
10. Headache associated with metabolic disorder
11. Headache or facial pain associated with disorder of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cranial structures
12. Headache associated with cranial neuralgias, nerve trunk pain, and deafferentation pain
13. Headache not classifiable

Table 2.10-1 Headache Classification System of the International Headache Society

Migraine Migraine is a complex debilitating condition characterized by either the presence or absence of aura symptoms. Migraine presentation is multifaceted and symptoms emanate from multiple systems, including vascular, neurological, gastrointestinal, endocrine, and visual manifestations. These symptoms may be accompanied by a variety of changes in behavior and cognition, including mood alterations and confusion. Historically, the usual definitions of migraine included the presence of cyclic headaches associated with a variety of gastrointestinal and neurological symptoms. There is general agreement that a thorough evaluation is required for all patients who present with headache complaints.

The IHS criteria for migraine with and without aura are presented in Table 2.10-2 and Table 2.10-3. The core features of most definitions of migraine include recurrent headache, accompanied by gastrointestinal symptoms such as nausea or vomiting, and hyperesthesia manifested by photophobia or phonophobia. The headache generally has a pulsatile or throbbing quality exacerbated by routine physical activity involving movement of the head, and is often unilateral. The IHS criteria operationalize these features of headache to establish common thresholds and distinctions between migraine and other types of headache. Migraine was formerly divided into two major subtypes, *common* and *classic*, with the latter being distinguished by the presence of neurological symptoms that precede the onset of the headache. The new classification of migraine by the IHS no longer includes the common-classic distinction; instead migraine is subtyped according to the presence or absence of aura symptoms (reversible neurological dysfunction).

A. At least 5 attacks
B. Duration between 4 and 72 hours
C. At least 2 of the following:
   1. Unilateral
   2. Pulsating pain
   3. Moderate to severe intensity
   4. Worsening with exertion
D. One of the following:
   1. Nausea or vomiting
   2. Photophobia and phonophobia

Reprinted with permission from Olesen J: Classification and diagnostic criteria for headache disorders, cranial neuralgias and facial pain. Cephalalgia 8(Suppl):1, 1988.

Table 2.10-2 International Headache Society Criteria: Migraine Without Aura

A. At least 2 attacks that fulfill criteria in B and C
B. At least 3 of the following 4 characteristics:
   1. One or more completely reversible aura symptoms that indicate local cerebral cortical or brainstem dysfunction (or both)
   2. At least one aura symptom develops gradually over >4 min or two or more symptoms occur in succession
   3. No aura symptom; lasts >60 min
   4. Headache follows aura in <1 hour
C. No evidence of related organic disease

Reprinted with permission from Olesen J: Classification and diagnostic criteria for headache disorders, cranial neuralgias and facial pain. Cephalalgia 8(Suppl):1, 1988.

Table 2.10-3 International Headache Society Criteria: Migraine With Aura

Despite recent progress in the standardization of the classification of migraine by the IHS, the diagnostic criteria have not been subjected to intensive investigation with respect to reliability or validity. However, several studies currently under way are examining these issues. Several features unique to the headache syndromes constitute impediments to developing a valid set of diagnostic criteria. These impediments include: the co-occurrence of multiple headache syndromes within individual persons; the tendency for headache characteristics to change across the life span; the effects of professional and self-treatment of headache in obscuring the manifestations of the underlying headache syndromes; and the lack of generalizability of treated samples from which the diagnostic criteria were derived. Specific areas of the classification system require additional clarification; these are the specification of procedures for ensuring standardized methodology for the ascertainment of the diagnostic criteria, methods for assessing and coding multiple headache syndromes within individuals, and the development of standardized methods for discriminating between primary headache syndromes and those whose etiology is known (i.e., secondary headaches).

Tension-Type Headache The definition of tension-type headache according to IHS criteria is presented in Table 2.10-4. Tension headache is characterized by episodes of bilateral pain lasting several days at a time. It is distinguished from migraine headache by its generally longer duration, the lack of pulsating quality of the pain, the lack of worsening with physical activity, and the absence of gastrointestinal concomitants. However, migraine and tension-type headache may often coexist, either simultaneously or alternating over time. Tension-type headache is no longer believed to result from muscle tension; indeed, neck pain may result from head movement to reduce headache pain.

1. Episodic tension-type headache
   A. At least 10 previous headache episodes fulfilling criteria B-D listed below; number of days with such headache: <180/year
   B. Headache lasting from 30 min to 7 days
   C. At least two of the following pain characteristics:
      1. Pressing/tightening (nonpulsating) quality
      2. Mild or moderate intensity
      3. Bilateral location
      4. No aggravation by walking stairs or similar routine physical activity
   D. Both of the following:
      1. No nausea or vomiting (anorexia may occur)
      2. Absence of photophobia and phonophobia, or presence of one but not the other
2. Chronic tension-type headache
   A. Average headache frequency ≥15 days/month for ≥6 months (180 days/year) fulfilling criteria B-D listed below
   B. At least two of the following pain characteristics:
      1. Pressing/tightening quality
      2. Mild or moderate severity
      3. Bilateral location
      4. No aggravation by walking stairs or similar routine physical activity
   C. Both of the following:
      1. No vomiting
      2. No more than one of the following: nausea, photophobia, or phonophobia

Reprinted with permission from Olesen J: Classification and diagnostic criteria for headache disorders, cranial neuralgias and facial pain. Cephalalgia 8(Suppl): 1, 1988.

Table 2.10-4 International Headache Society Diagnostic Criteria for Tension-Type Headache

Cluster Headache Cluster headache is a distinct syndrome characterized by frequent attacks (often several per day) over a 1- to 2-month period, separated by headache-free intervals for as long as 1 or 2 years. Although it is commonly grouped with migraine, current evidence including epidemiological data, treatment response, and clinical features suggests that cluster headache may comprise a distinct syndrome. Table 2.10-5 shows the IHS diagnostic criteria for cluster headache.

A. At least five attacks fulfilling criteria B-D listed below
B. Severe unilateral orbital, supraorbital, or temporal pain lasting 15–180 min untreated
C. Association with at least one of the following signs, which must be present on the pain side:
   1. Conjunctival injection
   2. Lacrimation
   3. Nasal congestion
   4. Rhinorrhea
   5. Forehead and facial sweating
   6. Miosis
   7. Ptosis
   8. Eyelid edema
D. Frequency of attacks from one every other day to eight per day

Reprinted with permission from Olesen J: Classification and diagnostic criteria for headache disorders, cranial neuralgias and facial pain. Cephalalgia 8(Suppl): 1, 1988.

Table 2.10-5 International Headache Society Criteria: Cluster Headache and Chronic Paroxysmal Hemicrania

Cluster refers to a “clustering in time,” with the headache bouts occurring every day to several times a day over a period of days to weeks, followed by a lengthy headache-free interval. Cluster headache is generally retro-orbital in location and is accompanied by autonomic changes such as lacrimation, rhinorrhea, erythema of the eye, and agitation. Patients with cluster headache do not retire to dark rooms and lie down to avoid the stimulation; they may do quite the opposite, appearing almost manic in their agitation. The pain can be so intense that the sufferer may appear to be psychotic because of the screaming and thrashing that may be associated with the pain.

Chronic paroxysmal hemicrania is a type of cluster headache that is specifically responsive to treatment with indomethacin (Indocin) and characterized by many daily focal attacks of pain, each lasting for about 15 or 20 minutes.

Posttraumatic Headache Posttraumatic headache is variable in symptom presentation, severity, and duration. A set of diagnostic criteria was recently established by the IHS, in 1988, as presented in Table 2.10-6. The key symptoms include a headache following head trauma and accompanied by a loss of consciousness, posttraumatic amnesia, and abnormal laboratory tests.

A. Head trauma with at least 2 of the following:
   1. Loss of consciousness
   2. Posttraumatic amnesia >10 minutes
   3. Abnormal results in at least 2 of the following tests:
      a. neurological
      b. spinal fluid
      c. skull x-ray
      d. psychophysiological
      e. neuroimaging
      f. vestibular function
      g. ERP
B. Headache occurs <14 days after trauma or regaining consciousness
C. Headache continues (chronic) or disappears (acute) within 8 weeks after trauma or regaining consciousness

Reprinted with permission from Olesen J: Classification and diagnostic criteria for headache disorders, cranial neuralgias and facial pain. Cephalalgia 8(Suppl): 1, 1988.

Table 2.10-6 International Headache Society Criteria: Posttraumatic Headache

Although headache following a traumatic head injury has often been attributed to emotional factors, empirical evidence suggests that emotional factors are more likely

to be sequelae rather than causes of posttraumatic headache. Nevertheless, the etiology of posttraumatic headache is unknown. The major hypotheses of the pathogenesis of posttraumatic headache include cerebral edema, cortical spreading depression, innate vulnerability to cerebral vasospasm, and transient elevation of intracranial pressure. There is no direct relationship between the prevalence or chronicity of posttraumatic headache and several indicators of severity of head injury including duration of unconsciousness, posttraumatic amnesia, electroencephalographic abnormalities, presence of skull fracture, or the presence of blood in the cerebrospinal fluid. There appears to be an inverse relationship between the severity of the head injury and the development of postinjury headache; posttraumatic headache is more common after injuries that do not result in skull fracture.

The onset of typical migraine attacks following acute head trauma occurs so frequently that it has been hypothesized that head trauma serves as a trigger for migraine in persons with underlying susceptibility to migraine. There is a substantial body of literature suggesting that individuals with either a personal or family history of migraine are particularly susceptible to headache following head trauma. Moreover, relatives of persons who have posttraumatic migraine have a higher rate of neurological symptoms, suggesting a propensity to the neurological manifestations of migraine.

Epidemiology and Course Epidemiological studies have shown that approximately 60 percent of the general population report a history of severe headaches. Milder headaches are reported by about 80 percent of the general population. Migraine without aura and tension-type headache are the most common headache syndromes in the general population. The lifetime prevalence of migraine derived from systematic population surveys is about 12 percent. Epidemiological studies that have applied the IHS criteria reveal lifetime prevalence rates of approximately 6 percent among men (range of 4 percent to 19 percent) and 17 percent among women (range of 8 to 29 percent for women). The severity of migraine ranges from mild to nearly total disability. Over 80 percent of those with migraine report some degree of disability. Recent epidemiological studies have underscored the enormous personal and social burden of migraine in terms of both direct and indirect costs.

Migraine is more common among women and persons between the ages of 20 and 45 years, with the incidence decreasing after the fourth decade of life. Migraine may often begin in childhood when boys and girls are equally likely to suffer from migraine headache. Migraine in childhood is more likely to be associated with gastrointestinal complaints, particularly episodic bouts of stomach pain, vomiting, or diarrhea, and the duration is shorter than that commonly observed in adults. Children with migraine are often misdiagnosed as suffering from “psychosomatic headaches” or school refusal. In women, migraine is strongly associated with reproductive system function, with increased incidence during puberty and the first trimester of pregnancy; migraine is also associated with exogenous hormone use. After menopause, the frequency of migraine attacks generally decreases dramatically, unless estrogen replacement therapy is administered.

A family history of migraine is one of the most potent and consistent risk factors for migraine. Although migraine has been postulated to have an autosomal dominant mode of transmission, recent reviews of the genetic studies of migraine indicate that the mode of transmission has not been well established. However, approximately 30 percent of migraine patients have no family history of this condition.

Migraine is strongly associated with a variety of medical disorders, particularly asthma, allergies, and cardiovascular disease. Comorbid psychiatric conditions include mood disorders (particularly the bipolar subtype), phobias, and panic disorders. The course of migraine is variable. In general, the frequency and duration of migraine decrease at midlife in both men and women, and the symptomatic manifestations may change substantially over time.

Compared to studies of migraine, far fewer studies have investigated the epidemiology and risk factors associated with tension-type headache. The prevalence of tension-type headache has been estimated to range from approximately 30 to 80 percent depending on the definitions used. It is difficult to estimate the true prevalence of tension-type headache given that migraine and tension-type headaches may co-occur in the same individual. Tension-type headaches are also more common in women and young adults, but there is a less steep decrement in prevalence with age.

Although posttraumatic headache is quite rare in the general population (i.e., about 1 percent lifetime prevalence), it is not uncommon among those with a history of a concussion or head injury. The estimates of the prevalence of severe and long-term headache following severe head injury based on retrospective data range from 28 to 62 percent. Children and young adults appear to be particularly susceptible to developing headache after head trauma. The results of prospective studies of the incidence of headache following severe head injury, usually termed *postconcussion headache*, reveal that approximately 50 percent of each series of admissions continue to suffer from headache at the time of discharge from the index admission, with a gradual dissipation to 20 percent in 1 year. Persistence of headache has been related to female sex; age over 45; the presence of dizziness; lack of skull fracture; intracranial hematoma; disorders of smell, hearing, or vision; depression; and impaired concentration.

Cluster headache has a very low population prevalence (less than 1 percent of the general population) and occurs nearly exclusively in males. The age at onset of cluster headache is somewhat later than that of migraine and tension-type headache; the first attack of cluster usually begins in the late 20s or 30s and may recur intermittently throughout life; risk factors include smoking and heavy alcohol use.

ETIOLOGY

The causes of the major types of headaches are still unknown. Although progress in neuroimaging allows for the study of changes in blood flow and electrical activity during headaches, the widespread changes in neural and vascular function during the progression of headache have complicated the understanding of the primary event that triggers migraine. Migraine is believed to result from a combination of external trigger factors such as hunger, sensory input, and hormonal fluctuations that activate serotonin and norepinephrine-containing neurons in the brainstem. This activation alters the physiology of neurons, glia, and blood vessels, which provokes pain and generates neuroinflammatory mediators in the brainstem, thalamus, cerebral cortex, and supporting tissues. The activation of sensory vascular terminals within the blood vessel walls releases substance P and other neuropeptides that trigger a sterile inflammatory process, causing prolonged pain. Although disturbances in serotonin regulation are associated with migraine, numerous other brain chemicals, particularly the neuropeptides and nitric oxide, are also involved in a complex way. Far less is known about the etiology of tension-type headache. It is clear however, that the term *tension-type headache* is a misnomer because there is no evidence that muscle tension is the underlying cause of this headache subtype. Current theory of the cause of cluster headache holds that hypothalamic and central pain control regions trigger a cascade of events in the brainstem comprising afferent pain and efferent parasympathetic pathways.

DIFFERENTIAL DIAGNOSIS AND CLINICAL EVALUATION

A very skillful workup is essential because headache is a nonspecific complaint with an enormous number of causes that range from the trivial to the acutely life-threatening. A thorough examination should include a description of the type and location of pain, timing, precipitants, prodromal events, and associated symptoms. The following factors must be determined in order to define whether or not the headache is migrainous: (1) onset; (2) frequency; (3) location; (4) duration; (5) quality; (6) severity; (7) precipitants; (8) precursors; (9) triggers; (10) phenomena that worsen or relieve the pain; (11) warning signs; (12) prodromal events; (13) specific symptoms including visual changes, gastrointestinal symptoms, or neurological symptoms; (14) sensitivity to light, noise, sound, or touch; (15) mood changes; and (16) cognitive changes. In addition, it is important to obtain a detailed family history, description of course, and history of previous evaluation and treatment. Differential diagnosis of headache is based on a neurological examination to rule out pathognomonic signs that might indicate other brain disorders.

In addition to a history and physical examination, laboratory studies are crucial when metabolic, structural, vascular, or other sources of headache are suspected. Even if the results are negative and do not uncover a metabolic, endocrine, or autoimmune etiology, this information may serve as a baseline for subsequent drug therapy. Application of the IHS criteria require that all the potential causes of headache shown in Table 2.10-1 be considered. The diagnosis of headache requires the exclusion of other conditions, including structural lesion, vascular malformation, viral or bacterial meningitis encephalitis, intracranial abscess or hemorrhage, cerebral contusion, metabolic disorders (urea cycle disorders, aminoacidopathies, mitochondrial disorders), pseudotumor cerebri, vasculitis, brain tumors, sinusitis, and ocular disorders, any of which may be concurrent rather than causal.

Based on the low frequency of detection of lesions such as arteriovenous malformation or brain tumors, the American Academy of Neurology issued a practice parameter discouraging the routine use of neuroimaging procedures in patients with headaches who have normal neurological examination. However, headache experts, who often serve as tertiary referral sources, may ignore this recommendation because of the lack of diagnostic certainty in headache, lack of curative properties of current treatment, and unacceptable medical and legal risks of any missed diagnosis. Table 2.10-7 lists the headache symptoms that indicate further diagnostic workup.

• First headache
• Worst headache
• Gradual worsening over days or weeks
• Vomiting prior to headache onset
• Abnormal neurological examination
• Ongoing systemic illness
• Onset after age 50
• Accompanied by fever
• Occurs during sleep

Table 2.10-7 Headache Symptoms Indicating Further Diagnostic Workup

An image of the brain is mandatory for the evaluation of patients with severe or persistent headache, the first or worst headache, or when a subdural hematoma is suspected. Magnetic resonance imaging (MRI) is indicated when hydrocephalus, brain tumor, sinusitis, vasculitis, or posterior fossa lesions are suspected, or when exposure to electromagnetic radiation is contraindicated. X-rays of the jaw and cervical spine are useful to rule out malocclusions and the degenerative changes of arthritis.

TREATMENT OF HEADACHE SYNDROMES

Migraine The mainstay of migraine treatment is pharmacological intervention. Treatment of migraine can be prophylactic, with medication taken daily; abortive, with medication taken at the onset of an attack; or palliative, with medication taken after the pain has begun. Prophylactic treatments for migraine are of varying effectiveness. Clinical trials of migraine treatment are complicated by the high placebo response rate among subjects with migraine, the heterogeneity of diagnostic subtypes of headache, the intermittent nature of the condition, and the frequent use of additional analgesics to treat headache pain. The treatment of migraine chosen for an individual depends not only on the diagnosis of migraine headache but also on specific patient factors. Excellent reviews of both the short-term and prophylactic treatment of migraine are available. There are also a variety of nonpharmacological approaches to reduce headache. These include eliminating the triggers of attacks; maximizing the regularity of daily schedule, particularly with respect to sleeping and eating habits; biofeedback; and relaxation treatment.

Symptom Relief The nonsteroidal anti-inflammatory drugs (NSAIDs), including ibuprofen (Motrin), naproxen (Naprosyn), and indomethacin and the analgesics aspirin and acetaminophen (Tylenol) are commonly used as first-line treatment of mild to moderate migraine. In 1998 the Food and Drug Administration (FDA) approved an acetaminophen-aspirin-caffeine formulation (Exedrin) for the treatment of migraine. Other classes of drugs that are commonly prescribed for more severe attacks include ergot derivatives, serotonin agonists, and narcotics. Combination agents generally comprised of barbiturates, analgesics, and caffeine are also highly effective in the treatment of migraine episodes. Clinicians should be particularly alert to the potential of drugs such as ergotamine (Ergomar) and opioids being abused. In general, opioids should be restricted to severe attacks that are not responsive to other agents. Oxycodone-acetaminophen (Percocet) and oxycodone-aspirin (Percodan) are two of the most popular drugs among opioid addicts because oxycodone is short acting, effective orally, and a euphoriant with a high street value. With short-term use, however, opioids do not produce dependence. Ergotamine tartrate (Ergomar) and dihydroergotamine (DHE) are two of the most commonly prescribed ergot derivatives for moderate to severe attacks of migraine. In order to counterbalance the common adverse effect of nausea, metoclopramide (Reglan) or prochlorperazine (Compazine) are recommended.

Sumatriptan (Imitrex), a selective serotonin (5-hydroxytrytamine [5-HT]) subtype 1D (5-HT_{1D}) agonist, was introduced for self-administered parenteral treatment of acute, severe migraine. It is also available for oral administration and more recently as a nasal spray. Although relief from headache is almost instantaneous, the major criticism of this drug is the high frequency of rebound headache, which may be a function of the short half-life of the drug. The efficacy of sumatriptan has spurred the development of other serotonin agonists with attempts to reduce the adverse effects associated with sumatriptan. A new serotonin agonist, zolmitriptan (Zomig), administered in oral form, has recently been shown to be effective in the reduction of migraine. In general, the use of narcotics for the treatment of migraine should be restricted to a severe attack that is difficult to abort with other agents. Morphine usually is a better choice than the synthetic narcotics opioids such as meperidine (Demerol) and hydromorphone (Dilaudid).

Migraine Prophylaxis There are six major classes of drugs that have been investigated in the prophylaxis of migraine headaches. These include the b-adrenergic receptor antagonists, antidepressants, calcium channel blockers, serotonin antagonists, NSAIDs, and anticonvulsants. Table 2.10-8 presents the six classes of drugs used in migraine prophylaxis and a range of recommended daily doses. Use of the NSAIDs, particularly aspirin, on a daily basis may be highly effective in migraine prophylaxis. Similarly, antihypertensive drugs of the calcium-channel class or b-adrenergic receptor antagonists have also been widely employed to prevent migraine. Recent studies suggest that the angiotensin-converting-enzyme (ACE) inhibitors and enalapril (Vasotec) may also be effective in the prevention of migraine.

Drug	Daily Dosage (mg)
β-BLOCKERS	
Atenolol	50–150
Metoprolol	100–200
Propranolol	40–240
CALCIUM-CHANNEL INHIBITORS	
Flunarizine	5–10
Verapamil	240–320
SEROTONIN ANTAGONISTS	
Methysergide	4–8
Pizotyline	1–6
ANTIDEPRESSANTS	
Amitriptyline	10–150
Doxepin	10–150
Phenelzine	15–60
ANTIEPILEPTICS	
Sodium valproate	500–1500
NSAIDs	
Naproxen	550

Table 2.10-8 Prophylactic Treatment of Migraine

The b-adrenergic receptor antagonists are currently the most popular treatment choice in migraine prophylaxis. However, the effect of this class of drugs is moderate at best. No study has reported complete elimination of migraine; however, the average duration and severity are reduced by 50 percent in most subjects. Clinicians should be particularly cautious in prescribing this class of drugs to individuals with a history of depression, since b-adrenergic receptor antagonists are associated with the development of anhedonia, irritability, and lassitude, which may occur after many months on any of these agents. In contrast, patients with high levels of autonomic anxiety may actually benefit from this class of drugs.

Given the overlap of symptoms of the actual migraine episode, including short-term changes in energy, appetite, mood, and level of anxiety as well as those that occur between attacks, and those on the anxiety and depression spectrum, it is not surprising that similar pharmacological agents have been successfully used to treat migraine, anxiety, and depression. However, the antidepressant drugs, particularly the tricyclic drugs, have also been shown to be superior to the conventional first-line agents of migraine treatment irrespective of comorbid depression or anxiety. However, patients often report excessive sedation from tricyclic agents, as well as dry mouth, constipation, and weight gain. Combinations of these classes of drugs have also been used for patients who fail to respond to first-line treatments. Tricyclic drugs plus b-adrenergic receptor antagonists and tricyclic drugs plus monoamine oxidase inhibitors (MAOIs) have been used concomitantly in the preventive treatment of severe migraine. Use of tricyclic drugs other than amitriptyline (Elavil) should be encouraged because this agent is the most sedating of all of the drugs in this class. The secondary amines [e.g., nortriptyline (Aventil) and desipramine (Norpramin)] appear to be equally efficacious in the treatment of depression, but have fewer adverse effects than do the parent tertiary amines [e.g., amitriptyline, imipramine (Tofranil)]. However, the relative efficacy of tricyclic agents in migraine prevention has not been examined.

The MAOIs have also been reported to be efficacious in the prevention of migraine headache, particularly in patients who have been unresponsive to first-line

prophylactic treatment. Phenelzine (Nardil) has been considered to be one of the most efficacious antimigraine agents. However, clinicians have generally been reluctant to prescribe MAOIs because of the possibility of a hypertensive reaction to dietary tyramine and the other adverse effects of these agents (i.e., orthostatic hypotension, weight gain, and excessive stimulation). The use of oral calcium-channel blockers such as verapamil (Isoptin) to treat the hypertensive crisis associated with MAOIs may reduce clinicians' reservations about prescribing these agents. Addition of a b-adrenergic receptor antagonist such as atenolol (Tenormin) may reduce the cardiovascular adverse effects of phenelzine. In general, the doses of antidepressant agents that have been studied in migraine prophylaxis are far lower than those used in the treatment of depression.

Valproate (Depakene), which is currently a first-line treatment for bipolar I disorder, has also been used to treat both migraine and mood disorders. Recent evidence reveals that valproate may also be effective for migraine prophylaxis in patients who do not necessarily suffer from bipolar I disorder. Thus, valproate may be the treatment of choice in patients with migraine and bipolar I disorder or recurrent depression.

The strong association of migraine with both depression and anxiety should be considered in the treatment of individuals with migraine. Systematic evaluation of the lifetime history of depression and anxiety is necessary for determining the optimal treatment strategy. If there is a subtype of migraine associated with anxiety and depression, it is critical to treat the entire syndrome rather than to limit the treatment goal to headache cessation. In general, comorbid depression and anxiety are more important in the selection of migraine prophylaxis than in the treatment of an acute attack of migraine. The use of prophylactic medications with adverse effects of lassitude, fatigue, or depression should be avoided, if possible; if not, careful clinical evaluation of these cited manifestations of depression including anergia, hypersomnia, and irritability should be monitored. When nonpharmacological approaches have failed and the frequency and severity of migraine attacks lead to impairment in functioning, preventive treatment is indicated.

Tension-Type Headache Treatment of tension-type headache may be either pharmacological or nonpharmacological, depending on the frequency and severity of headaches. Nonpharmacological approaches such as biofeedback, massage, relaxation, cervical traction, chiropractic manipulation, hot packs, and cold packs have all been reported to be effective, although there are no convincing guidelines to suggest one modality over another. Similar to the short-term treatment of migraine, analgesics and the NSAIDs are the first-line treatment for tension-type headache. Aspirin is the most commonly used agent, followed by ibuprofen and naproxen. It is important to note that symptoms of tension-type headache may arise iatrogenically from drugs such as ergotamine used to treat migraine, often as a result of overuse of the drug. Up to 40 percent of chronic headache cases are associated with overuse of drugs intended to alleviate headache. A mixture of butalbital (a short-acting barbiturate), aspirin, and caffeine (Fiorinal) is frequently used by nonneurologists for treatment of headache. However, tolerance and drug dependence may occur. The treatment of chronic tension-type headache is similar to that of migraine; the most commonly used drug treatment for chronic tension-type headache is the tricyclic drug amitriptyline (100 to 150 mg per day).

Cluster Headache Prophylactic medicine is almost always indicated for treating cluster headache because of the extreme severity of pain induced by an acute attack, which often occurs at night. Inhaled oxygen, narcotics, and self-injected dihydroergotamine and sumatriptan are the most commonly used agents for the treatment of acute attacks. Medications that have been shown to be effective in preventing attacks of cluster headache are lithium (Eskalith), the corticosteroids, methysergide (Sansert), the calcium channel inhibitors and valproic acid (Depakote); combinations of these agents are often necessary to achieve success.

Posttraumatic Headache Posttraumatic headache is often treated on an emergency basis but long-term posttraumatic headache is commonly encountered in psychiatry. Steroids are often given immediately subsequent to the acute injury, and diagnostic imaging will reveal the presence of skull fracture or subdural hematoma. NSAIDS are the most commonly prescribed agents for headache that persists beyond the acute injury; thereafter, the prophylactic treatment approaches to migraine can be implemented.

2.11 NEUROPSYCHIATRIC ASPECTS OF NEUROMUSCULAR DISEASE

JAMES C. EDMONDSON, M.D., PH.D.

The sensory fibers of the peripheral nervous system transmit somatic and visceral sensory information from all parts of the body to the brain. The extraction of relevant sensory features from the totality of sensory experience begins in the peripheral sensory organs and is refined at all levels of the sensory pathway, most importantly in the brain. The peripheral somatic sensory fibers can be viewed as accurate point-to-point transmitters of data from the skin to the spinal cord, and the visceral sensory fibers as reporters of less precise localizing ability. Under ideal circumstances the peripheral fibers color the perception of touch as little as possible and therefore afford the central nervous system (CNS) as faithful an internal image of the external world as possible. However, peripheral fibers are susceptible to physical compression and metabolic insult, which can compromise the quality of their data transmission. For example, diabetes can slowly eliminate peripheral sensory fibers and reduce sensory acuity, and can cause aberrant sensations to be transmitted to the brain. How the CNS handles inaccurate sensory information is complex and is influenced by a person's psychological state. Depressed mood and anxiety tend to intensify unpleasant somatic sensations. Conversely, persons with somatoform disorders may perceive sensations that do not correlate with physical reality. This discussion defines the function of the peripheral nervous system and of its principal disease states, and describes their relationship to conscious experience.

ANATOMY

The peripheral nervous system contains motor and sensory fibers. Motor fibers conduct action potentials from the CNS to the muscles, where they trigger the contraction of muscle fibers. Sensory fibers carry information from the peripheral receptors to the CNS. In cross-section a peripheral nerve consists of fibers of various diameter; some are wrapped in a myelin sheath and others are unmyelinated. The fibers are grouped into fascicles and are enmeshed in connective tissue layers called *endoneurium, perineurium, and epineurium.* Nerves also contain blood vessels and small amounts of adipose tissue (Fig. 2.11-1). The functional unit is the nerve axon and its myelin sheath (Fig. 2.11-2). Without myelin, an action potential can be propagated along the nerve fiber at a rate of only 1 meter per second, whereas large myelinated fibers can conduct impulses at a rate of up to 70 meters per second. Peripheral nerve disease can affect the myelin, in which case conduction velocity is slowed, or it can affect the axon, in which case the amplitude of the action potential is reduced, or both.

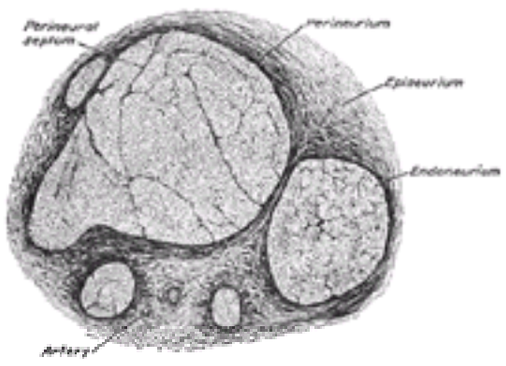

FIGURE 2.11-1 Cross-section of the sciatic nerve. Fascicles of myelinated and unmyelinated nerve fibers are enmeshed in endoneurium and are separated from other fascicles by perineurium. The outer layer of connective tissue is the epineurium, in which are embedded blood vessels and adipose tissue. (Reprinted with permission from Parent A: *Carpenter's Human Neuroanatomy*, ed 9. Williams & Wilkins, Baltimore, 1996.)

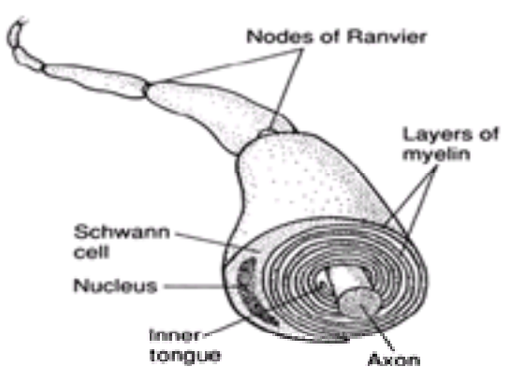

FIGURE 2.11-2 Representation of the axon and its myelin sheath. The inner tongue of Schwann cells wraps layers of hydrophobic myelin around the axon. Individual Schwann cells are separated about every 1 mm by a bare section of axon called the node of Ranvier. Action potentials jump from one node to the next, which increases the rate of propagation of the action potential. (Reprinted with permission from Kandel ER: Nerve cells and behavior. In *Principles of Neural Science*, ed 3, ER Kandel, JH Schwartz, TM Jessell, editors. Elsevier, New York, 1991. © 1996 by Appleton & Lange).

Each peripheral nerve corresponds to one or a few segments of the spinal cord. There are eight cervical spinal segments, twelve thoracic spinal segments, five lumbar spinal segments, and five sacral spinal segments. The skin monitored by nerves that enter a particular spinal segment is called a *dermatome*, and the muscles innervated by nerves exiting a particular spinal segment constitute a *myotome.* The posterior pattern of sensory dermatomes is shown in Figure 2.11-3. Once nerve roots in the cervical and lumbar regions leave the spinal canal, they converge and diverge in a plexus and emerge as the named peripheral nerves. The organization of the brachial plexus is shown in Figure 2.11-4, and a comparison of the innervation of the skin according to dermatome or named nerve is shown in Figure 2.11-5. It is usually possible to localize a lesion in the peripheral nervous system quite accurately by physical examination, noting the particular combination of sensory and motor defects produced by the lesion.

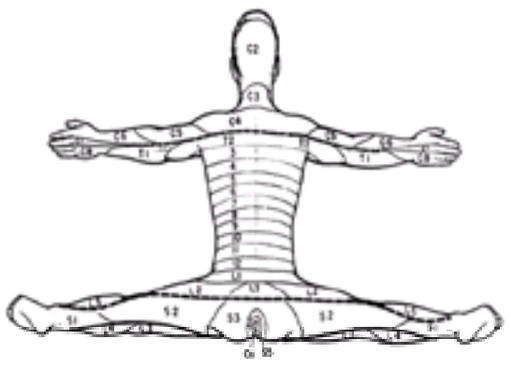

FIGURE 2.11-3 Posterior distribution of dermatomes. The arms expand the cervical dermatomes and the legs expand the lumbosacral dermatomes. (Reprinted with permission from Parent A: *Carpenter's Human Neuroanatomy*, ed 9. Williams & Wilkins, Baltimore, 1996.)

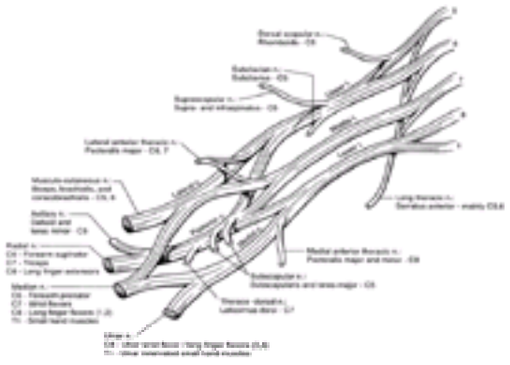

FIGURE 2.11-4 The brachial plexus. The cervical spinal roots are at the upper right. They first fuse to form three trunks *(t)*. Each trunk splits into an anterior and a posterior division, and these then fuse to form three cords *(c)*. The main named nerves of the arm *(n)* emerge from various segments of the brachial plexus. Each muscle is therefore innervated by a named nerve carrying fibers from a particular set of spinal roots. (Reprinted with permission from Oh SJ: *Clinical Electromyography: Nerve Conduction Studies*, ed 2. Williams & Wilkins, Baltimore, 1993.)

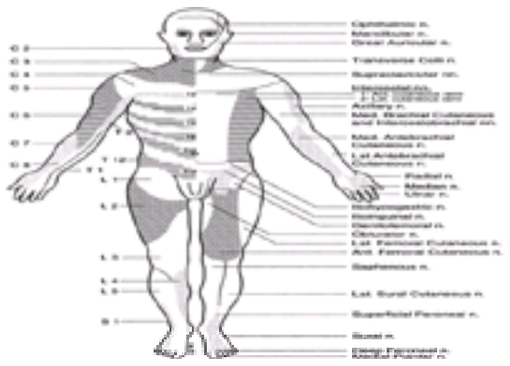

FIGURE 2.11-5 Anterior distribution of the dermatomes **(left)** and cutaneous areas supplied by named peripheral nerves **(right)**. Dermatomal patches overlap considerably with their neighboring dermatomes, whereas the distributions of peripheral nerves are sharply demarcated on the skin. (Reprinted with permission from Parent A: *Carpenter's Human Neuroanatomy*, ed 9. Williams & Wilkins, Baltimore, 1996.)

Motor fibers terminate on muscle fibers forming the neuromuscular junction. At the nerve terminus the action potential triggers the influx of calcium ions, which cause the release of acetylcholine from vesicular stores. Acetylcholine enters the synaptic cleft and binds to receptors on the muscle cell that trigger release of intracellular calcium and initiate contraction of the muscle fiber (Fig. 2.11-6). Acetylcholine is degraded and inactivated in the synaptic cleft by acetylcholinesterase, and the resulting acetic acid and choline are taken up by the nerve terminus and recombined into acetylcholine for storage in vesicles. Neuromuscular transmission is usually highly efficient, but it may be compromised in myasthenia gravis and other disorders of neuromuscular transmission.

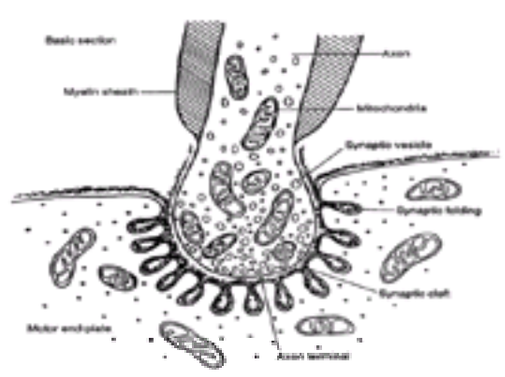

FIGURE 2.11-6 Cross-section of the neuromuscular junction. The nerve fiber terminus enters from the top and releases acetylcholine from synaptic vesicles. Acetylcholine diffuses through the matrix of the synaptic cleft to activate muscle contraction. (Reprinted with permission from Oh SJ: *Clinical Electromyography: Nerve Conduction Studies*, ed 2. Williams & Wilkins, Baltimore, 1993.)

Each motor nerve branches within the muscle and innervates a handful of muscle fibers. If a nerve ending dies, the resulting denervated muscle fibers initially exhibit spontaneous activity, then eventually are reinnervated by collateral sprouts of neighboring nerves; the resulting motor units cover an unusually large area (Fig. 2.11-7).

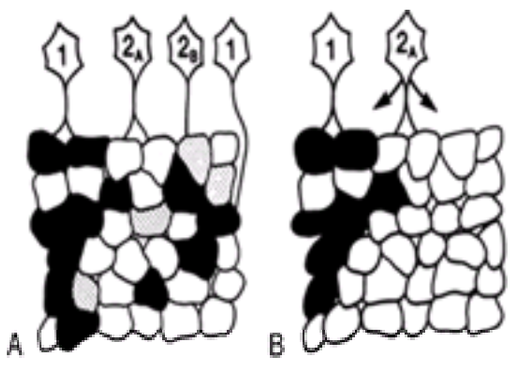

FIGURE 2.11-7 A, Normal muscle fibers have a mosaic pattern of innervation: in this figure, four individual nerve endings each branch to innervate a small subset of muscle fibers. A contiguous set of fibers constitutes a motor unit. Fibers are either type 1 (*black*), type 2_A (*white*), or type 2_B (*stippled*). The specific type of a given muscle fiber is determined by the nerve fiber that innervates it. The muscle fiber type may change if the fiber is re-innervated by a nerve fiber of a new specificity. **B**, After loss of nerve fibers, remaining nerve fibers sprout to create unusually large motor units. (Reprinted with permission from Poirier J, Gray F, Escourolle R: *Manual of Basic Neuropathology*, ed 3. Saunders, Philadelphia, 1990.)

PHYSIOLOGY

Nerve impulses are called *action potentials.* In the resting state the intracellular compartment of the neuron is negatively charged at a potential of –70 to –80 mV, but during an action potential the inside of the neuron becomes positively charged. For an action potential to be generated by a neuron, ion channels open and sodium ions begin to enter the cell, gradually making the inside of the neuron less negatively charged relative to the outside. The point at which the interior of the neuron is sufficiently less negatively charged to initiate an action potential is called the *spike threshold* and is characteristically approximately –60 mV. The action potential itself is a brief (0.1 to 2 msec) wave of reversal of membrane potential that moves along an axon (Fig. 2.11-8). During an action potential the interior of the neuron is positively charged in comparison with the outside of the neuron. The initial ion channel involved in the action potential is the Na+ channel, which, when opened, allows positively charged sodium ions to enter the neuron. The Ca_{2+} channels open next, allowing the positively charged calcium ions to enter the neuron and further contribute to the spike of the action potential. Entry of the calcium ion activates ion channels that carry an outgoing flow of potassium ions that are involved in arresting the action potential. The activation of these K+ channels results in the afterhyperpolarization of the neuron after an action potential. During the afterhyperpolarization the inside of the neuron is even more negatively charged than it was at baseline. The afterhyperpolarization contributes to the refractory period of a neuron after an action potential; during this period, another action potential cannot be generated.

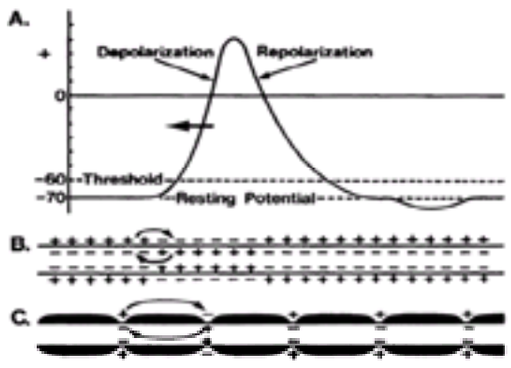

FIGURE 2.11-8 Phases of the action potential during its propagation. **A**, Changes in the membrane potential as the action potential moves from right to left. **B**, In unmyelinated fibers, an action potential triggers changes in the immediately adjacent membrane, called local circuit conduction. **C**, In myelinated fibers, the action potential jumps from one node of Ranvier to the next, called saltatory conduction. (Reprinted with permission from Oh SJ: *Clinical Electromyography: Nerve Conduction Studies*, ed 2. Williams & Wilkins, Baltimore, 1993.)

ELECTRODIAGNOSIS

Nerve Conduction Studies In clinical neurophysiological testing, a nerve action potential can be initiated by application of a brief electrical stimulus to the skin directly over the nerve, and the action potential may be recorded with surface electrodes. Thus, by stimulating the nerve at one point and recording the action potential at another point a defined distance away, a nerve conduction velocity can be calculated. Extensive studies have established reference values for each of the measurable nerves against which patient values can be compared. In the case of motor nerves, recording is usually made over the muscle, which has a much larger action potential amplitude than the nerve. In this case the time interval between the nerve stimulus and the muscle action potential includes both the time of conduction of the nerve action potential and the time of neuromuscular transmission. This interval is called the *latency.* If the point of stimulation is near the muscle, a distal latency is recorded, and if the point of stimulation is closer to the spinal cord, a proximal latency is recorded. The distal latency can be subtracted from the proximal latency to eliminate the factor of the time of neuromuscular transmission and isolate the nerve conduction velocity (NCV) (Fig. 2.11-9). Slowing of nerve conduction can be either focal, multifocal, or diffuse.

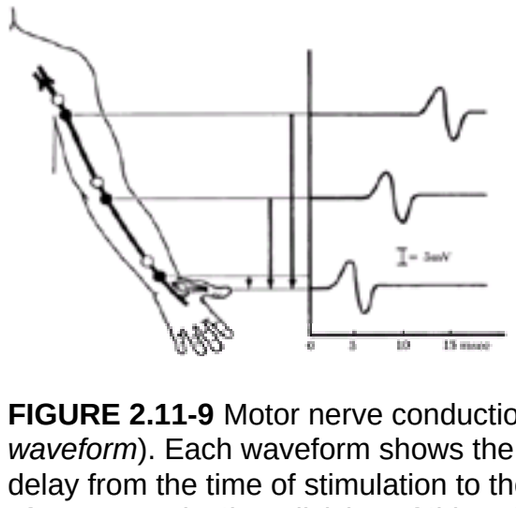

FIGURE 2.11-9 Motor nerve conduction study in the median nerve. The nerve is stimulated at the axilla (*top waveform*), elbow (*middle waveform*), and wrist (*bottom waveform*). Each waveform shows the muscle action potential recorded from the abductor pollicis brevis muscle as a function of time following nerve stimulation. The delay from the time of stimulation to the onset of the muscle action potential is the latency. Subtraction of the proximal latency from the distal latency isolates the time of nerve conduction; division of this value by the distance between the two points of stimulation gives the nerve conduction velocity. (Reprinted with permission from Oh SJ: *Clinical Electromyography: Nerve Conduction Studies*, ed 2. Williams & Wilkins, Baltimore, 1993.)

Electromyography The activity of individual motor units—the muscle fibers innervated by a single nerve ending—can be recorded with an electrode placed directly into the muscle. The morphology, amplitude, and duration of the muscle action potential are noted and compared to normal values. After nerve injury the first abnormal activity, noted at 2 to 3 weeks, is spontaneous firing of denervated muscle fibers. Over the following weeks to months, nerve endings sprout and reinnervate these muscle fibers, and spontaneous activity is replaced by motor unit potentials of very large amplitude and duration. In contrast, injury to muscle fibers themselves

produces brief, low-amplitude motor potentials (Fig. 2.11-10). Examination of 20 or more individual muscle fibers in a specific muscle can reveal whether there is an injury to the innervating nerve fiber at some point along its pathway, even if the nerve conduction velocity is normal. Electromyography therefore complements the nerve conduction velocity studies, and the combination of the two techniques usually permits a more exact localization and quantification of neuromuscular disease than is possible with physical examination alone.

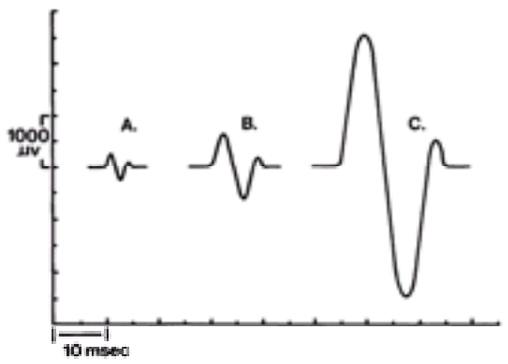

FIGURE 2.11-10 Motor unit potentials. **A**, Small amplitude and duration motor unit potential in myopathy. **B**, Normal motor unit potential. **C**,. Large amplitude and duration motor unit in neuropathy as a result of denervation, collateral sprouting, and reinnervation. COMMON NERVE COMPRESSION SYNDROMES

Carpal Tunnel Syndrome The median nerve travels from the distal arm into the hand through the carpal tunnel, which is a fascia-lined passage in the ventral wrist. Compression of the nerve at the carpal tunnel produces a characteristic set of symptoms and signs in the hands and arms. Carpal tunnel syndrome is more common among people who perform repetitive hand movements, such as typing, sorting mail, playing a keyboard instrument, or lifting heavy weights, but it may also occur in the absence of such repetitive stresses. The classic symptoms include pain, numbness, and tingling in the hands, which are worse in the morning. Patients with carpal tunnel syndrome may complain that items suddenly fall out of their hands. The complaints may extend up to the ipsilateral shoulder, neck, or side of the head, or down the leg. Some patients may be only vaguely aware of tingling somewhere in their body, yet may be very unsettled by the sensations. Physical examination may show decreased light touch in the median nerve distribution in the hand, weakness of the median-innervated abductor pollicis brevis muscle, positive Tinel's sign (tingling in the fingers caused by percussion over the carpal tunnel), or positive Phalen's sign (reproduction of the symptoms of carpal tunnel syndrome by sustained palmar flexion of the wrist). Nerve conduction studies first reveal slowing and loss of amplitude of the sensory fibers, then, in more advanced cases, slowing and occasionally loss of amplitude of the motor fibers. Electromyography of the APB muscle may yield normal results or may show signs of acute or chronic denervation. Conservative treatment consists of wearing splints that prevent palmar flexion of the wrist, especially at night. Antidepressant drugs may reduce or eliminate subjective tingling. If the symptoms do not begin to improve after 3 months of wearing splints, surgical release of the trapped median nerve is beneficial in about 80 percent of cases, although the symptoms may recur months to years later.

Compression of the Ulnar Nerve at the Elbow (Cubital Tunnel Syndrome) The ulnar nerve is prone to compression in the ulnar groove between the olecranon process of the ulna and the medial epicondyle of the humerus. The clinical symptoms and signs of ulnar neuropathy at the elbow are generally less well defined than in carpal tunnel syndrome, ranging from asymptomatic to sensory loss and rarely weakness in the ulnar-innervated pattern distal to the elbow. Patients may complain of tingling and numbness throughout the arm. Nerve conduction studies show a significant slowing of the ulnar nerve conduction velocity in the segment passing through the ulnar groove, either (1) as an isolated finding or (2) in association with carpal tunnel syndrome or a more diffuse peripheral neuropathy. There is no practical way to immobilize the elbow, but patients should be advised not to lean on their elbows. The tingling and numbness may be reduced with antidepressant medications. Surgical transposition of the ulnar nerve is successful in severe cases, but the rate of surgical failures exceeds 50 percent in some series.

Peroneal Palsy The peroneal nerve is vulnerable to compression as it passes over the head of the fibula, just distal and lateral to the knee. It may be injured because of pressure of the opposite leg when the legs are crossed above the knee, during improper positioning during surgery, or during immobilization of the leg in a cast. Sensory loss extends down the anterolateral surface of the leg and foot, and there may be complete or partial weakness of foot elevation and eversion. Nerve conduction studies show slowing or loss of conduction across the fibular head, and electromyography may show evidence of denervation of the peroneal-innervated muscles. Patients with peroneal palsy should wear an ankle-foot orthosis to prevent the toes from dragging as the leg swings forward. Recovery may take as long as 2 years, and is often incomplete. Antidepressant medications often reduce neuropathic pain significantly, whereas nonsteroidal anti-inflammatory agents are generally of little benefit. Physical therapy can assist the patient to adapt to the difficulties of ambulation.

Meralgia Paresthetica The lateral cutaneous nerve of the thigh passes under the inguinal ligament just before it reaches the skin, where it may be compressed by prolonged wearing of a heavy belt, such as a carpenter's belt. Compression may also arise spontaneously, particularly in obese individuals. Meralgia paresthetica—literally ‘tingling pain in the thigh'—describes the resulting sensations in a sharply delineated patch of skin on the lateral surface of the thigh extending down to the knee. Management begins with removal of the heavy belt or loss of weight. Antidepressant medications offer relief in most cases. Gabapentin (Neurontin) has also been used.

Of interest to psychiatrists is that Sigmund Freud suffered from meralgia paresthetica at age 39. He published a paper describing his experience with the disorder in which he described his symptoms. He attributed its cause to his habit of taking cold showers daily.

Radiculopathy Commonly described as a “pinched nerve in the neck or back,” true spinal radiculopathies are in fact a relatively rare cause of neck or back pain. The sensory or motor roots (or both) may be compressed by a herniated intervetebral disk or as they leave the vertebral column by bony prominences formed by degenerative changes. Sensory loss is in a dermatomal distribution, with vague borders caused by overlapping of neighboring dermatomes. Weakness occurs in a myotomal pattern, and there may be loss of characteristic deep tendon reflexes. Nerve conduction studies are usually normal, and electromyography may show signs of denervation and reinnervation in the first 3 to 4 months of compression. Neuroimaging, either magnetic resonance imaging or myelography with computed tomography, is essential. Conservative management is always indicated first, consisting of rest, muscle relaxers such as benzodiazepines, effective analgesia, heating pads, and nonstrenuous exercises. If conservative management fails to relieve the pain, and neurological deficits persist, referral to a neurosurgeon is indicated. In carefully selected cases where a nerve root is clearly compressed, surgical removal of the offending structure can provide definitive relief. It should be noted, however, that arthritic pain and muscle pain are far more common causes of low back pain than are true radiculopathies. According to the physiatrist John Sarno, 95 percent of low back pain is psychosomatic. The first approach to such uncomplicated low back pain is conservative management. Where surgery is not appropriate, several techniques have been developed for injection of steroids or local anesthetics in the epidural space, but the pain relief afforded by these methods is usually temporary, lasting sometimes just for a few hours and only for weeks to months in the most favorable of situations. Patients who develop chronic low back pain in the absence of demonstrable radiculopathy may benefit from weight loss, physical therapy, psychiatric support, and antidepressant medications.

ACQUIRED NEUROPATHIES

Peripheral nerves are vulnerable to several metabolic and infectious conditions. Prevention is the best approach to acquired neuropathies, as the ability of the nerves to regenerate is best in cases of trauma and worst in cases of metabolic injury.

Diabetes Mellitus Diabetes promotes thrombus generation in the tiniest capillaries, and it slowly eliminates peripheral nerve endings over several years. About 15 percent of patients with diabetes have symptoms and signs of peripheral neuropathy, but 50 percent have either neuropathic symptoms or slowing of nerve conduction velocity. The longest nerves are the most vulnerable, and symptoms usually begin in the feet. Several clinical forms are seen: (1) a distal, symmetrical, predominantly sensory painful neuropathy; (2) autonomic neuropathy; (3) a painful, asymmetrical multiple neuropathy, also called *mononeuropathy multiplex*; (4) acute mononeuropathies; and (5) diabetic ophthalmoplegia. The burning pain of the sensory neuropathy may respond to antidepressant or anticonvulsant medications. Tight control of plasma blood sugar can slow the progression of the neuropathy and reduce the symptoms.

Other Acquired Metabolic Neuropathies Several medical conditions producing diffuse damage to peripheral nerves include vitamin deficiency states, heavy metal poisoning, drug intoxications (including chronic use of lithium), uremia, collagen-vascular disorders, and paraneoplastic syndromes. The principal neuropathic syndromes are listed in Table 2.11-1.

Table 2.11-1 The Principal Neuropathic Syndromes

Postherpetic Neuralgia Herpes zoster can infect and remain dormant in dorsal root ganglion cells for as long as decades, and then may be reactivated under conditions of emotional stress or immune compromise. Reactivation of herpes zoster causes several days of burning, itching, and tingling, followed by the emergence of very painful blisters in a dermatomal distribution. These resolve in 1 to 4 weeks in most patients, but up to one third of patients may suffer pain for months and sometimes for years. The antiviral agents acyclovir (Zovirax), famciclovir (Famvir), or valacyclovir hydrochloride (Valtrex) may shorten the acute course. Antidepressant medications are most effective for chronic postherpetic neuralgia, and carbamazepine (Tegretol) may be useful for lancinating pains.

Guillain-Barré Syndrome *Acute inflammatory demyelinating polyneuropathy*, or *Guillain-Barré syndrome*, is a postinfectious, autoimmune condition in which antibodies elicited by an infectious agent cross-react with the myelin sheaths of the peripheral nerves. Inflammatory loss of myelin results in slowing and blockade of nerve conduction. Initially there is tingling in the toes, followed by loss of deep tendon reflexes and motor weakness affecting the longest nerves first. The weakness thus begins in the toes and appears to ascend over the course of a few days. Once a patient cannot walk, he or she should be admitted to an intensive care unit, closely monitored for respiratory distress, and mechanically ventilated if necessary. Recovery usually begins by the fourth week and may not be complete for months. Intensive inpatient rehabilitation may be necessary and the patient may need continuous psychiatric support during the recovery. Tingling, pain, and numbness may be treated with antidepressant medications.

Autonomic Neuropathies Hereditary and acquired damage to the autonomic nervous system may produce fluctuations in blood pressure, heart rate, temperature control, bowel and bladder function, or sexual function, all of which may resemble the effects of emotional instability. Patients may develop orthostatic hypotension upon rising from a seated or lying position and complain of persistent dizziness. Blood pressure may rise excessively in response to emotional stress, such as visits to the doctor (“white coat syndrome”). Patients with these symptoms may be considered to have hysteria, anorexia nervosa, or hypochondriasis. Careful medical evaluation of somatic and visceral complaints, including autonomic electrophysiological evaluation, should be done before a strictly psychiatric condition is diagnosed. Electrical evidence of autonomic neuropathy includes decreased beat-to-beat variability of the heart rate and absence of a sympathetic skin response.

CORRELATION OF COMPLAINTS AND ELECTRODIAGNOSTIC FINDINGS

Patients are referred for electrodiagnostic evaluation because their complaints of pain, numbness, tingling, and weakness are suspected to be caused by injury to the peripheral nerves. The most common referral is to determine whether a patient's signs and symptoms of CTS, which is a clinical diagnosis, correlate with electrodiagnostic evidence of nerve injury. The majority of patients with convincing signs of CTS on examination will have at least some electrodiagnostic abnormalities, usually prolongation of the distal sensory latency and reduction of the sensory amplitude. Some patients who are asymptomatic or barely symptomatic will nevertheless have very advanced sensory and motor nerve injury on electrodiagnostic studies. Conversely, some patients with prominent complaints and classical signs of CTS will have electrodiagnostic values completely within the normal range. Questioning such patients often reveals high levels of anxiety and depression, which appear to amplify the symptoms of even extremely minor nerve compression. Such patients often respond very satisfactorily to antidepressant medications.

MANAGEMENT

Diagnostic Workup History should emphasize the location and quality of the pain, whether it is constant or intermittent, how long it has been present, and whether it is improving, remaining steady, or worsening. Past medical history should cover diabetes, thyroid disease, autoimmune disease, cancer, and infections, and a thorough history of medication use. The physical examination should test muscle bulk and strength, all sensory modalities (light touch, pain, temperature, vibration, and position sense), and deep tendon reflexes, with particular attention to patterns of abnormalities that define a dermatome or the distribution of a particular named nerve. Electrodiagnostic studies can corroborate the clinical suspicion of neuropathy and quantitate the abnormalities. If a metabolic disorder is suspected, appropriate blood and urine tests should be ordered. If a radiculopathy that may be amenable to surgery is suspected, then high–field-strength MRI scanning of the spine is indicated.

Medical Treatments Any underlying medical condition such as diabetes, vitamin B_{12} deficiency, or thyroid disease must be vigorously treated. In some cases the neuropathic symptoms and signs will resolve upon adequate management of the underlying medical problem.

Surgical Options Surgical release of entrapped nerves is most effective for carpal tunnel syndrome and certain radiculopathies, and is less uniformly effective for ulnar neuropathies. Nerve ablation has been of benefit in trigeminal neuralgia, but should be avoided for other chronic pain syndromes. Although nerve ablation may temporarily cut off sensation to a painful area, secondary sensory routes often emerge and painful sensations therefore return.

Adjunctive Medications Regardless of the cause of neuropathic symptoms, the distressing pain, numbness, and tingling can be reduced or eliminated by antidepressant medications. Neurologists have traditionally relied on low doses of tricyclic drugs, especially amitriptyline (Elavil) and nortriptyline (Pamelor). Some studies have suggested that norepinephrine reuptake inhibition is more effective for pain control than is serotonin reuptake inhibition, but other data show no therapeutic advantage of tricyclic drugs over the newer antidepressant medications. The selective serotonin specific reuptake inhibitors (e.g., fluoxetine [Prozac], sertraline [Zoloft], paroxetine [Paxil], and fluvoxamine [Luvox], bupropion (Wellbutrin), nefazodone (Serzone), trazodone (Desyrel), venlafaxine (Effexor), and mirtazapine (Remeron) are probably all equally effective for neuropathic symptoms. Low dosages usually suffice, but higher dosages may be needed. Lancinating pain, such as that seen in some types of postherpetic neuralgia, may respond to the anticonvulsants carbamazepine (Tegretol) or phenytoin (Dilantin). A few uncontrolled studies have reported that gabapentin (Neurontin) reduces neuropathic pain, but controlled trials are needed to establish a role for gabapentin in the management of neuropathic pain. Dextromethorphan has been shown in one study to provide some relief of diabetic painful neuropathy. Psychotherapy for underlying depression and anxiety may be beneficial. Vitamin therapies have been widely discussed, particularly vitamins B_6 and B_{12}, but true vitamin deficiency states are quite rare in developed countries; massive quantities of vitamin B_6 can cause a sensory neuropathy. Alternative therapies, such as herbal medicines, meditation, or acupuncture, work to the extent that they elicit the placebo effect, which may be a powerful therapeutic modality in suggestible individuals.

SUGGESTED CROSS-REFERENCES

Chronic pain is discussed in Section 28.6. Psychosomatic disorders are covered in Chapter 25. Drugs used in psychiatry (including antidepressants and benzodiazepines) are discussed and organized pharmacologically in Chapter 31.

2.12 NEUROPSYCHIATRIC ASPECTS OF CHILD NEUROLOGY

JAMES C. EDMONDSON, M.D., PH.D.

Neurological disorders during infancy, childhood, and adolescence may adversely affect the acquisition of cognitive and emotional milestones. Developmental delays may profoundly influence the psychological state of both the affected individuals and their caregivers. Many of the neurological conditions discussed in earlier sections of this chapter appear in infantile and childhood forms. In addition, a large number of rare genetic disorders appearing only in infants and children have specific effects on behavior. A neuroscientific model is evolving, in which the brain's synaptic connections are dramatically molded by environmental influences during developmental windows of time in the first years of life. A growing body of investigations has confirmed that an individual's lifelong emotional repertoire reflects an internal representation of the reactions of caregivers in the first years of life, in the form of specific synaptic networks that remain relatively stable after the developmental windows have closed. The diagnosis and treatment of biochemical and physiological disorders of the developing nervous-system—the province of child neurology—therefore has begun to yield insights into the biological basis of behavior.

The clinical neurological approach to infants and children includes localization and identification of the lesion, including determining whether a disorder is genetic or acquired. The diagnosis is synthesized from history, physical examination, neuroimaging, and laboratory tests. Many of the rules of neurological localization that have been finely determined for adults apply with equal accuracy to children, but the developing brain is generally capable of greater plasticity. For example, children may recover more rapidly and more completely from a stroke involving a specific region of the cortex, because the developing brain can more readily redistribute mental functions to unaffected regions of the brain.

PRINCIPLES OF BRAIN DEVELOPMENT

The adult brain consists of approximately 10_{11} neurons, each of which receives on average 10_3 to 10_4 synapses from 10_3 other neurons. The study of the development of the nervous system is an actively evolving body of knowledge. In the brain, the life cycle of a neuron consists of cell birth in circumscribed proliferative zones, migration to the adult position, extension of an axon, elaboration of dendrites, synaptogenesis, and finally the onset of chemical neurotransmission. At the peak of neuronal proliferation in the middle of the second trimester of gestation, 250,000 neurons are born each minute. Postmitotic neurons migrate to their adult locations in the cortex, guided by glial fibers (Fig. 2.12-1). Glial-guided neuronal migration in the cerebral cortex occupies much of the first 6 months of gestation. In the cerebellum, glial-guided neuronal migration continues through the second postnatal year. Some neurons in the prefrontal cortex migrate over a distance 5000 times the diameter of the neuronal cell body. Radial migration forms cortical columns that function as a unit in processing tasks (Fig. 2.12-2). Neuronal migration requires a complex set of cell-cell interactions, and it is susceptible to errors, in which neurons fail to reach the cortex and instead reside in ectopic positions. A group of such incorrectly placed neurons is called a heterotopia (Fig. 2.12-3). Neuronal heterotopias cause epilepsy and are highly associated with mental retardation. In a classical neuropathological study of four patients with dyslexia, for example, heterotopias were common. Heterotopias in the frontal lobe have been postulated to play a causal role in some cases of schizophrenia. Cortical neuronal migration abnormalities have been found in some people with autism, smaller cortical structures in people with Down syndrome, larger basal ganglia in people with schizophrenia, hypoplastic basal ganglia in people with Tourette's disorder, and hypoplastic cerebellar structures in numerous developmental disorders. Normal cerebral asymmetries appear to be disrupted in a number of disorders, including schizophrenia, Tourette's disorder, attention-deficit disorders, and reading disorder. Table 2.12-1 relates developmental events to severe malformations.

Days of Gestation	Event	Effect of Toxic Stimulus
0-18	Three germ layers elaborate and early neural plate forms	No effect or death
18	Neural plate and groove develop	Anterior midline defects (18–25 days)
22–23	Optic vesicles appear	"Induction" hydrocephalus (18–40 days)
24–26	Anterior neuropore closed	Anencephaly (after 25 days to 5)
26–28	Posterior neuropore closed; ventral horns form	Cranium bifidum, spina bifida cystica, spina bifida occulta (after 26 days to ?)
28–32	Anterior and posterior motor roots form	
32	Cerebellar primordium; vascular circulation	Microcephaly (30–130 days); cellular proliferation anomalies (30–175 days); migration anomalies (50 days to completion of development of each brain subdivision)
33–35	Prosencephalon cleaves to form paired telencephalon, four cerebral vesicles, choroid plexi, dorsal root ganglion development	Holoprosencephaly
41	Region of olfactory bulb appears in forebrain	Arhinencephaly
56	Differentiation of cerebral cortex, meninges, ventricular system, CSF circulation	Dandy-Walker syndrome
70–100	Corpus callosum	Agenesis of corpus callosum
70–150	Primary fissures of cerebral cortex; spinal cord ends at L3 level	Lissencephaly; pachygyria
140–175	Neuronal proliferation in cerebral cortex ends	Defects of cellular architectonics, myelin defects (175 days to 4 years postnatally)
7–9 months	Secondary and tertiary sulci	Destructive pathological changes first noted
175 days to 6 years postnatally	Neuronal migrations; glial cell proliferation; myelin formation; asymmetric and unidendritic synaptic connections; spinal cord ends L1–L2 level

Each column responds to a specific stimulus as a functional unit. (Reprinted with permission from Rakic P: Specification of cerebral cortical areas. Science *241:*170, 1988.)

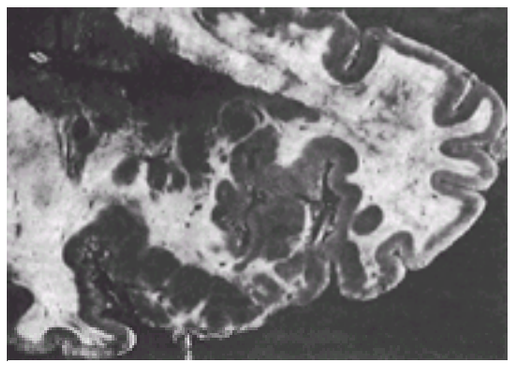

FIGURE 2.12-3 Heterotopic neurons. In addition to the neurons of cortex, visible along the gyri and sulci, large nests of neurons are located aberrantly along the ventricular wall. Heterotopic neurons may generate seizure activity. (Reprinted with permission from Layton DD: Heterotopic cerebral gray matter as an epileptogenic focus. J Neuropathol Exp Neurol *21:*244, 1962.)

Many neurons lay an axon down as they migrate; others do not initiate axon outgrowth until they have reached their cortical targets. Elaboration of a characteristic branched dendritic tree occurs once the neuron has completed migration (Fig. 2.12-4). Synaptogenesis occurs at a furious rate from the second trimester through the first 10 years or so of life. The peak of synaptogenesis occurs in the first 2 postnatal years, when as many as 30 million synapses form each second. Ensheathment of axons by myelin begins prenatally, proceeds most rapidly in early childhood, and reaches its full extent late in the third decade of life (Fig. 2.12-5). Glucose utilization, protein synthesis, and cellular metabolic rates in the brain reach their highest levels in the first decade of life, as the brain forms its adult intercellular connections (Fig. 2.12-6).

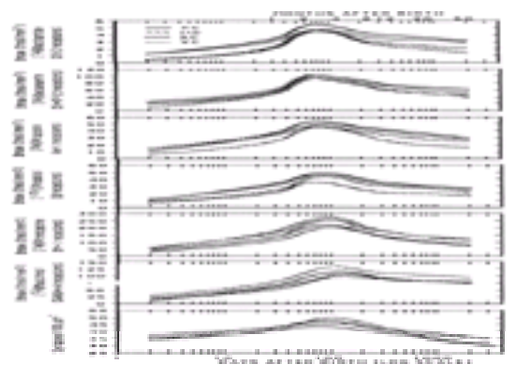

FIGURE 2.12-6 Developmental changes in the density of synapses and receptors in the prefrontal (*PC*), primary motor (*MC*), somatosensory (*SC*), and primary visual (*VC*) cortical regions. Age is presented in postnatal days on a logarithmic scale. Density of synapses is greatest at 2 to 4 months of age, then it declines as functionally irrelevant synapses are pruned according to experience. (Reprinted with permission from Rakic P: Development of the cerebral cortex in human and nonhuman primates. In *Child and Adolescent Psychiatry: A Comprehensive Textbook*, ed 2, M Lewis, editor. Williams & Wilkins, Baltimore, 1996.)

The effect of experience on the formation of brain circuitry in the first years of life has generated a tremendous interest among neuroscientists. There are clear examples of the impact of early sensory experience on the wiring of cortical sensory processing areas. Similarly, early movement patterns are known to reinforce neural connections in the supplemental motor area. A common mechanism has emerged, in which neurons rapidly form a roughly fivefold excess of synaptic connections, then, through a Darwinian process of elimination, only the synapses that serve a relevant function persist. Synaptic pruning appears to preserve input in which the presynaptic cell fires in synchrony with the postsynaptic cell. This serves to reinforce neural circuits that are activated repeatedly. Neuroscientists assume that, as demonstrated experimentally in sensory and motor areas, experience plays a critical role in the modulation of the synaptic connectivity of cognitive and emotional association areas.

An emerging concept of great significance to both child and adult psychiatry is the existence of early windows of time, during which the brain establishes the basic circuitry for language, emotion, logic, mathematics, movements, and music. These windows open within the first few months of life and may close in some cases by 1 year of age. For example, a perceptual map of phonemes, the building blocks of language, is formed within the higher auditory processing areas of Wernicke's area during the first 12 months of life. The significance of this perceptual map is illustrated by the fact that certain sounds used by non–English-speaking peoples are not found in English. Studies have shown that American babies less than 6 months of age can be taught to discriminate these non-English sounds, but babies older than 6 months are no longer capable of hearing them. Moreover, the map for English differs from that for Japanese, for example, in the location of neurons that respond to the sounds “ra” and “la.” In English, these neurons are located far apart within the auditory cortex, whereas in the Japanese brain, which has difficulty distinguishing these sounds, they are so closely intertwined as to be virtually overlapping. Thus, to a Japanese individual, /la/ and /ra/ elicit nearly the same pattern of neural activity, a fact that may underlie the difficulties of the Japanese in distinguishing these sounds. In the English language, studies have shown that babies of mothers who spoke loquaciously to them acquired a larger vocabulary than babies of taciturn mothers. These findings suggest that very early experiences may establish the density and fidelity of neural circuits for specific perceptual functions, the consequences of which may affect individuals for the rest of their lives.

In the realm of emotion, early childhood experiences have been suspected to be at the root of psychopathology since the earliest theories of Sigmund Freud. Franz Alexander's psychoanalytic method aimed at tracing the threads of the earliest childhood memories to allow the patient to relive them in a less pathological environment, a process he termed a “corrective emotional experience.” While neuroscientists have no data yet to bring this method down to the level of neurons and circuits, emerging results demonstrate a profound effect of the reactions of early caregivers on an adult individual's emotional repertoire. For example, *attunement* is defined as the process by which caregivers play back a child's inner feelings. If a baby's emotional expressions are reciprocated in a consistent, sensitive manner, then certain emotional circuits are reinforced. These circuits likely include the limbic system, and in particular, the amygdala, which serves as a gate to the hippocampal memory circuits for emotional stimuli. In one study, for example, a baby whose mother repeatedly failed to mirror her level of excitement emerged from childhood an extremely passive girl, who was unable to experience a thrill or joy. The ability to learn and to respond to psychotherapy in adulthood must involve reorganization of synaptic connections. Such reorganization, as documented by functional neuroimaging, may progress over weeks to months.

The relative contributions of nature and nurture are perhaps nowhere more indistinct than in the maturation of emotional responses. In part, this is because the localization of emotion within the adult brain is only poorly understood. However, it is reasonable to assume that the reactions of one's caregivers in the first years of life are eventually internalized as distinct neural circuits, which may be only incompletely subject to modification through subsequent experience. For example, axonal connections between the prefrontal cortex and the limbic system, which very likely play a role in the modulation of basic drives, are established between ages 10 and 18 months. Recent work suggests that a pattern of terrifying experiences in infancy may flood the amygdala and drive memory circuits to be specifically alert to threatening stimuli, at the expense of circuits for language and other academic skills. Thus, infants raised in a chaotic and frightening home may be neurologically disadvantaged for the acquisition of complex cognitive skills in school.

Results documenting the organizing effect of early experiences on the internal representation of the external world have been found in the related realms of mathematics, logic, and music. A series of recent studies have shown that groups of children who were given 8 months of intensive classical music lessons in the preschool years subsequently showed significantly better spatial and mathematical reasoning than a control group. In grade school, nonmusical tasks such as navigating mazes, drawing geometric figures, and copying patterns of two-color blocks were performed significantly more skillfully by the musical children. Early exposure to music may thus be an ideal preparation for later acquisition of complex mathematical and engineering skills.

These observations suggest a neurological basis for the developmental theories of Jean Piaget, Erik Erikson, Margaret Mahler, John Bowlby, Sigmund Freud and others. Erikson's epigenetic theory states that normal adult behavior results from the successful, sequential completion of each of several infantile and childhood stages. According to the epigenetic model, failure to complete an early stage is reflected in subsequent physical, cognitive, social, or emotional maladjustment. By analogy, the experimental data discussed above suggest that early experience, particularly during the critical window of opportunity for establishing neural connections, primes the basic circuitry for language, emotions, and other advanced behaviors. Clearly, miswiring of the brain in infancy may later lead to severe handicaps when the individual attempts to relate to the world at an adult level. Brain development is achieved through the molecular interactions of thousands of gene products. Neurological disorders of infancy and childhood resulting from genetic mutations or from influences external to the brain therefore may hinder the proper emergence of mature emotional reactions.

CLASSIFICATION OF NEUROLOGICAL DISORDERS

An abnormality of mental function due to a neurological condition is called an encephalopathy. Encephalopathies are broadly defined as *static* or *progressive*. Patients with static encephalopathies gain developmental milestones at a slower rate than normal age-matched controls but do not lose abilities they have acquired. *Progressive encephalopathies* are characterized by a loss of milestones and are prognostically much more ominous. Either type of encephalopathy may be due to a genetic defect or to an acquired condition, such as infection, trauma, asphyxia, or tumor. Genetic variants that encode defective versions of crucial organellar proteins may prevent the proper maintenance of cellular homeostasis and may lead to accumulation of toxic molecules, on a time-scale of days, months, or years. Examples of these disorders include lysosomal storage diseases, mitochondrial disorders, peroxisomal disorders, and metal transport disorders. Compromise of the vascular supply to the brain caused by stroke or hypotension can interfere with cellular metabolism and produce permanent neuronal damage. Infectious agents can injure neurons directly or indirectly, as a result of an excessive immune response. Space-occupying lesions can disrupt neuronal activity by interrupting intercellular pathways or by compromising the blood supply.

Disorders of the gray matter are called *poliodystrophies* and are characterized by dementia and seizures. Disorders of the white matter are called *leukodystrophies* and are characterized by spasticity, ataxia, and optic atrophy. Many progressive encephalopathies contain features of both gray and white matter disease. Storage diseases consist of accumulations of unmetabolized waste products, which may be found in any of a large number of cell types. The combination of specific cell types in which storage products accumulate determines the neurological deficits.

The age of the patient at the time of an acquired insult and the extent of the insult are the main determinants of the prognosis of an acquired encephalopathy. Younger patients are more susceptible to infection and metabolic stress, but they are also more resilient than older patients in that they generally can recover more previous function after a comparable insult. Premature birth is a major cause of static encephalopathy, and there is a strong correlation between low birth weight and delays in cognitive and emotional development.

NEUROLOGICAL ASSESSMENT

Neurological assessment consists of a thorough history beginning with conception and proceeding through pregnancy, birth, early neonatal course, subsequent hospitalizations, chronic medical conditions, acquisition of milestones in each category of normal development, medications, allergies, family history including consanguinity, social history, and review of systems (Table 2.12-2). Neurological examination includes mental status examination, cranial nerves, motor system, associated motor system (coordination), sensory system, and reflexes. The neurological examination must be tailored to the age and abilities of the infant or child. Normal development is assessed in the categories gross motor, fine motor, speech and language, and social/adaptive. In younger patients, assessments often rely

more on observation and play interactions than on direct questioning. Subtle adaptive deficiencies may be missed in very young children even with detailed testing and may only become apparent as the age-appropriate context becomes more complex.

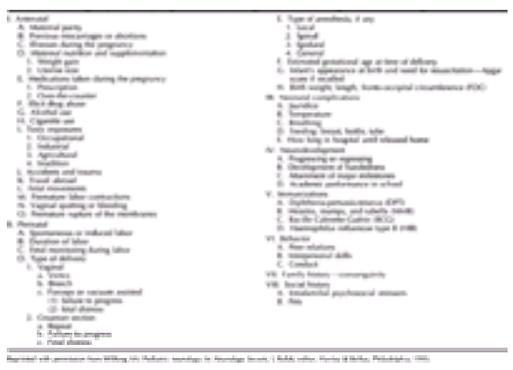

Table 2.12-2 Pediatric Neurological History

Standardized tests of neuropsychological functions may help discriminate between adaptive disorders and primary psychiatric conditions. Parents are the best sources of information about a child's behavior, and confirmatory assessment by teachers or other caregivers may yield important clues to a child's behavioral repertoire.

STATIC ENCEPHALOPATHIES

Static encephalopathies result from either acute insults to the developing brain that damage brain cells or a genetic deficiency that renders information processing abnormally inefficient but does not cause storage of metabolic products or ongoing cellular damage. Static encephalopathies are much more common than progressive encephalopathies, yet they are much less likely to have a specific identifiable cause. In the absence of neurocutaneous stigmata, a thorough diagnostic evaluation for static encephalopathies is usually fruitless.

Prematurity The ability to support the survival of premature infants who weigh as little as 450 grams at birth represents one of the technological triumphs of medicine. Longitudinal studies following the neurodevelopmental progress of premature infants for 10 and more years, however, have found very high rates of developmental delay and mental retardation among infants born prematurely. These delays have been attributed to a combination of the same high-risk factors that may have led to the premature birth (low socioeconomic status, lack of prenatal care) and, more importantly, to the intensive medical interventions necessary to sustain the extrauterine life of underdeveloped babies (high ventilatory pressures, tube feeding, and broad-spectrum antibiotics).

Classification Low birth weight is defined as less than 2500 grams, very low birth weight is defined as less than 1500 grams, and extremely low birth weight is defined as less than 1000 grams. The main factor determining the morbidity and mortality of premature infants is their pulmonary status: immature lungs can only oxygenate the blood sufficiently when ventilated at high pressures. These pressures increase the intrathoracic pressure and in turn increase the intracranial venous pressure, which may cause hemorrhage of blood from the capillaries of the germinal matrix of the brain. In other patients, the lungs cannot oxygenate the blood at any pressures, and the blood oxygen concentrations fall so low that irreversible neuronal damage occurs. A comparable mechanism of hypoxic-ischemic injury in a full-term newborn is birth asphyxia (Fig. 2.12-7). Each of these conditions is strongly associated with subsequent development of a static encephalopathy.

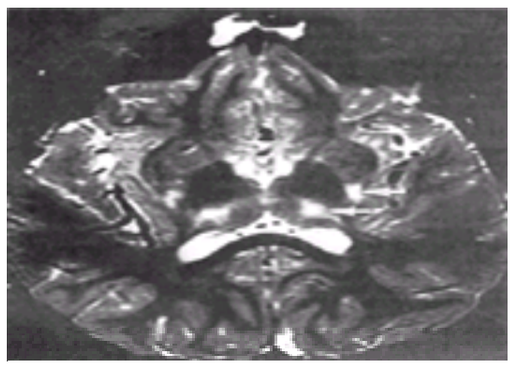

FIGURE 2.12-7 Axial T2-weighted MRI image at the level of the thalamus, illustrating bilaterally symmetrical hyperintensities in the thalamus (*arrows*). These scars are the result of severe hypoxic-ischemic injury due to birth asphyxia. At age 6 years, this child had predominantly choreoathetotic cerebral palsy and low-normal intelligence. (Reprinted with permission from Menkes J: *Textbook of Child Neurology*, ed 5. Williams & Wilkins, Baltimore, 1995.)

Intracranial Hemorrhage Four grades of intracranial hemorrhage in premature infants are recognized. *Grade I* consists of hemorrhage due to high venous pressures limited to the germinal matrix; in *grade II*, blood also bursts into the adjacent lateral ventricle but does not cause ventricular dilatation, and *grade III* occurs when the ventricles dilate because the intraventricular blood clogs the drainage of cerebrospinal fluid. *Grade IV*, in a contrasting mechanism, results from hypoxic-ischemic injury to cerebral blood vessels in states of very low blood oxygen tension and low blood pressure. When blood at normal pressures subsequently reperfuses damaged vessels, it leaks into the brain in several areas. In extreme cases, large regions of cortex are destroyed, leaving cerebrospinal fluid–filled cysts.

Neurodevelopmental Outcome Very-low-birth-weight babies are 8 times more likely to have mental retardation and 24 times more likely to have movement disorders known as cerebral palsy than are full-term babies. The types of cerebral palsy are spastic quadriparetic, spastic diplegic, hemiplegic, pseudobulbar, and choreoathetotic. Several longitudinal studies have documented an average lowering of intelligence quotient (I.Q.) scores of 6 to 14 points in cohorts of very low birth weight infants. Among extremely low birth weight infants, as many as 50 to 80 percent required some level of special education by age 10 years, compared with 15 percent of full-term infants by the same age. In infants who suffered intracranial hemorrhage, grades I and II generally were not associated with additional cognitive delays, but grade III and especially grade IV hemorrhages posed a considerable increased risk of scholastic underachievement during childhood.

Expremature infants register higher scores on scales of childhood anxiety, depression, social isolation, conduct disorder, and aggressivity. The best predictors of these outcomes is degree of prematurity, whereas neurological evaluations or cranial ultrasonograms in the neonatal period are not predictive of emotional outcome. In general, premature infants are rated less temperamental as young toddlers, but as late toddlers they are rated more withdrawn and more prone to tantrums. In childhood, 5 to 35 percent of expremature infants fit the diagnostic criteria for attention-deficit/hyperactivity disorder, compared with 3 to 15 percent of ex–full term infants. Particular reasons for this increased risk of attention-deficit/hyperactivity disorder among expremature infants may include the fact that low socioeconomic status is associated with both prematurity and attention-deficit/hyperactivity disorder. Another possible reason is that the germinal matrix in which hemorrhages occur in premature infants later gives rise to the caudate nucleus, which has been increasingly implicated in the pathogenesis of attention-deficit/hyperactivity disorder in neurobiological studies.

Strokes Prenatal strokes most commonly occur in the distribution of the middle cerebral artery and therefore damage the frontal and parietal lobes. The most common presenting features are seizures and hemiparesis. In longitudinal follow-up studies, mean I.Q. was in the normal range, but the laterality of the lesion did correlate with lower scores on specific subtests: left middle cerebral artery infarctions reduced verbal I.Q. scores, while right middle cerebral artery infarctions lowered nonverbal I.Q. scores. Studies of hemispherically injured infants have suggested, with variable consistency, that the adult model of hemispheric localization of emotional responses, in which activation of the left frontal lobe raises mood and activation of the right frontal lobe depresses mood, is evident even below the age of 1 year. Other data appear to contradict this model: lesions that inactivate the right frontal lobe in children unexpectedly elicit more-negative behavior. The frontal cortex

has various specialized regions that play largely unknown roles in the expression of emotions, and the clinically documented lesions have not yet been systematically characterized to allow specific correlation between lesion site and behavioral manifestation, even in adults. At this time, no generalizations can be made from longitudinal studies regarding the emotional consequences of prenatal and childhood ischemic injuries. Children with cognitive and motor disabilities caused by strokes use special education resources much more than children who have not had strokes, and they are more susceptible to a range of psychiatric symptoms, especially depression.

Chromosomal Anomalies The genetic basis of behavior is only beginning to be understood. Epidemiological studies have suggested a significant heritable component to all major psychiatric disorders. Most static encephalopathies are due to spontaneous genetic variations. Most children with static encephalopathies do not have characteristic dysmorphic features, and currently no genetic screening tests are available to determine the cause of their delays. There is reason to believe that such diagnostic tools may emerge in the coming decades, but the inherent variability of clinical expression of current well-characterized genetic variants must temper enthusiasm for establishment of a genetic explanation for behavior. At the same time, isolation of genes even partially responsible for specific cognitive functions and emotional repertoires is a high priority. Three chromosomal syndromes have characteristic neuropsychiatric manifestations other than simple mental retardation: fragile X syndrome, Williams syndrome, and Down syndrome.

Fragile X Syndrome *Fragile X syndrome* is characterized by mental retardation (I.Q. 35 to 70), hyperlexia without comprehension, deficits in executive function and visuospatial attention, autism, aggressivity, impulsivity, and depression. Dysmorphic features include macroorchidism, large head, elongated palpebral fissures, and large ears. There are no characteristic abnormalities in brain structure. It is the most common identified genetic cause of mental retardation (1 in 4000 people) and affects boys almost exclusively. The genetic defect is the expansion of a trinucleotide deoxyribonucleic acid (DNA) repeat in the gene *FMR*-1 on the X chromosome. This expansion causes fragility of the chromosome when cells are grown in folate-deficient medium. The mutation silences expression of the gene, resulting in absence of the FMR proteins (FMRP), a series of ribosome-associated ribonucleic acid (RNA)-binding proteins generated by alternative splicing of *FMR*-1 transcripts. Recently, a highly accurate polymerase chain reaction (PCR) test has become available to identify affected individuals and carrier females. It is reasonable to screen mildly to moderately retarded male children with the PCR test, if the family wishes to exhaust the diagnostic possibilities. However, fragile X syndrome accounts for less than 4 percent of people with mental retardation and is not a cause of academic difficulties in the absence of mental retardation. There is no specific treatment for fragile X syndrome, other than special education and psychiatric care.

Williams Syndrome Children with Williams syndrome exhibit a relative preservation of language abilities and may have an unusually large vocabulary. In marked contrast, their visuospatial abilities are severely impaired. For example, they may be able to describe the parts of a house in great detail, but cannot draw a recognizable image of a house. They can recognize individual details but cannot recognize overall patterns in an image. The deficient functions are those usually ascribed to the right hemisphere, though the correlation is not complete. Neuropathological studies show small parietal lobes, narrowing of the corpus callosum, and abnormal proportions of the cortical layers. Genetic studies have implicated a mutation in the LIM-kinase I gene as the probable cause of the perceptual disturbance. Further studies are needed to establish the role of the LIM-kinase I gene in Williams syndrome. The function of this gene is unknown. The relationship between the genotype and the phenotype is not understood, but further study promises to yield interesting insights into the biological basis of perception.

Down Syndrome In contrast to children with Williams syndrome, children with Down syndrome have relatively preserved visuospatial skills and more-impaired verbal skills. Down syndrome children are generally docile and cheerful, but they may have outbursts of anger and hyperactivity. Children with the full Down syndrome phenotype harbor a third chromosome 21, whereas a portion of the Down syndrome phenotype is seen if only part of an extra chromosome 21 is present. There are several genes in the extra segment, and efforts to correlate specific gene triplications with specific cognitive skills are ongoing.

Head Trauma The neuropsychiatric consequences of head trauma are directly related to the nature and severity of the impact. Mild injuries may or may not cause loss of consciousness, and if no bleeding occurs, such injuries are called concussions. A postconcussional syndrome consisting variously of headache, somnolence, vomiting, syncope, dizziness, irritability, and amnesia for the event may last for days, weeks, or in some cases months. A longer duration of symptoms is associated with pretrauma depression and anxiety. The vast majority of children suffering mild head trauma have complete recovery.

Severe injuries are associated with intracranial hemorrhage, intracranial swelling, or both, and children who regain consciousness after such injuries have a high incidence of long-term behavioral changes (Table 2.12-3). Cognitive and learning disabilities are common, and aggressive outbursts of behavior are characteristic, especially of frontal lobe damage. A multidisciplinary approach to the physical and mental handicaps caused by severe head trauma, including pharmacological and behavioral therapies, is available at specialized rehabilitation units.

Primary lesions
Intra-axial
Diffuse axonal injury
Cortical contusion
Subcortical matter injury
Primary brainstem injury
Extra-axial hematomas

Table 2.12-3 Classification of Traumatic Intracranial Lesions

Acute Infections Meningitis consists of an infection in the cerebrospinal fluid, and encephalitis consists of an infection in the brain itself. The principal organisms are viruses and bacteria, and less commonly, fungi and tuberculosis are involved. When aggressively treated with antibiotics and supportive care, most children recover fully. The most common neurological sequela of bacterial meningitis is hearing loss (Table 2.12-4). A minority of patients with acute meningitis or encephalitis, especially those with hypoxic-ischemic injury, exhibit long-term cognitive deficits and may become depressed or anxious.

Complication	Number of Cases
Mental retardation	3
Seizures	3
Hemiparesis or quadriparesis	1
Bilateral deafness	4
Vestibular disturbance	1
Hydrocephalus	1

PROGRESSIVE ENCEPHALOPATHIES

The neuropsychiatric consequences of progressive encephalopathies initially affect the child, but as the child's mental functions progressively deteriorate, the caregivers increasingly demonstrate psychiatric symptoms. The stresses of watching a beloved child gradually lose skills, become vegetative, and eventually die are

extreme and try even the strongest of families. A thorough neurological evaluation is always indicated when children begin to lose developmental milestones or cease to gain milestones at their usual rate. The history and physical examination often suffice to narrow the differential diagnosis significantly, and a focused neuroimaging and laboratory evaluation frequently confirms the diagnosis. Potentially treatable diseases must be considered and prompt treatment offered to counteract the biochemical abnormality. Establishing a diagnosis even in untreatable conditions helps the family accept their situation and permits genetic testing in future pregnancies, when applicable. For a small but increasing number of diseases, presymptomatic or even prenatal treatment can avert the appearance of symptoms in patients with the disease genes.

Poliodystrophies *Poliodystrophy* refers to a disorder of the neuronal cell bodies, generally those in the cerebral cortex. The main presenting symptoms are seizures and loss of cognitive functions. Major psychiatric symptoms include loss of verbal communication, oppositional behavior, irritability, and inattentiveness. The poliodystrophies include the lipidoses, such as Tay-Sachs disease, Sandhoff's disease, Niemann-Pick disease, Gaucher's disease, Fabry's disease, and neuronal ceroid lipofuscinosis; the mucopolysaccharidoses, such as Hunter's syndrome, Hurler's syndrome, and Sanfilippo's syndrome; Alper's syndrome; the mitochondrial encephalomyopathies, such as mitochondrial encephalopathy with lactic acidoses and strokelike episodes (MELAS), Kearns-Sayre syndrome, myoclonic epilepsy with ataxia and ragged red fibers (MERRF), and Leigh's disease; the epileptic encephalopathies, such as infantile spasms, Lennox-Gastaut syndrome, and Rett's disorder, and the hereditary movement disorders with dementia, such as Huntington's disease, ataxia-telangiectasia, Wilson's disease, and Lesch-Nyhan syndrome.

Leukodystrophies *Leukodystrophy* refers to a disorder of white matter, which consists of myelinated fiber tracts. The main presenting symptoms are spasticity, ataxia, and optic atrophy. Major psychiatric symptoms include disinhibition, impulsivity, poor judgment, and emotional lability. The leukodystrophies include metachromatic leukodystrophy, globoid cell leukodystrophy, adrenoleukodystrophy, Pelizaeus-Merzbacher disease, Canavan's disease, and Alexander's disease.

Treatment Recent experimental bone marrow replacement protocols have shown prevention of progression and even reversal of disease in metachromatic leukodystrophy, globoid cell leukodystrophy, adrenoleukodystrophy, and Hurler's syndrome. Gaucher's disease has been successfully treated with enzyme replacement therapy. Several dietary restrictions or supplements have been tried with varying success for leukodystrophies.

Slow Infections

Acquired Immune Deficiency Syndrome Pediatric acquired immune deficiency syndrome (AIDS) is most frequently transmitted transplacentally. This transmission can be greatly reduced if the human immunodeficiency virus (HIV)-positive mother takes zidovudine (Retrovir) in the second half of pregnancy. Despite concerns that HIV-positive women would not seek prenatal care because they did not wish to have their HIV status entered in their medical records, it is clearly indefensible for prenatal clinics not to seek such women for testing and, if HIV-positive, to offer treatment with zidovudine. This approach has been bolstered by the recent institution of mandatory HIV testing for all newborns, positive results of which immediately identify HIV-positive mothers, albeit too late for zidovudine treatment. Perinatal transmission via breast milk or blood transfusions is much less common and tends to cause milder neuropsychiatric symptoms. Survival in congenitally or perinatally acquired HIV infection is rare beyond the age of 10 years.

Neurological symptoms, consisting of progressive motor dysfunction and loss of developmental milestones, and signs, particularly deceleration of head growth, are the presenting features of AIDS in up to 18 percent of children and adolescents. Unlike HIV-positive adults, who frequently have acute psychosis, HIV-positive children more often exhibit inattentiveness, impulsivity, depression, anxiety, and adjustment disorders as the main psychiatric symptoms. HIV-positive adolescents may also develop acute psychotic symptoms. Any acute change in mental status in an HIV-positive patient of any age requires a thorough neurological evaluation, possibly including neuroimaging, serologic testing, cerebrospinal fluid examination, and brain biopsy. Nutritional status, especially thiamine levels, electrolyte homeostasis, thyroid function, and other metabolic or endocrine indicators, should also be checked.

Any chronic infection in children may elict a reactive depression, especially if family members are ill. The organic effects of HIV tend to exacerbate depression. The best therapeutic approach is to maintain a high level of activity for as long as possible, including schooling and peer activities.

Other Slow Infections Other viral infections that may have minimal acute effects on the nervous system but may produce a slowly progressive encephalopathy include progressive multifocal leukoencephalopathy (caused by the JC virus), subacute sclerosing panencephalitis (caused by the measles or rubella viruses), and chronic enteroviral infections. Spongiform encephalopathies, such as Creutzfeldt-Jakob disease, thought to be caused by a prion, may affect children, causing anxiety, impaired judgment, and rapid cognitive decline.

Inborn Errors of Metabolism Genetic defects in cellular metabolism may affect the functioning of specific regions of the brain. Wilson's disease, a treatable disorder of copper transport, if left untreated may cause personality changes, impulsivity, social withdrawal, and flapping movements of the arms. Copper accumulates in the globus pallidus and putamen, cell loss is also seen in the substantia nigra and dentate nucleus, and astrocytes proliferate in the cerebral cortex, basal ganglia, brainstem nuclei, and cerebellum. Chelation therapy may reverse the symptoms, but the initial mobilization of copper by chelators may transiently increase neurological toxicity, sometimes for as long as several years. Infantile nephropathic cystinosis may cause visuospatial deficiencies due to loss of volume in the parietal and occipital regions prior to the initiation of therapy. Disorders of fatty acid oxidation may selectively affect verbal skills. Acute intermittent porphyria may cause panic attacks, depression, and agitated psychosis. Galactosemia, phenylketonuria, and ornithine transcarbamylase deficiency may cause mental retardation.

Acquired Metabolic Disorders Systemic metabolic disorders may affect behavior. Congenital hypothyroidism may cause severe retardation that may be only partially mitigated by postnatal thyroid replacement therapy. Acquired hypothyroidism in infants and children may cause disorders of spatial orientation, as well as general learning delays. Hyperthyroidism in children may cause hyperactivity, restlessness, and inattentiveness. Chronic hepatic and renal failure may cause deficits in visual learning and in memory.

Brain Tumors Brain tumors have been associated with the entire spectrum of behavioral disorders. The particular behavioral manifestations of a brain tumor are determined by its location, histological type, and size. Posterior fossa tumors may cause cerebellar and brainstem signs and hydrocephalus. Supratentorial infiltrative glial tumors may disable nerve fiber tracts and produce dementia.

In addition to the effects of the tumor itself, a larger risk factor for intellectual decline is the amount of cranial irradiation, which damages all cell types of the nervous system. For example, cystic cerebellar astrocytoma is a posterior fossa tumor typically treated with surgical resection but no irradiation, whereas surgical resection of another posterior fossa tumor, medulloblastoma, is usually followed by irradiation. In one long-term follow-up study, 62 percent of patients with cerebellar astrocytoma had I.Q.s above 90, whereas only 11 percent of patients with medulloblastoma and irradiation had I.Q.s above 90. Over time, the discrepancy widened. Addition of chemotherapy compounded the radiation-induced cognitive deficits.

The most common psychiatric disturbances in patients with brain tumors include reactive depression, oppositional behavior, anxiety disorders, and thought disorders. In some cases, treatment of the tumor improved these conditions, but in others, new symptoms emerged during treatment. Family members may also be severely affected, especially siblings of the patient, some of whom may view the patient as no longer part of the family. Treatment should include cognitive interventions for the patient and psychiatric support for both the patient and the family.

SEIZURE DISORDERS

Much of the study of the neuropsychiatric aspect of epilepsy applies to children, although fewer detailed studies have been done in children than in adults. Several types of epilepsy are only seen in infancy and childhood, including infantile spasms, benign rolandic epilepsy, idiopathic generalized epilepsy of childhood, idiopathic absence epilepsy, and febrile seizures (Fig. 2.12-8). Focal seizures are relatively rarer in childhood, but they may produce a wide range of behavioral manifestations (Table 2.12-5).

Seizure Manifestation	Number of Patients With Manifestations (Total 23): Age 1–5	Age 1–16	Total
Aura	6	10	16
Altered consciousness	12	13	25
Change in position of body or limbs	10	11	21
Integrated but confused activity	8	11	19
Staring or dazed expression	10	8	18
Epigastric sensation, nausea, vomiting	9	5	14
Oral movements, drooling	8	5	13
Muttering, mumbling, hissing	5	5	10
Walking, wandering	4	6	10
Pallor or flushing	5	4	9
Rubbing or fumbling	4	5	9
Speech (usually irrelevant or incoherent)	3	5	8
Affective disturbance (fear, anger)	5	3	8
Stiffening of body or limbs	5	3	8
Falling	4	3	7
Aggressive activity	4	3	7
Dreamy state	2	3	5
Forced thinking or ideational blocking	1	4	5
Searching or orienting movements	1	3	4
Abdominal pain	3	1	4
Incontinence (urinary)	2	1	3
Perceptual disturbance (visual, auditory)	0	3	3

Table 2.12-5 Clinical Manifestations of Complex Partial Seizures in Childhood

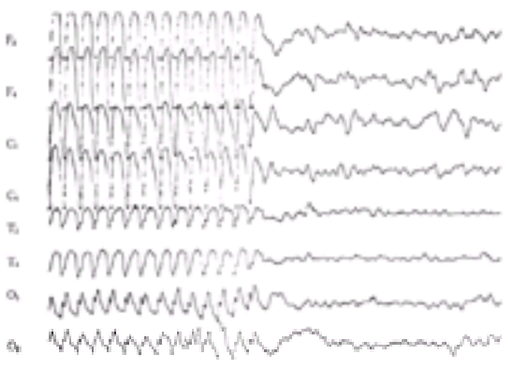

FIGURE 2.12-8 Three per second spike-wave discharges in an 11-year-old girl with frequent absence seizures induced by hyperventilation. *F3*, left frontal; *F4*, right frontal; *C3*, left central; *C4*, right central; *T3*, left temporal; *T4*, right temporal; *01*, left occipital; *02*, right occipital. (Reprinted with permission from Menkes J: *Textbook of Child Neurology*, ed 5. Williams & Wilkins, Baltimore, 1995.)

Some 70 to 80 percent of patients with seizures can expect good control with anticonvulsant medications. At a minimum, most seizure patients must take daily medication. Patients whose seizure control is inadequate live with the specter of a seizure striking them at any time. Thus, an event lasting in some cases 0.001 percent of the person's lifetime exerts a pervasive influence on the person's activities. This may lead to parental overprotection, teasing from peers, and disruption of social adjustment. If seizures have been controlled for at least 6 months and drug concentrations in serum are in the therapeutic range, then activities may usually include all but climbing, horseback riding, diving into deep water, unsupervised swimming, or use of dangerous equipment.

No single behavioral disorder is attributable to all patients with epilepsy. Children with childhood absence epilepsy tend to be passive and dependent. Children with temporal lobe focal epilepsy, in contrast, have variously been observed to be irritable, excitable, compulsive, stubborn, hyperactive, aggressive, depressed, or moody. Like adults, children with temporal lobe epilepsy are at increased risk for development of psychosis. Among children who have attempted suicide, there is a 15-fold increased appearance of children with epilepsy, especially those taking phenobarbital.

One third of children with epilepsy have psychiatric disorders, compared with 6.6 percent of healthy children and 11.6 percent of children with physical illnesses not involving the brain. Anticonvulsant medications, especially phenobarbital, may cause hyperactivity and irritability, whereas phenytoin (Dilantin) and carbamazepine (Tegretol) may cause sedation.

Pseudoseizures Pseudoseizures, also called nonepileptic seizures, are psychiatric fugue states caused by an unacceptable emotional conflict. They often occur in patients who have epilepsy or a family member with epilepsy. Nonepileptic seizures usually do not result in physical harm and are typically precipitated by a situation from which the patient would like to escape. Patients with nonepileptic seizures often have a history of physical or sexual abuse. Electroencephalograms (EEGs) show no abnormalities unless there is a concurrent epileptic seizure disorder. The events can sometimes be induced by suggestion. Once the nonepileptic nature of the events is determined, psychiatric care is important in the management of the disorder.

HEADACHE

Migraine Migraine headaches are relatively more common than tension-type headaches in children, which is the opposite of the prevalence in adults. Children may suffer from migraine with aura (classic migraine) or migraine without aura (common migraine). Association with vomiting, true vertigo, visual aura, menstrual cycle, or certain foods, and relief with sleep, permit distinction of migraine from tension-type headache. True migraine headaches rarely occur more than once per week. In some extreme cases, amnesia, confusion, and psychosis may result from migraine headaches. Frequently, a family history of migraine exists. Each patient with headaches, particularly of recent onset, should have a neuroimaging study. Migraines must be managed with patient education regarding avoidance of risk factors and prompt treatment, including sleeping.

Treatments for acute migraine include sumatriptan (Imitrex), naratriptan (Amerge), zolmitriptan (Zomig), rizatriptan (Maxalt), caffeine-ergotamine (Cafergot, Wigraine), butalbital-caffeineacetaminophen (Fioricet, Esgic), dihydroergotamine (DHE), phenothiazines, and opioids. Migraine prophylaxis has been achieved with serotonin agonists (eg., cyproheptadine [Periactin]), antidepressants, antihistamines, anticonvulsants (e.g., valproate [Depakene]), calcium channel blockers, b-adrenergic receptor antagonists, and hormones. Several flawed double-blind controlled trials have shown benefit of each of these agents, though the response in the placebo arm of many of the studies was unexpectedly low. It is difficult to separate the placebo effect from true migraine prophylaxis.

Chronic Tension-Type Headaches Tension-type headaches are frequent band-like, frontal, or shifting headaches sometimes associated with dizziness, nausea, and scotoma during the headache. Periods of daily headache may be interspersed with headache-free periods lasting days to weeks. The severity of an individual headache waxes and wanes over the course of the day. Migraine and tension-type headaches may coexist in a patient, who usually can describe distinct patterns of pain. The specter of a brain tumor looms in the minds of even young children, and a thorough history and neurological examination followed by an imaging study, which is usually normal, may allay anxieties and allow the headache to remit fully. An ophthalmological examination to rule out refractive errors, particularly astigmatism, is essential. Once structural causes of headache have been ruled out, psychological issues should be explored. Family conflicts, particularly parental conflicts or parental divorce, are at the root of tension-type headaches in a large number of children. Other factors to be addressed are difficulties meeting expected school performance, violence in the school, illness in other family members, and psychiatric conditions such as depression, anxiety, and attention-deficit/hyperactivity disorder. Both the affected child and the parents should be interviewed.

Treatment begins with reassurance that the headache does not reflect a serious medical condition. Patients should be instructed to keep a log of each headache, what triggered it, what was done to treat it, and (in girls) whether it is associated with menstrual periods. This serves to focus attention on the headaches as a valid medical condition rather than an inevitable nuisance for which there is no cure. Occasionally, an identifiable trigger can be identified and avoided. Patients should take an adequate dose of over-the counter analgesics at the earliest opportunity once a headache begins. Such medicines are much more effective at nipping a mild headache in the bud than at halting a full-blown headache. If the headaches persist despite the above interventions, prophylaxis often may be achieved with antidepressant drugs. All available antidepressants have equivalent efficacies, and the choice of drug should be based on adverse-effect profiles. Relaxation exercises or biofeedback may be effective.

Other Causes of Headache Fatigue or excessive exertion may cause an acute tension-type headache that responds to analgesics and rest. Sinusitis may cause facial pain in the context of fever and nasal congestion. Headache may be the sole manifestation of an acute viral syndrome. Dental pain, injury to the temporomandibular joint, or malocclusion that forces a child to chew on only one side of the mouth may strain one masseter muscle and produce unilateral headache.

Neck or head injury may cause muscle strain that can persist for weeks to months, especially when ongoing legal action is based on the presence of disability. Occipital headache may be caused by carpal tunnel syndrome, which can appear in adolescence. Headaches may be associated with epileptiform discharges even in the absence of clinical seizures. Twenty-four-hour ambulatory EEG may be necessary to demonstrate that spike and wave activity correlates with the duration of the headache. Headache may be the presenting symptom of collagen-vascular disease, hypersensitivity reaction, hypertension, or nervous system infection. Drugs and toxins with vasodilating properties may cause headaches. Headaches are especially associated with alcohol, caffeine withdrawal, nitrites, monosodium glutamate, and marijuana.

MOVEMENT DISORDERS

Involuntary movements are usually a sign of dysfunction of the basal ganglia. They may cause a disproportionate amount of anxiety and distress in children, who may be subject to teasing by their peers. Involuntary movements may be distinguished from seizures by their persistence with preservation of consciousness, their disappearance during sleep, and the absence of EEG abnormalities during the involuntary movements.

Classification *Chorea* is a rapid, random jerk of a limb, that may be incorporated into a movement that appears voluntary. *Athetosis* is a slow, writhing movement of the limbs, often associated with perinatal brain injury, especially hypoxic-ischemic injury or kernicterus. *Ballismus* is a high-amplitude, violent shooting of the limb from the shoulder or pelvis. It is an extreme version of chorea and is seen in Sydenham's chorea and lupus erythematosus. *Dystonia* is a persistent, simultaneous contraction of agonist and antagonist muscles. Tardive dyskinesia, dystonia, and tremor may be induced by medications in children as well as adults. *Myoclonus*, a sudden jerk of a body part, is not stereotyped, cannot be suppressed, and is nonrhythmic. *Tremor* is a continuous to-and-fro movement. *Tics* are instantaneous, stereotyped, low-amplitude movements. All movement disorders may involve one body part (focal), two or more continguous body parts (segmental), one side of the body (hemispheric), or the entire body (generalized).

Diagnosis and Treatment Movement disorders may be primary (idiopathic) or secondary (symptomatic) (Table 2.12-6). A thorough evaluation should be done, including history, especially of perinatal course, drug use, and systemic diseases; physical examination to characterize the movements, which may be difficult even for experts; neuroimaging, including magnetic resonance imaging (MRI) with contrast and possibly angiography; and laboratory examination, including toxicology screens, electrolytes, antinuclear antibodies, antistreptolysin-O titer, thyroid studies, pregnancy tests, and screening tests for specific genetic disorders. Among the genetic disorders that may cause movement disorders in children are Tourette's disorder, Hallervorden-Spatz disease, glutaric aciduria, hepatolenticular degeneration (Wilson's disease), Huntington's disease, abetalipoproteinemia, ataxia-telangiectasia, benign familial chorea, familial paroxysmal choreoathetosis, Lesch-Nyhan syndrome, ceroid lipofuscinosis, dopa-responsive dystonia, and myotonic dystrophy. Each disease has a specific treatment.

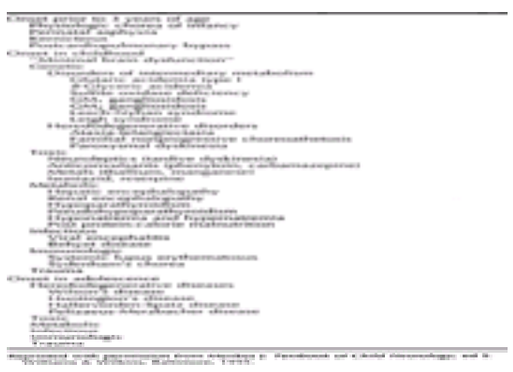

Table 2.12-6 Major Causes of Chorea

SUGGESTED CROSS-REFERENCES

Developmental neuroanatomy is described in Section 1.3. Adult manifestations of each of the conditions described in this section are discussed in the previous sections of Chapter 2. Narcolepsy is discussed in Chapter 21. Genetic counseling is discussed in Section 28.4. Normal child and adolescent development are described in Chapter 32. Mental retardation is discussed in Chapter 34. Tic disorders are discussed in Chapter 42. Psychiatric sequelae of HIV and AIDS are discussed in Section 2.8 and Section 49.6.

2.13 NEUROIMAGING IN CLINICAL PRACTICE

JOSEPH C. WU, M.D., DANIEL G. AMEN, M.D., AND H. STEFAN BRACHA, M.D.

Neuroimaging has evolved tremendously, providing psychiatrists with unprecedented information about brain structure and function. Computer tomographic (CT) scanners, the first widely used neuroimaging devices, allowed assessment of structural brain lesions such as tumors or strokes. Magnetic resonance imaging (MRI) scans, developed next, allowed greater gray-white matter distinction than CT scans provided and allowed visualization of smaller brain lesions as well as white matter abnormalities. In addition to structural neuroimaging with CT and MRI, a revolution in functional neuroimaging has enabled clinical scientists to obtain unprecedented insights into the diseased human brain. The foremost techniques for functional neuroimaging include positron emission tomography (PET) and single photon emission computed tomography (SPECT). Primary observations of structural and functional brain imaging in neuropsychiatric disorders such as dementia, movement disorders, demyelinating disorders, and epilepsy have not only contributed to a greater understanding of the pathophysiology of neurological and psychiatric illnesses, but can also be of help to the practicing clinicians in difficult diagnostic situations.

STRUCTURAL NEUROIMAGING TECHNIQUES

CT Imaging CT imaging was developed in 1967 by Sir Godfrey Hounsfield using theories developed by Allan Cormack. CT imaging is based upon the use of X-ray beams that are absorbed differentially by various tissues. The attenuation of the X-ray beam caused by tissue absorption is measured by radiation detectors. Views of the tissue are obtained from different angles by rotation of the X-ray tube, the detector, or both. In the images air and cerebrospinal fluid (CSF) (which have low attenuations) are typically black; bone (which has high attenuation) is typically white; and brain tissue is a shade of gray. Dyes are sometimes used to allow better visualization of blood vessels for examination of lesions such as aneurysms. CT scans have difficulty imaging brain near bony regions, such as the basal frontal lobes. CT scans have relatively poor gray-white matter differentiation but are also relatively inexpensive.

MRI Imaging MRI is based upon the fact that certain atomic nuclei that are magnetically active (when they have an odd number of protons or neutrons) can absorb energy from radiofrequency waves that are tuned into the natural frequency of those nuclei and can reemit the absorbed energy when the radiofrequency waves are turned off. This is analogous to a vibrating tuning fork stimulating a stationary tuning fork if it shares the same resonant frequency. MRI was discovered by Edward Mills Purcell of Harvard and Felix Bloch of Stanford in 1946. In 1973, Paul Lauterbur of the State University of New York in Stonybrook suggested spatial encoding of MRI measurements, which allowed the development of visual images from MRI data.

To prepare the magnetically active nuclei to receive the energy, the nuclei must first be aligned with an externally imposed magnetic field, like a compass with the Earth's magnetic field. The magnetically active nuclei oscillate with a characteristic frequency referred to as the Larmor frequency. The frequency increases with stronger magnetic fields. There is a net magnetization vector, which is called the longitudinal vector when it is aligned with the external magnetic field. When the radiofrequency waves strike the net magnetization vector, the vector tilts away from the longitudinal vector toward the transverse vector as energy is absorbed from the radiofrequency waves. When the radiofrequency waves are stopped, the net magnetization vector relaxes back toward the longitudinal vector and releases the absorbed energy as radio waves. The time required for 63 percent recovery is called the T1 relaxation time or the spin-lattice relaxation time; it takes approximately 3 seconds (3000 ms) for water. Fat has a very short T1 time (approximately 150 ms); white matter has a moderate T1 time (approximately 750 milliseconds); and gray matter has a little longer T1 time (approximately 900 ms). T1-weighted images show CSF as darker than brain tissue and can provide good anatomical images (Fig. 2.13-1C). T1-weighted images are produced by spin echo pulse sequences with short repetition time (TR, e.g., 530 ms) and short echo time (TE, e.g., 15 ms).

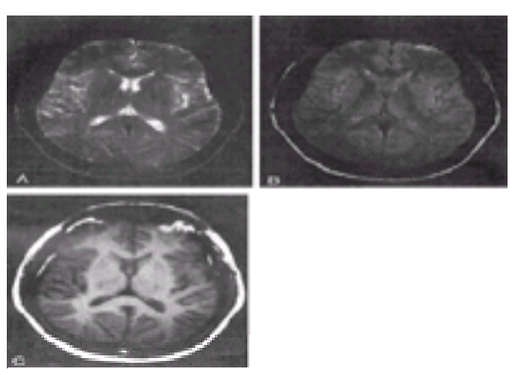

FIGURE 2.13-1 Normal MRI of a healthy elderly man: T2 weighted **(A)**, intermediate **(B)**, and T1 weighted **(C)**.

When the radiofrequency waves strike the magnetically active nuclei, they tilt toward the transverse vector, with synchronization of the phase of precession (i.e., with the magnetic nuclei spinning in alignment, or phase, around the axis like a group of gyroscopes spinning in the same direction). When the radiofrequency waves are stopped, the transverse vector disappears as the protons dephase. This is called spin-spin relaxation, and the time at which 63 percent of the transverse vector disappears is referred to as T2. Typically T2 is one-fifth to one-tenth of T1. For example, CSF has a T2 of approximately 300 ms whereas brain typically has a T2 of 70 ms. CSF is light and brain tissue is dark on a T2-weighted image (Fig. 2.13-1A). Brain lesions with high fluid content are also brighter than normal brain tissue on a T2-weighted image. T2-weighted images are visualized with spin echo pulse sequences with long TR (e.g., 3000 ms) and long TE (e.g., 100 ms).

MRI scans are more expensive than CT scans, but they can provide more information regarding gray and white matter distinctions. This can be helpful with white matter diseases such as multiple sclerosis. Bone does not affect MRI scans the way it can adversely affect CT imaging of brain regions such as the anterior area.

FUNCTIONAL NEUROIMAGING TECHNIQUES

PET Imaging PET scans rely on a variety of positron-labeled chemicals, including a glucose tracer called 18-fluorodeoxyglucose (FDG) and a blood flow tracer (e.g., oxygen-15 H_2O) to provide images of brain function or brain activity as opposed to the structural images provided by MRI. Other radioligands used in PET include 18-fluorodopa (FDOPA), a tracer that has been used to study presynaptic dopaminergic activity, and receptor ligands that are positron labeled (e.g., carbon-11 or fluorine-18) and can be used to study, for example, dopamine (e.g., raclopride, *N*-methylspiperone) and serotonin (*N*-methylspiperone) receptors. A positron emitter is created by a cyclotron via high-speed bombardment of a target material. *Positron* is a contraction for “positive electron.” Since electrons primarily carry a negative charge, a positive electron has a charge opposite that of normal electrons and is regarded as a form of antimatter. Antimatter cannot survive for long in a normal matter universe because as soon as it meets its corresponding oppositely charged matter, the two particles undergo what is referred to as annihilation decay, whereby

the mass in the matter and the antimatter particles are converted into pure energy. The positron and electron are converted into two gamma rays that emerge at a 180° angle from each other. The PET scanner is composed of crystal detectors that are tuned to these gamma rays and emit a photon when bombarded. The photons are detected by photomultiplier tubes and amplified so that a measurable signal can be generated from the positron-electron annihilation decay.

The use of positron-labeled chemicals to localize brain tumors was first described over 40 years ago in 1953 by Gordon Lee Brownell and R. D. Sweet. The first positron scanner was described in 1962 by William Higgenbotham and his colleagues. The first tomographic PET scanners were described in 1974 by Zang Hee Cho. PET scanners have improved in resolution capabilities since they were first invented approximately 30 years ago. The first scanners had a resolution of about 15 to 20 mm, whereas current state-of-the-art scanners have resolutions closer to 4 mm, which is approaching the theoretical limit. Scans can be viewed from transverse, sagittal, and coronal views, as well as with three-dimensional reconstructions. Scan images can be displayed using a color scale or a gray scale. Most clinical reports rely upon visual examination and comparison of a scan with previously studied scans to create a report that describes qualitative differences if any. In addition to these qualitative methods, quantitative methods that rely upon creating statistical probability maps, which create a z-transform of each pixel in a normalized image that is compared with a database, have been used by some centers to complement the qualitative approach. Quantitative methods can also be based upon measurements within defined brain regions of interest. Brain regions of interest can be defined by automated algorithms or can be individually drawn for specific anatomical regions.

Single Photon Emission Computed Tomography Brain SPECT imaging is a nuclear medicine technique that uses minute doses of radioactive isotopes (such as iodine-123 or technetium Tc-99m) bound to neurospecific pharmaceuticals (e.g., ^{123}I-amphetamine or ^{99}Tc-hexamethylpropyleneamineoxime [HMPAO]) to study cerebral perfusion and thus, indirectly, brain metabolic activity. SPECT can provide clinically useful information in several areas relevant to neurology and psychiatry. Currently enough published articles and extensive clinical experience exist to substantiate its use in evaluating head trauma, dementia, cerebral vascular disease, and temporal lobe epilepsy. Refractory suicidal behavior and substance abuse are other disorders about which SPECT may provide useful information. Unfortunately, the interface between psychiatry and nuclear medicine is uncommon, and SPECT is perhaps underused in clinical practice.

With continued improvement in technology, brain SPECT image resolution is nearing the same realm as PET at less cost. SPECT scans are relatively easy to perform, requiring only an intravenous line, and with multiheaded cameras the acquisition time for the scan is approximately 15 minutes. High-resolution SPECT cameras are also widely available. Unfortunately, at the time of this writing few trained physicians have extensive experience in reading brain SPECT images for neuropsychiatric indications. Some clinicians have reservations about the use of SPECT in children and teenagers, feeling it may be unsafe. The radiation exposure from SPECT, however, is about the same as that with a brain CT scan or an abdominal X-ray. As a specialty, nuclear medicine has been doing studies on children for over 30 years without identified untoward effects. Having an unresponsive or poorly understood psychiatric condition has many more risks than the risk of low-dose radiation exposure from a SPECT scan.

Brain SPECT studies can be displayed in a variety of ways. Traditionally, the brain can be examined in three different planes: horizontally, coronally, and sagittally. A normal study shows relatively symmetrical uptake of the isotope throughout the brain. Overactive areas of the brain are indicated by an increase in color (depending on the color scale used), and those with decreased activity are shown by diminished color. With advancements in computer technology the brain can be represented in three-dimensional images. Three-dimensional surface images are one way to represent brain activity, looking at the cerebral metabolism or blood flow of the brain's cortical surface. These images are helpful in evaluating strokes, brain trauma, effects from drug abuse, and so forth. A normal three-dimensional surface scan shows good, full, symmetrical activity across the brain's cortical surface. Three-dimensional active brain images compare average brain activity with that of the most active parts of the brain. These images are helpful for picking up areas of overactivity, as seen in active seizures, obsessive-compulsive disorder, and bipolar I disorder. Physicians are usually alerted that something is wrong in one of three ways: (1) too much activity in a certain area; (2) too little activity in a certain area; or (3) asymmetrical areas of activity that ought to be symmetrical or symmetrical areas of activity that are typically asymmetrical.

Magnetic Resonance Spectroscopy Magnetic resonance spectroscopy (MRS) measures the concentration of different chemicals in the brain by examining the chemical shift that occurs in different chemical environments associated with different structural moieties. The chemicals to be measured must have a concentration of at least 1 mmol per liter. MRS requires more magnetic field homogeneity than does conventional MRI. There are several different scanning protocols that are used such as stimulated echo-mode acquisition method (STEAM) and image selected in vivo spectroscopy (ISIS). The two most common forms of MRS are proton spectra and ^{31}P spectroscopy. Proton spectroscopy allows measurement of chemicals such as *N*-acetylaspartate (which is used to assess neuronal function), glutamine, glutamate, creatinine, choline, and inositol. *N*-acetylaspartate is used to assess neuronal function. The resolution for proton spectroscopy approaches 7 mm. ^{31}P spectroscopy allows measurement of adenosine triphosphate (ATP), phosphocreatinine, inorganic phosphate, phosphomonoesters, and phosphodiesters. Larger voxels are required for ^{31}P spectroscopy, and thus spatial resolution is lower. MRS provides a noninvasive way of measuring brain chemicals but has poor spatial and temporal resolution and is largely a research tool at this time.

Functional MRI Functional MRI (fMRI) allows assessment of T_2 dephasing due to changes in blood flow. Deoxygenated hemoglobin can be used as a naturally occurring contrast agent compared with oxygenated hemoglobin. Oxygenated areas have a larger signal than deoxygenated regions. Functionally activated brain regions have increased blood flow with greater oxygenation. This technique is called BOLD (blood oxygen level dependent) imaging. High-field magnets allow faster acquisition of the fMRI signals.

DEMENTIAS

Dementia or mental decline associated with aging occurs in approximately 11 percent of the population of the United States over 65 years of age and affects 2 million Americans over the age of 50. The most common form, dementia of the Alzheimer's type, accounts for approximately 70 percent of dementias. The second most common form of dementia is vascular dementia due to many small strokes. The third most common form of dementia is associated with degenerative diseases such as Huntington's disease and Parkinson's disease. The differential diagnosis of dementias now requires the use of imaging techniques to rule out treatable causes of dementias. Structural imaging techniques are primarily used by clinicians. Functional imaging techniques are more sensitive for detecting features that would help confirm the diagnosis of conditions such as Alzheimer's disease, but they are less commonly used because of issues of equipment availability, staff training, and cost containment.

Alzheimer's Disease Alzheimer's disease, the most common degenerative brain disease, results in progressive memory loss and accounts for over two thirds of dementia. Definitive diagnosis of Alzheimer's disease requires a neuropathological examination to determine whether the characteristic neurofibrillary tangles and senile plaques are present. These findings occur primarily in the medial temporal cortex and parietotemporal cortex in the early phase; in later phases the frontal lobe is also involved. Primary sensory cortex (e.g., visual cortex, somatosensory system) shows relative sparing. The onset of the disease is usually insidious and includes forgetfulness, confusion, and poor judgment. Recent memory consolidation is affected whereas long-term memory recall is initially spared. As the disease progresses, patients often experience language difficulties with failure to recall words. In later stages, patients may have difficulty forming complete sentences and with visuospatial orientation. The differential diagnosis includes treatable forms of dementia such as normal pressure hydrocephalus, nutritional deficiencies (e.g., Wernicke-Korsakoff syndrome), drug intoxication (e.g., barbiturates), brain tumors, and pseudodementia of depression.

CT and MRI CT scans are useful for screening for potentially treatable conditions that can present as dementia such as subdural hematoma, normal pressure hydrocephalus, and brain tumors in frontal or temporal regions. Alzheimer's disease CT findings overlap with those of normal control subjects and show cortical atrophy (especially in the sylvian fissure) and enlarged ventricles (especially in the anterior temporal horns). MRI T1-weighted images show generalized atrophy (as does the CT scan) but are more sensitive at showing reduced volumetric size of medial temporal regions such as amygdala and hippocampus. MRI T1-weighted images also show enlarged ventricles. MRI T2-weighted images show no difference between subcortical hyperintensities in Alzheimer's disease and normal controls.

PET and SPECT PET scans of Alzheimer's dementia patients typically show bilateral metabolic decreases in the temporoparietal association areas as well as decreases in the frontal lobe. The occipital and primary sensorimotor cortex, striatum, and cerebellum show sparing. Asymmetries are not uncommon in Alzheimer's disease. Left hemisphere decreased activity is associated with language impairment, whereas right hemisphere decreased activity is associated with greater visuospatial orientation impairment. PET scans allow high accuracy in the differentiation of normal subjects from patients with dementia of the Alzheimer type, especially in moderate and severe cases. Medications for the treatment of Alzheimer's disease (e.g., tacrine [Cognex]) have been shown to reverse the decrease in metabolism. The SPECT pattern for Alzheimer's disease is typically bilateral hypoperfusion in the parietal and temporal regions of the brain with frontal lobe hypoperfusion occurring later in the illness.

Patient A is a 70-year-old man who had been more forgetful to the point that his family was worried about him. The patient's family was interested in getting a diagnostic workup to evaluate the possible causes for his memory disorder. His PET scan showed that he had marked parietotemporal decreases (Fig. 2.13-2), which corroborated other neurological evaluations suggesting that the patient had Alzheimer's disease. The patient was treated with tacrine and benefited from some stabilization of his symptoms.

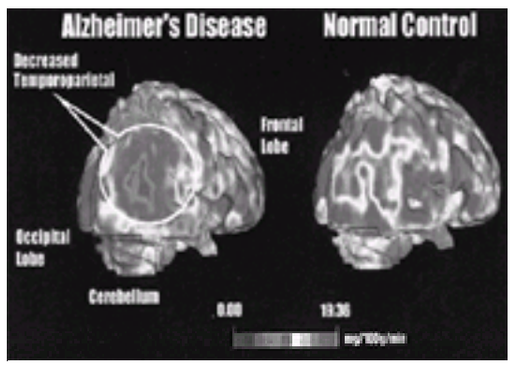

FIGURE 2.13-2 Three-dimensional PET FDG images demonstrate markedly lower glucose metabolism in temporoparietal region in patient with Alzheimer's disease than in normal control. (See Color Plate 3.)

Vascular Dementia Vascular dementia can result from multiple small infarcts that generally involve white matter lesions in deep cerebral locations. On T2-weighted images, these lesions show up as hyperintensities. These changes can be seen in normal elderly individuals, although not to the same extent as in individuals with vascular dementia. Over half of normal control subjects over age 70 have subcortical hyperintensities that typically occur in periventricular regions. The pathophysiology of these hyperintensities is not well understood but has led to theories such as leakage from vessels secondary to hypertensive damage.

Vascular dementias have a deteriorating course characterized by sudden onset with focal neurological signs and showing small stepwise decrements due to multiple small infarcts as opposed to the more insidious course of Alzheimer's disease. Lesions in specific regions of brain result in functional changes associated with that region (e.g., infarction in dominant angular gyrus can result in visuospatial defects, acalculia, agraphia). The size of the vascular lesion may be a key factor in whether or not dementia results, with a critical threshold involvement of approximately 100 cm^3 total of brain tissue.

The PET scan pattern of vascular dementia is characterized by scattered multifocal cortical and subcortical regions of hypometabolism, with metabolic defects exceeding the boundaries of the infarcted tissue. This scattered pattern differs from that of Alzheimer's disease, which is primarily localized in association cortex. The SPECT pattern in vascular dementia is characterized by multiple areas of decreased perfusion. Neuropsychological deficits correlate better with brain metabolism abnormalities found with functional neuroimaging than with white matter lesions or lacunar infarcts seen on MRI. Treatments such as propentofylline or hydergine have been found to increase brain metabolism in some studies.

Pick's Disease Patients with Pick's disease show cognitive deterioration similar to that of patients with Alzheimer's disease. It is a relatively rare cause of dementia that typically occurs before age 65, and women are more often affected than men. Patients often show greater impairment in social judgment with greater behavioral disinhibition than do patients with typical Alzheimer's disease. Apathy is a common early symptom; another symptom is difficulty performing sequences of motor tasks. In postmortem studies, argentophilic (Pick's) bodies are found in only 20 percent of patients. The atrophy encompasses both gray and white matter and was termed *lobar atrophy*, compared with Alzheimer's disease, which shows relatively greater involvement of gray matter. CT and MRI scans show frontal and temporal atrophy including white matter. Patients with Pick's disease differ from those with Alzheimer's disease by showing decreases on PET or SPECT scans primarily in frontal and temporal lobe in early stages.

Lewy Body Dementia Lewy body dementia is characterized by dementia and parkinsonian-like symptoms with fluctuations in cognitive and motoric symptoms, hypersensitivity to antipsychotic drugs, orthostatic hypotension, and psychotic symptoms. Patients with Lewy body dementia show a functional brain imaging pattern that is similar in many respects to that seen in Alzheimer's disease, with a pattern of hypometabolism in frontotemporoparietal regions. Some studies have found that Lewy body disease differs from Alzheimer's disease in showing metabolic decreases in occipital regions, which are characteristically spared in Alzheimer's disease. As with Parkinson's patients, Lewy body dementia patients show increased striatal activity on the side contralateral to parkinsonian symptoms.

Jakob-Creutzfeldt Disease Jakob-Creutzfeldt disease is caused by a prion, a proteinaceous infectious agent, and typically presents at approximately 60 years of age and then declines in incidence with age so that it is relatively rare after 80. The symptoms include rapid memory loss, myoclonic movements, cerebellar ataxia, delirium (e.g., hallucinations, confusion) and visuospatial disorders. The neuropathological findings include spongiform changes resulting in widespread vacuolization. MRI scans may be normal initially but then may show hyperintensities on T2-weighted images in striatum and cortex. The PET scans of patients with Jakob-Creutzfeldt disease show marked decreases in global regional brain metabolism.

Acquired Immune Deficiency Syndrome (AIDS) Dementia Complex Chronic human immunodeficiency virus (HIV) encephalitis can present as a form of dementia characterized by cognitive decline and motor symptoms such as ataxia, limb incoordination, leg weakness, and bowel incontinence. Patients may also have frontal release signs, seizures, or parkinsonian symptoms. Psychiatric symptoms such as depression or psychosis can sometimes be the first signs of this AIDS dementia complex. Neuropathological examinations find nonfocal abnormalities in cerebral white matter, and nearly 90 percent of AIDS patients show some neuropathological abnormalities. Twenty-five percent of patients have peripheral neuropathy in association with dementia. In the final stages, AIDS dementia complex can result in akinetic mutism with urinary incontinence.

CT or MRI scans can show ventricular enlargement with cortical atrophy, and T2-weighted MRI scans can show hyperintensities. With functional brain imaging, patients with AIDS dementia complex have been found to have hypermetabolism of the basal ganglia and limbic regions. In cortical regions, adult patients with AIDS dementia complex have been reported to have increased metabolism in frontal, temporal, and parietal cortex, whereas children with HIV have been reported to have diffuse hypometabolism in right temporo-occipital regions. Treatment with zidovudine (Retrovir) may improve functional brain imaging abnormalities.

Focal brain masses occur commonly in AIDS patients and include tumors (e.g., lymphomas), infections (e.g., cryptococcomas, toxoplasmosis), and progressive multifocal leukoencephalopathy. MRI scans are generally more sensitive at detecting these lesions than CT scans. MRS shows some promise in differentiating lesion types, with infections showing increased lactate concentrations and tumors showing increased choline concentrations. SPECT images in dementia due to HIV disease often show patchy areas of decreased activity across the cortex.

Normal Pressure Hydrocephalus The major clinical difference between normal pressure hydrocephalus and Alzheimer's disease is that normal pressure hydrocephalus has the classical triad of gait instability, bowel incontinence, and dementia. There are no signs of headache or papilledema, and normal CSF pressures are noted with lumbar punctures. In advanced stages, normal pressure hydrocephalus is associated with frontal release signs. Normal pressure hydrocephalus often occurs after head trauma, meningitis, or subarachnoid hemorrhage but may not be manifested for weeks. CT or MRI scans show lateral ventricular dilatation but normal or compressed cortical sulci. T2-weighted images show periventricular hyperintensities, but this occurs in vascular dementia as well. Nuclear medicine studies of CSF flow can show reversal of the normal ventricular to subarachnoid space flow. The PET scan of normal pressure hydrocephalus looks very similar to that of Alzheimer's disease; however, treatment of normal pressure hydrocephalus with ventricular shunts reverses the metabolic defect.

MOVEMENT DISORDERS

Parkinson's Disease Parkinson's disease occurs in middle to late life and is characterized by progressive bradykinesia-hypokinesia and other symptoms such as resting tremor, rigidity, flexed posture, loss of postural reflex, and freezing phenomenon (motor block). On neuropathological examination, patients with Parkinson's disease show a decreased number of neuromelanin-containing neurons in the substantia nigra, thus resulting in decreased dopamine release in the striatum. These substantia nigra neurons sometimes contain Lewy bodies. MRI scans can show a decrease in size of the substantia nigra, and T2-weighted images show hypointensity of the putamen in some patients.

Functional neuroimaging of patients with Parkinson's disease shows hypermetabolism in the striatum, primarily in the putamen. Treatment with pallidotomy reduces and normalizes striatal metabolism. More-advanced Parkinson's disease patients have decreases in other neocortical areas such as the frontal cortex. Assessment of brain metabolism can help provide diagnostic corroboration, especially prior to invasive treatments such as pallidotomies. Depressed parkinsonian patients have

caudate and orbitofrontal hypometabolism and sometimes medial frontal and cingulate hypometabolism as well.

Patient G is an elderly patient with increasing rigidity and tremor who initially had a good response to antiparkinsonian medication but now has increasingly less response to medications, with severe symptomatic fluctuations. He is a candidate for pallidotomy. To confirm the diagnosis of treatment-resistant Parkinson's disease (as opposed to a mimicking illness such as multiple system atrophy), a PET scan is obtained. The patient has hypermetabolism in the striatum and decreased frontal lobe activity (Fig. 2.13-3) which confirms that the patient has true Parkinson's disease. The patient undergoes a pallidotomy, which restores the capacity to respond favorably to antiparkinsonian medication.

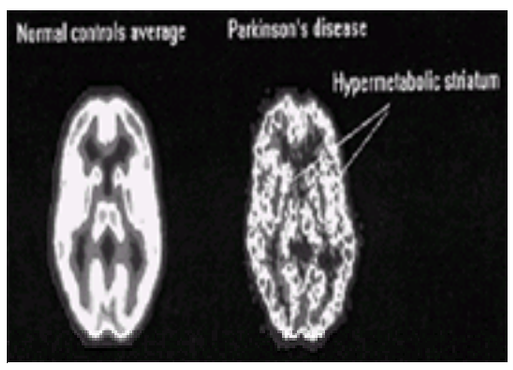

FIGURE 2.13-3 Transaxial section of PET FDG demonstrates hypermetabolism in striatum in patient with Parkinson's disease compared with normal control average image. (See Color Plate 3.)

Huntington's Disease Huntington's disease is the leading cause of adult-onset chorea, which is an irregular, rapid, involuntary movement that moves from one part of the body to another. It is a hereditary disorder with a frequency of 4 to 5 per million individuals. Typically, symptoms start in the fourth or fifth decade of life, although it can occur as early as childhood. Huntington's disease is transmitted by an autosomal dominant gene with complete penetrance. The gene for Huntington's disease has been located on the short arm of chromosome 4.

The initial symptoms may be behavioral, such as becoming very irritable, critical, or depressed. Patients show gradual deterioration of cognitive function with impaired attentional function. The first signs of motor abnormality involve the upper extremities and face (e.g., difficulty performing sequential actions). On neuropathological examination, there is a pronounced atrophy of the caudate, with loss of g-aminobutyrate (GABA)-ergic striatal efferent neurons to the lateral globus pallidus.

CT or MRI scans can show a bulge in the lateral ventricle reflecting loss of the caudate head resulting in a butterfly appearance of the lateral ventricles. T2-weighted MRI scans can show striatal hyperintensity in some forms of Huntington's disease. The most characteristic feature of regional brain metabolism with PET scans in Huntington's disease is hypometabolism in the caudate and the putamen. PET scans are more sensitive than SPECT scans for detecting striatal hypometabolism in Huntington's disease. PET scans are also more sensitive than CT scans or clinical examinations in detecting Huntington's disease. Decreased striatal metabolism is seen in presymptomatic individuals before development of caudate atrophy. Caudate metabolism is significantly correlated with bradykinesia and overall function in Huntington's disease. Gene-positive Huntington's disease patients show an annual decrease of approximately 3 percent of caudate metabolism.

Other Movement Disorders

Progressive Supranuclear Palsy Patients with progressive supranuclear palsy have symptoms such as akinetic parkinsonian symptoms, gait ataxia, pseudobulbar atrophy, and supranuclear palsy affecting vertical gaze. Patients have an intact reflex downgaze during oculocephalic maneuver despite being able to look down voluntarily. Patients typically exhibit tiredness and a tendency to fall backward. There is no familial connection. Cognitively, progressive supranuclear palsy patients show impaired verbal fluency and difficulty shifting from one task to another. CT or MRI scans show atrophy of the pons and midbrain. Progressive supranuclear palsy patients show decreases in frontal areas and striatal metabolism. FDOPA PET scans show decreased presynaptic dopamine uptake in caudate and putamen.

Hemiparkinsonism-Hemiatrophy Patients with hemiparkinsonism-hemiatrophy have unilateral motor symptoms and show decreased metabolism in the basal ganglia contralateral to the parkinsonian symptoms. Unlike Parkinson's disease, there is generally a more benign clinical course.

Multiple System Atrophy Multiple system atrophy comprises several similar disorders such as striatonigral degeneration, olivopontocerebellar syndrome, and Shy-Drager syndrome. Patients with multiple system atrophy have oligodendroglial microtubular tangles in white matter, which can result in neuronal loss and gliosis in different parts of the brain, including the neostriatum, substantia nigra, cerebellum, inferior olives, and anterior horn cells, thereby resulting in different clinical manifestations. Primary involvement of the neostriatum, referred to as *striatonigral degeneration*, results in parkinsonian symptoms without tremor and poor response to levodopa (Larodopa). Involvement of the preganglionic sympathetic neurons results in a condition known as *Shy-Drager syndrome*, with parkinsonian symptoms plus autonomic dysfunction (e.g., orthostatic hypotension, impotence, bladder and bowel dysfunction). If the degeneration occurs in the olives, pons, and cerebellum, then common associated symptoms include ataxia in addition to the parkinsonian symptoms. The most striking finding on functional imaging is the decreased metabolic activity in the striatum.

Corticobasal Degeneration Parkinsonian symptoms associated with apraxia are characteristic of corticobasal degeneration. PET scans show hypometabolism in the cortex, especially the parietal lobule, hippocampus, thalamus, and basal ganglia contralateral to the affected limb.

Hypoparathyroidism Hypoparathyroidism can result in parkinsonian symptoms or athetosis. This syndrome may occur after thyroidectomy or can be associated with primary adrenal failure due to autoimmune abnormalities. Calcification of the basal ganglia and cerebellum can occur and is detectable by CT or MRI scans. Some calcification of these structures occurs with normal aging also.

Hallervorden-Spatz Disease Hallervorden-Spatz disease is caused by excessive iron deposition in the globus pallidus, substantia nigra, and red nucleus. The symptoms include corticospinal signs (e.g., spasticity) and extrapyramidal signs (e.g., rigidity, dystonia). CT scans reveal hypodensities in the lenticular regions, and T2-weighted MRI scans show hypodensities in the pallidum except for a small area of the medial segment, thus known as the “eye of the tiger” sign. Parkinson's disease and striatonigral degeneration can also show increased iron concentration in the basal ganglia.

Hepatolenticular Degeneration (Wilson's Disease) Wilson's disease is due to abnormal metabolism of copper leading to deposition of copper in the liver, resulting in hepatitis and cirrhosis. The neurological manifestations of Wilson's disease include tremor and slowness with bulbar muscle dysfunction resulting in impairments of swallowing and speech. Emotional lability and cognitive impairments follow as the disease progresses. Characteristic corneal rings are golden brown (Kayser-Fleischer). Laboratory examinations find low serum ceruloplasmin concentration. CT scans show enlarged ventricles, brainstem atrophy, and lenticular nuclei hypodensity. MRI scans are more sensitive at detecting these abnormalities. PET scan studies of Wilson's disease show a diffuse decrease in metabolism, with marked hypometabolism in the lenticular regions and relative sparing of the thalamus.

CEREBROVASCULAR DISEASE

Strokes are the third most common cause of death (after cardiovascular disease and cancer) and are characterized by a sudden onset of an acute focal neurological event that lasts longer than 24 hours. Approximately 500,000 new or recurrent strokes occur each year, with approximately 175,000 deaths per year. Hypertension, smoking, obesity, and dyslipidemias are major risk factors for strokes. Several subtypes of stroke exist including thrombotic, hemorrhagic, embolic, and venous occlusion. Approximately 75 percent of strokes involve the internal carotid or middle cerebral artery. Embolic strokes have an immediate onset of peak symptoms. Thrombotic strokes also begin acutely but may evolve step-like over a period of time ranging from seconds to days. Symptoms such as headache or vomiting are more likely to be associated with hemorrhagic strokes than embolic strokes. Hemorrhagic strokes also have an acute beginning but then progress steadily over minutes to hours. Typically after the stroke, symptoms start to resolve gradually. The complete middle cerebral artery strokes involve the basal ganglia with a wedge-shaped region of infarction from the lateral ventricle to the cortex. Strokes are commonly preceded by transient ischemic attacks, whose symptoms often

include hemiplegia, hemianopia, diplopia, confusion, or spatial disorientation.

CT scans are often the initial imaging procedure used and can exclude conditions that mimic stroke including subdural hematomas or tumors. In the hyperacute stage (<6 hours), there may be only subtle abnormalities including mild parenchymal hypointensity. During the acute stage (12 to 24 hours), nonenhanced CT scans can show loss of gray-white matter interface and hypodensity in regions such as the basal ganglia. In the late acute stage (24 to 72 hours), nonenhanced CT scans can show wedge-shaped hypodensities with possible hemorrhagic transformation. Enhanced CT scans may highlight sites of infarction. In early subacute stage (4 to 7 days), mass effect from enlargement of the affected area can persist. In late subacute stages (1 to 8 weeks), the mass effect can resolve, although gyral enhancement may persist. In chronic stages, there may be atrophy and encephalomalacia with ventricular or sulcal enlargement.

MRI scans have greater sensitivity than CT scans, especially in the basal ganglia region, brainstem, and subcortical white matter. MRI scans can also visualize small arteriovenous malformations, angiomas, and lacunar infarcts sooner and with greater sensitivity than CT scans. In the immediate stage, T1-weighted MRI scans can show intravascular contrast enhancement. In the hyperacute stage (1 to 6 hours), T1-weighted MRI scans show gyral swelling and loss of gray-white matter interfaces. In the acute state (6 to 24 hours), T1-weighted images can show mass effects and meningeal enhancements next to the infarct; T2-weighted scans will show increased signal intensity in stroke regions. During the late acute stage (24 to 72 hours), T1-weighted images show increased mass effect, and T2-weighted images show hyperintensities. In early subacute stages (4 to 7 days), T1-weighted images show parenchymal enhancement with contrast, and T2-weighted images show several possible changes including subcortical hyperintensities, hemorrhage, or acute Wallerian degeneration. In late subacute stage (1 to 8 weeks), T-weighted image can show persistent parenchymal enhancement. In chronic stages, T1-weighted images can show atrophy in affected regions and Wallerian degeneration and T2-weighted images can show encephalomalacia.

PET PET scans are useful in assessing strokes and show metabolic disturbances that extend beyond the site of the primary lesions. PET studies of poststroke aphasia reveal that the ability to recruit right posteroinferior temporal activity is associated with recovery. Poststroke neglect is associated with hypometabolism in the hemisphere contralateral to the stroke. Homonymous hemianopsia after a middle cerebral artery stroke is associated with significant and extensive decrease in activity throughout the affected hemisphere.

SPECT SPECT is often helpful in the evaluation and management of cerebral vascular disease. In acute stroke, early SPECT depicts the area of ischemia with greater accuracy than either CT or MRI. When the perfusion defect is large, the likelihood of hemorrhagic complications or herniation increases. Reperfusion of an arterial territory after thrombolysis can be documented more conveniently with SPECT than with angiography. SPECT before and after the injection of acetazolamide has been used to assess the vascular reserve in patients with severe stenosis of the proximal vessels of the cerebrovascular tree. Figure 2.13-4 and Figure 2.13-5 show a typical stroke.

FIGURE 2.13-4 Stroke. Left side surface view shows marked decreased left frontal, temporal, and parietal lobe. (Note: SPECT cortical surface images are rendered by setting the threshold at 55%, looking at most active 45% of brain activity; SPECT active images are rendered by setting blue color threshold set at 55%, looking at average brain activity in the brain compared to red [or white] threshold set at 85%, looking at the most active 15% of brain activity.) (See Color Plate 3.)

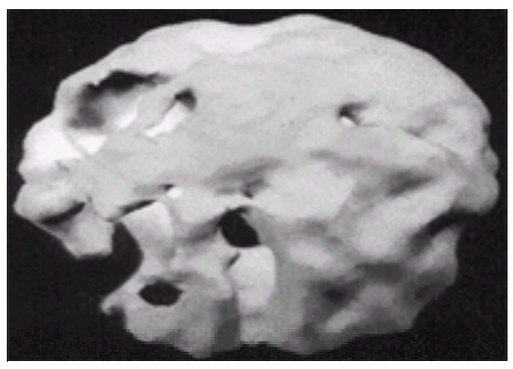

FIGURE 2.13-5 Two right hemisphere strokes with depression as presenting symptom. Top-down surface view shows marked decreased right frontal, temporal, and parietal lobe. (See Color Plate 3.)

Patient N, a 59-year-old woman suffering from severe depression, had been nonresponsive to treatment. A SPECT study was ordered to evaluate her unresponsive condition. Since she had not experienced any neurological symptoms, it was surprising to discover two large right hemisphere strokes. Her nonresponsive depression became clearer, since 60 percent of persons with frontal lobe strokes experience severe depression. As a result of the SPECT study, immediate neurological consultation was obtained and N was placed on blood-thinning medication to prevent further strokes.

MELAS Mitochondrial myopathy, encephalopathy, lactic acidosis and strokelike episodes (MELAS) is one of several mitochondrially inherited disorders. Other examples of this class of disorder includes MERRF (myoclonic epilepsy and ragged red fibers), Kearns-Sayre syndrome, and chronic progressive external ophthalomoplegia. MELAS is characterized clinically by slow growth, stroke-like episodes, seizures, and mental retardation or dementia with onset before age 40. Although the primary deficits are cerebral, muscular deficits can also occur. It is caused by mutations in the mitochondrial deoxyribonucleic acid (DNA). Imaging studies show multifocal infarcts throughout cortex and white matter. CT scans can show confluent hypolucencies consistent with infarcts. T2-weighted MRI images show hyperintensities in both cortical and subcortical regions.

DEMYELINATING DISEASES

Multiple Sclerosis Multiple sclerosis is a chronic neurological illness associated with white matter demyelination and glial scarring (sclerosis) in multiple cerebral locations, with varying symptoms such as weakness, numbness, dysesthesia, optic neuritis, diplopia, ataxia, and psychiatric symptoms that fluctuate over time. Multiple sclerosis typically strikes young adults between the ages of 20 and 40, with a predilection for Northern Europeans and a slightly greater preference for females. Familial vulnerability to multiple sclerosis is inherited. CSF examination indicates that approximately one third of multiple sclerosis patients show moderate pleocytosis and increased protein content.

CT scans can detect lesions in multiple sclerosis, which may appear as contrast-enhanced ring lesions. MRI scans, however, are more sensitive. T2-weighted images show periventricular hyperintensities and white matter lesions that are well demarcated. Atypical presentations of multiple sclerosis on MRI can mimic tumors. Contrast enhancement can be helpful in increasing sensitivity in the MR scan. Gadolinium can aid in estimating the age of a plaque with acute attacks of 8 weeks or less showing enhancement. Lesions are usually at least 3 mm in diameter on MR scan and are located in various places such as spinal cord, brainstem, and cerebellum. There are clinical correlations between the size of the lesions and cognitive impairments. MRS scans show normal *N*-acetyl asparatate (NAA) in acute

lesions but decreased NAA in chronic lesions.

Patients with multiple sclerosis show lower global metabolism on functional brain imaging studies. Multiple sclerosis patients with fatigue show reduced metabolism in the frontal, premotor supplementary motor area, and adjacent white matter and increased metabolism in the anterior cingulate and cerebellar vermis. Active white matter lesions have been reported to be hypermetabolic. Decreases in left frontal and temporal cortical metabolism have also been reported in multiple sclerosis.

Inherited White Matter Disorders (Leukodystrophies) Leukodystrophies are progressive genetic disorders that affect the metabolism of myelin. The most common is metachromatic leukodystrophy, which occurs in 1 of 100,000 births and results from deficiencies of arylsulfatase-A in the lysosome. Initial symptoms can include dementia, gait unsteadiness, progressive spasticity, and rigidity. Metachromatic leukodystrophy can also present initially as a psychiatric disorder with symptoms similar to those of schizophrenia. CT scans typically show generalized atrophy with symmetrical hypodensities in periventricular regions. T2-weighted images show symmetrical hyperintensities in periventricular white matter with cerebellar involvement. White matter in the basal ganglia region is typically not affected in the early stages of the disease.

Adrenoleukodystrophy is related to an X-linked recessive gene near chromosome region Xq28 and seen only in males. Typically, adrenoleukodystrophy is first seen between the ages of 4 to 10 years. The first symptoms can include such brain-related symptoms as cognitive decline and personality changes. Later symptoms can include pseudobulbar paralysis, cortical blindness, hemiplegia, and ataxia. Signs of adrenal insufficiency can also occur and can precede neurological signs. Laboratory findings are low serum and chloride concentrations and high potassium concentrations. CT scans typically show symmetrical hypodensities in the corpus callusom splenium and possibly puncate calcifications. MRI scans show posterior white matter involvement in 80 percent of patients and anterior white matter involvement in 15 percent of patients. MRS shows decreased NAA concentration and an increase in choline-containing compounds.

Krabbe's disease (globoid cell leukodystrophy) involves a deficiency of galactocerebroside-b-galactosidase, with several forms of clinical presentations. The adult form is characterized by dementia, pyramidal signs, and optic atrophy. CT scans show hypodensities in white matters with high attenuation of deep subcortical structures such as thalamus and basal ganglia. T2-weighted MRI scans show nonspecific, symmetrical, confluent hyperintensities that first affect the parietal region and optic pathways.

Leukoencephalopathies There are a variety of inherited leukoencephalopathies that involve subcortical white matter at an early stage including Pelizaeus-Merzbacher disease, Canavan-Van Bogert-Bertrand disease, and Alexander's disease. Spongy degeneration of infancy (Canavan-Van Bogert-Bertand disease) is an autosomal-recessive genetic disorder that is characterized by an enlarged head (macrocephaly) and regression of motor skills, optic atrophy, and corticospinal signs with hypotonia and then spasticity. T2-weighted images show hyperintensities throughout the brain and hypointensities in basal ganglia and thalamus. MRS can show significant increase in NAA.

WERNICKE-KORSAKOFF SYNDROME

Wernicke's encephalopathy, typically associated with chronic alcohol dependence, is characterized by rapid onset of ocular abnormalities (e.g., nystagmus, paralysis of movement), mental confusion (e.g., drowsiness, disorientation, amnesia), and gait ataxia. It is caused by a deficiency of thiamine, which can be reversed in the early stages by administering parenteral thiamine. Neuropathological examination reveals punctate hemorrhage around the third and fourth ventricles involving the thalamus, midbrain, and pons. If left untreated, the syndrome can become fatal or Korsakoff's syndrome can follow. T2-weighted MRI images show hyperintensities that may be enhanced in medial thalamic and periaqueductal regions and atrophy in mammillary bodies. Korsakoff's syndrome patients show decreased activity in frontal regions and in diencephalic (i.e., thalamic) regions.

HEAD TRAUMA

Trauma, the leading cause of death in individuals up to 44 years of age, accounts for almost 10 percent of all deaths. Approximately half of the deaths associated with trauma include traumatic brain injury. Those who do not die are often left with significant disabilities. The injuries most commonly involve motor vehicles. The peak age for brain trauma is young adults between 15 to 24 years of age. Head injuries can be subdivided into closed head injuries, depressed skull fractures, and compound skull fractures. Closed head injuries with no gross structural damage to the brain are called concussions.

Emergency CT scans are indicated for head injuries with loss of consciousness or amnesia, focal neurological abnormality, a Glasgow Coma Scale score of 14 or less, depressed skull fractures, and penetrating injuries and those in persons above 60 or less than 2 years of age. Common types of neurosurgically treatable lesions include acute epidural or subdural hematoma. Epidural hematomas result from laceration of a dural artery (e.g., middle meningeal artery), which collects between the outer layer of the dura and the inner table of the skull. Epidural hematomas on CT or MRI scans are indicated by a biconvex extraaxial mass. Subdural hematomas usually occur when sudden deceleration causes tearing of cortical veins that cross the subdural space. Subacute subdural hematomas may have the same density as brain tissue and can be missed on CT scan. Chronic subdural hematomas may have a variety of shapes including biconvex or crescent-shaped and may be hypodense. Acute subdural hematomas typically show up as hypointensities on T2-weighted images. Chronic subdural hematomas typically show up as hyperintensities on T2-weighted images, and these lesions are enhanced with contrast. Chronic subdural hematomas can present as psychiatric symptoms including alterations in mood, cognition, and attention.

CT scans are often normal in traumatic brain injury, especially in the early stages. In later stages, CT scans can reflect patchy hypodense or hyperdense regions. MRI scans can be more sensitive than CT scans for assessment of intraaxial brain trauma. T2-weighted images may show multifocal hyperintensities, which may be due to diffuse axonal injury that results in tearing or shearing of axons and penetrating blood vessels.

Head injuries can result in pathological sequelae following the acute injury. Cerebral herniation due to swelling and edema secondary to traumatic brain injury can be life threatening. Other potential complications include ischemia due to compression of vascular cerebral supplies such as the carotid artery or cerebral artery. Head trauma can also produce communicating hydrocephalus after subarachnoid or parenchymal bleeding. Severe head injuries can result in brain death due to severe edema that impedes blood flow to the brain. MR or CT scan can show descending transtentorial herniation. Functional imaging studies such as SPECT or PET scans show profound loss of activity in the brain.

PET or SPECT scans are useful for the assessment of traumatic brain injury. Over 45 articles on functional brain imaging studies of head trauma have been published from 1988 to 1998. Traumatic brain injury can be visualized with PET imaging and is characterized by abnormalities such as decreased metabolism in the frontal or temporal lobes relative to other brain regions. Crossed cerebellar diaschisis is seen in many patients with focal cortical injuries. These abnormalities are correlated with neuropsychological deficits. Damage to the hippocampal regions has been associated with impaired memory. In patients with concurrent evidence of damage on other imaging modalities such as MRI, the corresponding abnormalities on PET show disturbances that extend beyond structurally identifiable borders. Functional brain imaging studies are more sensitive for the detection of abnormalities than MRI or CT scan. Compensatory changes such as increased metabolism in the occipital lobe are often seen in closed head injury.

The impact of head trauma is often overlooked in psychiatry. Even minor injuries to vulnerable parts of the brain can cause problems for years to come. In addition to PET, SPECT is one of the best tools in evaluating functional deficits from head trauma that are often not seen by other studies, leading to more understanding and effective treatments for patients. Typically, SPECT findings in head trauma include focal areas of decreased activity, often in a contracoup pattern (such as decreased activity in the left anterior prefrontal cortex and right occipital lobe or the anterior and posterior aspects of a temporal lobe) and, in some cases, marked hyperactivity over the site of the injury. The authors have seen increased off-center cingulate gyrus activity after a head injury.

Documentation of head injuries is essential for several reasons. It allows school-age children and teenagers to receive more specialized services. Knowledge of the injuries is often essential for legal and insurance reasons. Patient and family understanding of the effects of brain trauma enhances treatment compliance and develops a deeper understanding from family and support systems.

Patient H was in a motor vehicle accident and struck his head on the dashboard. He had a momentary loss of consciousness. His MRI and CT scans were normal, but he complains of severely impaired ability to concentrate and remember and is no longer able to work as an accountant. He has abnormalities on neuropsychological testing including impaired performance on memory tests. A PET scan finds significantly decreased metabolic activity in orbitofrontal cortex (Fig. 2.13-6). His physician recommends rehabilitation for traumatic brain injury to help the patient develop new coping skills to compensate for the brain injury and help both him and his family to readjust their expectations of what he may be capable of achieving.

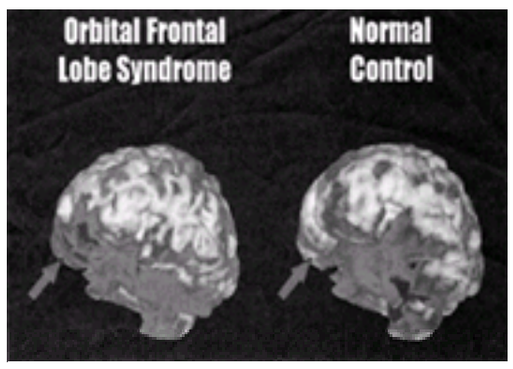

FIGURE 2.13-6 Three-dimensional PET FDG images demonstrate lower orbitofrontal metabolism in orbital frontal lobe syndrome in patient secondary to traumatic brain injury than in normal control. (See Color Plate 4.)

SOLVENT SYNDROME

Toxic exposure to organic solvents (such as toluene) exceeding OSHA limits can result in neurological symptoms (e.g., dizziness, nausea, weakness, incoordination), neuropsychological damage (e.g., cognitive deficits in memory and learning), and psychiatric symptoms (e.g., depression, anxiety) and can present as a significant problem in occupational medicine and neuropsychiatry. CT and MRI scans are typically normal. SPECT and PET brain imaging can display abnormal patterns of functional brain activity in regions such as the hippocampus, frontal and temporal regions which are consistent with predictions from neuropsychological abnormalities.

CARBON MONOXIDE POISONING

Carbon monoxide poisoning is a frequent event which can result in a wide variety of neurological and psychiatric sequelae such as mental deterioration, gait disturbance, and frontal lobe signs. Up to 40 percent of those who survive have permanent neuropsychiatric complications. Neuropathological findings include necrosis in the globus pallidum and possibly in other regions of cerebral cortex. CT scan findings can include cortical atrophy and low density lesions in the globus pallidus although these findings are often not present. SPECT and PET scans are more sensitive than CT or MRI scans at detecting damage and have reported decreased activity in basal ganglia and patchy diffuse hypoactivity in the cerebral cortex (especially in the frontal cortex) of carbon monoxide poisoning patients.

CHRONIC COCAINE USE

Chronic cocaine use has been reported to be associated with widespread vasoconstriction, neurological symptoms such as seizures and strokes; neuropsychological changes (such as abstract thinking, impairment of spatial memory and cognitive flexibility) and neurobehavioral symptoms such as paranoia and depression. CT scan studies have found evidence for atrophy which correlates with drug use. SPECT scan studies have found multifocal defects in frontal and temporal cortex and basal ganglia. PET scan studies have reported decreased frontal activity during withdrawal and a delayed decrease in FDOPA striatal uptake. Magnetic resonance spectroscopy of polydrug abusers have found 15 percent increase in phosphomonoesters and 10 percent decrease in nucleotide triphosphates. A functional MRI study of cocaine infusion reported signal increases in nucleus accumbens, striatum, thalamus, insula, hippocampus, cingulate, and prefrontal and temporal cortices and decreases in medial frontal cortex, amgydala, and temporal pole.

TUMORS

The most common initial symptoms of primary malignant brain tumors are headaches and seizures. Typically, other symptoms such as mental status change or hemiparesis occur before the tumor is diagnosed. An MRI scan is recommended for assessment of seizure onset after age 25. Symptoms consistent with increased intracranial pressure such as periodic bifrontal and bioccipital headaches, projectile vomiting, bowel incontinence, and papilledema can also be an initial presentation for tumors. Brain tumors can also present initially psychiatrically, with symptoms such as depression, nonfluent aphasia, or (if the tumor is located in the frontal lobes) impaired judgment. Visual hallucinations can occur if brain tumors are located in the occipital lobes. Temporal lobe tumor can result in symptoms such as memory impairment and linguistic deficits. Brain tumors account for 2 percent of solid tumors in adults and 15 percent of solid tumors in children. Approximately 70,000 cases of metastatic intracranial tumors and 15,000 cases of primary brain tumors are diagnosed in the United States each year. Approximately 25 percent of all patients with cancer have brain involvement during the course of their illness. Brain tumors are the second leading cause of death from neurological disease, exceeded only by strokes. Tumors located within brain parenchyma are intraaxial, in contrast to tumors located outside, which are called extraaxial. Tumors can have pathological effects by direct infiltration of brain tissue or indirectly through compression and pressure. The most common primary intracranial neoplasms are gliomas, which account for almost half of all primary intracranial tumors. The most common types of gliomas are astrocytomas, which comprise approximately 70 percent of all gliomas. Astrocytomas can vary markedly in terms of prognosis; low-grade astrocytomas have long survival (e.g., approximately 70 percent at 5 years), while high-grade astrocytomas can have low survival (e.g., approximately 10 percent at 2 years). The second most common primary intracranial neoplasms are meningiomas, which are extraaxial tumors. Modalities of treatment include surgery, radiation therapy, and chemotherapy.

CT scans show regions of hypodensity in tumor sites, with mass effects causing changes such as compression of ventricles, effacement of cerebral sulci, or midline shifts. Contrast enhancement can be very helpful in increasing the detection of brain tumors. Nonenhancing tumors are less likely to be aggressive. Calcification can occur in brain tumors and can be detected by CT scans. CT scans are less sensitive for assessing brain tumors in regions next to bone such as brainstem (e.g., cerebellopontine neurofibromas). Primary brain tumors are usually unifocal, whereas metastatic brain tumors are often multifocal. MRI scans are more sensitive than CT scans in detecting smaller tumors and assessing pathological changes such as edema. T2-weighted images show hyperintensities in tumor sites. Gadolinium can be used to enhance contrast in some tumor sites for MRI scans, although all tumors will not necessarily show enhancement. T_1-weighted scans often show decreased signal in tumor sites. Proton MRS shows a decrease in NAA, which is a neuronal marker in tumors. ^{31}P MRS can show increased phosphomonoester concentration in tumors.

Tumors are not the only reason for focal brain mass. Other causes include bacterial abscesses and cysticercal cysts. Cysticereal cysts are common in Mexico and many areas of the third world. CT scans show hypolucency at the site of the lesion, typically surrounded by enhancement. MRI can visualize the cysticercal cyst with greater sensitivity than CT scan.

FDG PET scans currently serve as the gold standard for the differentiation of recurrent brain tumors from tumor necrosis, because changes can occur in irradiated tissues months after the exposure which can be impossible to distinguish with structural imaging approaches such as MRI. However, recurrent tumors are hypermetabolic whereas radiation necrosis is hypometabolic (Fig. 2.13-7). FDG PET scans can be useful for grading tumors and predicting survival and can also be used to assess response to new approaches such as gamma-knife surgery.

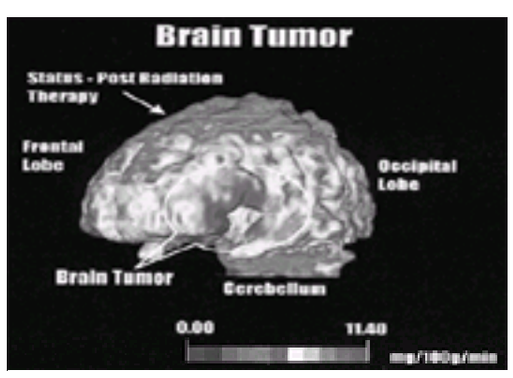

FIGURE 2.13-7 Three-dimensional PET FDG image demonstrate hypermetabolism in region of brain tumor in frontal cortex and decreased metabolism in parietal cortex secondary to postradiation injury. (See Color Plate 4.)

EPILEPSY

Epilepsy is a common neurological condition characterized by self-limited, excessive discharge of cortical neurons resulting in convulsive movements or change in consciousness and mental function. Approximately 2 million individuals in the United States have epilepsy, which is subdivided into two major categories: partial and generalized. Partial seizures usually originate in a circumscribed region of the brain; generalized seizures are associated with more diffuse abnormalities. Progression of seizures can spread and is referred to as a Jacksonian seizure. Another common type of partial seizure is psychomotor or temporal lobe epilepsy. The two major types of generalized seizures are convulsive (grand mal) and nonconvulsive (petit mal).

Clinical evaluation of seizures includes consideration of an extensive differential diagnostic list such as syncope, transient ischemic attack, migraine, and cataplexy. Different causes are associated with different ages of onset. Seizures in late life are associated with vascular disease, brain tumor, abscess, or trauma. Seizures in adolescence and early adulthood are associated with idiopathic epilepsy, trauma, or withdrawal from drugs or alcohol. Seizures in infancy are associated with congenital defects, birth trauma, metabolic disorders (e.g., hypoglycemia, phenylketonuria) or anoxia. Common neuropathological abnormalities include hippocampal sclerosis, although other causes include brain tumors, brain trauma, arteriovenous malformation, or cortical dysgenesis. The clinical workup includes neurological examination, electroencephalogram (EEG), brain imaging (structural such as enhanced CT or enhanced MRI, functional such as SPECT or PET), laboratory analysis of CSF or blood to evaluate for systemic disease (e.g., abnormal electrolyte, calcium, magnesium concentrations) and drug screenings.

MRI scans are more sensitive than CT scans at detecting lesions such as glial tumors, cortical dysplasia, hamartomas, and arteriovenous malformations. Coronal sections perpendicular to the hippocampal long axis may increase the sensitivity for detection of hippocampal lesions such as atrophy or sclerosis. Structural imaging should be done in patients over 18 years of age and in pediatric patients with abnormal development.

PET The pattern for temporal lobe epilepsy is defined by interictal temporal lobe hypometabolism. FDG PET is generally regarded as more sensitive than cerebral blood flow PET at detecting an epileptogenic focus. There is some controversy as to whether proton spectroscopy is more or less sensitive than PET for the detection of a temporal lobe epileptogenic focus.

SPECT Temporal lobe epilepsy is one of the most frequently encountered chronic epileptic disorders, and it is associated with many psychiatric symptoms such as depressive mood, anergia, irritability, euphoric mood, atypical pain, insomnia, fear, and anxiety. The imaging abnormalities in the temporal lobe typically are found in the medial aspects, which are difficult to find with routine EEG studies. SPECT findings in temporal lobe epilepsy and epilepsy in general reveal decreased activity in the interictal period and increased activity during the ictal phase. Proper diagnosis of temporal lobe epilepsy, especially when it presents with psychiatric symptomatology, is essential for effective treatment.

> A 7-year-old boy became very upset when his mother read *Alice in Wonderland.* He said that he felt like Alice. “I have weird things happen to me,” he told her. “I see things.” During the day he saw objects change shapes, often getting smaller. He also saw green, shadowy ghosts at night. He had a lot of anxiety symptoms. His mother brought him for evaluation. He had a normal EEG. A SPECT study was ordered for further evaluation. During the scan he complained of visual changes. The SPECT study showed increased activity in the medial aspects of his right temporal lobe. Within 2 weeks of divalproex (Depakote) treatment the boy's strange experiences disappeared, and over the next 6 months his anxiety significantly lessened.

FUTURE DIRECTIONS

Although PET and SPECT have made tremendous inroads into a better scientific and clinical understanding of brain disorders, there is still room for further growth and studies. These data are being correlated with other clinical variables to develop better prognostic and diagnostic perspectives. New technologies such as MRI are currently used primarily in a research context, and provide the basis for a rapidly evolving body of knowledge. This accumulating knowledge will eventually allow the use of structural and (especially) functional neuroimaging techniques in the diagnosis and assessment of psychiatric and neurological disorders.

SUGGESTED CROSS-REFERENCES

The principles of neuroimaging are discussed in Section 1.15 and Section 1.16, the neuropsychiatric aspects of multiple sclerosis and other demyelinating disorders are discussed in Section 2.7, and medical assessment and laboratory testing are discussed in Section 7.7. The psychiatric aspects of the acquired immune deficiency syndrome are discussed in Section 2.8. The use of neuroimaging in geriatric practice is discussed in Section 51.2e and Section 51.2f.

CHAPTER 3. CONTRIBUTIONS OF THE PSYCHOLOGICAL SCIENCES

3.1 PERCEPTION AND COGNITION

DANIEL J. SIEGEL, M.D.

The fields of psychiatry and psychology have at their etymological core the term “psyche.” Efforts to understand psychological development, mental processes, psychiatric disturbance, and psychotherapeutic and psychopharmacological interventions will benefit greatly from an open approach to understanding the psyche. The functions of the mind parallel those of the psyche, which can be defined as: (1) the human soul; (2) the intellect; (3) psychiatry—the mind considered as a subjectively perceived, functional entity, based ultimately upon physical processes but with complex processes of its own: it governs the total organism and its interaction with the environment.

COGNITIVE SCIENCE

The fields relevant to this overview are a part of the interdisciplinary studies of cognitive science, which includes anthropology, cognitive psychology, developmental psychology, psycholinguistics, artificial intelligence and computational science, and neuroscience. Each of these disciplines provides an important and unique perspective on how to understand the human psyche. Biological, psychodynamic, and social psychiatry can find a common home and language within cognitive science. The common divisions of nature versus nurture and biology versus psychology disappear when the origins of mental processes are examined.

The last ten years of the twentieth century, called the “Decade of the Brain,” led to discoveries in the neurosciences that revealed a wide range of findings relevant to psychiatry. One of the major discoveries was that the brain's structure and function are a result of the transaction of several factors, including genetic, physiological, and experiential variables. In particular, brain development requires specific forms of experience in order to foster the growth of neural circuits involved in a wide array of mental processes, including attention, memory, emotion, and self-reflection. Thus, experiences shape the unfolding of genetically programmed development of the central nervous system. Genes function both as a template of information and as a mediator of transcription of the proteins that determine neural structure. Experience directly shapes the selection and timing of how the activity of genes influences the structure of the brain. In particular, the nature of the relationship between child and caregiver shapes the emerging growth of areas of the brain that are essential to cognitive and emotional processes.

The human brain at birth is immature compared to the differentiated state of other bodily organs, such as the heart or kidneys. This immaturity requires that the infant and young child's brain utilize the mature state of the adult caregiver's brain in order to organize its own functioning. These findings from developmental neuroscience have raised the important integration of interpersonal relationships and brain development. The cooperative communication of infant-caregiver attachments is thought to provide the building blocks for emotional development as well as for abstract reasoning and cognitive abilities. The patterns of interaction between child and caregiver have a direct impact on the way the brain develops and the mind of the child functions. Thus, cognitive processes need to be considered as the way in which the mind emerges from within the genetic, physiological, and experiential factors that shape the development and maintenance of mental function.

MIND AND BRAIN

A generally accepted view of the mind is that it emanates from a portion of the activity of the brain. What is this activity of the brain and how does it give rise to such mental processes as perception and cognition? How do the human experiences of sensation, thought, emotion, attention, self-reflection, and memory emerge from neural processes?

The brain is composed of about one hundred billion neurons. An average neuron is connected to about ten thousand other neurons at synaptic junctions. Release of neurotransmitters at these junctions promotes or inhibits the firing of the postsynaptic neuron's membrane with an action potential that then sends an electrical signal down its long axon to influence other neurons downstream. With hundreds of trillions of connections among a weblike neural network, there are countless combinations of possible activation profiles. The term *neural net profile* is used to describe a certain pattern of activation of the complex layers of neural circuits.

The neural net profile is the fundamental way in which mental processes are created. These activations can lead to further neural processes in a cascade of dynamic interactions that produce a range of internal events and external behaviors. The essential components of the mind come directly from how these neural events create the flow of energy and information.

ENERGY AND INFORMATION

The mind is a processor of patterns in the flow of energy and information within the brain (Table 3.1-1). Activations of individual neurons, groups of neurons, circuits or networks of neurons all involve the flow of energy through the complex system of the brain. This energy reflects the flow of ions across membranes, the consumption of oxygen and nutrients by neural cells, and the active transport of molecules into and out of nervous tissue. However, the mind is much more than some outcome of energy flow—the function and purpose of this flow of energy is to process information.

The mind is a processor of energy and information.
Energy is contained within the activations of neural circuits.
Information is contained within the patterns of activation termed a *neural net profile* or *mental representation*.
These representations serve as symbols that cause further effects in the mind, leading to the processing of information.

Table 3.1-1 Basic Ideas of the Mind

Information is contained within the brain by a process of representation. A symbol carries information about another object in the world. For example, when an individual sees the Eiffel Tower, the brain responds in particular regions of the visual system with the activation of a neural net profile. When the Tower is recalled at a later time, the visual cortex activates a similar neural net pattern and the Tower is visualized. The activation of a particular pattern of neural firing thus contains within it information about something else (the Tower). Neural net activation profiles thus represent information in the brain. Examples of representational forms include

perceptual, sensory, linguistic, and more abstract representations of concepts and categories.

Computational science reveals that the nervous system can function as a parallel and serial process of information. This processing occurs when a symbol, such as a mental representation, causes an effect. Such effects can be seen as subsequent activations of neural net profiles. Information processing becomes even more complex when the effects themselves carry information. Within cognitive psychology, these information-processing events can be seen as the contrasting, comparing, generalizing, chunking, clustering, differentiating, and extracting processes that lead to a more highly interwoven set of mental representations.

INFORMATION PROCESSING

Several elements of the brain's function as an information processor can be described (Fig. 3.1-1). At the most basic level, (A), energy leads to neural responses. This energy can be in the external form of light on the retina or soundwaves vibrating the tympanic membrane. It may also take an internal form in which the flow of energy within neural activations themselves produce subsequent neural responses.

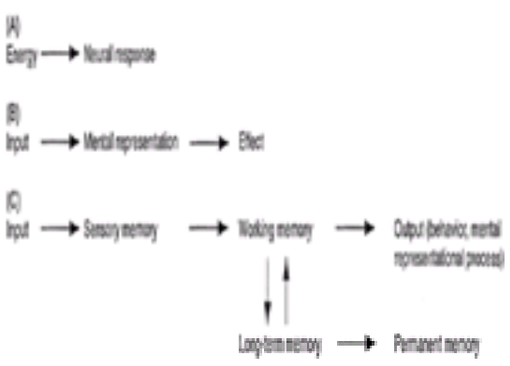

FIGURE 3.1-1 Information-processing models.

A second level of understanding information processing (B) is in the idea that an input (internal or external) leads to a representational response (a neural net profile of activation), which in turn produces a downstream effect or output. This output can be internal, such as the generation of other representations, or external, in the form of observable behavior.

A third level of viewing information processing in the mind (C) is the conceptualization of forms of sensation, perception, attention, and memory. According to this view, external energy is sensed by the peripheral nervous system and registered as sensation within the brain. The selective processing of aspects of these sensations, called “filtering,” leads to the production of perception. These perceptions are themselves subject to further filtering in which only a select few are placed within working memory. This is sometimes called the “chalkboard of the mind” and is thought to be able to handle seven plus or minus two items. It is within working memory that representations can be consciously manipulated, contrasted, clustered, and reassembled. Thus, consciousness may be intimately related to this aspect of mental functioning.

Sensation refers to the initial stages of the basic information-processing model (Fig. 3.1-1) Sensory memory lasts for about one quarter of a second. Items in sensory memory are then filtered into working or short-term memory, where they last for about one half-minute. Working memory is able to handle about seven items unless further processing creates linkages to other items within longer-term memory. Rehearsal allows these representations to remain for longer periods of time. Cognitive processes that can group bits of information into large chunks *(chunking)* can increase the capacity of working memory by making each unit more information-rich. Representations are then processed and placed within long-term memory where they can be retrieved for future use. A process called *cortical consolidation* is thought to involve some form of rehearsal and perhaps rapid eye movement sleep in which items in long-term memory are further processed and placed within permanent memory storage.

ATTENTION

Attention is the process that controls the flow of information processing. There are many aspects to attention that may derive from their neuroanatomic localization. Three components of attention have classically been used to describe certain deficits in psychiatric disorders; future studies may reveal more neurophysiologically based descriptions. These components are selectivity, capacity, and sustained concentration.

Early conceptualizations of attention were based on Donald Broadbent's idea of a filter that selects a limited amount of incoming stimuli to be further processed. Limited capacity of attention was thus attributable to the inability to process the overwhelming amount of incoming stimuli. An attention bottleneck was described as occurring either early in the sensory process and, thus, automatically or late in the perceptual processing stage and involving such processes as identification and classification. More recent views have considered the concept of general cognitive resource capacity, which limits the stimuli processed. These perspectives have been applied to understanding various psychiatric conditions, such as schizophrenia and attention-deficit/hyperactivity disorder.

Selective Attention One aspect of attention is that it focuses a metaphorical spotlight on external stimuli or internal mental representations. In Broadbent's conceptualization, selectivity has three dimensions: (1) filtering, focusing on specific attributes (e.g., large squares versus small squares); (2) categorizing, based on stimulus class (e.g., attending to letters in whatever script they are written); and (3) pigeonholing, reducing perceptual information needed to place a stimulus into a specified category (e.g., using only long hair to classify individuals as female). Each of these aspects of attention acts on incoming stimuli to make a determination of fit for the sought-after characteristic. Schizophrenia patients show greater difficulty with pigeonholing than with filtering when they are symptomatic. Another conceptualization of selective attention distinguishes between two interactive ways of processing sensory input. *Preattentive processing* (a parallel function) assesses global, holistic patterns and appears to be an early component of the perceptual process. *Focal attention* (a serial process) follows preattentive processing and involves a detailed analysis of stimuli characteristics. Focal attention can be directed at one stimulus form only and is thus limited in its capacity. In contrast, parallel (preattentive) attention processes do not appear to have limited capacity and can detect gestalt aspects of environmental stimuli from numerous sources. The ability to hear one's name called out by a nonattended voice in a crowded, noisy room is an example of an ongoing parallel process with the ability to detect gestalt features and extremely familiar (and thus automatically processed) stimuli.

Attention Capacity The concept of processing capacity involves the idea that a given task makes a demand on a limited pool of resources. A task with a high processing load draws more resources from the finite pool than does a task with a low processing load, thus inhibiting the accessibility of resources for other simultaneous functions drawing from the same pool. Focal attention requires cognitive effort and thus has a high processing load demand. Cognitive models describing several resource pools suggest an executive process that distributes resources to various cognitive functions. Serial processes that demand processing capacity inhibit the simultaneous action of other serial high-load processes. In contrast, parallel processes have low or no processing capacity demands and can function simultaneously with numerous other functions without inhibiting them.

Optimal performance is attained with moderate levels of arousal that allow for the establishment of task goals and feedback from the performance of the task, leading to appropriate resource allocation. Low levels of arousal impair those processes and lead to inadequate resource allocation. High levels of arousal may be detrimental to the performance because of poor discrimination of stimuli and diminished efficiency of allocation, resulting in poor attention functioning. Pupillary dilation is directly proportional to the level of arousal and has been used as a measure of the degree of processing demand for specific cognitive tasks.

Sustained Attention The ability to sustain attention is called *vigilance* and can be tested with task demands for alertness and concentration over a period of a few minutes to an hour. The tests usually involve detection requirements for target stimuli that occur infrequently at random intervals. An example of such a test is the continuous performance test, which has been used to study various psychiatric disorders. Important aspects of the tests are derived from signal detection theory and include the factors of sensitivity and response criterion. Sensitivity is the distinguishing of target from nontarget stimuli. The response criterion is the amount of perceptual evidence required to support the decision regarding a target versus a nontarget item.

FORMS OF REPRESENTATIONS

The essential feature of information processing in the brain is that the patterns of activation of neural circuits, the neural net profile, contains information within it. These mental representations themselves produce a neural activation effect that both contains information and produces further neural events. The localization of the neuronal firing and the particular pattern of neural activations determine the nature of what the neural net profile represents. For example, activity in the optic nerve in response to light leads to a cascade of neural responses within the visual cortex, which then gives the perceiver the sensation of a visual image. Future activation of those layers in the visual cortex in that general pattern will be the recollection of the visual image. Pattern and localization determine the kind of representation and the information it specifically contains.

SENSATION AND PERCEPTION

Forms of representations include sensory and perceptual ones that derive from input from the external world via the peripheral sensory nervous system. Sensory representations are the least processed of mental representations and are thought to be as close as the brain can get to representing the world as it is. This is a form of processing termed *bottom-up* and is in contrast to more elaborately processed representations that are directly influenced by more abstract aspects of prior experience, called *top-down* processing. As the initial sensory activations are processed (classified, compared, linked to representations from prior experience) they become influenced by “higher”-order processes and become classified as perceptual representations.

The initial stage of encoding a visual sensory representation is called an *iconic image* and is held within sensory memory for a brief period. Features of the initial stimulus, such as its linearity, size, direction, and color, are the information held within this sensory memory representation. Attentional processes at the level of sensory memory act on the initial image with higher cognitive functions such as classifications and chunking. In their essence, these top-down processes compare, contrast, and transform the initial representation to create new perceptual images within working memory. Studies of patients with schizophrenia reveal specific deficits at this early stage of perceptual processing.

Perception is created by the top-down transformations of sensory images. Perception does not necessarily involve the experience of consciousness. Blindsight patients provide an example of perception without awareness. Long-term memory can encode nonconscious perceptions. This has important clinical implications in that patients may be able to indirectly recall and be influenced by events and stimuli that they cannot consciously recall having perceived. However, if conscious, focal attention is involved in perception then the representations are processed differently. The involvement of focal attention appears to be necessary for the activation of the hippocampus in memory processing, which allows for the encoding of explicit, consciously accessible autobiographical memory. Posttraumatic and dissociative states may involve the blockage in focal processing of perceptual representations, thereby leading to psychogenic amnesia.

Imagery involves the activation of brain circuits responsible for perceptual processing. Representations (neural net profile activation patterns) can thus be created by external or internal means. Mental imagery can involve the generation, inspection, retention, and transformation of perceptual images. This processing involves similar effort and timing as when the object is perceived from an external source. Thus, complex visual images require more effort and time to rotate in internal and external reality. The ability of the mind to generate mental images is used in various forms of psychotherapy and may also be an important mechanism in the pathological production of hallucinations and illusions seen in several disorders.

MEMORY SYSTEMS

The neural networks of the brain are capable of responding to experience by the activation of particular patterns of distributed activation. Donald Hebb described a basic principle of memory that has been repeatedly supported by research: “Neurons which fire together, wire together.” Neurons that are activated in a particular pattern at one time will tend to fire together in a similar pattern in the future—this is the essence of memory.

The brain has various forms of circuits responsible for different systems of memory (Table 3.1-2). The form of memory most commonly thought of as “memory” is termed *explicit* or *declarative memory*. This form involves the conscious sensation of something being recalled at the time of retrieval and allows for the awareness of the autobiographical or factual knowledge to be shared, often verbally, with others and the self. This explicit memory system requires the involvement of focal attention and the activation of the hippocampus within the medial temporal lobe memory circuits for encoding and retrieval. Items focally attended are placed in working memory, processed further, and then placed in long-term memory. After a period of weeks to months, items are thought to undergo a process called *cortical consolidation* that places them in permanent memory where their retrieval no longer requires the hippocampus. Cortical consolidation helps to explain the phenomenon of retrograde amnesia following a physical trauma to the head. The finding that cortical consolidation may require rapid eye movement (REM) sleep also raises important questions regarding the relationships among posttraumatic stress disorder, disturbances in REM sleep, and unresolved traumatic memory.

Implicit
A behavioral, emotional, and perceptual form of memory devoid of the subjective internal experience of recalling, of self, or of past. Can include schema or mental models that are summations of representations from numerous experiences.
Also known as *early, procedural, nondeclarative memory*. Cannot be expressed in words.
Present from birth. Does not involve the hippocampus or require focal, conscious attention. Probably involves various circuits, including those of the basal ganglia, limbic system (amygdala, anterior cingulate, orbitofrontal cortex), and perceptual cortices.
Explicit
A form of memory requiring conscious awareness and involving the subjective sense of recollection and, if autobiographical, of self and past.
Also known as *late, episodic/semantic*, or *declarative memory*. Can be expressed in words or drawings.
The autobiographical component of explicit memory does not fully develop until past the first 2 years of life as the hippocampus and orbitofrontal cortex upon which it depends are maturing.

Table 3.1-2 Memory Systems

Before explicit autobiographical memory processing becomes available after the first years of life (during which time the hippocampus and orbitofrontal cortex are maturing), a form of memory called *implicit* or *nondeclarative memory* is already in place and remains active throughout the lifespan. Implicit memory involves a wide range of systems including behavioral, emotional, and perceptual memory. When these circuits are activated in retrieval, they do not have the sensation of something being recalled. For example, when riding a bicycle a person may not recall having learned to ride and may not even feel that anything is being recalled. Similarly, a person with a fear of dogs may be unable to explicitly recall (consciously) any event that may explain such an emotional response. The existence of intact implicit recollection in the absence of explicit memory is found in various conditions including surgical anesthesia, hypnotic amnesia, the adverse effects of some benzodiazepines, neurological conditions such as Korsakoff's syndrome and bilateral hippocampal strokes, divided attention, and childhood amnesia. Such a dissociation in usually associated mental processes may also occur in response to trauma and in individual with dissociative disorders. Thus, patients with post-traumatic stress disorder may have an inability to recall a traumatic event and yet may avoid contextual stimuli similar to the initial trauma, evidence startle response and anxiety, and have intrusive perceptual images each reflecting impaired explicit memory and intact elements of behavioral, emotional, and perceptual implicit memory. Supported by initial imaging studies, this explanation needs further validation through research into memory processes in the disorder.

CONSCIOUSNESS

The vast majority of mental processes are outside of conscious awareness. These processes can impact thinking, feeling, and behavior despite the lack of conscious awareness. Consciousness can be thought to include two elements: awareness and sentience, the quality of the experience. Each form of consciousness has intrigued philosophers and scientists for many years and various theories have been proposed to explain these phenomena. Little is known about the basic mechanisms that underlie the sentient experience of consciousness. Phenomenal awareness has been the focus of active research and has yielded some basic ideas about the role of consciousness in cognition. One essential issue is that the effective processing of mental representations does not require conscious awareness. However, the intentional, strategic alteration in patterns of processing may necessitate the involvement of consciousness in order to achieve a new outcome. Thus, consciousness is not required for most processes, but its involvement allows for a qualitatively different result in representational transformations. One example of this is in memory processing in which explicit memory requires focal, conscious attention or awareness in order to encode events into explicit form. Such representations

are later available for conscious retrieval when they can be examined and transformed for intentional purposes, such as the recollection of facts or autobiographical knowledge.

Conscious awareness thus is a specialized aspect of some cognitive processes. Two leading hypotheses focus on the way in which representational processes are linked or bound together during the flow of informational transformations within the mind. One hypothesis suggests that 60-cycle-per-second sweeping process that extends from the thalamus to the neocortex. This sweep may serve to bind representational processes together in the internal experience of consciousness. Processes that are active at the time of the sweep thus become linked within consciousness. Another view implicates the role of the lateral prefrontal cortex and its role in working memory. Working memory serves as the chalkboard of the mind and representational processes that become linked to the activity in this region are then a part of the attentional spotlight of conscious awareness.

Based on a biological assessment of brain function, Gerald Edelman's theory describes two forms of consciousness that derive from the resonant interactions between groups of neurons. In his model primary consciousness stems from the interaction between perceptual categorizations and conceptual categorizations. This form of consciousness, called the *remembered present*, is also found in higher animals and is unable to transcend momentary awareness. It is embedded in the present but is influenced by categorizations from the past. In human beings the capacity for lexical or language processing enables a secondary or higher-order consciousness to exist and stems from the resonance between those processes and conceptual categories. Higher-order consciousness frees inner experience from the prison of the present and allows for views of the past and plans for the future. Included in these forms of consciousness is a scene of the present situation in which the self is placed in a temporospatial context.

Cortically blind patients state that they cannot see visual stimuli, but they respond behaviorally as if they were fully sighted. They describe being unaware of visual perception, but they make eye and hand movements that reflect the processing of information about stimulus location, shape, orientation, and direction of motion. In information-processing terms behavioral tests reveal that blindsighted patients do sense and perceive visual stimuli but do not have conscious awareness of the perceptual process, an example of a dissociation of the normally associated processes of perception and consciousness or awareness of phenomena.

Misidentification syndromes are other examples of subjective, conscious experience disturbances. In prosopagnosia patients are unable to consciously access memories regarding persons familiar to them. In the Capgras syndrome patients are able to recognize a familiar person's face but feel that it is not really that person. Being certain, as in recognition, is one aspect of consciousness as a cognitive process. The pathological uncertainty of patients with obsessive-compulsive disorder theoretically can be viewed as a disturbance in that aspect of conscious functioning.

Consciousness provides a sense of continuity. Various studies find perceptual discontinuity (e.g., the presence of a blind spot in the visual field, blurred peripheral vision, saccadic eye movements that displace the visual field with sudden shifts) but the subjective experience of continuity in consciousness.

Many psychiatric patients experience a profound sense of discontinuity and confusion that may be related to a dysfunction in the sense-making, continuity-creating process of consciousness. Some psychiatric symptoms, including derealization and depersonalization, may be understood in terms of alterations in conscious functioning (as seen in some patients with schizophrenia, mood disorders, anxiety disorders, dissociative disorders, posttraumatic stress disorder, and some personality disorders), distorted body image (as in eating disorders or mood disorders), intrusive memories and flashback phenomena (as in posttraumatic stress disorder), and hallucinations (as in psychotic states).

Many psychiatric disturbances may thus involve alterations in the experience of conscious awareness and sentience. Various forms of amnesia may involve the blockage of explicit recollection and prevent certain representations from entering consciousness. Body image distortions; obsessive thinking; dissociative symptoms, such as depersonalization and derealization; and perceptual distortions, such as hallucinations and illusions may involve disturbances in conscious sentience. Primary disturbances in thought, such as loose associations and delusions, may also involve disruptions in the process of conscious awareness and sentience.

Mental Models and Schemata Studies of perception and memory support the view that the mind has organizational structures that influence the interpretation of sensory data, shape the encoding of information into long-term memory, bias the retrieval of items stored in memory, and help determine the behavioral response. Those organizing cognitive functions are called *mental models* or *schemata*.

Mental models are unconscious, highly organized structural processes that are derived from past experiences, that aid in interpreting present stimuli, and that influence the direction of future behavior. Mental models exist for various situations. When a situation is appropriate for a given mental model, that model is activated or instantiated. The process, which regulates which model is activated at a given moment, helps to carry out the appropriate information processing and subsequent behavior. The regulation process depends on the accurate reading of the situation and the selection of the appropriate mental model. Aaron Beck's theory of depression is based on the idea that mental models or schemata can produce depressive thinking and depressed moods. John Bowlby used the concept of internal working models to describe the development of early forms of schemata for attachment relationships. Difficulties in intimate relationships and related behavioral dysregulation can be seen as derivatives of models of inadequate early attachment and the presence of multiple, conflictual models. Mardi Horowitz's view of certain personality disorders and maladaptive interpersonal behavior also includes the role of mental models or person schemata. Among those schemata are models of the self, another, and the self in relationship to another in specifically defined maladaptive role relationship models. Some psychiatric signs and symptoms can be seen as derivatives of conflictual schemata and situations. Classic descriptions of interpersonal patterns in some patients with personality disorders, such as idealization and devaluation, can be seen as maladaptive schema functions.

Thought, Language, and Cognition There is no universally accepted definition of thought. Suggested basic elements include propositions (functions containing meaning), images, and lexical and semantic symbols. Cognitive processes can be carried out in parallel, simultaneously, and without consciousness. Cognitive processes, such as thoughts, are often directly known only through translation into consciousness and language. As in the study of mental models, clinical observation and experimental paradigms can infer the nature of thought processes only through indirect measures. These concepts are important in defining the term *thought disorder*.

Thinking involves the mental representation of some aspect of the world or of the self and the manipulation of those representations. Thinking depends on explicit memory and implicit memory for prior experiences. In addition, thought processes can be influenced by a person's emotional state and mental models. The basic components of thinking include categorization, judgment, decision-making, and general problem solving. The assignment of representations of events or objects to categories is important to subsequent thought processing because thoughts can act on the general class to which an item belongs rather than on individual representations; this is another example of top-down processing influences.

The ability to judge the probability of uncertain events, a primary role of judgment, is a fundamental aspect of the rationality of thought. The lack of conformity of thinking to the rules of logic is one aspect of disordered thought processing. Thinking is important in choice, the decision to choose among various options. Each of these processes contributes to the goal of problem solving; data are assessed, classified, transformed, and compared on the basis of logical rules to produce a choice that solves a problem. Failures in these steps can result in limitations and distortions in normal thought processes.

Psycholinguistics is a complex domain that focuses on the cognitive process of language formation and semantic analysis. Cognitive science views language as a dominant influence on subjective experience. It is the medium that dominates human social communication and is one of the major features distinguishing *Homo sapiens* from other species. In the human infant language shapes the ways in which the world is perceived, the manner in which desires are communicated and satiated, and the way in which society responds. Disorders in receptive and expressive language functions influence both the subjective experience of the world and social functioning; children with such disorders often have multiple levels of maladaptation. The ability to communicate through nonverbal language depends on social cognitive processes.

Modes of Processing The mind is capable of distinct modes of processing mental representations. A serial mode utilizes sequential processing in a linear fashion, which is said to be slow and energy-consuming because only a few items can be processed serially at a time. Focal, conscious attention is believed to occur in serial fashion. A parallel mode is more common throughout the brain and involves the simultaneous manipulation of large numbers of representations in a nonlinear fashion. Pattern recognition is an example of such a rapid, low-energy consuming process that can deal with a wide array of stimuli at the same time.

Jerome Bruner has described the distinction between the earlier mode of thought, called narrative cognition, versus the later mode, which is the scientific, logical, paradigmatic mode. Narrative thinking is a context-dependent form of processing that incorporates the internal experiences of the teller and the perceived expectations of the listener in the production of a story. Stories also involve the subjective experiences of the characters involved in the unfolding sequence of events. Logicoscientific paradigmatic processing is said to occur in a context-independent manner that focuses on abstract concepts and their logical, cause-and-effect

relationships. Children develop narrative thinking by the age of 2 years and the co-construction of stories between parent and child is a primary mode of communication in all cultures throughout the world.

Another distinction in contrasting modes of processing has been identified in the type of mental processes primarily attributed to the right or left cerebral hemisphere. Studies drawing on the findings of patients whose corpus callosum has been surgically severed, who have unilateral neurological lesions, or in subjects undergoing brain-imaging protocols have found a remarkable consistency in trends of left- versus right-hemisphere functioning. Some general principles from this array of studies suggest that many processes involve both hemispheres; however, there are distinct patterns primarily originating from each side of the brain. Studies of gender differences in laterality suggest that women are less lateralized in that their processes appear to be distributed across both hemispheres simultaneously whereas men appear to be more lateralized with less “cross-talk” across their hemispheres. For example, the semantic meaning of words is distributed more bilaterally in women than in men. The following generalizations relate to right-handed individuals and to most left-handed people as well. In the right hemisphere are fast-acting, parallel, holistic processes including visuospatial perception. The right side specializes in representations such as images and sensations and the nonverbal meaning of words, sometimes referred to as analogic representations. The right hemisphere is thought to work as a pattern recognition center, capable of assessing the gestalt context of a scene and providing a synthetic interpretation. On the left side are primarily more slowly acting, linear, time-dependent, serial processes. Left hemispheric processes manipulate the verbal meaning of words, known as digital representations, in a logical analytical mode of processing. A generalization from a number of studies is that the right hemisphere tends to note the patterns in the world and creates contextual meaning; the left hemisphere can only make a rationalization of the details of what it perceives in order to create a sense of meaning from a logical view that lacks context and thus may actually seem like a discontinuous and irrational set of data.

The processing of emotion also appears to have a lateralized distribution. The expression of emotion appears to be mediated primarily by the right hemisphere. Facial recognition of the affective expression of others also appears to be a specialty of the right hemisphere. Of note is that the right hemisphere appears to have a more integrated representation of the body's status, information that may be essential for individuals to know how they feel.

Metacognition Metacognition concerns processes that act on the cognitive processes themselves—thinking about thinking. The thinking can be conscious or unconscious and is revealed through either metacognitive knowledge or the regulation of cognition. Knowledge about cognition appears to develop by the age of about 6 when a child enters elementary school; this knowledge takes various forms, including what is known as the appearance-reality distinction—that things may not actually be as they appear to be. Two components of this awareness are representational diversity (the same object may appear to be different to different people) and representational change (thoughts today are different from those of yesterday and may be different again tomorrow). This form of knowledge about the person-specific meaning of cognitive representation requires some sense of the person's awareness of the separateness of minds, a theoretical domain in developmental cognitive psychology called the *theory of mind*.

The regulation of cognition, also called *metacognitive monitoring*, includes such processes as planning activities, monitoring activities, and checking outcomes. Metacognitive monitoring may involve the assessment of thinking sequences for fallacious logic, factual errors, and contradictions in the content of speech.

Social Cognition Bridging the fields of social psychology and cognitive psychology, the study of social cognition focuses on the mental processes involved in social interactions. The domains include the study of empathy, interpersonal communication (verbal and nonverbal), person perception, relationship scripts, and group processes. Other related areas include studies of attribution bias, memory for social interactions, stereotyping, mental control of social cognitive processes, and cognitive origins of a sense of self. Social cognition can be seen as a domain of social psychology that uses information-processing theory to assess the components of attention, perception, encoding, memory, retrieval, and schemata. A dominant theme in social cognition research has been that top-down, theory-driven processing influences interpretations of social situations and actions in such situations. Developmental psychologists have focused on the origins of social cognitive functioning and its deviations. For example, children with autistic disorder have significant deficits in empathic capacity and in the ability to interpret social cues. Social cognitive deficits may be present in different domains in other psychiatric disorders.

Discourse and Narrative Discourse is communication from one person to another; it is thought to involve a sense of intention or plan. Normal discourse follows a set of rules that ensure the coherence and effectiveness of communication: what is intended to be stated by the sender is understood by the listener or receiver. Some researchers support the idea that discourse is a cognitive function that follows the basic principles of information processing, including a schema for effective communication, and of social cognition, such as taking into account the listener's perspective. Incoherent discourse can be noted by analyzing unlicensed violations of the primary maxims of discourse. Another technique is that of discourse analysis, which examines the ways in which discourse deviates from an assumed discourse plan. The exact method to quantify abnormalities in discourse remains controversial, but clinical impressions of incoherence remain important for assessing deficits in social communication. The deficits may result from learned behavior, inherent cognitive abnormalities in thought or language, or deviations in social cognitive functioning. Deviations from normal discourse can be a general finding in need of further assessment. Abnormal discourse is clinically evident in psychosis, specifically in schizophrenia.

Narrative is a broad domain ranging from the literary study of fiction to the developmental psychology investigations of the origin of autobiographical accounts. From a cognitive point of view narrative is important in understanding the relations of language, memory, consciousness, mental models, self-schemata, and social cognition. Narrative can be generally defined as the way in which a person creates a verbal account of a sequence of events in the world and the internal subjective experience of the characters of the story.

Autobiographical narrative begins early in life as the capacity for language develops. Studies of early monologues find that young children interpret and assign meaning to events in their world from an early age. Narrative helps to record and make sense of the past, interpret the present, and anticipate the future. The brain has been called an “anticipation machine” and mental models, prospective memory, and narrative are the major ways in which top-down processing attempts to prepare for the possible future. The enactment of narrative themes directly affects the way in which individuals live out the story of their lives.

As with other areas in development, debate concerns whether this aspect of cognition develops from a biological imperative (i.e., the brain needs to make sense of the world, and narrative is the language output derived from that innate process) or from an internalization of social experiences (i.e., families tell stories, and children practice taking the narrator role). Anthropologists who study psycholinguistic development across cultures have described a phenomenon called *coconstruction*, in which family members collaboratively create a story of daily events in their lives. How those family behaviors influence the child's emerging capacity to organize experiences and encode them into long-term memory to be retrieved later in the production of autobiographical narrative is a fundamental question for many disciplines in cognitive science. Specific deficits in early family experiences and in innate cognitive capacities may theoretically impact the child's narrative capacity. These differences can be seen both in how different individuals tell the stories of their lives and the way they make decisions in life.

Cognitive Development Developmental theories and research can be divided into several views. Stage theories (Jean Piaget, neo-Piagetian, the sociocultural school of Alexander Luria and Lev Vygotsky) describe discontinuous periods of development, with times of stability and consolidation alternating with instability and transition. Information-processing models have not been explored in as much detail with regard to child development, but the models postulate a nonstage theory, in which the emergence of cognitive capacity is a continuous process that does not require a set of invariant sequences. Both stage and nonstage views embrace the idea that a hierarchial integration and an ongoing differentiation are fundamental aspects of cognitive development.

Another distinguishing feature is the degree to which the theories view the contributing role of innate, biological factors and the role of culturally determined social learning experiences. Do cognitive capacities emerge from a genetically determined plan, as in the Piagetian view or do they develop in response to experience, as in the sociocultural view? Developmental psychologists have found features of both views, supporting the idea of a transaction between innate factors and environmental experiences. More recent conceptualizations have drawn on the functioning of complex systems in order to conceptualize development as the continual emergence of ever-more complex capacities.

Psychiatric disturbances in cognition may reflect arrested patterns of normal cognition (as in mental retardation), deviant developmental pathways (e.g., social cognitive functioning in persons with autistic disorder), and specific cognitive impairments (e.g., schizophrenia) that may have been present early on or only became evident as life requirements, such as school, became demanding (some cases of attention-deficit/hyperactivity disorder). Investigations into the developmental features of those disorders is a major focus of the field of developmental psychopathology.

Self-Organizational Processes An understanding of both the development and subjective experience of cognitive processes has been greatly informed by the insights from the fields of evolutionary neurobiology and the nonlinear dynamics of complex systems, otherwise known as *chaos theory*. In selectionist theory, the billions of neurons become clustered into groups that have similar functions and when activated become reinforced. Neuronal groups that are not activated die off; those that are activated survive. The brain, as in species in nature, generates a diversity of activity that can then be selected by interaction with the environment. In addition, the brain has value systems that selectively reinforce the activity of neuronal groups that enhance survival. In this way the brain's neuronal groups compete

and differentiate within the brain and create an ongoing living system perpetually evolving or developing through time.

In chaos theory, complex systems from the inanimate to animate organisms have been shown to have self-organizational processes. Three principles are relevant to psychiatry and include their nonlinear nature, self-organizational processes, and movement toward complexity. *Nonlinear* refers to the finding that small changes in input or initial conditions lead to large and in the long run unpredictable changes in output. These systems function on the rules of probability, which predict that certain combinations of activity within the system are more likely than others and tend to move the system towards self-organization. This probability also predicts that the system will move itself toward increasingly complex states of functioning.

The state of activation of the various parts of the system can cluster into repeated patterns called *states*. In the brain a state of mind or mental state describes the way in which the various neuronal groups may become activated at a given time. Repeated patterns of neuronal group activation, a neural net profile, can become reinforced if they occur frequently or if the value system of the brain engrains their profile. These engrained patterns of activation are called *attractor states*; those states that are least likely to occur are called *repellor states*. The mental states are determined by the constraints on the system. Modification of constraints allows the nature of attractor and repellor states to be altered. Constraints are both external and internal. Thus, features of the external environment such as the way other people behave and relate to an individual can directly affect which mental state is more likely to be activated within the person. Internal constraints include the synaptic strengths of association as determined by both constitutional features and genetics, and those learned from experience as encoded within memory processes.

Psychiatric disturbances may be conceptualized as disturbances in self-organizational processes. Inherited and experiential internal determinants and ongoing external, environmental and social influences on the constraints of the system can thus directly affect both the development and effective use of self-regulatory mechanisms. Viewing psychiatric disturbances in this way allows for a synthesis of the unnecessarily but often historically divided views of psychodyamic, biological, and social psychiatry.

States of Mind With perhaps one hundred billion neurons, each with an average of ten thousand synaptic connections with other neurons, the brain may be capable of a huge, incomprehensible number of possible activation patterns estimated to be over ten to the millionth power. The organization of these possible neural network profiles may be the fundamental goal of cognition and perception. One way of describing the self-organizational process is in the concept of states of mind. Engrained patterns of neuronal group firing become reinforced into repeated patterns that cluster the cognitive processes of attention, perceptual bias, memory, mental models, behavioral response patterns, and emotional tone and regulation. For example, in a depressed state of mind, one may pay conscious attention to negative aspects of experience, interpret incoming stimuli in a pessimistic manner, have greater access to depressing past experiences, have the activation or instantiation of a mental model of the self and others as bad or guilty, have the behavioral pattern of withdrawl, and have a depressed mood with difficulty regulating intense affect.

States of mind are the primary mechanism by which the brain organizes its activity. Healthy mental functioning may depend on a flow of states of mind through time that are adaptive to the ever-changing environment and allow the individual to draw freely from the learning from past experience. Chaos theory suggests that nonlinear complex systems must move continually towards maximizing the complexity of the system. Achieving such a goal requires a balance between the elements of continuity, familiarity, and predictability with those of flexibility, novelty, and uncertainty. Dysfunctional mental states may be conceptualized as a disruption towards either end of this balance: with excessive rigidity, as in the case of character pathology, or excessive fluidity, as in the case of disorders of thought or of mood.

Emotion Emotion has long been considered fundamental to cognitive processing. Research paradigms have required careful control of variables and therefore have often attempted to not focus on the role of emotions in various measures of processing, such as attention, perception, and memory. However, the role of emotion in these and other aspects of cognition is now well established. What is an emotion? The answer to this question is as complex as the mind itself. One view considers emotion as a primary value system of the brain, allowing activations to be selectively reinforced. For example, emotionally charged experiences may be more readily recalled than uneventful ones. According to this view the most fundamental aspect of emotion is the arousal/appraisal system in which the brain responds to a given stimulus with the signal of “This is important—take note and pay attention now!” Emotion thus gives value to a representation by arousing attentional mechanisms and focusing a spotlight of attention on the stimulus. The second stage would then appraise the meaning of such emotional arousal by assessing its hedonic tone: “Is this good or is this bad? Should this be approached or avoided?” Emotion thus directs the flow of energy—the activations within specific circuits of the brain—as the arousal/appraisal system focuses cognitive processes on elements of the internal and external environment. A third level of emotional processing is the elaboration of this appraisal into a more specific form, called a *categorical emotion*, such as joy, interest, surprise, fear, anger, sadness, or shame. These categorical emotions have universal facial expressions of affect found in all cultures, which may have distinct psychophysiological manifestations.

An additional view examines the way in which the changes in the body's state is represented in the brain in the form of what Antonio Damasio has called a *somatic marker*. According to this view, the energizing or deenergizing bodily responses let the brain know how the individual feels about an experience. Such a somatic marker can then be used in future emotional assessments, or gut reactions, to an experience.

A part of the brain called the orbitofrontal cortex has been implicated as the sight of somatic marker processing. Allan Schore has also noted the importance of early experiences with caregivers in the maturation of this region and also its central role in coordinating self-regulatory functions early in development with basic emotional reactions and social functioning. The orbitofrontal cortex has been implicated not only to monitor but also to regulate bodily states and to possibly be involved in psychiatric disturbances ranging from autism to mood disorders. Disorders in self organization and social functioning may be better understood by examining the central role of emotion, and perhaps the orbitofrontal cortex and related regions, in the development and maintenance of dysfunctional mental states. Studies also suggest that this region is responsible for the capacity for self knowledge and the subjective experience enabling the mind to reflect on the self in the past, present, and the potential future. Both inborn and experiential factors may play important roles in allowing this region to develop the capacity to integrate a wide range of important functions of the mind including the appraisal of meaning, emotional regulation, social cognition, and autobiographical consciousness.

COGNITION AND PSYCHIATRIC DISORDERS

Since the time of Emil Kraepelin and Eugen Bleuler psychiatrists have known that certain disorders include profound deficits in mental functioning, such as attention and reasoning in the case of schizophrenia. Since the 1950s researchers have attempted to determine the exact nature of such deficits. With the advances in computer technology and the technical ability to analyze stimulus presentation and response times of the order of tens of milliseconds, cognitive psychologists have been able to devise research paradigms capable of testing when such deficits are present. Those advances led to revisions in the proposed structural models of processing.

Processing research has focused on the three domains of sensation, perception, and cognition. Sensory-processing studies focus on poststimulus events up to a maximum of 1 second, using simple stimuli. Perceptual studies examine processing after a period of up to about 5 seconds after a slightly more complex stimulus. Cognitive processing experiments can examine early processing (e.g., phenomena occurring within the first 30 seconds) of complex, long-term cognitive processes that can occur over minutes, hours, or days. Studies of long-term memory can examine processes that involve an indefinite poststimuli period. Recent attempts have been made to correlate complex cognitive findings with clinical presentations. General problems with the approach include the diversity of patients falling under the same syndrome classification. Thus schizophrenia can more appropriately be considered as the schizophrenias or schizophrenia spectrum disorder. The same may be true for other disorders, such as attention-deficit/hyperactivity disorder and major depressive disorder. An array of cognitive dysfunctions identified for certain subsets of syndromes must be interpreted in the light of the heterogeneity of some patient populations.

A related problem is the distinction between general deficits and specific deficits. Care must be taken in interpreting experimental data that show a difference in results between normal controls and a patient group. Do psychiatrically ill patients perform less well on a given paradigm because they are ill or because of a deficit specific to the disorder? The creative design of experimental tasks can help distinguish between general deficits and specific deficits. A comparison of target patient populations with matched normal persons and other psychiatric patients can help to determine disorder-specific cognitive dysfunction.

Another general issue is that of state markers versus trait markers. For example, a patient with schizophrenia may have a persistent cognitive deficit when actively psychotic (state) and also when asymptomatic (trait). These abnormal results have been found in certain cognitive tests of attention that correlate with improvement on medications; the abnormal results are also found in nonschizophrenic first-degree relatives. Is the marker of genetic vulnerability a coincidental finding or part of the core deficit in schizophrenia? An exploration of the implications of these cognitive abnormalities for the daily life of the patient is an important application of the research findings to clinical psychiatry.

Schizophrenia In the late 1890s Kraepelin described a primary attention deficit in his elaborate clinical description of patients with schizophrenia. Numerous investigators since that time have attempted to define the nature of the cognitive deficits in schizophrenia. A general approach is that an early perceptual processing

deficit leads to problems in perceptual organization. In general, information-processing models note that two things are processed: energy (in the form of external stimuli impinging on the senses) and information (a stimulus that carries a signal value based on significance derived from the prior processing of similar energy configurations). Schizophrenia patients appear to have deficits in the processing of energy as well as information.

Some cognitive tasks have been identified as trait-linked markers of schizophrenia: reaction time crossover, backward masking, dichotic listening, serial recall tasks, vigilance (sustained attention) tasks requiring high processing loads, and span-of-apprehension tests with large visual arrays. Deficits in those areas have been explored through thousands of cognitive studies examining various aspects of processing.

Crossover and Modality Shift Effects Those paradigms examine the general finding that schizophrenia patients have a slower than usual response on tasks that require rapid reaction times. A stimulus is presented with varied combinations of warning signals and preparatory intervals. Schizophrenia patients show an advantage only with short preparatory intervals and long response times with regularly spaced stimuli, a pattern distinct from that of normal controls (crossover effect). In a related paradigm, when the modality of the stimulus is varied (e.g., light is interspersed with tone), the latency (delay) of the response in schizophrenia patients, when compared with controls, is longer if the preceding stimulus was of a different modality. That is termed the *modality shift effect*, revealing a greater degree of cross-modal retardation in schizophrenia patients than in controls.

A number of theories have been proposed to explain these effects. They may be quantitative rather than qualitative distinctions from normal control groups. However, both the crossover and modality shift effects support the idea that schizophrenia patients are overly influenced by stimuli that occurred immediately before the effect. The information-processing stages that explain the persistence of prior stimulus effects is under investigation.

Visual Backward Masking, Sensorimotor Gating, and Habituation The aspect of cognitive functioning in which rapidly presented stimuli are abnormally attended to by schizophrenia patients as compared with normal controls has been examined. In visual backward masking a stimulus is followed by an interstimuli interval, and then a subsequent stimulus is presented. Figure 3.1-2 shows a typical masking experiment. The presentation of the secondary stimulus leads the schizophrenia patient to not report, to mask, the initial stimulus. Lengthening of the interstimulus interval beyond 500 milliseconds can lead to normalization, with no masking present. Thus, the rapidity of presentation of the secondary stimulus is the factor determining whether it will influence the perception or at least the reporting of the initial stimulus. Some studies find that the impairment improves with treatment by medication and can be induced in normal patients given catecholaminergic agents. Other studies find that the impairment may be a marker of increased vulnerability to schizophrenia.

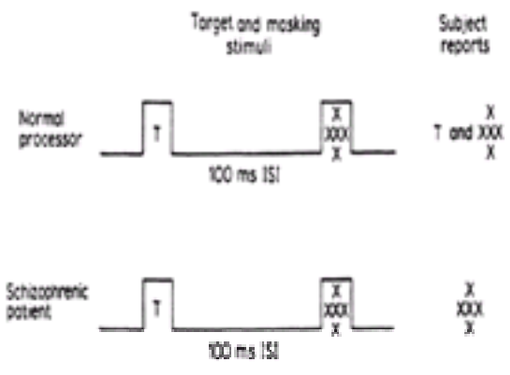

FIGURE 3.1-2 Diagram showing the difference in the verbal reports of normal versus schizophrenic subjects presented with a single backward masking trial with a 100-ms interstimulus interval (ISI). The T represents the target stimulus and the Xs represent the masking stimulus. (Reprinted with permission from Braff DL, Saccuzzo DT, Geyer MA: Information processing dysfunctions in schizophrenia: Studies of visual backward masking, sensory motor gating and habituation. In *Handbook of Schizophrenia*, vol 5, Neuropsychology and Information Processing, SR Steinhauer, JH Gruzelier, J Zubin, editors. Elsevier Science, New York, 1991.)

Sensorimotor gating and habituation are the processes by which stimuli become less attended to with rapidly repeated presentation. Habituation is believed to involve preattentive processing, and the visual masking requires higher cognitive functions. Schizophrenia patients show a markedly diminished capacity to habituate. One common study examines the persistent acoustic startle reflex as the person continues to blink with repetitive tones. Parallel findings are those of the studies that showed that lysergic acid diethylamide (LSD) administration and the intracerebral injection of dopaminergic agents in rats lead to similar findings, supporting the idea that excessive dopamine activity, thought to be central in schizophrenia, can induce those deficits.

In general, the diminished habituation and visual backward masking lend further cognitive support to the idea that schizophrenia patients have a markedly diminished capacity to regulate the flow of rapidly presented information, leading to an inundation by stimuli that in a normal person are gated out. The disruptive effects of the externally derived stimuli, as demonstrated in those experimental paradigms, are thought to occur also for internally generated stimuli.

Psychomotor Slowing A general deficit, not specific to schizophrenia, is a generalized slowing of response rate. Cognitive science is concerned with all stages in information processing, from attention, sensation, perception, and cognition to action. Multiple neural integrative systems are involved in the processes, from stimulus to response. Numerous disorders may result in a common finding of diminished reaction time. The general nature of the deficit should not lead clinicians and researchers to ignore the importance of response rate deficits in interpreting clinical and experimental data. Attempts to assess the interdependence of input, central processing, and action are part of psychomotor studies in schizophrenia patients.

Selective Attention Numerous studies have attempted to determine the nature of deficits in selective attention in schizophrenia patients. Early studies were based on the idea of a bottleneck that limits the attention-processing capacity at some stage in the information flow. These studies were based on the idea that some cognitive structure devoted to filtering is impaired. Analysis of the studies revealed consistent deficits in shadowing (the ability to repeat what the person is selectively focusing on in a dichotic condition) and in verbal recall. In general, selective attention paradigms present the person with a target stimulus and distracters to be nonattended. Findings reveal that schizophrenia patients have an impairment in their ability to avoid distracting stimuli (to filter) and to pigeonhole (to use category features to reduce stimulus qualities needed to respond). The studies found that distractibility is a core cognitive deficit, supported by its high incidence in genetically vulnerable persons, its improvement with medications, and its worsening in acutely psychotic states.

These findings were explained by using the framework of an impaired filtering structure and pigeonholing process, but recent conceptualizations have examined a generalized impairment of the information-processing capacity in schizophrenia. The capacity model examines the way in which a pool or pools of attention capacity can be allocated across mental activities. Two components are quantity of resources available (capacity) and executive allocation policy. Other areas of deficit may involve an impaired response selection process, leading to abnormal results on tasks.

Several possibilities have been proposed to explain attention deficits in schizophrenia patients on the basis of the capacity model: (1) deautomatization of normally automatic preattentive processes, (2) disproportionate allocation of attention to schema-relevant but task-irrelevant information, (3) inability to sustain controlled processes needed to maintain attention allocation without shifting, (4) inability to shift allocation biases to correct wandering attention, and (5) disorganized response selection because of heightened arousal under distracting conditions. Studies of selective attention may begin to examine these possibilities in a capacity model rather than in the previously explored structural framework.

Sustained Attention Sustained attention, or vigilance, is required to process stimuli of long duration. The most common research paradigm in cognitive studies of sustained attention and psychopathology is the Continuous Performance Test. The test is a rapidly paced set of vigilance tasks with varied spacing and timing of target and nontarget stimuli. Continuous Performance Tests have the following features: the presentation of a random sequence of visual stimuli on a small screen (numbers or letters), a fixed stimulus pace with a rapid rate (1 to 2 seconds), a brief stimulus exposure time (40 to 200 milliseconds), designated stimuli or sequences of stimuli as targets, and the use of a button with which the person can respond. The processing load for a Continuous Performance Test can be varied by blurring the stimulus presented or by changing the rapidity of presentation.

Vigilance tests, such as the Continuous Performance Test, require analysis of response features on the basis of the signal detection theory. The two elements distinguished are sensitivity and the response criterion. Diminished sensitivity is a sign of decreased vigilance and results in a high miss rate (errors of omission). The

response criterion can be diminished, leading to a high false-positive rate (error of commission). The analysis is important in the interpretation of results.

Schizophrenia patients appear to have a specific diminishment in sensitivity but not a lowering of the response criterion for both verbal and spatial stimuli. The impaired responses were significantly associated with specific clinical features in the patients and first-degree relatives. Test abnormalities, although present in other disorders, appear to be most robust in schizophrenia.

Positron emission tomography (PET) in schizophrenia patients performing a Continuous Performance Test found differential activation, with lower metabolic activity than in normal persons, in the prefrontal cortex bilaterally but normal or elevated activation in the occipital region, leading to a hypofrontal pattern. That finding is consistent with other findings supporting the idea of impaired frontal function in schizophrenia.

The vigilance studies using the Continuous Performance Test reveal that schizophrenia patients have a deficit in their ability to distinguish target stimuli from nontarget stimuli when the stimuli are presented as brief signals at a rapid pace. This finding is consistent with the other features of attention abnormalities revealed in other paradigms.

Language and Discourse Assessments of language dysfunction in schizophrenia have focused on the basic question of whether the abnormalities in speech are reflections of a core disorder of thought or an abnormality in speech production. The search for a schizophrenic language has yielded negative conclusions. Discourse analyses of conversations with schizophrenia patients suggest that they may have significant difficulties in the maintenance of a specific topic (derailment) and in the lack of a discourse plan directing speech (disorganization).

Other investigators have argued that schizophrenia patients have impaired capacities to perceive the needs of others and may be schema driven in the direction of their speech, rather than intending to communicate effectively. One study showed that delusion-consistent material presented in the nonattended channel in a dichotic listening task leads to diminished attention to the target channel. A clinical implication of this experimental finding is the possibility that schema-driven processing during speech production may be diverting attention to internal stimuli and away from the potentially confusing social demands of conversation.

Span of Apprehension Span of apprehension is an experimental paradigm that illustrates a cognitive psychological approach to the core deficit of schizophrenia patients. In the span-of-apprehension test an array of letters is displayed for a brief period (from 50 to 100 ms in most studies). One of the letters is a “t” or an “f” and the person must detect which letter is present. The number of nontarget letters is increased, and significant differences in detection are found for displays of 10 or more letters. Figure 3.1-3 provides an example of a visual display for the span-of-apprehension test.

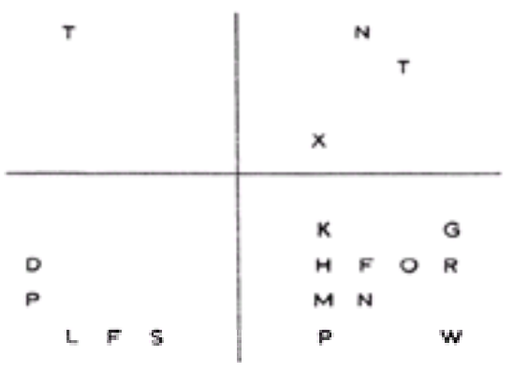

FIGURE 3.1-3 Sample arrays used in the wide-visual-angle version of the partial report span-of-apprehension task. (Figure courtesy of Robert F. Asarnow, Ph.D.)

The serial scanning process is an element of focal attention. Parallel processing in the search involves increased aspects of assessment of figure-ground and textual segregation and is thought to be an automatic process.

Studies have shown that the sequential scanning of the attention spotlight is directly affected by increasing the complexity of certain display characteristics, leading to increased errors in detection. This is logical because the iconic image has a limited display time and the scanning of the image may be incomplete by the time it decays from such an ultrabrief form of memory.

Findings in Schizophrenia Patients Schizophrenia patients show significantly increased errors in the span-of-apprehension test under conditions of increased complexity of display. Their scores are also worse in psychotic conditions and are improved with symptomatic improvement while taking medications. Increased errors are also found in nonschizophrenic mothers of children with schizophrenia. Thus the span-of-apprehension test is a measure of both state and trait in some cases of schizophrenia.

Only about half of the patients with the diagnosis of schizophrenia have abnormal results on span-of-apprehension tests. Those who do have abnormal results also have the clinical symptom of anergia. Other psychiatric disorders studied did not reveal these findings. Thus, the abnormal results on the test appear to be specific to some forms of schizophrenia. Both short-term and long-term outcome studies have found that those patients with abnormal test results whose scores improve after receiving antipsychotic medication have a good clinical response to pharmacotherapy.

The span-of-apprehension test taps into some aspect of cognitive function specific to some patients with schizophrenia, their nonschizophrenic relatives, and persons at risk for developing the symptoms of schizophrenia. To scan the iconic image the person must (1) engage attention to the iconic register, (2) move the focus of attention, and (3) disengage the focus of attention. Impairments in performing any one of those tasks can explain the test-result abnormalities. Another cause of the deficiency may be that, with each fixation of attention, less information is processed. Thus, although the individual steps of iconic scanning may be intact, less visual information is processed and more errors occur. A third possibility is that the initiation of the attention process is delayed; this possibility is consistent with the increased reaction times revealed on numerous other tasks. The delay in the face of a rapid decay rate of sensory memory places the patients at a disadvantage when rapid responses are required; this possibility is also consistent with the other forms of attention deficit described earlier.

In contrast to the structural models described, another view focuses on the capacity model of attention. With a general limit on the cognitive resources available at a given moment, tasks that require an increased processing load (as in the case of time requirement or more letters on the display) diminish the resources available for other processes (such as scanning the image for the target letter and reporting the determination). Schizophrenia patients may have a number of structural and capacity deficiencies and these hypotheses are not mutually exclusive. Further studies are needed to elucidate the nature of the cognitive state-trait marker for schizophrenia patients and persons vulnerable to the disorder.

Attention-Deficit/Hyperactivity Disorder The change in 1980 of the terms “hyperkinetic” and “minimal brain dysfunction” to “attention-deficit disorder” in the third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) and the change in 1987 to “attention-deficit hyperactivity disorder” in the revised third edition (DSM-III-R) emphasized the role that attention factors are thought to play in children, adolescents, and adults with the disorder. In the fourth edition of DSM (DSM-IV) attention-deficit/hyperactivity disorder integrates two categories from DSM-III-R: attention-deficit hyperactivity disorder and undifferentiated attention-deficit disorder. Diagnostic criteria embrace a number of forms of the syndrome, and research into the cognitive deficits has outlined a wide array of tasks in which attention capacity is abnormal. The pervasive findings of cognitive impairment in the setting of numerous intact cognitive functions has left the research field with no clearly accepted view of a core deficit in the disorder. Clinically, child and adolescent patients present with problems in school, with peers, and at home that reflect both academic and behavioral dysfunctions. Many studies suggest that the cognitive and behavioral dysfunctions in the disorder may be independent processes with different neurophysiological bases. For example, the finding that children with attention-deficit/hyperactivity disorder are impulsive may be true behaviorally but cannot be stated as a generalization about their cognitive functioning.

Researchers have attempted to find clearcut diagnostic criteria to help clarify the disorder, but individuals classified as meeting diagnostic criteria at this point appear be quite heterogeneous. There is no definitive test for the disorder nor is a positive response to psychopharmacological intervention pathognomonic. Biochemical studies have found abnormal urinary catecholamine metabolites that normalize as the patient's behavior improves when taking psychostimulants. Those findings and

PET scan data suggest abnormal brain functions in patients with attention-deficit/hyperactivity disorder.

Data from numerous studies show that the patients with attention-deficit/hyperactivity disorder have dysfunctions on a variety of tasks ranging from those involving monitoring, perception, memory, and motor control. Intact performance has been found on a number of memory tasks requiring verbal processes (e.g., digit span, word tests, story recall) and nonverbal processes (e.g., recall, visual arrays, block series).

A number of theories have been elaborated to explain those differences between patients with the disorder and normal persons. Each theory has strengths, weaknesses, and varied support from the data, but each highlights the complexity of the cognitive dimensions of the disorder. In general, patients with the disorder evidence behavior that has been compared to that of patients with frontal lobe damage: deficits in the control of motor responses, in the execution of fine-motor movements, and in the inhibition of ongoing response patterns. Memory tasks and basic aspects of information processing are intact, but the patients have impaired performance across modalities (auditory, visual, motor, perceptual-motor), suggesting some global deficit. The patients also appear to be unusually susceptible to boredom when the required tasks are long and repetitive.

Another view examines two proposed systems—an underactive behavioral inhibition system and an impaired behavioral reward system—to explain the behavioral problems that children with the disorder often have. A related view is that the rule-governed behavioral system is not intact; patients with the disorder appear to do especially poorly in a system with delayed or nonexistent rewards as in tasks that require sustained attention, accuracy, or task-directed activity governed by another person's direction or rules. Under those conditions the patient's poor regulation and inability to meet functional demands are revealed. A related issue is a diminished motivational drive and possibly a diminished arousal regulation system.

Yet another approach supported by research data is that the patients have metacognitive deficits. According to this perspective, metacognitive processes that help plan, monitor, and regulate performance are impaired. The patient's ability to assess the task and determine strategies also has deficits. That is an example of top-down aspects of attention, with impairment of the higher cognitive processes that regulate information flow. Additional bottom-up deficiencies involve basic aspects of attention focus because of abnormalities in arousal, selectivity, and capacity.

The finding that numerous factors can influence the appearance of deficits led Virginia Douglas to the hypothesis that attention-deficit/hyperactivity disorder is a self-regulatory disorder with pervasive effects. The impairments affect each of four domains—attention, inhibition, reinforcement, and arousal—resulting in deficits in several aspects of self-regulation: (1) the organization of information processing, including planning, metacognition, executive functions, adapting appropriate cognitive sets for a given task, regulating arousal levels and alertness, and self-monitoring and self-correction; (2) the mobilization of attention, including the deployment and the maintenance of adequate attention; and (3) the inhibition of inappropriate responses such as withholding responses to extraneous stimuli and reinforcers. These deficits in self-regulation imply that increased processing demands would lead to a diffusion of attention processes and to a subsequent impairment of the indepth, coherent acquisition of knowledge and understanding. One line of research has been based on the additive factor method, in which experimenters attempt to isolate the stage of the deficit. The model for that approach entails four stages: encoding (the identification of a stimulus), serial comparison (of the stimulus with elements related to the category in long-term memory), decision (pertaining to the category into which the stimulus is stored), and translation and response organization. Studies using evoked potentials suggest that deficits are found after the search and decision stages (the first three stages). The response preparation and execution processes appear to be impaired. Features that increase the processing load—such as speed demands, complexity of stimuli, distractors leading to divided attention, and increased duration of task—reveal different areas of deficit. This fact may explain the diversity of methods and research data supporting various theories. The variables affecting outcome include information-processing demands, the availability of alternate stimuli to which to attend, and the presence of an external regulator.

The diversity of research findings and theoretical explanations is paralleled by the clinical finding that children who are severely impaired in the classroom may have no attention problems in the confined, one-on-one setting of the psychiatrist's or psychoeducational examiner's office. Such children may also be able to attend for indefinite periods to video games and yet be unable to follow complex conceptual information. The important principle is that cognitive dysfunction in psychopathological conditions may be task specific as a function of the nature of the cognitive impairment. The patient's clinical history and evaluation must consider potentially hidden domains of abnormal cognition.

Autistic Disorder Early descriptions of autism delineated the social functioning deficits that impair normal functioning. Autistic children were seen as having difficulties in normal emotional contact. Cognitive dysfunctions in autistic disorder were described later and were found to involve a number of areas, including abstraction, sequencing, language, and comprehension. Researchers are now focusing on the nature of the core deficit in the disorder. Issues of specificity and universality of areas of dysfunction in the disorder are important. How the cognitive domains relate to the social-affective deficits is of particular interest.

Seventy-five percent of patients with autistic disorder are also mentally retarded. Mental retardation involves global cognitive and language impairments that may make it difficult to distinguish autistic disorder features. General cognitive impairments may be especially difficult to assess if language functioning is severely limited. Studies of high-functioning patients with autistic disorder have permitted various deficits to be determined.

Studies of the cognitive deficits in autistic disorder have distinguished an array of dysfunctional areas, including numerous language problems, excessive or impaired responsiveness to stimuli of various modalities, different encoding of auditory stimuli, and impairment in the ability to extract important features from incoming information. This range of deficits is thought to require the transformation of symbolic representations. In contrast, some patients with autistic disorder have relatively intact visuospatial and gestalt functions, musical abilities, and rote memory. Performances on standardized tests reveal relatively good results in object assembly and block design but poor results in comprehension.

Language deficits vary and include syntactic and phonological domains. These findings initially suggested a left-hemisphere deficit, but other findings, including deficits in prosodic and pragmatic language functions, suggested right-hemisphere involvement as well. The findings can be interpreted as deviations from normal language functioning as well as delays in language functioning. The wide array of dysfunctions in autistic disorder may be due to a number of subtypes, with characteristic deficits and possibly different brain loci of dysfunction.

Other studies have focused on the social cognition of patients with autistic disorder. They have examined the nature of the patient's emotional behavior and understanding to assess the earliest clinical descriptions of an abnormal emotional connection between autistic children and their parents. Recent work in neurobiology suggests a role of the orbitofrontal cortex and the cerebellum in mediating some of these deficits. Two findings support the initial impressions: autistic children are much less likely than usual to imitate adult vocalizations and gestures, and they show much less sophisticated representational play with objects than do normal children. These findings led to the suggestion that a core deficit in autistic disorder is the representation of representations (metarepresentations), leading to deficits in symbolic play and the inability to understand the mental states of others. The inability to transfer cognitive representations into language symbols may also be a related metarepresentation deficit.

A series of studies explored the relation of these possible cognitive impairments to socioemotional behavior. In contrast to clinical lore, children with autistic disorder were found to look at their parents; they had eye contact with their parents when social interactions were parentally elicited, and they revealed normal behavioral patterns of attachment. The studies found a marked lack of social referencing (looking to parents for emotional cues in ambiguous situations) and protodeclarative gestures (pointing to objects and showing objects to familiar adults). Three domains have been proposed to explain these findings: (1) autistic children may not have the capacity to have a representation of another person as having ideas, perspectives, or emotions that can be shared. This proposal is consistent with a theory-of-mind hypothesis, in which the core deficit is believed to be the inability to have a sense of another's mind; (2) autistic patients may have an impaired ability to perceive or comprehend the emotional (usually facial) signals of others; and (3) the core deficit may involve either a lack of interest in others or an aversion to responding to others. Studies have found that although children with autistic disorder do express emotions, they have less positive affects in response to their (relatively infrequent) periods of joint attention. Furthermore, they have an impairment in their responsivity to the display of strong emotion by another, whether of distress or of pleasure. Tests of high-functioning autism patients reveal poor performance on emotion-recognition tasks, little comprehension of and empathy with depictions of social situations, and difficulty in talking about socially derived emotions such as pride and embarrassment. Autistic patients with relatively high intelligence use adaptive cognitive strategies to interpret social stimuli to compensate for impaired emotion-processing abilities. The development of social cognition and socioemotional understanding requires complex interactions among the cognitive, perceptual, and emotional processes. A series of interactive elements essential to the development of social understanding has been proposed (Fig. 3.1-4). This model describes the basic precursors of emotional responsiveness; the ability to attend to, encode, and interpret verbal and nonverbal social stimuli; the awareness of one's own and others' emotional responses; and the ability to contrast oneself with others. Out of that matrix develops the ability to understand others' views, desires, and beliefs. Accordingly, a deficit in any of those basic elements may explain the characteristic deficits observed in the social understanding of persons with autistic disorder.

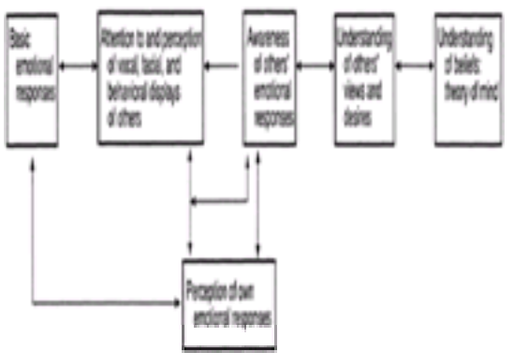

FIGURE 3.1-4 Sigman's model for the development of socioemotional understanding. (Figure courtesy of M. Sigman.)

Mood Disorders In contrast to schizophrenia, attention-deficit/hyperactivity disorder, and autistic disorder, the mood disorders do not appear to have core cognitive deficits that are diagnosis specific. Instead, cognitive abnormalities appear to be related to the degree of psychopathology and to the severity of the mood disturbance. Most studies have examined patients with depression; only a few studies have assessed cognitive functioning in patients with bipolar I disorder in a manic state. In depressed patients the severity of the depression has ranged from mild depression in students to severe illness in hospitalized patients with major depressive disorders. The studies have primarily examined attention and memory for neutral and emotionally toned stimuli. For the majority of these studies, the concept of self-organizational processes and state regulation has not been the primary focus of attention. These recent conceptualizations of the brain's functioning as a nonlinear complex system capable of self-organization may aid in the future investigation of the primary dysregulatory aspect of disorders of mood.

Depressive Disorders Depressed patients often complain of difficulties with concentrating, learning, and remembering. Studies have documented that such patients perform poorly on tasks that require sustained attention or effortful and elaborate rehearsal. Thus controlled limited-capacity processes appear to be impaired in major depressive disorder. This limitation on access to capacity-demanding resources appears to be directly related to the severity of the depression and normalizes with remission from a depressive episode.

In contrast to patients with dementia, who have impaired semantic recall, depressed patients have intact access to long-term knowledge stores. Studies have found that although explicit memory for recently learned tasks is impaired in depressive disorder as well as dementia, implicit memory (as shown by priming tasks) is intact in depression but impaired in dementia. This finding supports numerous studies showing that effort-requiring tasks are impaired in states of depression.

A dual-process model distinguishes between elaboration and activation. *Activation* makes items accessible and readily available to subsequent cognitive processes and is thought to be an automatic process fundamental to implicit memory. *Elaboration* is defined as the way in which the associative linkages are formed and strengthened between the current stimuli and other representations in memory. Elaboration occurs over an extended time and makes an item retrievable by the creation of several retrieval paths. The finding of intact implicit memory suggests that the automatic process of activation is unaffected in depression, whereas the effortful process of elaboration is impaired, thus influencing explicit memory. Other studies of memory function reveal that depressed patients are likely to remember emotionally negative words and negative events in their lives during a depressive episode. Although studies of anxious patients have found consistent attention biases favoring attention to threat-related words, studies of attention effects in depression have yielded inconsistent results. Thus processing and recall in depressed patients appear to be more related to emotional effects on cognition than to attention biasing.

Depressed patients have also been found to have an increased response criterion; they require increased supportive data from the presented stimuli to respond in a test situation. Whether this need to be certain before responding is a psychological response to being depressed or a specific feature of the depression itself has not yet been determined. The reluctance to respond needs to be considered in interpreting research data and clinical interview findings.

The attention and memory findings have suggested several theoretical frameworks that are clinically useful. A schema theory of depression outlines a positive feedback loop in which negative self-schemata prime persons to have negative thoughts, to recall negative events in their lives, and to interpret present events with a negative bias. Whether as a cause or as a maintaining influence, these depressogenic schemata are thought to create a series of cognitive functions that produce and maintain a depressed mood.

A network theory of memory and emotion has been supported by research on depressed and nondepressed persons in which mood leads to a spreading activation of items in memory that are congruent with the mood. Thus emotion directly influences retrieval by a process of state-dependent learning and memory. While depressed, patients are likely to encode items in a form that makes them readily accessible when retrieved in a depressed state; depressed mood thus becomes an internal context cue that accesses depression-related memories.

Both the network and schemata theories of depression are consonant with research findings but do not explain all the cognitive and clinical findings in depression. They provide a framework for understanding how emotions and moods influence cognitive processing, such as memory retrieval and mental models. The conceptualization may be applicable to both transient mood states and severe mood episodes. Thus emotions in both health and illness can shape the mental state instantiated at a given time and thus act as a context cue, leading to the activation of previously formed schemata for oneself and others. The activated schemata in turn can produce retrieval biasing and behavioral responses, fundamental to a mental state, that can further elicit a negative emotional response. A reinforcing loop is established to support the continuation of the depressed mood and depressive cognition.

Some patients may be especially prone to marked cognitive alterations because of an emotional state that may be a fundamental part of a clinical presentation. Thus, rapid shifts in state of mind may be a learned or constitutional feature of the individual. From the nonlinear dynamics view, these rapid shifts in mental state can be conceptualized as sudden and intense changes in the constraints on the system, which determine the flow of states of mind across time. Activating a set of constraints that establish and maintain a depressed state can then lead to the persistence of the very factors that created the shift in probabilities of that state being active. The depressed state becomes a deeply engrained attractor state that becomes difficult to alter. Pharmacological interventions may directly alter the synaptic constraints maintaining such a state. Psychotherapeutic interventions, such as cognitive behavioral and interpersonal therapy, can be proposed to produce changes in the internal processing of constraints and in external social constraints, respectively.

Bipolar I Disorder Patients with manic episodes present with a spectrum of cognitive dysfunctions that appear to be related to the severity of their mood episode and that normalize with remission. The disturbances have been described clinically as rapidly paced thinking and speech, quick associations to self-generated or other-generated stimuli, grandiosity, and increased distractibility.

Formal studies of patients with bipolar I disorder are technically difficult to carry out because of the patient's lack of cooperation and restlessness and because such patients are few in number. The studies have suggested a high rate of combinatory thinking, the inclusion of loosely associated but related intrusions, and increased distractibility. The clinical impression of humor (even in the face of an underlying dysphoria) in some patients with bipolar I disorder is corroborated by playful, extravagant, or flippant elaborations and intrusions in speech. These findings seem to indicate primarily state-dependent symptoms that improve on recovery. Thus forced-choice span-of-apprehension and backward masking tasks reveal impairments similar to those seen in actively schizophrenic patients but unlike those seen in schizophrenic patients who have persistent deficits in the remitted state. Bipolar I disorder patients who are not actively ill reveal normal information processing. Thus, bipolar disorders can also be viewed as a disorder of self-organization in which the system fluctuates between the extremes of highly activated manic and highly deactivated depressed states of mind.

Posttraumatic Stress Disorder Studies of posttraumatic stress disorder have extended the findings of information-processing abnormalities in anxiety disorders: attention biases toward fear-related and threat-related stimuli. Many of the studies were hampered by poorly defined clinical populations and control groups. However, some general trends, noted especially in the well-controlled paradigms, are promising and provide important insights into the psychopathological cognitive mechanisms in posttraumatic stress disorder.

Cognitive studies of patients with anxiety disorders have focused primarily on either attention or memory. Various research paradigms have been applied to assess attention bias and memory retrieval for neutral and emotionally activating stimuli. Studies find that anxious patients have an increased tendency to attend to

fear-related and threat-related words. One research approach includes a dichotic listening task in which an anxious patient is more easily distracted than are controls by fear-related stimuli in the nonattended channel. This finding suggests that the patients have automatic, parallel attention processes that are primed to detect certain types of stimuli. Another approach uses the Stroop paradigm, in which words are presented in different-colored inks, and the person's task is to look at the word and state the color of the ink. Anxious patients have a significant delay in their response times for fear-related words, a finding that suggests that increased attention capacity or cognitive processing is necessary when those words are perceived and the color of the ink is determined.

One theory that explains these findings is the idea of a fear network that encodes fear-related information in a memory structure that is readily accessible and able to influence cognitive, motor, and psychophysiological responses. The theoretical fear networks, which may be similar to mental models, are thought to contain three related forms of information: fear-eliciting stimulus cues, specific response patterns, and the meaning of both the cues and the responses for that particular person. According to this theory patients with anxiety disorders are believed to have fear networks that are especially coherent and stable and that require few environmental cues to become activated.

Patients with posttraumatic stress disorder have been found to have attention biases toward threat-related stimuli specific to the experienced traumatic event. Many of the patients studied were combat veterans, and further work is needed to establish the generalizability of those findings to other forms of posttraumatic stress disorder. The disorder is clinically characterized by both intrusive processes (memories, images, emotions, thoughts) and avoidance elements (psychic and emotional numbing, amnesia, behavioral avoidance of environmental cues resembling the initial trauma). The patients are thought to have a unique configuration of fear networks with stimulus cues (environmental stimuli), response components (cognitive, motoric, and psychophysiological), and meaning elements (e.g., the moral implications of the trauma, survivor guilt, and the meaning of intentional trauma versus accidental trauma).

Some theories argue that states of excessive arousal during trauma impair attention capacity and memory encoding during the event. Emotional processing during and after the traumatic experience may also be hampered by the states of psychophysiological arousal and altered memory storage. The part of the brain necessary for explicit memory processing, the hippocampus, has been shown to be abnormal in individuals suffering from chronic posttraumatic stress disorder. The subsequent clinical syndrome may have some aspects that are adaptive: cognitive attention biases that are primed to detect fear-related stimuli may permit the early detection of threatening situations that, if not avoided, would produce incapacitating psychophysiological arousal. Automatic, nonconscious behavioral avoidance response patterns, embedded in the proposed fear networks or mental models, allow the patients to minimize excessive arousal by avoiding trauma-related situations. Patients who used dissociative mechanisms during and after a traumatic experience appear to be at far greater risk for developing posttraumatic stress disorder. Dissociation is a complex process that essentially involves the dis-association of usually associated processes, such as attention, perception, memory, consciousness, and sense of self.

The psychopathological aspects of posttraumatic stress disorder can be cognitively exemplified as follows: a combat veteran with chronic posttraumatic stress disorder may have no direct recall (impaired explicit memory) of a helicopter crash in which his best friend, who was seated next to him, was killed. Years later continued avoidance of airports, amnesia for combat, general apathy, and social withdrawal (avoidance elements)—combined with startle response, panic attacks, intrusive images, and nightmares (intrusive components)—all suggest intact implicit memory for the combat trauma. The veteran is emotionally, behaviorally, and cognitively impaired.

The evaluation and treatment of patients can be greatly enhanced by an understanding of development, dissociation, and the cognitive processes (including memory) and its careful application to the assessment of presenting symptoms and signs. Several areas that have interested clinicians for decades have become of great societal concern. Two topics that inspire intense controversy are the delayed recall of repressed memories of traumatic events and the suggestibility of patients influenced by clinicians, society, or friends to believe that they are the victims of childhood trauma.

Delayed Recall Many scientists and clinicians believe in the cognitive capacity of patients to be unaware for years or decades of severely traumatic experiences that took place in their childhoods. Other researchers disagree and emphasize the paucity of studies of corroborated cases of childhood trauma that have been followed prospectively into adulthood with documentation of impaired access of consciousness to events presumably stored in memory. A cognitive science view of delayed recall can examine the role of memory processes, development, and the effect of trauma on the processing of information to describe a theoretically coherent but yet-to-be-proved set of mechanisms.

A repressed memory can be thought of as originating from the active, intentional suppression of memory from consciousness. The mechanisms underlying the process then may become automatic and the contents of memory inhibited from retrieval into consciousness. The blockage may exist to avoid flooding the person's awareness with information that is associated with excessive anxiety or fear that would impair normal functioning. This is an example of knowledge isolation in which information may be layered in the nervous system and certain aspects kept from conscious awareness.

In contrast, a traumatic event may be so overwhelming that normal processing may be impaired. If focal attention is divided, the nonfocally attended (traumatic) material will only be processed implicitly. Thus, in order to adapt to a traumatic event, some persons may have the capacity to focus their attention on a nonthreatening aspect of the environment or on their imagination during the trauma; this may be an underlying mechanism in a process called *dissociation*. Traumatic memory that has been only implicitly encoded will affect behavior and emotions and possibly will contain intrusive images and bodily sensations that are devoid of a sense of past, of self, or of something being recalled. This may partly explain the findings of posttraumatic stress disorder with amnesia (blocked conscious access to a memory or its origin) in the setting of avoidance behaviors, hyperarousal, intrusive images, and flashbacks.

Thus, two distinct mechanisms that may explain delayed recall of childhood trauma are the concept of repressed memories and the concept of dissociated memories. A person may use both mechanisms for different aspects of a traumatic event. Recollection of the traumatic memory may take different forms. Repressed memories may have been processed to some degree in narrative form whereas dissociated memories probably lack that more integrative processing. The latter form thus may be experienced as nonpast and nonself, making the intrusive retrieval of dissociated memories a confusing and frightening experience.

Studies of the development of memory in children suggest that the shared construction of narratives about experienced events is often crucial in making the events accessible to long-term retrieval. The establishment of a personal memory system appears to be a function of such memory talk in which parents discuss with children the contents of their memory. In children who have been forced to keep traumatic events a secret, as may occur with childhood abuse, the normal developmental process of narration may be blocked. This may be an additional cognitive mechanism underlying the inaccessibility of some forms of childhood trauma to consciousness in adult patients.

Suggestibility Knowledge isolation, such as in dissociation and repression, provides a theoretical scientific explanation for the underlying mechanisms that may lead to delayed recall of childhood trauma, but clinicians must also be aware of other cognitive processes that influence memory. Numerous studies have demonstrated that the human mind is easily influenced. Human suggestibility can be used to the benefit or detriment of others. Suggestibility is adaptive for a social being that relies on the experiences of others to inform its knowledge of the world and thus to increase its chance for survival. Thus listening to the stories of others, reading a textbook, and being coached in athletics all require the receiver to accept data from the sender. The learner (listener) needs to trust the reliability of the teacher (teller) in order to accept the incoming information. Critical analysis of the data received is an important component of learning. The metacognitive function of assessing the accuracy or usefulness of newly acquired information may be suspended under certain conditions, including hypnosis, drug-altered states, and conditions of severe threat.

Studies of human suggestibility indicate that postevent questioning can bias the metamemory processes that help to determine the source and accuracy of a retrieved memory. The verbal and nonverbal cues given by the interviewer may influence a person to believe that aspects of an event or an entire event that may have never happened actually took place. A person can be convinced of the accuracy of an event despite its lack of correspondence with actual experience. Factors that may influence the biasing of interviewees include a belief in the trustworthiness and authority of the interviewer, not being aware that “I don't know” is a permissible response, repetition of a question that already has been answered, and the interviewer's beliefs as communicated through emotional tone and nonverbal gestures.

It is crucial for clinicians to be aware of human suggestibility in order to avoid iatrogenic distortions. Similarly, it is important for persons who experienced severe trauma early in life to receive informed and empathetic evaluations and treatment. There is a delicate balance between supportive neutrality and active advocacy in assessment and intervention. Awareness of these fundamental cognitive processes may help guide the clinician toward achieving that goal.

Approaches to the treatment of patients with posttraumatic stress disorder need careful evaluation but generally include the view that the impaired emotional processing of the traumatic event requires the active recollection, in explicit terms, of the details of the experience. The process of effectively treating unresolved trauma usually involves the active cognitive processing of specific memories, including emotional responses, derived belief systems, and the psychophysiological

arousal at the time of the traumatic event. The provision of new cognitive information in the course of psychotherapy can in theory alter the configuration of the fear networks and allow previously inaccessible information to be explicitly processed and made available to consciousness for incorporation into an ongoing autobiographical narrative. Specific techniques, such as those which facilitate such cognitive processing of previously dissociated or in other ways isolated cognitions such as beliefs, images, and sensations, may be useful in alleviating the symptoms and dysfunction following acute or chronic trauma. Such therapy and changes in mental processing may diminish the avoidant and intrusive components of the clinical syndrome of posttraumatic stress disorder and improve social, emotional, and cognitive functioning.

FUTURE DIRECTIONS

Cognitive science offers a breadth of conceptualizations for understanding the way in which the mind functions in health and disease. The broad interdisciplinary field provides numerous research paradigms helpful in further elucidating the nature of psychopathology through techniques from the neurosciences to computer models of brain functioning and biological applications of chaos theory. The cognitive understanding of emotions and consciousness may also expand psychiatry's framework for knowing about human subjective experience. Clinical tools, from medications to in-depth psychotherapy, may also find wider application as the processes of self-organization and psychological change are better understood.

Psychiatry in turn has much to offer the field of cognitive science. The long history of descriptive psychopathology and the attempt to synthesize views of the mind and the brain can provide nonclinical cognitive scientists with unique data and relevant questions. Psychiatry is invited to join in the search for understanding the cognitive processes of the human mind.

SUGGESTED CROSS-REFERENCES

Piaget and emotional development are discussed in Section 3.2, memory is discussed in Section 3.4, cognitive disorders in Chapter 10, schizophrenia in Chapter 12, mood disorders in Chapter 14, and anxiety disorders in Chapter 15. Dissociative disorders are discussed in Chapter 18 and personality disorders are discussed in Chapter 24. Behavior therapy is discussed in Section 30.2, hypnosis in Section 30.3, and cognitive therapy in Section 30.6. Mental retardation is discussed in Chapter 34, learning disorders in Chapter 35, pervasive developmental disorder in Chapter 38, and attention-deficit/hyperactivity disorder in Chapter 39.

3.2 EXTENDING PIAGET'S APPROACH TO INTELLECTUAL FUNCTIONING

STANLEY I. GREENSPAN, M.D., AND JOHN F. CURRY, ĥH.D.

Jean Piaget (1896–1980) was born in Neuchatel, Switzerland. Building on the work of the German philosopher Immanuel Kant, Piaget explored how intelligence develops from a child's actions on his world. While Piaget focused predominantly on the development of impersonal cognition, he recognized affect also had an important role. Lev Semenovich Vygotsky and Reuven Feuerstein further explored the social context of learning. More recently, the authors have developed a model to understand how affect and cognition unfold as integral parts of the same developmental process.

GENETIC EPISTEMOLOGY

Widely renowned as a child (or developmental) psychologist, Piaget referred to himself primarily as a genetic epistemologist. That self-designation reveals at once that Piaget's central project was not the articulation of a child psychology, as this term is generally understood, but rather an account of the progressive development of human knowledge.

On the classic question of the origins of knowledge Piaget was neither a nativist nor an empiricist; however, his position should not be considered an amorphous form of interactionism. Piaget stated in detail the interactionist position to which he ascribed. It is, in his words, a “constructivist structuralism,” according to which the origin of mental structures is to be sought in the actions of the subject (the child) on objects as the subject strives to adapt to its environment. Structures are constructed within the subject as a consequence of interactions between subject and object. What Piaget judged to be innate is an intelligent functioning that makes possible the production of progressively more adequate structures of knowledge on the basis of abstraction from actions performed during the stages of development.

For example, the concept of space is a fundamental mental structure developed in the earliest period of children's lives. In earliest infancy the child is aware of not one homogeneous space but several heterogeneous spaces, each centered on a certain part of the child's body (for example, visual space and tactile space). As children act on objects that may traverse these various spaces (e.g., a rattle occupying visual, tactile, and auditory spaces), they come to coordinate these individual spaces. Eventually, actions representing displacements in space are organized mentally into the general concept of space. That concept is a structure that can be described in logicomathematical terms.

EQUILIBRATION

For Piaget the general criterion for intelligent functioning is equilibration, briefly defined as “a compensation for an external disturbance.” Hans Furth described equilibration as “the factor that internally structures the developing intelligence. It provides the self-regulation by which intelligence develops in adapting to external and internal changes.” At every level of development the equilibration mechanism operates to further adaptation, but as development proceeds toward the highest level of cognitive functioning, equilibration becomes progressively more adequate in enabling the organism to adapt to a wider range of internal and external disturbances. Piaget's notion of intelligence as adaptation is therefore essentially bound to an equilibration model of intelligent functioning.

ASSIMILATION AND ACCOMMODATION

To explicate the equilibration model further requires introducing Piaget's concepts of the assimilation and accommodation processes. The biological foundation of Piaget's developmental theory is nowhere more clearly evident; these processes are considered functional invariants of all intelligent behavior. At every level of intellectual development, from infancy to adulthood, the processes operate in adaptation.

The assimilation-accommodation account of development stresses the interaction between organism and environment. A certain readiness within the organism is postulated to be necessary for change or development to occur. In Piaget's view, associationism (empiricism) in psychology has committed the fallacy of crediting only half of those conditions necessary for learning with all explanatory power. A full account of human development must include not only the influence of stimuli on respondents (S ® R) but also the influence of the responding organism on incoming stimuli (S ¬ R). Such an account is provided by Piaget's assimilation-accommodation viewpoint:

From a biological point of view, assimilation is the integration of external elements into evolving or completed structures of an organism. In its usual connotation, the assimilation of food consists of a chemical transformation that incorporates it into the substance of the organism.

Furth referred to assimilation as “an inward-directed tendency of a structure to draw environmental events towards itself.” Assimilation is the conservative side of intellectual development, ensuring continuity and coherence by incorporating new aliments into existing mental structures. However, assimilation alone cannot account for growth or change within those structures.

Accommodation occurs during the developmental periods when new data cannot be wholly assimilated into the child's existing mental structures, and yet the data are not so foreign to those structures that they can be ignored. Furth referred to accommodation as “an organism-outward tendency of the inner structure to adapt itself to a particular environmental event.” Read Tuddenham pointed out the variations in accommodation relative to levels of intellectual development as follows:

At the lowest psychological level, accommodation refers to the gradual adaptation of the reflexes to new stimulus conditions—what others have called conditioning or stimulus generalization. At higher levels it refers to the coordination of thought patterns to one another and to external reality.

This line of thought reveals in what sense intelligence is defined by Piaget in terms of equilibration. His equilibration is not a static, balanced system, but a dynamic, or mobile, equilibration between assimilation and accommodation s the child responds to the environment.

STRUCTURALISM

Intelligence has been discussed in terms of an equilibration process involving assimilation of ailments to structures and accommodation of structures to new, somewhat different ailments. Before the stages of intellectual development through which that process passes can be analyzed, one must more fully understand Piaget's notion of intellectual structure and to take a more fundamental look at the origins and developmental forms of the cognitive structures.

The term Piaget used for a cognitive structure is scheme (schema): “A scheme is the structure or organization of actions as they are transferred or generalized by repetition in similar or analogous circumstances.” Schemata exist in the infant as perceptual-motor behavior patterns (e.g., the grasping reflex). They also exist in mature intelligence, although as Furth pointed out, *schema* is more commonly used to refer to an early mental structure, whereas general schemata resulting from use of higher intelligence are referred to as *operations*.

The abstraction process that leads to the formation of cognitive structures is called *reflective* or *formal abstraction*. It is an abstraction from *actions*, according to which the similarities inherent in various behavioral acts are dissociated from their particularized contexts. (See, for example, the earlier example of the rattle in space.) According to Furth and colleagues, “More precisely, reflective abstractions are an enriching feedback into the structures of the organism from the most general coordinations of actions.”

THEORY OF STAGES

An integral part of Piaget's theory on genetic epistemology is a psychology of cognition that seeks to describe how knowledge develops and changes. The genetic framework for that and the process of intellectual adaptation during the ajor early periods of life are provided in Piaget's theory of the stages of cognitive development.

The stages of cognitive development that Piaget and his associates delineated empirically are not defined merely by the dominance of some aspect that remains present but less-dominant throughout development. Rather, each stage constitutes a structured whole that can be defined by a set of criteria.

Piaget was not entirely consistent concerning his stages of cognitive development, but the only possible source of confusion in his later writings is whether the so-called preoperational period is to be considered apart from the period of concrete operations in which it culminates. John Flavell's 1963 study and Piaget's 1983 summary define three major periods and one subperiod of intellectual development (Table 3.2-1). These periods contain subdivisions called stages. The major developmental periods are as follows:

Age (Years)	Period	Cognitive Developmental Characteristics
0–1½ to 2)	Sensorimotor	Divided into six stages, characterized by (1) inborn motor and sensory reflexes (2) primary circular reaction (3) secondary circular reaction (4) use of familiar means to obtain ends (5) tertiary circular reaction and discovery through active experimentation (6) insight and object permanence
2–7	Preoperations subperiod*	Deferred imitation, symbolic play, graphic imagery (drawing), mental imagery, language
7–11	Concrete operations	Conservation of quantity, weight, volume, length, and time based on reversibility by inversion or reciprocity; operations; class inclusion and seriation
11 through end of adolescence	Formal operations	Combinatorial system, whereby variables are isolated and all possible combinations are examined; hypothetical-deductive thinking

* This subperiod is considered by some authors to be a separate developmental period.

Table 3.2-1 Stages of Intellectual Development Postulated by Piaget

1. The sensorimotor period, which extends from birth until approximately 1½ years of age. The period is divided into six stages, which are described in general below with reference to the development of the concept of the permanent object.
2. A period of preparation for, and acquisition of, concrete operations. This period extends from the appearance (at about age 2) of the symbolic (semiotic) function to the beginning (at about age 7) of higher mental operations applied to concrete objects.
3. The period of formal operations, which begins at approximately 11 years of age. During this period, full adult intelligence develops as the operations are extended to apply to propositional, or hypothetical, thinking.

Sensorimotor Period The sensorimotor period of intelligence is so named because the child's construction of mental schemata is in no way aided by representations, symbols, or thoughts. Rather, schemata depend totally on perceptions and bodily movements.

Stage 1 of sensorimotor development is marked by a relatively few organized reflexes that stand out from the spontaneous general activity of the neonate. Among those early reflexes are the sucking reflex and the palmar reflex. These primitive reflexes take on the nature of the first schema through three types of assimilation: (1) reproductive (repeating the actions); (2) generalizing (repeating the actions on new objects); and (3) recognitory (performing different varieties of the actions on different objects).

Stage 2 contains the first habit and the primary circular reaction. The first habits develop out of the original schemata as they are applied to objects in the environment or parts of the infant's body without any differentiation between means and end. In a primitive state of consciousness, the infant is aware only of action sequences and is not even aware of self. Primary circular reactions occur when by chance the infant experiences a new consequence of a motor act and tries to repeat the act.

In stage 3 of the sensorimotor period an initial distinction between means and end becomes apparent, but in a primitive sense. The infant repeats a particular action pattern that achieved one end for the purpose of achieving other (unrelated) ends. For example, a baby who succeeds in shaking a rattle by pulling a string may repeatedly pull the string in an attempt to effect other sounds or results.

In stages 4 and 5 infants use a variety of available means to obtain particular goals. The distinction between stages 4 and 5 lies in the relative creativity or newness of the means. Stage 4 is marked by use of already familiar means. Stage 5 is marked by a search for new means based on further differentiations of already known schemata and by the tertiary circular reaction. The latter differs from a secondary circular action in that the child no longer produces schemata that were effective in one situation to produce magically efficacious results in every situation. Instead, the child explores the environment and varies means to test for effectiveness. Discovery is a hallmark of stage 5. For example, a child may use a stick to move an object not within reach.

Stage 6 is transitional, leading into the preoperational subperiod. In stage 6 the child becomes capable of inventing new means, not by direct actions on objects but by mental combination. Whereas discovery marked stage 5, insight is a characteristic of stage 6. For example, a child who has seen the father bang on a drawer to loosen it may bang on a toy box to make it easier to open.

During the sensorimotor period, a number of significant concepts are developed, including the child's concepts of space, time, and causality. These categorical concepts develop in a process parallel to the sequence of the six stages outlined above. Most important, during the sensorimotor phase, the child develops the schema of object permanence, the first major victory of conservation and the foundation of all future knowledge.

Schema of Object Permanence The knowledge that objects in the external world have an existence independent of the child's actions on them or interactions with them is a major accomplishment of the sensorimotor period. Flavell has outlined Piaget's observations and interpretations of infants' reactions to the disappearance of interesting objects, which are the foundation for the theory of development of object permanence. In stages 1 and 2, for example, a child simply continues to look at the place where the object was last seen. In stage 3, if an object such as a spoon drops to the floor, the infant will look for it (e.g., by leaning over and looking at the floor). In stage 4 if an object is repeatedly hidden at point A (in sight of the child) and then hidden at point B (also in sight of the child), the child searches for it at the original, rather than the current, hiding place (i.e., at A, not B). Stages 5 and 6 mark the child's increasing understanding of object permanence; the infant is able to follow multiple displacements of the object through points in space, even if the object is hidden within another object.

Preoperational Subperiod and Semiotic Function The advent of the preoperational subperiod is marked by the appearance of what Piaget called the *semiotic function*. This new ability was defined by Piaget and Bärbel Inhelder as follows: “It consists in the ability to represent something (a signified something object, event, conceptual scheme, etc.) by means of a signifier which is differentiated and which serves only a representative purpose: language, mental image, symbolic gesture and so on.”

During the sensorimotor period, a thing could be represented in a limited sense by a part of itself (e.g., the mother's voice might represent the presence of the mother in the room). However, such signifiers are indexes undifferentiated from their significants (the voice is part of the mother). Symbols and signs are signifiers that are differentiated from their significants. They become available to the child only with the appearance of the semiotic function, which makes representational thought possible. As Furth pointed out, representation has first of all an active meaning in Piaget's theory. The child becomes capable of summoning up a symbol or sign to

stand for a given significant. For Piaget, representation is not at the essence of thought; it has an auxiliary function.

Characteristic Behavior Patterns The semiotic function is heralded by five characteristic behavior patterns in evidence during the second year of life: (1) deferred imitation or imitation that starts after the disappearance of the model; (2) symbolic play or the game of pretending; (3) drawing or graphic imagery; (4) mental image, which appears as an internalized imitation and not as a function of perception; and (5) verbal evocation of events not occurring at the time. Each behavior pattern shows the origins of representational thought as the preoperational subperiod of cognitive development begins. For Piaget the semiotic function, which so enlarges the children's worlds—liberating them from the bonds of immediate space and time and enabling them to begin to manipulate symbols and to think rather than just to act on immediately present objects—is rooted in imitation.

IMITATION One can follow the development of imitation through the same six sensorimotor stages delineated for the concept of object permanence. Piaget did this in his volume *Play, Dreams and Imitation in Childhood*. A radically new form of imitation occurs during the second year of life: deferred imitation. For example, a child may put on Father's hat and walk as Father does, even hours after Father has gone off to work.

For Piaget, intelligence is an equilibration process in which assimilation and accommodation are in balance. However, in imitation, accommodation outweighs assimilation. According to Piaget, imitation is behavior in which “the subject's schemes of action are modified by the external world without his utilizing this external world.” In imitation the child's cognitive structures undergo temporary change without simultaneously incorporating new aliment.

SYMBOLIC PLAY A second new behavior pattern that now appears is symbolic play. In imitation the imbalance between assimilation and accommodation is weighted in favor of accommodation; however, the opposite is true in symbolic play, which is a lessening of the demand of the adaptive process.

Development of play can also be followed through the six stages of sensorimotor intelligence, but symbols are used in play only after the sensorimotor period, in the type of play characterized by games of pretending. For example, a little girl may pretend that she is asleep, that a box is her pet cat, or that she herself is a church. In each instance symbols are generated “to express everything in the child's life experience that cannot be formulated and assimilated by means of language alone.”

According to Piaget's theory, these symbols are created by the same process of imitation that gives rise to deferred imitation at this time. In fact, Piaget views imitation as the process underlying the development of the entire semiotic function. In symbolic play, then, symbols are generated by a process in which accommodation outweighs assimilation. But instead of being used accurately (i.e., to represent what they are derived), they used in a process in which a liberating assimilation outweighs accommodation.

DRAWING A third behavior pattern associated with the rise of the semiotic function is drawing, or graphic imagery. Piaget sees elements of both play and imitation in this activity. In developmental terms, he considers drawing “halfway between symbolic play and the mental image,” appearing at about age 2 or 2½ years. Drawing is playful activity, an end in itself characterized by reproductive assimilation; in other words, the child enjoys producing drawings for their own sake. However, graphic play also has accommodative elements, especially as the child grows older and attempts to draw not just formless scribble but some thing.

MENTAL IMAGE Closely related to drawing is the mental image. Piaget tied the genesis of mental imagery to accommodation and imitation. He explicitly denies that mental images can be the product of perception; they are a construction, something the child creates. The mental image is not directly given by perceptual input; it is constructed by the process of accommodation.

VERBAL EVOCATION OF EVENTS The fifth behavior pattern associated with the rise of the semiotic function concerns language, the verbal evocation of events that are not present. Piaget gave the example of a little girl saying “Anpa, bye-bye” (Grandpa went away) while pointing to the path he had taken when he left. The parallel with deferred imitation is clear, but the new representational ability is supported by the social system of language.

Concrete Operations A crucial difference between preoperational and concrete-operational thought is the presence within operative thinking of concepts of conservation. When concrete operations have been organized into a system, the child can conserve, that is, “discover what values do remain invariant . . . in the course of any given kind of change or transformation.” The progressive and continual structure building that occurs in the concrete operational period is evident in the increase, with development and age, in the scope of such concepts, such as conservation of quantity, substance, and number.

Conservation of Quantity The clearest sign that a child remains in the preoperational subperiod is the absence of the concept of conservation. For example, if liquid is poured from a short, wide glass into a tall, narrow one, the child in the preoperational stage thinks the amount of liquid has changed. At the level of concrete operations, however, children are no longer overwhelmed by the perceptual discrepancy between the two configurations. They begin to reason about the transformation, and their correct judgments regarding the conservation of quantity of liquid are accompanied by explanations grounded in logical properties. It is assumed that children are not aware of the logic they use.

When problems of conservation begin to be solved, the child passes from the preoperational subperiod into the period of concrete operations, for which the former was a long time of transition and preparation.

Conservation of Substance At the age (on average) of about 7 or 8 the child can solve the conservation-of-quantity problem and can perform similar judgments of conservation when, for example, a lump of clay is transformed in shape. Between the ages of 9 and 10, the child discovers that the weight of a given object is also conserved even when its shape is transformed. However, not until approximately age 11 or 12 do children have a logical comprehension that the volume displaced by a given object is conserved even after transformation of the object's shape. Conservation entails the logical certainty that one characteristic of an object remains invariant while the object itself undergoes some type of perceived transformation.

Concept of Cardinal Numbers The concept of cardinal numbers also develops from an initially nonconserving to a conserving stage. Children in the preoperational subperiod can be presented with two horizontal rows of colored dots in one-to-one correspondence (i.e., imaginary vertical lines could be constructed between each red dot and its corresponding blue dot). When the experimenter destroys this optical correspondence by spreading out one of the rows of dots, the child in the preoperational period thinks the larger row contains more dots. Only after conservation of cardinal number has been established as a logical necessity does the child maintain the numerical equivalence of the spread-out row. Clearly, preoperational concepts of number provide inadequate bases for arithmetic skills. It is possible that a lag in the development of number conservation could underlie certain types of arithmetic-related learning disabilities. Again, that points to the importance of children's active experience as a foundation for subsequent concept formation.

Operations Notions of conservation are the mark of well-established concrete operational thinking; thus one must understand the meaning of *operation* in Piaget's thought. Operations, themselves, constitute essential thinking. For Piaget an operation is an action that is (1) interiorized, (2) reversible, and (3) part of an organized system of such actions.

The operations that form this system are interiorized actions. In the sensorimotor period external behavior patterns gave rise through a process of abstraction to the construction of sensorimotor schemata. In similar fashion internal thinking patterns later give rise to operations. According to Furth, the generalizable aspects of actions, “those which can be found in any coordination of action,” enter into the construction of operations. Saying that the crucial aspect of actions in this regard is their generalizability explains the importance of interiorization in the construction of operations. *Interiorization* refers to “the increasing dissociation of general form from particular content.” In other words, the notions of generalizability and interiorization merely point out the process of abstraction that is occurring. For example, a child adds two apples and three apples to obtain five apples. In another instance a child adds seven blocks and one block to obtain eight blocks. In a third instance a child combines the category of fathers with that of mothers to obtain the category of parents. The operation abstracted from these three mental actions is addition or combining, without reference to the particular content of numbers, objects, or categories.

Not only must an operation be interiorized action, it must also be reversible. The action of combining (addition) is not an operation until its relationship to the action of separating (subtraction) is comprehended. To understand reversibility is to understand the third criterion of an operation, its inclusion in a system.

The reversibility essential to operatory thought may be either inversion or reciprocity. In reversibility by inversion, an action + A is reversed by – A. For example, in the above conservation-of-quantity example, pouring liquid into container 2 (+ A) may be mentally reversed, that is, mentally pouring it back into container 1 (– A). In reversibility by reciprocity a relation A < B is reversed by a relation B < A. Referring again to the conservation-of-quantity example, let A stand for container 1, and B stand for container 2. The rising height of liquid in container 2 (A < B) is offset by its narrower width (B < A).

Corresponding to these two types of reversibility are the two major categories of concrete operations: those pertaining to classes and those pertaining to relations. In the system of operations performed on classes, reversibility is by inversion; in those performed on relations, it is by reciprocity. For example, subtraction and addition relate to inversion; comparing sticks of different sizes relates to reciprocity.

Class Inclusion The concrete operation demonstrating understanding of classes is the class inclusion task. In this task a child is shown, for example, an array of pets (superordinate class) consisting of dogs and cats (subordinate classes). After counting the number of dogs, cats, and pets, the child is asked whether there are more dogs or more pets. Children in the preoperational subperiod cannot keep in mind the superordinate class while perceiving only the subordinate classes. Thus, they fail the task frequently over a series of such arrays.

Relations The concrete operation that demonstrates an understanding of relations is seriation. Children are asked, for example, to arrange a set of rods in order of increasing size. Children in the preoperational subperiod may subgroup the rods but will have difficulty completing an entire array along the required dimension. They may understand the concept of smaller versus larger but have difficulty comprehending the gradual nature of change.

Formal Operations In the third and final stage in Piaget's conception of the intellectual development in the child the logical structures of concrete operations are superseded by structures referred to as formal operations.

The relationship between the real and the possible that characterizes adolescent thinking represents a reversal of that relationship in the thinking of the concrete operational child. Inhelder and Piaget note that the real has priority for the younger child and that possibility is conceived of merely as a prolongation or extension of real operations, “as, for example, when, after having ordered several objects in a series, the subject knows that he could do the same with others.” For the adolescent, however, the possible has priority and the real is seen as a particular instance of it. “Henceforth, they conceive of the given facts as that sector of a set of possible transformations that has actually come about.” This immediately presupposes that the adolescent can take a given empirical event (such as, “the long, thin rod bends”) and categorize it within a system of possible combinations of events (e.g., long rods or short rods, thin rods or thick rods, bending or not bending). Three characteristics follow from this fundamental reorientation in thought: (1) adolescent thought is hypothetical-deductive; (2) it deals in propositions rather than in concrete events; and (3) it can isolate variables and examine all possible combinations of variables.

Hypothetical-Deductive Thought As a hypothetical-deductive form of thought, formal operational intelligence proceeds from the possible to the real. In this sense, it mirrors scientific reasoning. The implications of a propositional statement are drawn and then tested against reality. Rather than building up a proposition by induction from disparate concrete examples to a loose generalization, formal intelligence operates systematically from general statement to particular instance by means of testable hypotheses. In Flavell's words, “To try to discover the real among the possible implies that one first entertains the possible as a set of hypotheses to be successively confirmed or infirmed. Hypotheses which the facts infirm can then be discarded; those which the data confirm then go to join the reality sector.”

Propositional Thought Saying that formal operations deal in propositions rather than in concrete events, implies increased freedom from immediate content, with a correspondingly greater intellectual mobility. At one level this freedom implies the ability to manipulate abstractions that have been tied to concrete examples or events. The adolescent, for example, can perform a transitive inference (A < B, B < C; therefore, A < C) without any empirical demonstration of referents for the terms A and B. At another level this freedom implies that having performed a concrete operation, the adolescent can abstract the results of that operation and perform further operations on them. For example, an adolescent can perform the concrete operation of combining two liquids to observe the color of the resultant mix and then take the result of this operation and systematically relate it to results of all other combinations of available liquids.

Isolating Variables and Examining Combinations The example that follows helps explain the third characteristic of adolescent thought mentioned by Flavell, the isolation of variables and the examination of all possible combinations. Instead of dealing with disparate concrete experiments, hypothetical-deductive adolescents can organize their investigations into a coherent pattern a priori, then perform all relevant combinations of variables to test their hypotheses, thus isolating causal factors. Piaget's theory of formal operational cognition focused on scientific thinking. For example, the weight, speed, shape, and size of an object may all be seen to contribute to the size of a hole the object will make when hitting the ground.

Children in the preoperational substage merely describe what they see, and causal thinking is expressed in an undifferentiated form (e.g., “It has to”). The child with concrete operational thinking can categorize and order the relevant variables independently but has difficulty integrating the system of all relevant variables. The adolescent, however, can generate all possible combinations of relevant variables and then systematically test the importance of each variable.

A complete combinatorial system appears only during the period of formal operations. Instead of focusing on empirical givens, as a child in the concrete operational stage does, the adolescent using formal operational thinking constructs a hypothetical system comprising the empirical givens. Whereas the younger child could classify events according to various categories, such as length, width, and weight, the adolescent uses that classification as a basis for abstracting all possible combinations of variables. Having done this, the adolescent can then test hypotheses derived from the combinatorial system. The result of this new ability is the capacity to test the causal significance of each individual factor in succession by holding all other factors constant.

Piaget interprets the rise of formal operational thought in the context of his equilibrium model of cognitive development. Thus, he considers neurological maturation and experience of the object and interpersonal world as necessary but not sufficient to explain this qualitative improvement in thinking. In essence, the equilibration explanation is as follows: During the stage of concrete operations, a number of qualitatively heterogeneous factors are constructed by the child, resulting in the achievement of conservation of the factor in question even in the face of perceptual transformations. Such factors include quantity, weight, volume, time, and length. Eventually, the child discovers that in many concrete instances the operation of these factors is interrelated. Thus, although the factors have been constructed mentally in relative isolation from one another, their presence in real objects is mixed. Through experience with both impersonal and interpersonal objects, the child's concrete operational understanding of these factors is shown to be insufficient, and a more comprehensive, more intelligent understanding is stimulated.

EGOCENTRISM

Each major period of cognitive development is characterized by a qualitative shift toward more comprehensive and more adaptive cognitive structures. In this sense, the adolescent is more intelligent than the infant. However, each transition to a higher level of cognitive organization is initially accompanied by a lack of full differentiation between self and object. Each period has an early organizational phase that is followed by the phase of accomplishment of cognitive developmental tasks. During the early organizational phase, the child's failure to differentiate fully the self from objects is manifest in behavior reflecting stage-specific forms of egocentrism. David Elkind has summarized the process. Each developmental period has characteristic forms of egocentrism.

In the sensorimotor period, egocentrism refers literally to a lack of differentiation between self and object, as perceived in the lack of object permanence. The existence of objects independent of action patterns of the self is not acknowledged. In the preoperational subperiod the capacity to engage in symbolic thinking is accompanied by initial failure to differentiate fully between symbols and their referents. That may be manifest, for example, in failure to differentiate such mental images as dreams from real objects. In the concrete operational period the capacity to engage in logical operations is accompanied by an unrealistic certainty in which probability is not appreciated and mental construction of the self (self-definition) is not differentiated from facts. Finally, at adolescence the capacity to engage in hypothetical thinking and to understand others' points of view is accompanied by characteristic patterns of thought in which others are unrealistically presumed to be focusing on the self. As Elkind has pointed out, adolescent egocentrism is a “belief that others are preoccupied with (the adolescent's) appearance and behavior,” when, in fact, the adolescent is preoccupied with these topics.

EXTENSIONS OF PIAGET'S THEORY

In his classic statement of theory and in the bulk of his scientific research, Piaget focused on the development of logicomathematical reasoning, the operative aspects of thinking. Others, however, have extended a similar structural model to the investigation of other domains. The best known example of such an extension of Piagetian theory is probably Lawrence Kohlberg's theory of the stages of moral reasoning. Kohlberg proposed six stages in the development of moral reasoning. These begin with the moral stance of the preschool child, based on reward or punishment, and proceed through middle childhood, when moral judgment tends to be based on desire to obtain the approval of others or to uphold authority. Only with adolescence does the morality of internalized principles, such as the rights of individuals or the notion of a natural law, begin to take effect. In Kohlberg's model each major stage of moral development requires that the child attain a commensurate level of cognitive development. For example, conventional morality, which develops during middle childhood, requires concrete operational thinking, and principled morality requires formal operational thinking.

A broader area of development in which Piaget's observations have been extended has been referred to as *social cognition*. A central construct throughout Piaget's developmental model is egocentricity versus decentration. In the social domain decentration has been referred to as role taking, or the ability to take the perspective of others. That skill may be observed at a perceptual, a cognitive, or an affective level. Perceptual role-taking involves the ability to recognize how a perceptual array appears from the perspective of another when that perspective differs from one's own. Cognitive and affective role-taking involve analogous processes in which the thoughts and feelings of others are taken into account when they differ from one's own. Thus, role taking is a condition necessary for the development of empathy. Kohlberg considered it also a necessary condition for the development of higher levels of moral reasoning.

In general, social cognitive processes refer to role taking and communication skills that enable children, adolescents, and adults to understand one another's thoughts and feelings. Social cognitive processes are central to the concerns of psychiatry, because deficiencies in these processes impair communication and correlate with symptomatology and because reconstruction of social cognitive processes is a direct concern of psychosocial interventions. For example, the deficiencies in social cognition that characterize aggressive, conduct-disordered boys have been delineated by Kenneth Dodge, John Lochman, and others and then identified as targets for intervention with these youngsters.

Flavell recently reviewed three decades of work in the area of perspective taking or role taking. After a period focused on communication skills, perspective-taking researchers concentrated on cognitive processes in which children develop knowledge of themselves and others as learners and rememberers. For example, during development children become aware of strategies for encoding bits of information that need to be recalled. Studies of such metacognition are another example of the extension of a Piagetian model to domains of practical importance to psychiatry and applied psychology. Deficiencies in metacognitive skills have been identified in youngsters with attention-deficit/hyperactivity disorder or learning disorders and can serve as targets for psychoeducational intervention.

Recently, post-Piagetian research on perspective taking has focused on what has been described as children's “theory of mind.” This pertains to children's awareness that others have cognitive processes similar to their own, or that others have an internal mental state and the ability to represent the mental states of others in their own mind. An example of a theory-of-mind task is the false-belief task. In that task, a child is shown a popular, brand name candy box and asked what it contains. The child is then shown and told that the box does not contain candy but instead contains a pencil. The pencil is then put back into the box, and the child is asked to predict what another child would say is in the box and to say what is actually in the box. Thus, the task involves predicting an erroneous belief in another that differs from one's own correct belief. Young children master this task at about age 4. However, children with autistic disorder show specific deficiencies on this task, whereas children in whom language is merely delayed have no such difficulty. Thus, “theory of mind” may be an area of cognitive deficiency specific to autistic disorders.

NEO-PIAGETIAN RESPONSE TO CRITICISMS OF PIAGET'S THEORY

Major criticisms of Piaget's theory have emanated from the Anglo-American empirical tradition and from sociocultural theorists. Empiricists have pointed to findings, including the effectiveness of training interventions in accelerating Piaget's proposed pace of cognitive development and to weak correlations among scores on tasks that purportedly measure the same underlying cognitive structure. Sociocultural theorists consider Piaget's emphasis on logicomathematical reasoning and the isolation and manipulation of variables as a bias inherent in Western forms of thought. Cross-cultural research has shown that different tasks are mastered at different ages in different cultures. In addition to these external critics Piaget has been criticized within his own school of thought for failing to address individual differences in cognitive abilities, for failing to investigate cognitive development during adulthood, and for giving an insufficient explanation of the processes by which stage transitions occur.

Neo-Piagetian theorists, such as Juan Pascual-Leone and Robbie Case, attempt to address these criticisms while retaining the core assumptions of Piaget's theory. Instead of positing broad cognitive structures that subsume a variety of specific tasks, these theorists focus more on narrow-band structures and elaborate on the mechanisms or processes by which such structures change. In so doing they have moved neo-Piagetian theory closer to other branches of cognitive science and have delineated processes that are more readily studied in relation to biological or neurological variables.

Pascual-Leone, for example, has emphasized the role of attention in the process of structural changes. To move from a lower to a higher level cognitive structure a child must first inhibit the application of an old cognitive structure to an environmental stimulus or aliment and then coordinate a new set of schemata through mental effort. That effort involves deployment and maintenance of attention. On the other hand, Case emphasizes the cognitive processes of problem solving and exploration in the transition from lower to higher levels of cognitive structure. Both theorists take the view that change occurs on one or a few structures at a time and that which specific structure undergoes change is a function of individual differences or environmental opportunities. Neo-Piagetian theory is thus less universal in its model of cognitive development and more accommodating of cultural and individual differences. Nevertheless it retains the basic Piagetian concepts of an active, developing child who is constructing cognitive structures on the basis of interaction with the external and social environment. However, even neo-Piagetian theory has not solved the key challenge of how to fully integrate emotional and intellectual development.

NEW CONCEPTS OF INTELLIGENCE: EMOTIONAL BASIS OF INTELLIGENCE

Human emotions have traditionally been viewed as somewhat separate from cognition and as a minor concern to overall development. New clinical observations and theoretical formulations by the first author and emerging findings from a number of recent studies suggest that emotions are central to cognition and may actually regulate and orchestrate cognitive capacities. They may also be critical to development of cognitive capacities. It is suggested that babies' emotional exchanges with their caregivers, rather than their ability to complete cognitive tasks, should become the primary measure of developmental and intellectual competence.

Twelve-month-old Cara sits in her mother's lap at a table, eyes locked onto the psychologist, who tries to get her to follow the bean he is putting under the cup and search for it. Cara knocks over the cup. Is this little girl, as her mother fears, cognitively delayed? Does a 1-year-old child who never babbles like other children her age and violently flings food and toys away from her show signs of a significant intellectual deficit? After a battery of similarly frustrating tests, the evaluator concludes that cognitive delay is the likely diagnosis in Cara's case.

For 50 years developmental testers have expected babies to sit still in their mothers' laps, pay attention, and perform prescribed tasks while adults assess their basic intelligence. Traditional wisdom has long insisted that carefully scoring how well a tiny child fits pegs into boards, sorts cards by shape, or hunts beads under cups can reveal an accurate measure of intelligence and developmental competence. However, recent results from research and clinical practice by the first author and others suggest that this entire approach to assessing children's capacities rests on false premises and has inadvertently led to mistaken diagnoses that can stigmatize children throughout their school years.

When an evaluator schooled in this new thinking assessed Cara, he focused on her spontaneous interactions with her caregiver. He looked at each of Cara's intentional behaviors as a sign of her emotional interests. For instance, he observed her delight in yanking her mother's nose. At the assessor's suggestion the mother permitted the tugging on her nose to continue and playfully responded, “Toot, toot.” Cara smiled and pulled again. The baby was rewarded with another “Toot, toot” and a big smile from her mother. Cara soon began to copy her mother's gestures and eagerly thrust her nose towards Mom. When the mother squeezed Cara's nose, the 1-year-old girl chirped, “Mo, mo,” her very first words.

Cara showed that she could initiate social interactions and comprehend their consequences. That demonstrated degree of understanding put Cara at least at the 12-month level of cognitive development. Further observation revealed an extremely energetic, active, highly physical toddler who liked to have her way and control her surroundings. With the consultant's help, Cara's mother later altered her parenting style. She learned to follow Cara's behavioral lead, then enthusiastically engage her daughter in creative interactions while simultaneously setting firm limits. Cara's energy quickly became more focused; her babbling, richer. Before long she was saying real words and actively cooperating with her parents.

If a series of such simple, pleasurable interactions with her mother could reveal and foster Cara's language development and organizational ability, then any conception of intellect that marked her as cognitively delayed because of an inability to search for a bean has serious flaws. Those flaws are based on a long-standing mistaken belief that the intellect is superior to and supervises the passions. Clearly, as Cara's linguistic debut demonstrates, analysis of a child's early relationships and sensory and emotional experiences is a vital key to accurate assessment of intelligence and developmental competence.

Until now, however, no one has offered an explanation of how emotions give birth to intelligence. In fact, a baby's earliest feelings play a pivotal role in all later intellectual development. Unlikely as the connection between feeling states and intelligence may seem, the emotions orchestrate a vast array of cognitive operations

throughout an individual's life span. Indeed, they make possible all creative thought.

Results from four distinct lines of inquiry have recently shed new light on the importance of emotions for intelligence. In work with Arnold Sameroff, this first author has found that children with four or more family emotional risk factors had 24 times the chance of scoring an intelligence quotient (I.Q.) below 80 than children without those risks. Stephen Porges and the first author have shown that measurements in 8-month-old infants of a part of the brain that regulates emotions correlate with these same children's I.Q. scores at age 4.

The first author's work with a group of children with autistic disorder, who suffer some of the most severe thinking and language problems imaginable, has also confirmed the inextricable linkage of emotional and cognitive development. Therapeutic programs for these severely challenged children have traditionally concentrated on trying to stimulate their cognition and teach them language. However, a program based on emotional cueing (like the one that revealed Cara's true abilities) proved to be more effective for a number of these children in fostering empathy, warmth, and creative thinking.

> One young patient, Ashley, neither spoke nor made any response or eye contact with those around her. The 2-year-old child spent hours staring into space, rubbing persistently at the same patch of rug. Her abnormal repetition was viewed by the clinician observing her as more than just a distressing symptom of her autism. That symptom revealed an underlying interest and motivation that could be harnessed and redirected toward interacting with others. To initiate her cognitive progress the clinician had to first motivate her to communicate with the simplest of emotional gestures—a smile, or smirk, or purposeful hand movements. He suggested that her mother place her hand next to Ashley, on the favorite stretch of rug. When Ashley pushed it away, the mother gently put her hand back. Each time the child pushed, the mother's hand would return. A cat-and-mouse game ensued, and after three sessions of these rudimentary interactions, Ashley was looking, smiling, and anticipating.

From that tiny beginning, through a comprehensive therapeutic program, grew a bridge to emotional relationships and eventual verbal exchanges. For example, as therapy progressed, the therapist helped Ashley use her imagination by repeatedly initiating pretend play. He recognized that each time Ashley repeatedly flung herself on her mother, the child was deriving sensory-based simple pleasure from her behavior. He instructed the mother to whinny like a horse each time Ashley lunged at her. Soon Ashley imitated mother's sounds and then started initiating her own sounds and words. In that way the therapist helped the mother stretch a pleasant sensation for Ashley into a richer, more complex interaction. Over time mother and child pretended to be neighing horses, mooing cows, and barking dogs. Their social and emotional interchange grew increasingly complex, passing through the same series of developmental stages identified in children without difficulties. At age 7 Ashley now enjoys warm friendships, argues as well as her lawyer father, and scores in the low-superior I.Q. range.

A fourth line of inquiry, microscopic clinical observations of children's thinking, further clarifies the relationships between emotion and reason by revealing two necessary elements of thinking. The first process—creating a new idea—stems from the ability to use one's own emotional experience to assign meaning and significance to daily events or concepts. The second process—reflection and logical analysis—examines the newly created idea according to whatever principles of logic the person possesses and places it in a wider frame of reference.

> To understand those processes in action, the authors put a simple question to two young boys seen in therapy not long ago. When asked by the clinician, “What do you think about people who act bossy to you?” Chris replied, “Well, teachers are bosses, babysitters are bosses, policemen are bosses.” That articulate 7-year-old child lacked the emotional pathways that permit creative and intuitive thought. He could provide a formal classification of different types of bosses but could not relate these categories to his own life. However, 7-year-old Josh had no such difficulties. In response to the same question about bosses, he announced, “Most of the time I don't like being bossed, especially when my parents try to tell me when I can watch TV and when I have to go to sleep. I'm big enough to decide for myself. Sometimes when I'm being bad, I guess I need bossing, though. Maybe bosses are okay some of the time, and some of the time they're not.” Josh finds his answer in his own, apparently generally irritating, brushes with bosses. Rather than simply listing categories or incidents, he can abstract a principle from the emotional core of those incidents.

How exactly did Josh's ability to think and abstract develop? A baby's experience begins with sensations like touch and sound. Each sensation, however, also gives rise to an emotion. A toy may feel interesting or boring; a voice, soothing or jarring. Even young infants react to sensations emotionally. They prefer the sound or smell of their mother, for example, to any others and by 4 months of age can react to certain persons with fear. Furthermore, contrary to long-held assumptions, basic sensations like touch and sound can be perceived differently by different people, giving rise to emotional differences.

Emotional meaning also adheres to early concepts like “big and little,” “more and less,” “near and far,” and “now and later.” “A lot” is a bit more than makes a child happy. “Near” is snuggled next to a child in bed. “Later” is a frustrating stretch of waiting. For a child without an intuitive sense of “few and many,” numbers have no meaning. Furthermore, a young child's experience of any sensation always occurs within the context of a relationship that gives it broader meaning. Playing with mother's hair, for example, may evoke smiles and hugs or an angry scolding.

Each sensory experience has such a dual aspect and is labeled by both its physical properties and its emotional qualities. This double coding helps the child both place the memory or experience in a catalogue of experience and retrieve or reconstruct it when needed. As the child grows, emotional reactions come to operate as a sixth sense that allows the child to recognize and understand situations.

Emotion orchestrates complex judgments as well. One of modern psychology's main enigmas is how children learn to discriminate among situations (“When can I yell and kick”) and generalize from one to another (“Should I behave at school like I do at home?”). Consider how a child makes a seemingly simple judgment about when to say “hello.” She doesn't learn a set of cognitive rules like greeting only those who live on her street or only those who wave at her. Rather, from countless specific encounters she abstracts an emotional pattern; there is a feeling of warmth and friendliness in situations that rate “hello.” Her interactions create an emotional signaling system that tells her when to say hello and that it is okay to punt the football but not to kick Sarah or Charlie in the shins. That emotional signaling system, which acts like an orchestra leader for the vast array of cognitive instruments, is a quintessentially human process. No computer, for all its apparent so-called brainpower, can ever get beyond limited elements of logical analysis and think like a person. Advocates of artificial intelligence may claim that current computational capacity limits creative, humanlike thought, but the real limit is a machine's inherent inability to engage the world emotionally. No collection of microchips can ever have a child's lived emotional experience of bosses and “hello,” of noses and rugs. None, therefore, can ever create the emotionally based meaning from which creative thought grows and on which it depends.

Looking at Piaget's theory from this perspective reveals the limitations of a cognitive theory that did not adequately deal with the central role of emotions. Piaget's experiments focused on how children comprehend the relationship between physical objects, developing the ability to classify them by such parameters as shape or size. But most children can classify their emotions and emotionally relevant relationships far earlier than they can physical objects. For example, they know members of their families from those who are not members, classifying the family as a unit. Some of Piaget's observations are limited because he depended so heavily on children's perceptual and motor performance to signal cognitive advances, even though motor skills often lag behind other skills.

More important, however, is Piaget's relative lack of focus on the role of emotions. He emphasized learning through doing but did not realize that the “doing” generates formative emotional reactions as well as perceptual, motor, and cognitive ones. Consider how a child learns what an apple is. You can have her handle an apple and determine it is something red and round, bigger than a peanut and smaller than a watermelon. Alternatively, the child can observe the aspects mentioned above, experience more satisfaction eating an apple when she is hungry than when she is full, and know the pleasure of giving one to her favorite teacher.

She can also imagine how the teacher feels when she gives her the apple. She may catalogue how she herself feels when she throws one at her younger brother and gets him on the shoulder, as well as her disgust when another one rots or she discovers half a worm inside. If you ask creative adults to write an essay on apples, they will probably bring an enormous amount of personal affective experience to their reflections.

Piaget did emphasize how children's thinking comes to incorporate multiple perspectives as they grow older. A classic Piagetian experiment shows how school-age children learn to solve a problem involving weights on a seesaw. Assessing the heaviness of the weights and noticing where they are placed, they are able to figure out how a seesaw works. But what was not appreciated by Piaget was that the children's postulated perspectives incorporated the additional almost infinite number of perceptions afforded by affective experiences. To neglect this element is therefore to fail to appreciate the rich array of experiences that contribute to forming abstract concepts.

TOWARD A GENERAL DEVELOPMENTAL MODEL

The diagnosis and treatment of emotional and developmental disorders in infants and young children requires that clinician take into account all facets of the child's experience. Thus one needs a model with which to look at how constitutional-maturational (regulatory), family, and interactive factors work together as the child progresses through each developmental phase, and each phase must be viewed from both affective and cognitive perspectives.

A developmental, structuralist model formulated by the first author integrates cognitive and affective development and applies the types of structure Piaget described to a range of experience. Most important, the model lso considers individual differences in terms of biology and interaction. New findings suggest that early interaction can alter the structure and wiring of the central nervous system. In this model, the biological differences express themselves in the unique way an infant processes sensations and organizes motor patterns. Interactions harness and change these basic processes. The model can be visualized with the infant's constitutional-maturational patterns on one side and the infant's environment, including caregivers, family, community, and culture, on the other side. Both sets of factors operate through the infant-caregiver relationship, which can be pictured in the middle. Those factors and the infant-caregiver relationship in turn contribute to the organization of experience at each of six developmental levels (consistent with both cognitive and affective milestones), which may be pictured just beneath the infant-caregiver relationship.

This particular clinical and research model enables the user to look at the back-and-forth influence of highly specific, verifiable constitutional-maturational factors on interactive and family patterns and vice versa, in relationship to specific developmental processes (and to relate these processes to later developmental and psychopathological disorders).

Developmental Levels The model contains six developmental levels, which include the infant-child's ability to accomplish the following:

1. Attend to multisensory affective experience and at the same time organize a calm, regulated state and experience pleasure.
2. Engage with and evidence affective preference and pleasure for a caregiver.
3. Initiate and respond to two-way presymbolic gestural communication.
4. Organize chains of two-way communication (opening and closing many circles of communication in a row), maintain communication across space, integrate affective polarities, and synthesize an emerging prerepresentational organization of self and other.
5. Represent (symbolize) affective experience (e.g., pretend play, functional use of language), which calls for higher-level auditory and verbal sequencing ability.
6. Create representational (symbolic) categories and gradually build conceptual bridges between these categories. This ability creates the foundation for such basic personality functions as reality testing, impulse control, self-other representational differentiation, affect labeling and discrimination, stable mood, and a sense of time and space that allows logical planning. This ability rests not only on complex auditory and verbal processing abilities, but also on visual-spatial abstracting.

At each level, one looks at the range of emotional themes organized (e.g., can the child play out [symbolize] only dependency themes and not aggressive ones? is aggression behaved out and dealt with presymbolically?). One also looks at the stability of each level. Does a minor stress lead a child to lose the ability to represent, interact, engage, or attend?

In their use in day-to-day clinical work the six developmental levels can be collapsed into four essential processes that characterize development in infants and young children. These processes concern how an infant and the parents or caregivers negotiate the various phases of their early interactions, and they serve as a basis for diagnosis and treatment.

A 12-month-old infant's mother worried that, “He cries any time I try to leave him, even for a second. If I'm not standing right next to him when he is sitting on the floor, he cries and I have to pick him up. He's a tyrant. He's waking up four times at night and is a fussy eater. He eats for short bursts (breast-feeding) and then stops eating. I'm feeding him all the time.”

The mother was feeling cornered, controlled, manipulated, and bossed around. Her baby was like a “fearful dictator” (therapist's term). She said, “That's the perfect way to describe him.” The father was impatient with the mother; he felt that she indulged the baby too much. He was getting “fed up” because she had no time for him.

The baby was interactive and sensitive to every emotional nuance. As he came into the room, he immediately caught the clinician's eye. They exchanged smiles and motor gestures. He interacted with his parents with smiles, coos, and motor movements. Father intruded somewhat. He would roughhouse until the baby would cry, put the baby down, and then roughhouse again. Mother, in contrast, was ever so gentle, but long silences passed between her vocalizations. During her long silences, the baby would rev up, get more irritable, and start whining. He whined with his mother and cried fearfully with his father. Even before he could finish his motor gestures or vocalizations, his mother moved in and picked him up, or gave him a rattle, or spoke for him. In this way she undermined his initiative. Even while whining, however, he was interactive and contingent.

On physical examination, this baby was sensitive to loud noises and light touch on the arms, legs, abdomen, and back. He had a mild degree of low motor tone and was posturally insecure. He was not yet ready to crawl.

His constitutional and maturational patterns did not compromise his mastering the first developmental challenge of shared attention and engagement. He was an attentive, engaged baby. But at the second developmental stage, intentional communication and assertiveness, he was a passive reactor. He was not learning to initiate two-way communication, to be assertive and take charge of his interactions. His low motor tone was compromising his ability to control his motor movements. His sensory hyperreactivity was compromising his ability to regulate sensation. He was frequently overloaded by just the basic sensations of touch and sound, and he was not receiving support from his mother through the nurturing and rhythmic caretaking that would foster self-initiative.

This family required therapeutic work on a number of tasks simultaneously. The infant's special constitutional-maturational patterns were discussed. Hands-on practice helped the parents help their baby be attentive and calm. Those tasks included helping the mother be more patient, wait for the baby to finish what he started, and support his initiative (e.g., putting something in front of him while he was on his tummy, to motivate him to crawl and reach); getting the mother to put more affect into her voice and to increase the rhythm and speed of her vocalizations; and getting the father to be more gentle. The parents' own feelings about the interactions were explored: the father's tough-guy background, the mother's fear of her own assertiveness, her fear of her baby being injured, and their own associated family patterns.

Gradually, the baby began to sleep through the night, and he became more assertive and less clinging and fearful. He also became happier. He was slow to reach his motor milestones, so an occupational therapist worked with him and gave the parents advice on motor development and normalizing his sensory overreactivity. In 4 months, this infant was functioning in an age-appropriate manner with a tendency toward a cautious, but happy and assertive, approach to life's developmental challenges.

As developmental clinicians and researchers build on Piaget's findings and formulations, the developmental model will serve as a basis for understanding social and emotional development and provide a framework for clinical and educational intervention.

Implications for Psychotherapy Piaget was not an applied psychologist and did not develop the implications of his cognitive model for psychotherapeutic intervention. Nevertheless his work formed one of the foundations of the “cognitive revolution” in psychology. One aspect of this revolution was an increasing emphasis on the cognitive components of the therapeutic endeavor. In contrast to classical psychodynamic therapy, which focused primarily on drives and affects, and in contrast to behavior therapy, which focused on overt actions, cognitive approaches to therapy focused on thoughts, including automatic assumptions, beliefs, plans, and intentions.

Cognitive theory, including Piaget's, has influenced psychotherapeutic approaches in multiple ways. Some therapists have taken developmental notions from Piaget's work and developed intervention techniques. Others have developed cognitive models of treatment independent of Piaget but with heavy reliance upon the role of cognition. Others have included Piaget's concepts in a broader set of constructs to undergird new developmental approaches to psychotherapy.

Some psychotherapists applied Piagetian notions directly to child interventions. Susan Harter, for example, discussed techniques for helping young children become

aware of divergent or contradictory emotions and integrate these complex emotions within a more abstract or higher class of emotions. One of Harter's techniques is to ask the young child to draw different and conflicting feelings in one person. This technique represents an application of the concrete operation of class inclusion to the realm of the emotions. Harter's work applied Piagetian findings to the common therapeutic problem of helping children recognize, tolerate, and integrate mixed or ambivalent affects within stable object relations. As such, it drew upon both cognitive theory and psychodynamic theory.

Other psychotherapists developed treatment models which, although not directly dependent upon Piagetian psychology, emphasized core ideas quite similar to those Piaget discovered in his naturalistic observations of cognitive development. Aaron Beck, for example, developed an entire school of cognitive therapy that focuses on the role of cognitions in causing or maintaining psychopathology. Cognitive therapy has been shown to be an effective treatment for problems as diverse as depression, anxiety disorders, and substance abuse.

A core idea in cognitive therapy is that the patient can be assisted to identify the negative automatic thoughts and underlying dysfunctional attitudes or beliefs that contribute to emotional distress or addictive behavior. The cognitive component of the therapy begins with identification of automatic thoughts, so designated because they are rapid, overlearned responses that instantaneously mediate between an event and an affective reaction. The key therapeutic process after identification of the maladaptive thoughts is to help the patient view these thoughts more objectively, not take them in an unquestioning manner as veridical.

In helping patients take an objective or distanced perspective on their own thoughts, cognitive therapists are enhancing the patient's cognitive role-taking ability. In the realm of emotional health and personality development, they are contributing to what Piaget might have referred to as increased emotional intelligence on the part of the patient. What the cognitive therapist accomplishes through such techniques as Socratic questioning and asking if there are other ways to look at the same event is similar to what the talented teacher does in guiding children to more adequate, more intelligent understanding of operational tasks. The notion of equilibration is relevant in both instances. By helping the individual see that previous cognitive structures are in some ways inadequate, the therapist or teacher disturbs the old cognitive structure, and the patient or student experiences a disruption that leads to the search for more-adequate structures. The compensation for external disturbance is what Piaget termed *equilibration*. New structures can only be constructed through a process of accommodation, enabling the subject to assimilate a wider array of data, a new perspective, or more-complex information.

Since it requires “thinking about thinking,” cognitive therapy seems to require formal operational thinking, although to our knowledge this has not been empirically tested. At the very least, it requires the ability to recognize and articulate affects, to recognize and label events that give rise to affects, and to translate into a thought the mediating process that occurs rapidly between the event and the affect. Cognitive-behavioral models of psychotherapy include both cognitive techniques and more-behavioral, interactive techniques such as increasing pleasant activities and improving communication and problem-solving skills. Gregory Clarke and his colleagues have shown that cognitive-behavioral treatment is effective in reducing adolescent depression. It is not clear which components of the treatment are responsible for the overall positive effects, however.

It may be that adolescence is the earliest developmental stage in which a person could benefit from cognitive therapy. Even among adolescents and some adults, such therapy is difficult to conduct. In working with depressed, substance-abusing adolescents, John Curry and his colleagues have found that the cognitive components of the treatment are too difficult for adolescents who lack ready access to their own emotional states or the ability to label affects. Similar findings were reported by the first author regarding the cognitive aspects of psychodynamic therapy with some adults.

Such findings have contributed to the third approach to using Piagetian insights in psychotherapy, namely, integrating Piaget's findings into a broader model. The first author, for example, has articulated a developmentally based psychotherapy that takes account of earlier, presymbolic levels of functioning that precede the ability to recognize, label, and articulate affects and their mediating cognitions.

Developmentally Based Psychotherapy Developmentally based psychotherapy, developed by the first author, integrates cognitive, affective, drive, and relationship-based approaches with new understanding of the stages of human development. Different therapies look at different aspects of the proverbial elephant, whether from a psychodynamic, object relations, self-psychology, behavioral, or cognitive-behavioral point of view. A comprehensive, cohesive developmental framework integrates elements from these approaches with a broader understanding of the developmental processes essential for emotional or mental health. It formulates series of principles that an understanding of human development says are prerequisite for emotional growth.

Developmentally based psychotherapy constructs its therapeutic strategies from these principles of human development and growth. The clinician first determines the level of the patient's ego or personality development and the presence or absence of deficits or constrictions. For example, can the person regulate activity and sensations, relate to others, read nonverbal affective symbols, represent experience, build bridges between representations, integrate emotional polarities, abstract feelings, and reflect on internal wishes and feelings?

After determining the developmental level, the clinician looks for constitutional and maturational contributions and difficulties with sensory processing, modulation, or motor planning. The clinician looks for interactive and family contributions. Each of these is explored in the present, the past, and the anticipated future. The patient's fantasies, sense of self and others, and conflicts are understood in the context of all these influences. These are how patients make sense of their ego structure, physical makeup, family patterns, and interactions with others. Developmentally oriented therapists do not permit themselves the luxury of overfocusing on one set of variables such as inner fantasies, family dynamics, biological proclivities, or prior experience. Similarly, the formulated therapeutic strategy cannot deal only with one or two factors. It must deal with all critical factors that influence the developmental process. As collaborators in the construction of experience, therapists use their understanding of the patient's development to help the patient construct interactions that will provide growth and overcome difficulties.

Often it is assumed that critical aspects of development occur through the maturation of the nervous system along with routine, expectable experiences. It is also assumed that from these routine, expectable maturational sequences and experiences, certain psychological structures having to do with the ability to regulate, engage, interact, represent (symbolize) experience, and reflect and compare experiences, are present in most people. With these capacities in place, it is believed that the therapeutic process can focus on conflicts and anxieties and selected maladaptive behaviors or thoughts. The authors have observed, however, that only a small percentage of individuals have these core capacities. For most, such capacities must be learned as part of the therapeutic process.

The developmental perspective shows how one learns these capacities during development. It suggests strategies that can be used in the psychotherapeutic process so that adults and children who have not achieved these capacities can learn them. From a developmental point of view, the integral parts of the therapeutic process include learning how to regulate experience; to engage more fully and deeply in relationships; to read and respond to boundary-defining behaviors and affects; to perceive, comprehend, and respond to complex self- and object-defining affects, behaviors, and interactive patterns; to represent experience; to differentiate represented experience; and to form higher-level differentiations, including the capacity to engage in the ever-changing opportunities, tasks, and challenges during the course of life (e.g., adulthood and aging) and, throughout, to observe and reflect on one's own and others' experiences. Mastering these core developmental processes makes dealing with conflicts, anxieties, maladaptive behaviors, and thoughts possible.

These processes are the foundation of the ego, and more broadly, the personality. Their presence constitutes emotional health and their absence, emotional disorder. The developmental approach describes how to harness these core processes and so assist the patients in mobilizing their own growth.

SUGGESTED CROSS-REFERENCES

Perception and cognition are discussed in Section 3.1, learning theory in Section 3.3, aggression in Section 27.3, biology of memory in Section 3.4, and brain models of mind in Section 3.5. Chapter 39 addresses attention-deficit disorders. Chapter 35, Chapter 36 and Chapter 37 focuses on learning disorders, motor skills disorder, and communication disorders. Feeding and eating disorders in children are the subject of Chapter 41, and mental retardation is covered in Chapter 34.

3.3 LEARNING THEORY

W. STEWART AGRAS M.D., F.R.C.P.(C) AND G. TERENCE WILSON PH.D.

From birth, learning plays a central role in the development of human behavior, including voluntary and involuntary motor behaviors, thinking, and emotion. The effects of the environment on the development or maintenance of disordered behaviors are, with the exception of effects such as injury, malnutrition, or infection, translated through learning; hence, learning plays an important role in the development and maintenance of psychopathology. Conversely, the basis of psychological change by means of psychotherapy depends on learning new and more adaptive behaviors. Both the theoretical basis for psychotherapy and its practical use depends on a grasp of the principles of learning.

In Russia at around the end of the nineteenth century, Ivan Pavlov (Fig. 3.3-1), a Nobel Laureate in physiology, established the foundations of classical conditioning. At roughly the same time in the United States, pioneering research on animal learning by Edwin Thorndike showed the influence of consequences (rewarding and punishing events) on behavior. Beginning in the late 1930s this process of instrumental learning was elaborated upon by B. F. Skinner in his research on operant conditioning. Research on conditioning and learning principles, conducted largely in the animal laboratory, became a dominant part of experimental psychology in the United States after World War II. In the tradition of Pavlov and Skinner, workers in this area were committed to the scientific analysis of behavior using the laboratory rat and the pigeon as their subjects.

FIGURE 3.3-1 Ivan Pavlov. (Courtesy of National Library of Medicine.)

During the first half of the twentieth century, isolated attempts were made to apply conditioning principles to a variety of problem behaviors. John B. Watson and Rosalie Rayner experimentally induced a phobic reaction in the famous case of Albert by using a simple classical conditioning procedure, and Mary Cover Jones antedated later investigations by describing the use of several different procedures for overcoming children's fears. Researchers Mowrer and Mowrer reported the successful treatment of enuresis by direct conditioning procedures.

These early applications had no impact on the practice of psychotherapy, in part because conditioning principles, which had been demonstrated with animals, were rejected as too simplistic and irrelevant to the treatment of complex human problems. Nevertheless, some attempts were made to integrate conditioning principles with psychodynamic theories of abnormal behavior, but these eclectic formulations had little effect and only obscured crucial differences between the respective behavioral and psychodynamic approaches. John Dollard and Neal Miller, for example, translated psychodynamic theory but with little consequence for any clinical innovation, since they were merely reinterpreting psychotherapy rather than advocating different concepts and procedures.

The emergence of behavior therapy as an alternative system of assessment and treatment to psychoanalysis in the late 1950s marked the first systematic extension of conditioning principles to clinical practice. Behavior therapy was originally defined as the application of “modern learning theory” to the treatment of psychiatric disorders. The phrase “modern learning theory” referred to the principles and procedures of classical and operant conditioning. In the 1950s and early 1960s, learning theory (i.e., classical and operant conditioning) was the obvious choice as a body of knowledge within experimental psychology on which to build an applied clinical science. In the 1970s experimental research on cognition (e.g., information processing) supplanted classical and operant conditioning as the major focus of theory development and research in experimental psychology. Throughout the 1970s behavior therapists increasingly incorporated cognitive processes and procedures within their clinical practice, and social-cognitive learning theory emerged as the most influential conceptual framework guiding the clinical application of learning principles and procedures. Social-cognitive theory embraces classical as well as operant conditioning procedures. However, in this approach the influence of environmental events on behavior is largely determined by cognitive processes that govern how environmental influences are perceived and how the individual interprets them. According to this view psychological functioning involves a reciprocal interaction among three interlocking sets of influences: behavior, cognitive processes, and environmental factors. In the opinion of Bandura personal and environmental factors do not function as independent determinants; rather, they determine each other. Nor can persons be considered causes independent of their behavior. It is largely through their actions that individuals produce the environmental conditions that affect their behavior in a reciprocal fashion. The experiences generated by behavior also partly determine what individuals think, expect, and can do, which in turn affects their subsequent behavior.

In social-cognitive learning theory, the person is the agent of change. The theory emphasizes the human capacity for self-directed behavior change. Strongly influenced by the social-cognitive learning model, the clinical practice of behavior therapy has increasingly included cognitive methods, especially those described by Aaron Beck. A primary focus of cognitive and behavioral techniques is to change the cognitive processes that are viewed as essential to therapeutic success. This theory assumes that it is not so much experience itself, but rather the person's interpretation of that experience, that produces psychological disturbance, a view also reflected in the work of Albert Ellis. Both cognitive and behavioral methods are used to modify misperceptions and misinterpretations of important life events; this approach is called *cognitive behavior therapy*.

It is now widely accepted that the principles of classical and operant conditioning have been extremely successful in stimulating a wealth of experimental and clinical research and innovative therapeutic techniques. A fundamental contribution of learning theory was the conceptual and methodological emphasis that the study and application of conditioning principles brought to clinical research and practice. The detailed specification of therapeutic techniques, the focus on behavior per se in assessment, treatment, and evaluation of therapy outcome, and the advances in measurement and methodology were all directly associated with the methodological behaviorism that characterized the conditioning approach. Moreover, because of the experimental, hypothesis-testing emphasis deriving from conditioning and social-cognitive theories, cognitive behavioral therapies have become the mainstream of psychotherapy research. These developments have helped to narrow the gap between the laboratory and the clinic.

Every psychotherapy session knowingly or unknowingly contains some of the procedures derived from learning theory. The most effective psychotherapies are targeted to alter a specific behavior or cluster of associated behaviors, are based on a rational model of factors maintaining the disorder, use a well-designed sequence of behavior change strategies sensitive to the individual problems presented by a particular patient, and are time-limited. Most of these psychotherapies

now appear in detailed manuals and have been rigorously tested in controlled outcome studies.

BIOLOGY OF LEARNING

Learning leads to neurochemical changes in the central nervous system. Research with simple organisms has revealed that the learning of avoidance behavior alters the chemical structure of cells in the nervous system; when the avoidance is unlearned, the chemical changes are reversed. Thus, the foundation for understanding the neurochemistry of learning has been laid, and a reciprocal interaction is evident between biological processes in the central nervous system and behavior changes resulting from environmental influences. Research conducted by Eric Kandel and his colleagues at Columbia University with *Aplysia californica* has been particularly well covered in the psychiatric literature. The aplysia, a sea mollusk, is a useful animal to study because of the simplicity of its nervous system, which contains about 20,000 neurons, many of which are large and readily identifiable. The specific behavior studied is a defensive reflex involving withdrawal of the snail's siphon when the animal is tactually stimulated. When the mollusk is touched repeatedly, it learns not to withdraw its siphon and gill, a process known as *habituation*. If the mollusk then receives a strong stimulus, such as an electric shock, it becomes sensitized, such that even a previously subthreshold tactile stimulation causes the animal to withdraw its gill and siphon. Furthermore, the snail can be classically conditioned so that it withdraws its siphon and gill to a conditioned stimulus. Habituation, sensitization, and classical conditioning of the reflex in the snail can be considered forms of learning and memory. In learning, a short-term stimulus has to be translated into long-lasting changes that involve a series of biochemical changes that are functionally interlinked and operate in overlapping time ranges.

Many but not all of the neuronal anatomical and chemical bases for the learning processes have been worked out in this animal model. Sensory neurons receiving tactile information form excitatory synapses with the gill and siphon motor neurons that cause the withdrawal activity. Habituation, sensitization, and classical conditioning all involve neurochemical changes in the sensory neuron, resulting in alterations in the amount of excitatory neurotransmitter released. The neurochemical basis of habituation is that, after repeated stimulation of the sensory neuron (e.g., repeated tactile stimulation), less calcium than usual enters the presynaptic nerve terminal, resulting in less neurotransmitter being released and, thus, less activity by the motor neurons. Sensitization requires the presence of additional neurons, called *facilitator interneurons*, that synapse onto the sensory neurons. The sensitizing stimulus, such as an electric shock, causes the facilitator interneuron to release serotonin that binds to serotonin receptors on the sensory neuron. Activation of the serotonin receptors activates adenylate cyclase, producing cyclic adenosine monophosphate (cAMP), thereby activating a cAMP-dependent protein kinase, which is believed to phosphorylate an S-type potassium channel. Phosphorylation of the potassium channel results in increased calcium influx during the action potential and increased neurotransmitter release. Although classical conditioning also results in an increased amount of neurotransmitter released by the sensory neuron, the neurochemical basis is less well understood at this time but may involve additional protein kinases.

Because psychotherapy is best viewed as a learning process, and learning produces changes in neuronal architecture, the behavior changes associated with therapy should produce anatomical changes in the central nervous system. As Eric Kandel notes, such changes should be detectable by imaging methods. In an interesting study of patients with obsessive-compulsive disorder, positron emission tomography was used to investigate changes in cerebral metabolic rates for glucose before and after treatment. The effects of two treatments were compared: fluoxetine hydrochloride, and behavior therapy consisting of exposure and response prevention. Although the study involved nine patients per group, glucose metabolic rates in the right head of the caudate nucleus changed when the obsessive-compulsive disorder was successfully treated with either fluoxetine or behavior therapy; these changes did not occur in patients who did not respond to treatment, which suggests that the changes in brain metabolism consequent upon learning-based changes in behavior may be similar to those induced by pharmacotherapy. These results underline the reciprocal interaction between learning and the central nervous system.

In the following sections classical conditioning, operant conditioning, and social learning theory are reviewed. Some common terms used in learning theory are listed and defined in Table 3.3-1.

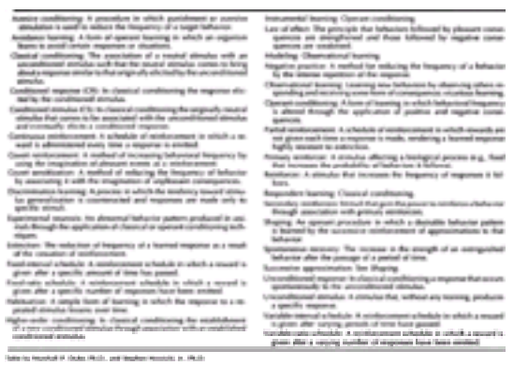

Table 3.3-1 Common Terms Used in Learning Theory

CLASSICAL CONDITIONING

History The idea that learning takes place when two events occur closely together in time has a long history, stemming from association theory developed by the British school of philosophical empiricism. It was the Russian physiologist Ivan Petrovich Pavlov and his coworkers who over many years documented the parameters of this form of learning in carefully conceived experiments. Traditional accounts of classical conditioning state that learning occurs when an initially neutral stimulus, the *conditioned stimulus*, is paired with a stimulus that naturally elicits a response, the *unconditioned stimulus*. The response elicited by the unconditioned stimulus is the *unconditioned response*. After repeated and contiguous pairing of the two stimuli, the conditioned stimulus elicits the unconditioned response, which is then called the *conditioned response*.

Pavlov's work was enthusiastically espoused by American psychologists, such as John B. Watson, who demonstrated that classical conditioning can give rise to phobia-like behavior. The subject of the experiment was Albert B., who was 11 months old. Watson demonstrated that a few pairings of a loud noise (unconditioned stimulus) with the sight of a white rat (conditioned stimulus) led Albert to avoid not only the rat, which had not caused fear before, but also similar objects, such as cotton wool and sealskin, an example of stimulus generalization in which stimuli similar to the original conditioned stimulus may elicit the conditioned response, although usually with a weakened response. According to that view, which is still widely held by psychologists and psychiatrists, classical conditioning was a rather simple, limited, and automatic form of learning. Current thinking, however, differs substantially from that traditional account.

Current Views Temporal contiguity between two stimuli is neither necessary nor sufficient for classical conditioning to take place. Two examples illustrate the point. In the first example a rat is exposed to five pairings of a tone and an electric shock in one situation. In another situation the tone is presented 10 additional times in the absence of shock. The contiguity of tone and shock is the same in both situations, but classical conditioning occurs only in the first situation because only in that situation does the tone predict or provide information about the unconditioned stimulus. In the other situation the unconditioned stimulus is equally likely whether or not the tone is sounded. Contiguity is not necessary for conditioning to occur. If the presentation of the tone and the shock is arranged so that shocks never occur in the presence of the tone, the tone comes to predict the nonoccurrence of the shock, a phenomenon called *conditioned inhibition*.

In the second example two groups of animals are exposed to a compound stimulus (tone plus light) that signals a shock. One group has a history of learning in which the light predicts a shock; the other group does not. Both groups have the same contiguous exposure to the tone-light compound stimulus, but for the group with pretraining the tone is redundant. When both groups are tested for their conditioning to the tone, the group with pretraining with the light stimulus shows significantly worse conditioning than the other group because despite equivalent contiguity, the tone conveys different information to the two groups.

Classical conditioning is not necessarily a slow process dependent on repeated pairings of stimuli. Learning is often rapid and efficient. As Robert Rescorla noted:

Pavlovian conditioning is not a process by which the organism willy-nilly forms associations between any two stimuli that happen to co-occur. Rather the organism is better seen as an information seeker using logical and perceptual relations among events, along with its own preconceptions, to form a sophisticated representation of the world. An analogy between animals showing Pavlovian conditioning and scientists identifying the cause of a phenomenon is useful. If one thinks of Pavlovian conditioning as developing between a conditioned stimulus and a unconditioned stimulus under just those circumstances that would lead a scientist to conclude that

the conditioned stimulus causes the unconditioned stimulus, one has a surprisingly successful heuristic for remembering the facts of what it takes to produce Pavlovian associative learning.

Classical conditioning has been viewed as either (1) learning that, in humans at least, requires conscious processing and awareness of the relations between events, or (2) an automatic process that occurs similarly in the mollusk and the human being, requiring little or no conscious processing or awareness. A good deal of evidence shows that awareness of a relation between events is often necessary for conditioning to occur and greatly facilitates learning. It seems reasonable to conclude that classical conditioning in humans occurs through hierarchically organized neural systems. The operation of some of these systems may predispose to automatic processing while others do not. On the other hand, evidence indicates that classical conditioning can occur in the absence of intention to learn, without awareness, and even if it is resisted. For example, both animals and humans acquire conditioned aversions to specific smells and tastes (the conditioned stimulus) if they are associated with drug-induced or illness-induced nausea (the unconditioned stimulus-unconditioned response). People develop highly specific aversions to food that they may have eaten at the onset of seasickness or of a gastrointestinal illness. The food becomes a conditioned stimulus for them, despite their knowledge that it did not cause their nausea. In those instances people seem to be biologically prepared to have some conditioned responses and not others. For example, nausea is readily conditioned to smell and taste but not to sight and sound. Some phobic reactions in humans may provide other examples of prepared learning of that sort (e.g., fears of animals and heights). The hypothesis is that people are biologically predisposed to learn certain fears as a result of their evolutionary past, when it was adaptive to do so. That explains the fact that people have phobias only to selected situations and objects, which presumably were once associated with threats to survival.

Classical conditioning may affect the responsiveness of the immune system. Animals were conditioned by pairing saccharinflavored water with injections of cyclophosphamide, an immunosuppressive drug. After a single trial, animals showed both immunosuppression and aversion to the taste of saccharin, phenomena not shown by the control group that received saccharin-flavored water paired with a placebo injection. It is well known that humans undergoing immunosuppressive therapy develop nausea that comes to be elicited by hospital cues; indeed, sometimes even the thought of the hospital elicits nausea. In a recent study women undergoing treatment with cytotoxic drugs for the treatment of ovarian cancer demonstrated nausea on return to the hospital combined with decreased immune function. This appears to replicate the work with animals and suggests that similar conditioning of immune function is found in humans. Clearly, the person is unaware of such conditioning.

Clinical Applications Classical conditioning has influenced the way in which clinical disorders have been conceptualized and has generated methods for their treatment. It has, for example, played a prominent role in the analysis and treatment of anxiety disorders. Exposure to a traumatic event is a necessary but insufficient condition for the development of posttraumatic stress disorder. Classical conditioning explains how stimuli associated with a severe trauma (the unconditioned stimulus) come to elicit stress responses that were part of the original trauma. As with phobic disorders, not everyone who experiences a traumatic event displays the stress response; predisposing genetic factors and adverse early learning experiences are determinants of posttraumatic stress disorder.

Another area of application has been in the treatment of substance abuse. Cues associated with repeated alcohol and drug use come to elicit conditioned responses. Some of the conditioned responses are opposite in nature to the unconditioned effects of the substance. They are known as *classically conditioned compensatory reactions*, which are believed to reflect homeostatic mechanisms. This conditioning process contributes to the development of behavioral tolerance to alcohol and drugs. In alcohol- or drug-dependent persons the conditioned responses are believed to be subjectively experienced as craving or anticipatory withdrawal reactions. An alternative view is that the conditioned stimulus triggers craving because it comes to signal the positively rewarding consequences of alcohol or drug use. In either case it follows that cues associated with substance abuse need to be addressed in treatment. Cue exposure treatment for alcoholic persons and drug addicts is based on the principle of *extinction*—the procedure of presenting the conditioned stimulus in the absence of the unconditioned stimulus. Doing so results in the elimination of the conditioned response when the conditioned stimulus no longer predicts its occurrence. For example, patients with alcohol-dependence are presented with alcohol-related cues (e.g., the sight and the smell of alcohol), which reliably elicit craving, without being allowed to drink alcohol (the unconditioned stimulus). Since negative emotional states can function as conditioned stimulus, cue-exposure treatment also involves the induction of relevant mood states.

Classical conditioning is no longer necessarily linked to the philosophy of behaviorism, with which it was once associated. Its concepts and methods lend themselves to current perspectives on human behavior, and they continue to play an important role in contemporary behavior therapy, which itself has become more eclectric and theoretically broader than it was during its early origins in behaviorism.

TWO-FACTOR CONDITIONING THEORY

O. H. Mowrer proposed a two-factor theory of avoidance behavior that has had a major influence on models of psychopathology and on treatment. The theory made two basic assumptions: (1) anxiety is an acquired drive established by classical conditioning in which a neutral stimulus comes to signal an aversive or traumatic event; and (2) the classically conditioned anxiety motivates escape and avoidance behavior, which is reinforced by the reduction of the underlying anxiety drive. This theory has been fruitfully applied to phobic avoidance and obsessive-compulsive behavior. The anxiety about dirt and contamination that compulsive hand washers experience is assumed to be a classically conditioned response that drives them to wash their hands repeatedly after touching anything they believe is contaminated. Hand washing removes the dirt and reduces the anxiety; the anxiety reduction then reinforces and maintains the hand-washing behavior.

Clinical Applications More important than the models of psychopathology it generated were the treatment methods that two-factor theory spawned. The techniques of exposure and response prevention followed directly from the theory. In *exposure treatment* for phobic disorders, patients are gradually and systematically exposed to the situations they fear and avoid until their phobic reactions are extinguished. In the technique of *systematic desensitization* pioneered by Joseph Wolpe, one of the founding fathers of behavior therapy, the exposure is to imagined representations of the feared stimuli while the patient is in a state of relaxation. That technique was thought to be an example of *reciprocal inhibition*, in which one response (anxiety) is inhibited by an opposite response (relaxation). However, it is more effective to conduct exposure to real-life situations (e.g., guiding an agoraphobic patient through shopping malls, supermarkets, crowded buses, and other feared situations) than to imagined scenes.

Problems Despite its historical significance in the field, two-factor conditioning theory has been criticized on several counts. One problem is the difficulty it encounters in explaining why phobic reactions are resistant to extinction. Classically conditioned fear reactions in laboratory animals extinguish rapidly when the US is omitted. But phobic fears persist, even though phobic persons frequently come into contact with the situations they fear (exposure to the conditioned stimulus) without any aversive event (the unconditioned stimulus)—by definition, the conditions for the extinction of the fear and avoidance behavior. A second problem with the theory is evidence showing that avoidance behavior is not causally mediated by fear or anxiety, whether the anxiety is defined as autonomic nervous system arousal or subjective self-report. Avoidance behavior can be eliminated without inhibiting the accompanying anxiety. Anxiety reduction may precede, accompany, or even follow changes in avoidance behavior—an impossibility if anxiety is said to cause the avoidance behavior. A more accurate conclusion is that both anxiety and avoidance behavior are correlated coeffects of a still undetermined central mediating state. Third, whereas the effectiveness of exposure treatments has been well documented, two-factor theory does not accurately account for its therapeutic mechanisms. The amount of exposure should be closely correlated with the degree of change in phobic avoidance behavior, yet it is a poor predictor of such change. An alternative explanation of exposure treatment is discussed next.

OPERANT CONDITIONING

The notion that learning occurs as a consequence of action was espoused in the pioneering work of Edward Lee Thorndike, whose learning theory dominated the field of psychology in the United States for the first half of the twentieth century. A typical experiment devised by Thorndike consisted of placing a hungry cat in a cage with some form of latching device that, when correctly manipulated, allowed the cat access to a second cage for a bite of food. Thorndike noted that the cat became efficient at opening the lock, a sequence of events termed *trial-and-error learning*, and he hypothesized that the appropriate behaviors were strengthened by the cat's experiences of success and failure. Following up on Thorndike's work, Skinner and his colleagues made the effects of environment on behavior a central aspect of learning.

The principles and procedures of operant conditioning are the product of Skinner's philosophy of *radical behaviorism*, according to which overt behavior is the only acceptable target of scientific investigation. Skinner argued that subjective experience (private events) should be included in the experimental analysis of behavior, but their role has always been restricted. Thoughts and feelings are epiphenomena in operant conditioning; they cannot exert a causal influence on behavior. Strictly speaking, aside from biological determinants (which have always been minimized), it is assumed that human behavior is exclusively a function of environmental events that are ultimately beyond personal control. Another hallmark of operant conditioning has been its emphasis on the study of the individual organism. The repeated measurement of the behavior of a person under controlled conditions is the methodological contribution of operant conditioning. Skinner rejected statistical comparisons between groups of subjects, claiming that group averages obscure what is important—namely, the behavior of individual subjects. The application of the

principles and the procedures of operant conditioning to human problems is known as *applied behavior analysis*.

Positive Reinforcement The best known learning principle contributed by operant conditioning is the principle of *positive reinforcement*—the process by which certain consequences of behavior raise the probability that the behavior will occur again. On the whole, positive reinforcers are viewed as pleasant (e.g., food, attention, praise, money). Reinforcers that affect biological processes, such as food, may be defined as *primary reinforcers*. However, events viewed as aversive by some people may be reinforcing for others. For example, the behavior of some children is reinforced by scolding, which, after all, is a form of attention. Many drugs including opioids, barbiturates, and such stimulants as amphetamine and cocaine, appear to be positive reinforcers. Animals and humans self-administer the substances, reliably discriminating between the active drug and a placebo. Complex patterns of behavior can be shaped in animals by using drugs as reinforcers.

Traditional textbook descriptions state that reinforcement of a response must be immediate. However, as with classical conditioning, temporal contiguity is not necessary for learning to occur in operant conditioning. Recent research shows that the behavior of even a simple organism, such as a laboratory rat, can be controlled by the aggregate consequences of a series of reinforcements of multiple responses over time. Revision of the requirement that reinforcement be immediate if it is to control behavior greatly extends the explanatory power of operant conditioning, but the mechanism by which the organism is able to integrate reinforcing consequences over time is never specified. Critics of operant conditioning point out that the delayed effect of reinforcement contingencies must be mediated by cognitive processes.

Negative Reinforcement Reinforcement increases the probability of behavior. *Negative reinforcement* is the process by which behavior leading to the removal of an aversive event strengthens that behavior. Negative reinforcers tend to be aversive events; for example, avoidance behavior, such as phobic reactions and compulsive rituals, is negatively reinforced because it forestalls actual or perceived aversive outcomes. Research shows that when patients with anorexia nervosa are placed in a restricted hospital environment to facilitate the use of positive reinforcement for eating and gaining weight, they work (eat and gain weight) in order to get out of the aversive environment, adding negative reinforcement effects to the positive reinforcement effects.

Punishment Punishment is the presentation of an aversive stimulus contingent on the occurrence of a particular response. The removal of a positive consequence contingent on behavior, known as *time out* from reinforcement, can also be viewed as punishment. The procedure is commonly used as a means of disciplining children with behavior problems; for example, sending a child to his or her room consequent upon misbehavior. It is necessary to distinguish punishment from negative reinforcement. Punishment decreases the probability that the behavior will occur, whereas negative reinforcement increases the probability. One must also distinguish between the usual use of the term *punishment* and the technical use of the term as meant here. In the punishment paradigm the punishing event is always delivered contingent on performance and demonstrably reduces the frequency of the behavior being punished, which is considerably different from the use of the term to denote imprisonment, for example, because the prison sentence follows long after the crime and may not affect future criminal behavior. Figure 3.3-2 summarizes the major principles of operant conditioning and the effects they have on behavior.

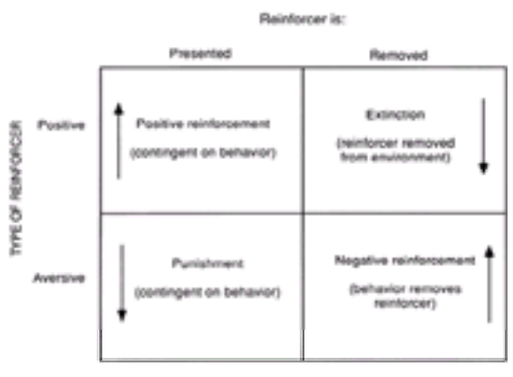

FIGURE 3.3-2 The principal procedures of operant conditioning depending on whether a positive or negative reinforcer is applied or removed after the behavior is performed. The arrows show the direction of the behavior change.

Reciprocal Influences Since much human behavior occurs within an interpersonal context, reciprocal influences occur; an example is afforded by the study of predelinquent behavior. Family studies suggest that predelinquent behavior patterns are set in motion by the excessive and inconsistent use of punishment on the part of parents. A mother may severely scold her small son, who in response may whine or have a temper tantrum. If the mother then responds by talking to the child to calm him down, the child stops whining. Thus, the child's whining punishes the mother's scolding and makes her less likely to scold in the future. The mother's attention to the child's whining reinforces that unpleasant behavior on the part of the child. Such a behavior pattern, when well established in the child, is viewed as unpleasant and aggressive by others and increases the likelihood that the child will be rejected by parents, peers, and teachers, thus initiating a complex series of events, such as poor school performance and joining a deviant peer group, which predisposes to delinquent behavior.

Clinical Applications Operant conditioning procedures have been applied to a wide range of problems in all age groups in psychiatry, education, rehabilitation, and medicine. In general, the procedures are most commonly used today to change the behavior of young children, persons with mental retardation, and institutionalized populations, such as chronically mentally ill patients. Behavior therapists in clinical practice, particularly with adult outpatient disorders, rarely describe themselves as applied behavior analysts, and they draw on broad theoretical perspectives. Reinforcement procedures may be used alone as applications of operant conditioning, or such procedures may be combined with techniques, such as extinction and punishment. However, reinforcement occurs in any form of psychotherapy because the therapist differentially attends to the verbal behavior of the patient. Moreover, most behavioral therapists today combine the use of reinforcement procedures with many other procedures derived from learning theory.

Positive Reinforcement Much is known about various *schedules of reinforcement*, defined as the patterns or frequencies with which a reinforcer is delivered as a consequence of behavior. The most frequently used schedules are listed in Table 3.3-2. One of the most frequently used schedules in clinical practice is *partial reinforcement*, in which reinforcement only occasionally results from a particular behavior. Such a pattern of reinforcement maintains the behavior at full strength. Moreover, partially reinforced behavior may be particularly resistant to extinction. Since many deviant behaviors provoke attention from others, they are maintained by the social environment. Observational and experimental work, for example, has shown that hospital staff members tend to reinforce their patients' abnormal behaviors by attending to them. When the staff members learn to stop giving such attention and to attend more frequently to adaptive behaviors, patient behavior improves. Similar findings have been made in school. Teacher attention reinforces disruptive behavior in the classroom; when such attention is withdrawn, the disruptive behavior decreases.

Fixed-ratio (FR) schedule
Reinforcement occurs after a fixed number of responses, (e.g., every 10 responses—10:1 ratio; 10 bar presses release a food pellet; workers are paid for every 10 items they make). Rapid rate of response to obtain greatest number of rewards. Animal knows that the next reinforcement depends on a certain number of responses being made.
Variable-ratio (VR) schedule
Reinforcement occurs at random intervals, (e.g., after the third, sixth, then second response, and so on). This generates fairly constant rate of response because of probability of reinforcement at any given time remains relatively stable.
Fixed-interval (FI) schedule
Reinforcement occurs at regular intervals (e.g., every 10 minutes or every third hour). Animal keeps track of time. Rate of responding drops to near 0 after reinforcement and then increases at about expected time of reward. This is known as scalloping and is seen in humans checking their mailboxes.
Variable-interval (VI) schedule
Reinforcement occurs at random intervals similar to variable ratio resulting in consistent responding. Response rate does not change between reinforcement. Animal responds at steady rate in order to get reward when it is available; common in trout fishermen, use of slot machines.

Table 3.3-2 Examples of Reinforcement Schedules in Operant Conditioning

The most used reinforcement procedure is a *shaping paradigm*, in which a behavior is changed in form by reinforcing components of the final behavior sequentially. For example, in teaching a mute patient with schizophoenia to talk, the first behavior to be reinforced may be simply looking at the therapist, followed by any mouthing movement, followed by any vocalization (perhaps in imitation of the therapist), and, finally, simple words and sentences. A *continuous reinforcement schedule* may first be used; in it reinforcement is delivered for every appropriate response. This schedule may be followed by partial reinforcement; each component behavior is first developed with continuous reinforcement and then strengthened with partial reinforcement. If speech is reinforced only in the presence of one therapist, the patient may remain mute with others, which is an example of *discriminative learning*. Similar behavior is seen in everyday life when a motorist stops at a red light and proceeds when the light changes to green—behaviors that are highly reinforced in this society. To overcome discriminative learning the therapist first establishes the beginnings of speech and then has several therapists reinforce speech to ensure generalization of the new behavior. When speech is fully developed, artificial reinforcement can be phased out because speaking should be more reinforcing than being mute. This is also an example of *chaining* of behaviors and reinforcement, because all the initial behavioral sequences are necessary for the final behavior of talking, and a complex sequence of behaviors is gradually built up and reinforced. Many problem behaviors seen in humans have been developed in animals by using various schedules of reinforcement. Thus, head banging, a behavior seen frequently in retarded and autistic children, has been developed in monkeys with the use of reinforcement such that the monkeys actually injure themselves to obtain reinforcement. Although such experiments do not prove that similar behaviors seen in humans are learned, they do call attention to the powerful effect of reinforcement in developing deviant behavior and to the fact that many behaviors are developed and maintained in this way.

Often given in the form of attention and praise contingent on certain behaviors, reinforcement is a basic ingredient of most therapies. Skilled therapists of most persuasions use contingent verbal reinforcement, as has been shown even in nondirective psychotherapy, so that certain therapeutic themes are strengthened. Other methods used in reinforcement paradigms include tokens exchangeable for goods or activities that cannot be bought or engaged in otherwise. What is reinforcing for one person may not be reinforcing for another, therefore, when reinforcement is used, the clinician must observe and measure the behavior being reinforced to make sure that it is being strengthened. The data from a clinical example of the use of token reinforcement to increase social communication is shown in Figure 3.3-3.

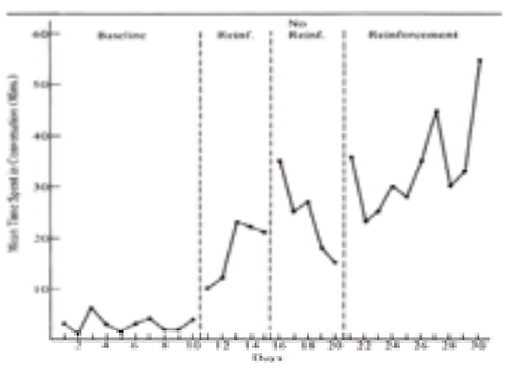

FIGURE 3.3-3 The time spent by a withdrawn patient conversing with nurses during sequential experimental phases: baseline (measurement only), reinforcement delivered in the form of tokens, after reinforcement was withdrawn, and when reinforcement was reinstated. The effect of positive reinforcement is demonstrated by an increase in conversational time during the two phases in which reinforcement was delivered, and by a decrease in conversation (extinction) when reinforcement was omitted.

The patient was a 21-year-old man who was extremely withdrawn. He spent most of his time in his hospital room, rarely approaching others or initiating conversation. Skilled psychiatric nursing care had not altered his behavior. As a first step in increasing his conversational ability, reinforcement for approaching nurses was instituted. The patient was first carefully observed, and it was noted that he enjoyed listening to the radio and watching television. He was told that for every 2 minutes during which he talked with the nurses in three daily sessions he would earn a token that could be exchanged for 3 minutes of listening to the radio or watching television, and that talking was the only way in which he would earn the right to engage in those activities. The nurses, in turn, were instructed not to approach him during the sessions but to engage in conversation only if he initiated and maintained it, thus reinforcing a chain of behaviors: approaching nurses, initiating conversation, and maintaining conversational behavior. The nurses also timed the number of minutes of conversation, using a stopwatch.

As can be seen in Figure 3.3-3, the patient engaged in little conversation with the nurses during the baseline measurement period. When the token system was introduced, he began to speak with the nurses for increasing lengths of time. In the third phase of the treatment study, the patient was given a free supply of tokens equivalent to what he had earned in the previous phase; the tokens were no longer contingent on his behavior. Under those conditions the amount of conversation gradually declined, an example of extinction. When the original reinforcement conditions were reintroduced during the final experimental phase, the patient's conversational ability improved. Similar procedures were used to generalized his newfound conversational ability to other staff members, eventually allowing the patient to engage successfully in a rehabilitation program.

EXTINCTION Disordered behavior is often developed and maintained by reinforcement in the form of attention from others. In such cases the clinician must identify the reinforcer and remove it from the patient's environment, a procedure known as *extinction*. A simple example of the use of extinction is the case of a young child who cries interminably before going to sleep. When the mother puts the child to bed, the crying begins after a few minutes, and the mother returns to find out what the problem is. She then reads to the child or engages in some other activity. When she leaves, the pattern is repeated. Clearly, maternal attention is reinforcing the crying. The treatment is to persuade the mother not to return to the child's bedroom once the child is settled for the night. However, she needs to be warned that the amount of crying may increase for two or three nights before it diminishes. That phenomenon is known as an *extinction burst:* the person exhibits more behavior in order to increase the probability of gaining positive reinforcement. When the reinforcement is not forthcoming, the behavior diminishes in frequency.

Punishment Punishment is less useful as a therapeutic procedure than either reinforcement or extinction because it may produce unwanted effects, such as aggressive behavior, and the possibility of inflicting physical damage is always present. For the most part, punishment is used only in situations in which the behavior to be changed is injurious to the patient.

A clinical example of such a condition is rumination disorder in which infants regurgitate their food mouthful by mouthful, which leads to malnutrition and dehydration and is frequently a threat to life. One treatment is to use the principle of punishment, making an unpleasant event contingent on each episode of regurgitation. In the case illustrated in Figure 3.3-4, a drop of lemon juice applied to the infant's tongue was used as the unpleasant event. During the baseline period before treatment the infant ruminated for between 40 and 70 percent of the time that he was awake. Once the lemon juice was presented contingent on spitting up food, the frequency of rumination steadily declined. Punishment was then briefly removed, and rumination returned to the baseline levels, demonstrating the efficacy of punishment. The reintroduction of punishment eventually led to the virtual elimination of the behavior and a return to normal weight with no relapse at 1-year follow-up.

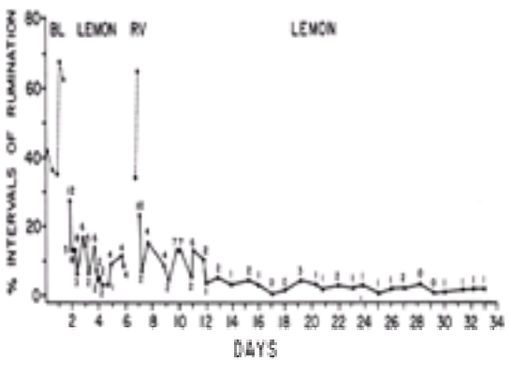

FIGURE 3.3-4 The effects of punishment in an experiment in which lemon juice was delivered contingent on ruminative vomiting in an infant. The frequency of rumination was rapidly reduced from the baseline (*BL*) and was increased only when punishment was withdrawn during the reversal phase (*RV*). The number of

applications of punishment (*lemon juice*) is shown by the number above each data point.

The use of punishment in a clinical situation should be carefully supervised and should follow certain rules. The behavior to be addressed should have been resistant to appropriate behavior-change procedures involving the use of positive reinforcement. Behaviors incompatible with the problem behavior can often be reinforced and the problem thus eliminated. In addition, the behavior to be changed should be severely incapacitating and should threaten physical integrity (e.g., the self-injurious behavior of some children with autistic disorder). Punishment procedures that themselves cause tissue damage should not be used. The behavior to be changed should be observed, measured, and recorded (as shown in Fig. 3.3-4) such that the effects of punishment and the amount of punishment used can be seen. If effectively used, punishment rapidly brings a behavior under control and behaviors can then be built up with the use of positive reinforcement.

SOCIAL-COGNITIVE LEARNING THEORY

Modes of Learning The psychologist Albert Bandura has integrated traditional classical and operant conditioning principles into a theoretically rich account of behavior and behavior change. A primary tenet of his approach is that the influence of environmental events on the acquisition and the regulation of behavior is primarily a function of cognitive processes. These processes are based on prior experience and determine what environmental influences are attended to, how they are perceived, whether they will be remembered, and how they may affect future action.

Reinforcement is regarded not as an automatic strengthener of behavior but as a source of guidance for behavior by anticipated outcomes. By observing the consequences of behavior, the person learns what action is appropriate in what situation. By symbolic representation of anticipated future outcomes of behavior, the person helps to generate the motivation to initiate and maintain behavior. Classical conditioning and operant conditioning are viewed as sources of learning about predictive relations among events. A third mode of learning is *modeling* (vicarious learning). In *modeling*, learning occurs through observation alone. The person need not exhibit any behavior or be directly reinforced for behavior. Modeling expands the scope and the complexity of learning influences on behavior. For example, it helps to explain how phobic reactions may be acquired in the absence of any direct traumatic experience. Young monkeys acquire a severe and lasting fear of snakes after observing their wild-reared parents act fearfully in the presence of a snake. Modeling has many therapeutic applications; it has prepared children for pending surgery by having them observe a film in which a child successfully copes with the novel and frightening events associated with preparation for and recovery from surgery.

The traditional emphasis on conditioning principles gives short shrift to verbal instruction as a mode of learning. The potential therapeutic effects of verbal instructions are illustrated by a study of hypertensive patients (Fig. 3.3-5). All participants in the experiment were told that relaxation training would help to lower their blood pressure. Half of the participants were also told that their blood pressure would show reductions after three sessions of relaxation training given in one morning; the other half were told that they could expect reductions only after prolonged relaxation practice. As shown in Figure 3.3-5 the groups have no difference in diastolic blood pressure readings. In systolic blood pressure, however, large and significant differences are shown; the group receiving immediate-lowering instructions showed lower blood pressure readings, but the other group did not. The mechanism underlying this effect is unknown. However, an expectancy of blood-pressure lowering may be needed to induce the biochemical changes necessary to lower blood pressure. This is an example of the complex interactions that occur between environmental events, in this case the instructions given to the patient, the patient's cognitive appraisal of the instructions, and neurochemical processes. Therapists tend to neglect the effect of therapeutic instructions, but experimental work suggests that the therapist should do everything to enhance the development of realistic outcome and efficacy expectations.

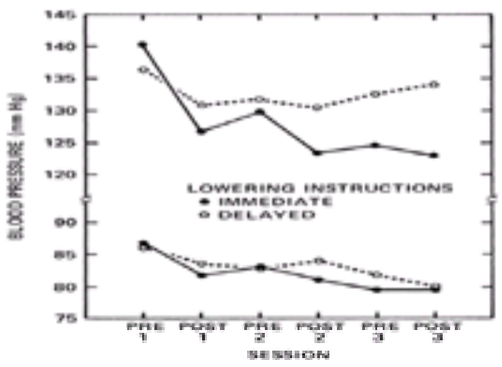

FIGURE 3.3-5 The effects of two expectancies on systolic (*top lines*) and diastolic (*bottom lines*) pressures of hypertensive persons. Systolic blood pressure was markedly reduced in the group told that relaxation training would lower blood pressure after one or two training sessions. In comparison the group told that blood pressure lowering would occur only after prolonged practice showed only slight reductions in systolic pressure.

Self-Efficacy Theory A component of social-cognitive learning theory with ramifications for the treatment of clinical problems is self-efficacy theory. *Efficacy expectations* are the degree of confidence that a person feels about coping effectively with a particular situation. *Outcome expectations* are defined as beliefs that particular actions will produce a certain outcome. *Self-efficacy* is the end product of different cognitive processes. To alter self-efficacy, people must actively appraise a specific experience and attribute successful coping to themselves as opposed to attributing it to some transient factor outside their control. Self-efficacy theory and cognitive-social learning theory in general draw heavily on the principles of attribution theory, a cognitive approach concerned with how people perceive the causes of behavior.

Self-efficacy theory predicts that the more people feel capable of predicting and controlling threatening events, the less vulnerable they are to anxiety and stress disorders in response to traumatic experiences; research with primates supports this prediction. Infant monkeys were reared in an environment in which they either exercised control over food, water, and special treats (the masters) or received reinforcers that were administered automatically and independent of their behavior (the controls). Months later, the masters were significantly less fearful in response to a threatening situation than were the controls.

The theory also predicts that psychological treatments such as exposure are effective because they enhance self-efficacy for coping with threatening events. Behavioral performance is the most powerful means of increasing self-efficacy, but self-efficacy is also influenced by sources of information derived from vicarious learning and verbal persuasion. Numerous studies have established that exposure treatment is one of the most effective methods for eliminating phobias. Exposure also produces greater increases in self-efficacy than do other methods. The greater the increase in self-efficacy, the greater the change in phobic behavior, regardless of the type of treatment. Outcome expectations (i.e., self-reports of anticipated anxiety about entering a phobic situation) tend to be correlated with efficacy expectations. If the correlation with efficacy expectations is eliminated statistically, outcome expectations fail to predict outcome, suggesting that change in self-efficacy is the important variable underlying behavior change.

Critics have charged that self-efficacy is only correlated with treatment-induced changes in phobic behavior and does not cause the behavior change. Bandura, however, points to the systematic covariation of experimentally induced levels of efficacy expectations and phobic behavior as evidence of their causal nature. Self-efficacy is related to measures of fear arousal. Increases in self-efficacy in phobic patients are associated with reductions in autonomic nervous system reactivity and neuroendocrine responses to phobic stimuli. The theory also suggests an explanation of the apparent resistance to the extinction of phobic behavior. Whether phobic reactions are eliminated by exposure to feared situations depends on the nature of the information that people derive from such experiences and not simply on the quantity of exposure. If people conclude that they can cope effectively, they no longer avoid the feared situations. But no change occurs if people conclude that they are unable to cope and hence experience unnerving anxiety. By strengthening patients' expectations that they cannot cope, exposure may even enhance their phobic sensitivity. Treatment should be aimed at increasing the patients' sense of predictability and controllability through enhanced self-efficacy. Treatment of patients with phobias along those lines produces results superior to treatment that passively exposes patients to feared stimuli without fostering coping skills, even if the length of the exposure is greater in the latter therapy.

Beyond furthering the analysis and the treatment of phobia disorders (panic disorder with agoraphobia, agoraphobia without a history of panic disorder, specific

phobia, and social phobia) self-efficacy has proved fruitful in the experimental analysis of a wide range of clinical problems, including pain management, the effects of stress on behavior and the immune system, and the prevention of relapse in substance abusers.

Self-Regulation In marked contrast to operant conditioning and radical behaviorism, social-cognitive learning theory emphasizes a capacity for self-regulation of behavior. Cognition is more than a passive conduit of external influences; it serves a generative function, allowing people to initiate thought, affect, and action to influence their circumstances, which, in turn, affect their cognition. People are neither driven inexorably by internal forces, nor are they passive reactors to environmental pressure; rather, they are both the agents and the objects of external influences.

Self-control strategies have become important components of most therapeutic interventions in behavior therapy. Among the most important elements of self-regulation of behavior are goal setting and feedback, self-monitoring, self-evaluation, and self-reinforcement.

Goal Setting and Feedback People set both long-term and short-term goals for themselves. The setting of sequential short-term goals leads to better performance than setting a distant goal. This is presumably related to the reinforcing qualities of goal attainment because reinforcing successive small steps is better than reinforcing the final behavior, at least until the behavior is well established. Goal definition is also important because the attainment of well-specified goals is more easily recognized than is the attainment of poorly defined goals. In general, the higher the goal set, the better the performance. At the highest levels of goal setting, performance begins to decline, underlining the fact that unrealistic goals undermine performance. Goal attainment enhances self-efficacy and affects future performance.

From a therapeutic viewpoint the therapist should help the patient define and set realistic, well-specified goals that signal small steps along the way to the overall goal so that demoralization can be kept at bay by success. Patients must set their own goals because self-determined goals lead to better performance than goals imposed by others. Teaching patients problem-solving strategies that they can use in many situations is a useful aspect of most therapies.

Goal attainment is not the only indicator of improvement in performance. Behavior change itself, if observed by the patient, can provide information regarding progress toward a particular goal. The process known as *informational feedback* enhances performance in a wide variety of tasks, such as learning to shoot accurately at a target, driving an automobile, and self-regulating autonomic processes. Removing informational feedback leads, at least temporarily, to setbacks. Information regarding therapeutic progress can be fed back to the patient in several ways. Patients can observe their own progress when the desired behavior change is relatively linear, such as approaching a phobic object or situation. Many behaviors, however, are complex. In such cases self-monitoring the behavior can enhance feedback. In addition, patients can plot the results of such feedback in graph form to examine their progress over long periods. Enhancement of information regarding progress is the central focus of biofeedback. In the typical biofeedback paradigm, processes that are not easily observed (e.g., blood pressure, small muscle contractions, and skin temperature) are made available for inspection by amplification. With sensitive and continuous feedback, the patient has the opportunity to learn to regulate invisible behaviors.

Self-Monitoring The basis of all self-control strategies is *self-monitoring*, which is the identification and recording of target problems and the conditions under which they occur. Typically, patients are asked to complete daily written records. For example, patients with panic disorder track all panic attacks and record the thoughts, feelings, and actions that preceded and accompanied the attacks. The goal is to identify the proximal determinants of the problem. Self-monitoring not only provides patients with an awareness of how their behavior affects or is affected by their social environment, it also prompts behavior change as patients identify specific influences on their behavior.

Self-Evaluation and Self-Reinforcement People who adopt certain standards and monitor their performances evaluate their success or failure in achieving those standards. That self-evaluation is the basis for self-reinforcement. Performances that match or exceed the standards serve as cues for rewards, and people deny themselves rewards for substandard performance. The essence of self-reinforcement is that people make freely available rewards contingent on behavior that meets preset standards. Common clinical problems, such as depression, involve the adoption of unrealistic or perfectionistic standards or excessively harsh and judgmental self-evaluation, regardless of objective performance.

Theories of Relapse One of the major problems facing therapists of all persuasions is that of patient relapse. Some instances of relapse can be easily understood; for example, the original environmental influences reinforcing symptomatic behavior may not have altered, and the patient's behavior is brought under their control once treatment has ended. This is an example of insufficient treatment; for example, perhaps the patient's family should have been brought into therapy. Sometimes, however, relapse denotes an impossible situation for the therapist, who is unable to alter a noxious psychological environment.

Less is known about the process of relapse than about the acquisition of behavior. For the most part, relapse has been studied in the addictive disorders, such as alcoholism and opiate addiction, and in related disorders, such as cigarette smoking and obesity. The basic theory concerning relapse involves situations that pose a high risk for engaging in the problem behavior, situations in which the behavior has occurred at a high frequency in the past. According to social-cognitive learning theory, if such a situation is coped with successfully, the person experiences an increase in self-efficacy, which leads to a low probability of relapse. The assumption is that the person has been taught or has developed usable coping skills. However, a former substance abuser who is deficient in coping with the high-risk situation develops a positive expectancy regarding the beneficial effects of the substance and starts using the substance again. This practice results in an *abstinence violation* effect, defined as the breaking of a self-imposed rule, leading to a diminished sense of self-efficacy.

FROM LEARNING THEORY TO PSYCHOTHERAPY

As a broad-based framework that emphasizes the multidimensional nature of psychological functioning, social-cognitive learning theory provides a flexible guide for the design of treatments for particular conditions. Treatment programs typically combine several principles and procedures. In formulating a therapy for a particular disorder, it is first necessary to develop a model, however simple, of the factors maintaining the symptoms of the particular disorder. Similarly, for the purposes of prevention, a model containing remediable risk factors for the development of the disorder is needed. The factors contained in a particular model and their relation to one another derive from a variety of sources, such as clinical observations, epidemiological studies, naturalistic observations, and laboratory experiments. The models developed at any one time may be updated when new findings concerning the disorder are made, or when controlled treatment studies suggest that additional factors need to be taken into account.

For example, the models of factors maintaining bulimia nervosa and depression differ in their details but both include behavioral antecedents and cognitive mediators of those antecedent behaviors. The treatments themselves share common elements derived from learning principles. The therapy sessions are structured to maximize learning, beginning with a review of self-monitoring, including the homework assignments. Based on this information and depending on the stage of therapy, the therapist sets an agenda for the session, which may include information on new procedures to be introduced in that session, followed by behavior change procedures deriving from the information gained from the self-monitoring records. This is followed by a summary of the session and the setting of homework. Within the therapy itself an array of procedures are used including: setting realistic outcome expectancies, strengthening efficacy expectancies, information and educational strategies, data collection, feedback regarding progress, reinforcement of adaptive behaviors, and cognitive change procedures.

Bulimia Nervosa Clinical, naturalistic, and laboratory studies all suggest that dietary restriction leads to excessive hunger and disinhibition of eating whereby individuals with bulimia nervosa develop a sense of loss of control over eating that leads to binge eating. The dietary restriction appears to be driven by overconcern about shape and weight, hence dieting (when it fails) is followed by various methods of purging to compensate for the actual or perceived excessive caloric intake. In addition, low self-esteem deriving from a multiplicity of developmental causes appears to enhance concerns about weight and shape. These considerations led to the development of the relatively simple model of factors that maintain bulimic behavior, illustrated in Figure 3.3-6.

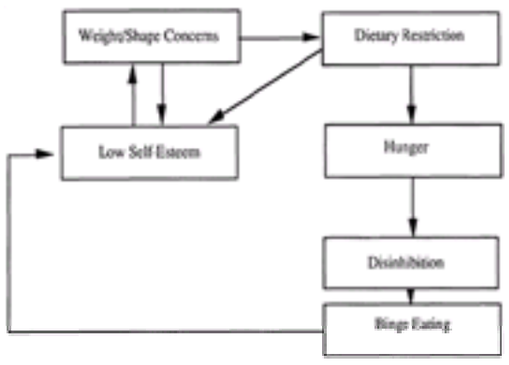

FIGURE 3.3-6 A hypothetical model of psychosocial factors maintaining bulimic behaviors.

Learning theory suggests that the antecedent events closest to the primary problem behavior should be addressed first. Hence, the first aim of cognitive-behavioral therapy for bulimia nervosa is to reduce the dietary restriction that leads to hunger and binge eating. To do this several learning principles are used. First, an educational approach is taken, presenting information concerning the factors maintaining binge eating and purging, together with a rationale for the treatment procedures stemming from the model. This is aimed at developing an expectation on the patient's behalf that reducing dieting will help to reduce the sense of loss of control and the consequent binge eating. Once the patient has accepted the rationale, the first phase of therapy begins. In this phase several additional principles are used. The patient is asked to monitor her eating behavior (i.e., meal content, binges, the circumstances surrounding binge eating and purging) on self-monitoring forms. This crucial aid to self-regulation provides information both to the therapist and the patient about the details of the problem and, in later sessions, about progress in changing the problem behaviors. The restrictive dieting is directly addressed by helping the patient to eat three meals and two snacks each day, followed by increasing the amount eaten on each occasion. Here, a process of shaping is used to allow gradual behavior change. Appropriate changes are reinforced by selective therapist attention and praise, and problems are discussed until a new solution is found. Such a solution is then tried out by the patient between sessions as homework.

Once a more stable pattern of eating has been attained the factors that drive dietary restriction such as overconcern about weight and shape are addressed. One of the learning procedures used is data gathering on the problem, including the hoped-for but unrealistic outcomes the patient believes she will attain by maintaining a thin body shape. Such outcome expectancies can be challenged regarding their reality, and alternative ways of achieving more reasonable outcome expectancies can be considered.

In the final phase of therapy, relapse prevention strategies are implemented. First, behavior change strategies that have proved successful in treatment are reviewed. Lapses occurring during this phase of treatment, for example, a small binge or even an urge to binge, are examined in detail. The events leading up to the lapse are reviewed and alternative coping strategies are considered for their potential effectiveness in preventing relapses. More generally, situations specific to the patient that are likely to precipitate relapse are identified and potential coping strategies are also identified. A case example in which cognitive-behavioral therapy was used to treat a patient with bulimia nervosa illustrates the use of these principles.

The patient was a 29-year-old married woman who, because of concerns about her weight had begun to diet in early adolescence. Although she was within the normal limits of weight for her height, her mother's concerns about her own weight and remarks about the patient's “plumpness” apparently drove her to ever-stricter dieting. This was followed later in adolescence by the occurrence of binge eating with a consequent weight gain of several pounds. To combat this weight gain the patient began to purge by inducing vomiting with her fingers following binges; later she was able to induce vomiting at will. When first seen at the clinic she was binge eating and purging almost fifteen times each week. Physical examination and electrolytes were normal except for a raised serum amylase, a finding not uncommon in patients with bulimia nervosa.

Therapy began by elaborating on her history, exploring in more detail the links between feelings of low self-esteem engendered by childhood experiences, and the importance of weight and shape to her morale, which led her to dieting and binge eating. The patient was able to perceive these links and to accept the model outlined in Figure 3.3-6. She accepted the possibility that reducing dieting would lessen binge eating and purging; however, she feared gaining weight if she gave up dieting. She was not particularly reassured by the findings from controlled trials that the average patient does not gain weight, but was willing to take an experimental approach to the problem. She was advised to weigh herself no more than once each week to reduce overreaction to natural weight fluctuations and was taught how to monitor and record her food intake, binge eating and purging, and the circumstances under which such behaviors occurred.

At the next session the food records were examined in detail with the therapist pointing out her pattern of eating little or no breakfast, a small salad for lunch, and then binge eating at least once during the evening. The link between dieting, hunger, and binge eating was again pointed out and the therapist told her to eat three meals and two snacks by the clock, rather than relying on her own hunger sensations, which were disrupted by her chaotic eating patterns. During the next three or four sessions the therapist and patient collaborated to gradually achieve this goal by using the principle of shaping and reinforcing positive changes by therapist praise and attention. By the fifth session the patient was eating three meals and two snacks on many days. The patient recognized from her food record that she was more likely to binge on days when the desired meal pattern was not maintained. This reinforced her adherence to eating three meals and two snacks daily, and also allowed her to experiment with consuming somewhat larger meals with continuing diminution of binge eating and purging. By the eighth therapy session she completed her first week free of binge eating and purging, without any noticeable weight gain. Such progress during the first half of therapy is undoubtedly a good prognostic indicator.

The next phase of treatment involved broadening food choices. The therapist recommended a behavioral task, namely, that the patient visit a supermarket and make a list of all the foods that she would *not* buy because she feared eating them. The patient complied and was asked to add some of the lesser-feared foods to her diet. With these additions continuing over the next few sessions, the bulk of the work then shifted to an examination of her distorted thinking about weight and shape. The patient was particularly prone to blame her appearance for any rejection she perceived. Such incidents were explored in detail and usually led her to accept an alternative conclusion regarding the perceived rejection. She then began to practice these exercises on her own when such thoughts arose. She was also convinced that her body was less “perfect” than the bodies of other women. Hence, she was given the task of actually looking at other women's bodies and considering their “imperfections.” She gradually became persuaded that she was not as overweight as she had thought. Although the patient occasionally lapsed into binge eating and purging, for most of the time during this phase of therapy she had been eating normally.

In the final few sessions the patient was asked to review the procedures that had helped her most in order to develop a written maintenance plan. Among the essential elements she listed eating regularly and not avoiding foods, giving up dieting, and being somewhat more accepting about her weight and shape. Circumstances that might lead to further lapses were also explored, focusing on the few lapses that had occurred during the past weeks; this allowed the patient to plan to cope better with such situations. For example, she reported being tempted to binge when she was made angry by an interpersonal interchange, particularly if she returned home alone following such an incident. She developed several alternate coping strategies such as talking the incident over with a friend or planning to eat out or go to a movie to ensure that she would not be alone under such circumstances. The systematic application of these cognitive and behavioral strategies illustrates the clinical use of relapse prevention strategies based on social-cognitive learning theory. The patient was monitored at 3-month intervals to check up on her progress and deal with any residual problems. One year following the end of treatment she had continued to abstain from binge eating and purging and treatment ended.

DEPRESSION

There are various models of the factors that maintain a depressed mood. One such model is shown in Figure 3.3-7. Distorted cognitive processes and a lack of reinforcing behavior, particularly of interpersonal behavior, are believed to maintain a depressed mood. A triad of cognitive dysfunctions is postulated; the most proximal to a depressed mood are automatic negative thoughts. Errors in information processing, which are state dependent, occurring only in the presence of a depressed mood, are the second element in the cognitive triad. Events are perceived and processed mistakenly to suggest a potential negative outcome, thus amplifying negative moods. At a deeper level, usually not easily accessible to the patient, are more general distorted attitudes and beliefs that give rise to the

automatic negative thoughts and to errors in information processing. Also, the interpersonal world of the patient is often inherently nonreinforcing, which leads to a decline in interpersonal activities that further cuts the patient off from potential reinforcers, with the potential to spiral into a deep withdrawal and a seriously depressed mood.

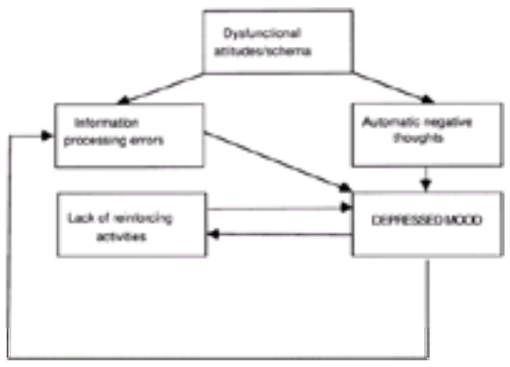

FIGURE 3.3-7 A hypothetical model of psychosocial factors maintaining depression.

Cognitive-behavioral therapy for depression begins by clarifying the patient's expectations regarding the outcome of treatment by engendering positive but realistic expectations. The relationship with the patient is described as collaborative—the patient gathers data and with the help of the therapist formulates behavior changes that are likely to ameliorate depression. Therapy usually begins with self-monitoring of mood states and the events surrounding them, and with encouragment and reinforcement of proactive behaviors that the patient will find reinforcing. The aim is to gradually shape a wider repertoire of behaviors leading to reinforcement in the patient's life by identifying behaviors associated with depressed or normal mood states, providing feedback regarding progress derived from further self-monitoring, and reinforcement of progress by the therapist. Feedback is also sought from the patient regarding the relevance and effectiveness of the procedures used in each therapy session. As the patient begins to make progress, automatic negative thoughts are examined in detail; Socratic questioning is used to teach the patient to evaluate the accuracy of the outcome expectancies involved in such thoughts. Self-monitoring is now focused on maladaptive thinking. As therapy continues, underlying attitudes and cognitive schemas are gradually uncovered and clarified in similar ways. In the final phase of treatment, relapse-prevention procedures are used, often attempting to identify broad behavior patterns associated with depressive thinking and helping patients to better cope with such problems.

SUGGESTED CROSS-REFERENCES

Applications of the principles and procedures discussed in this section, together with an assessment of the effectiveness of such therapeutic applications to various conditions, can be found in Section 30.2 on behavior therapy and Section 30.6 on cognitive therapy. Issues basic to learning are discussed in Chapter 1 on neural sciences and in Section 3.1 on perception and cognition. Derivations from the principles and procedures exemplified in this section are discussed in Chapter 6 on theories of personality and psychopathology that are derived from psychology and philosophy.

3.4 BIOLOGY OF MEMORY

LARRY R. SQUIRE, FH.D., AND KEN A. PALLER, FH.D.

The topic of memory is fundamental to the discipline of psychiatry. Memory provides the essential substrate for the cognitive activities that define human experience, it allows one to connect the present moment to what came before, and it is the basis of cultural evolution.

An individual's personality reflects habits and dispositions that have developed from experience. Adaptive and maladaptive coping strategies, anxieties, and phobias are largely products of learning. Neurotic or psychotic symptoms can be the consequences of specific experiences or repeated patterns of experience. Psychotherapy is a process by which new behaviors are acquired through the accumulation of new experiences. Thus, memory is at the heart of psychiatry's concern with the effects of early experience, the development of the individual, and the possibility of change.

Disorders of memory and complaints about memory lapses are pervasive in both neurology and psychiatry. Memory problems are also of special concern as side effects of psychopharmacological treatments and electroconvulsive therapy. Accordingly, the effective clinician needs to understand memory, its psychological and neurological foundations, the varieties of memory dysfunction, and how memory can be evaluated. The biological perspective on memory developed here rests on a growing body of neuroscientific evidence that relates mental events to the functioning of the brain.

MEMORY AS SYNAPTIC CHANGE

Memory is a special case of the more general phenomenon of *neural plasticity*. Neurons can show history-dependent behavior by responding differently as a function of recent input, and this plasticity of nerve cells and synapses is the basis of memory. In the last decade of the nineteenth century, researchers proposed that the persistence of memory could be accounted for by nerve cell growth. Others have restated this idea, developing the hypothesis that the synapse is the critical site of change. In principle, there are many possible ways for such structural change to be realized, including alterations in the number of synaptic contacts or in the strength of existing contacts.

Plasticity Neurobiological evidence from animal studies supports two basic conclusions about the biology of memory. First, specific synaptic events, including an increase in neurotransmitter release, are responsible for short-lasting plasticity, which may last for seconds or minutes. Second, long-lasting memory depends on new protein synthesis, physical growth of neural processes, and an increase in the number of synaptic connections.

A major source of information has been the extended study of the marine mollusc *Aplysia californica*. A sufficient number of individual neurons and connections between neurons have been identified to allow the wiring of some simple behaviors to be diagrammed. *Aplysia* is capable of both associative learning (including classical conditioning and operant conditioning) and nonassociative learning (habituation and sensitization). Figure 3.4-1 shows the circuitry responsible for the gill-withdrawal reflex, a defensive reaction whereby tactile stimulation causes the gill and siphon to retract. When tactile stimulation is preceded by stimulation to the head, gill withdrawal is facilitated. The cellular mechanisms underlying this sensitization are based on an enhanced release of neurotransmitter by the facilitatory neuron (labeled “Int” in Fig. 3.4-1) and accompanied by covalent modifications of preexisting proteins. Under some training conditions, sensitization can persist for weeks, and these longer-lasting changes can also be produced by repeated applications of serotonin, distributed over a period of 1½ hours. Although both short- and long-lasting plasticity are based on enhanced transmitter release, the long-lasting change uniquely requires the expression of genes and the synthesis of proteins. In addition, the long-term change, but not the short-term change, is accompanied by the growth of neural processes of neurons within the reflex circuit.

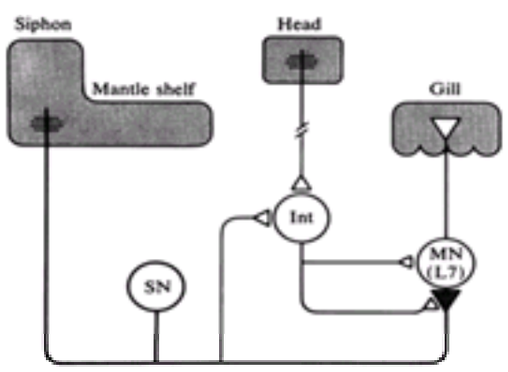

FIGURE 3.4-1 A schematic diagram of the neuronal circuit underlying behavioral habituation and sensitization of the gill-withdrawal reflect in *Aplysia*. The relative simplicity of the nervous system of *Aplysia* makes it a valuable organism for studying cellular and synaptic mechanisms of memory. The synapse between the sensory neuron (SN) and the motor neuron (MN) is an important site of habituation. Sensitization results from activation of the interneuron (Int) pathway. (Reprinted with permission from Kandel ER: *Cellular Basis of Behavior*. Freeman, San Francisco, 1976.)

In vertebrates, behavioral manipulations can also result in measurable changes in the brain's architecture. For example, rats reared in enriched environments show an increase in the number of synapses ending on individual neurons in neocortex. These changes are accompanied by small increases in cortical thickness, in the diameter of neuronal cell bodies, and in the number and length of dendritic branches. New synapses may be formed directly or synapses may be selectively preserved from a population that is continuously being replaced. Behavioral experience thus exerts powerful effects on the wiring of the brain.

Many of these same structural changes have been found in adult rats exposed to an enriched environment, and some have been found in adult rats given extensive maze training. In this case opaque contact-lens occluders were used to restrict vision to one eye, and the corpus callosum was transected to prevent information received by one cerebral hemisphere from reaching the other hemisphere. In these monocularly trained animals, increases in the size of dendritic fields of pyramidal neurons of occipital cortex were found only in the trained hemisphere. This finding rules out a number of nonspecific influences including motor activity, indirect effects of hormones, and overall level of arousal. Therefore it seems likely that long-term memory in vertebrates is generally based on specific changes within the neurons that lie along specific pathways.

Long-Term Potentiation The phenomenon of *long-term potentiation* (LTP) is a form of neural plasticity likely to be important for memory in vertebrates. LTP is observed when a postsynaptic neuron is persistently depolarized following a brief burst of high-frequency stimulation. LTP has a number of properties that make it a promising candidate as a physiological substrate of memory. First, it is established quickly and then lasts for a long time. Second, it is associative in that it depends on the co-occurrence of presynaptic activity and postsynaptic depolarization. Third, it occurs only at the potentiated synapses, not at all the synapses terminating on the postsynaptic cell. Finally, LTP occurs prominently in the hippocampus, a structure with important memory functions. The induction of LTP is known to be mediated postsynaptically and to involve activation of the *N*-methyl-D-aspartate (NMDA) receptor, which permits influx of calcium into the postsynaptic cell. The mechanism whereby LTP is maintained is not clearly established, but evidence has been presented in favor of a presynaptic locus of change (increased transmitter release).

Rapidly developing structural changes in the dendritic spines of the postsynaptic neuron have also been described in association with LTP.

A new method for studying molecular mechanisms of memory relies on introducing specific mutations into the genome. For example, by altering a single cloned gene, a mutant strain of mice can be produced with specific receptors or cell-signaling molecules inactivated or altered. This knock-out technique can provide greater specificity than pharmacological blocking methods. Recently, it has been possible to study mice with a selective deletion of one type of NMDA receptor in the CA1 field of the hippocampus. Although many aspects of CA1 physiology remain intact, the CA1 cells do not exhibit LTP. In addition, an impairment is observed on a learning task. If reversible gene knock-outs can be achieved, it will be possible to induce specific molecular changes in a developmentally normal adult.

Associative Learning Additional insights into memory have been gleaned from the study of the neural circuitry underlying classical conditioning of the eyeblink-nictitating membrane response in rabbits. Repeated pairings of a tone (conditioned stimulus) and an airpuff to the eye (unconditioned stimulus) lead to a conditioned eyeblink in response to the tone. Reversible lesions of the deep nuclei of the cerebellum eliminate the conditioned response without affecting the unconditioned response, which indicates that the cerebellum contains part of the essential circuitry for learned association, the conditioned stimulis–unconditioned stimulus link. Reversible lesions of the deep nuclei also prevent learning from occurring, and the rabbits begin learning from the naive state when the lesion is reversed. This finding does not mean that all the changes occurring in the animal during conditioning involve the cerebellum; it means only that essential neural changes responsible for the conditioned stimulus–unconditioned stimulus link depend on this circuitry. The relevant plasticity appears to be distributed between the cerebellar cortex and the deep nuclei (Fig. 3.4-2). An analogous pattern of plasticity is thought to underlie motor learning in the vestibulo-ocular reflex, and perhaps associative learning of motor responses in general. Based on the idea that learned motor responses depend on coordinated control of changes in both timing and strength of response, it has been suggested that synaptic change in the cerebellar cortex is crucial for learned timing, whereas synaptic change in the deep nuclei is crucial for learned changes in the strength of the response.

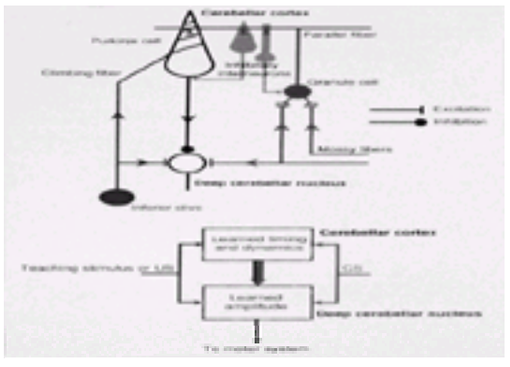

FIGURE 3.4-2 A schematic diagram of the circuitry of the mammalian cerebellum (**top**). In the classically conditioned blink response, input from the air-puff unconditioned stimulus and input from the auditory conditioned stimulus comes in through parallel pathways to the cerebellar cortex and to the deep cerebellar nucleus, and plasticity occurs in both pathways (**bottom**). (See Color Plate 4.)

Understanding the biology of memory requires more than just an understanding of the synaptic events that store memory. It is also essential to understand how and where synaptic events are organized in the brain. Many levels of analysis can be identified between synaptic change and behavioral memory, and many important questions about memory address levels of biological analysis that are intermediate to synapses and behavior.

CORTICAL ORGANIZATION OF MEMORY

The question of where memories are stored in the brain has long been a major research issue. In the 1920s Karl Lashley carried out a series of experiments that were directed at this problem. Lashley recorded the number of trials that rats needed to relearn a preoperatively learned maze problem after removal of different amounts of cerebral cortex. The deficit was proportional to the amount of cortex removed and, further, it seemed to be qualitatively similar, regardless of what region of cortex was removed. Lashley concluded that memory for the maze habit was not localized in any one part of the brain, but instead was distributed equally over the entire cortex. Subsequent work has led to a revision of this idea. Maze learning in rats depends on many forms of information, including visual, tactual, spatial, and olfactory information. These various forms of information are processed and stored in different areas. Thus, the correlation between retention score and lesion size that Lashley observed reflects the progressive encroachment on specialized cortical areas serving the many components of cognition important to maze learning.

The specialized cortical areas responsible for processing and storing visual information have been studied most extensively in nonhuman primates. Nearly half of the primate neocortex is specialized for visual functions. Cortical pathways for visual information processing (Fig. 3.4-3) begin in primary visual cortex (V1) and proceed from there along parallel pathways or streams. One stream projects ventrally to the inferotemporal cortex (area TE in the monkey) and processes information about the quality of visual percepts. Another stream projects dorsally to the parietal cortex and processes information about spatial location. Electrophysiological studies in the monkey show that neurons in area TE register specific and complex features of visual stimuli, like shape, and may even respond selectively to patterns and objects. These specific visual processing areas, along with connections to corresponding regions in dorsolateral prefrontal cortex, are involved in the immediate experience of perceptual processing, and in what has been called *immediate memory* or *working memory*. These areas also serve as the ultimate repositories of the memories that result from their activity. Accordingly, lesions in these areas lead to impairments in visual perception as well as in visual learning and memory, although elementary visual functions such as acuity remain intact. Inferotemporal cortex can thus be thought of both as a higher-order visual processing system and a storehouse of the visual memories that result from that processing. These stored visual memories can be used and manipulated according to current processing demands, and they can also be quite long-lasting.

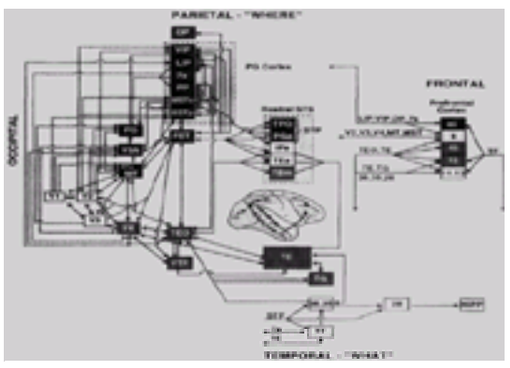

FIGURE 3.4-3 Summary of cortical visual areas and some of their connections. There are two major pathways from striate cortex (V1). The processing stream for object vision follows a ventral route into the temporal lobe via V4 (dark gray boxes) and the processing stream for spatial vision follows a dorsal route into the parietal lobe via MT (light gray boxes). Solid lines indicate connections arising from both central and peripheral visual field representations; dotted lines indicate connection restricted to peripheral field representations. Shaded region on the lateral view of the brain represents the extent of the cortex included in the diagram. Abbreviations: DP, dorsal prelunate area; FST, fundus of superior temporal area; HIPP, hippocampus; LIP, lateral intraparietal area; MSTc, medial superior temporal area, central visual field representation; MSTp, medial superior temporal area, peripheral visual field representation; MT, middle temporal area, MTp, middle temporal area, peripheral visual field representation; PO, parieto-occipital area; PP, posterior parietal sulcal zone; STP, superior temporal polysensory area; VIP, ventral intraparietal area; STS, rostral superior temporal sulcus; and VTF, visual responsive portion of area TF. (Reprinted with permission from Ungerleider LG: Functional brain imaging studies of cortical mechanisms for memory. Science *270:*769, 1995. © 1995 American Association for the Advancement of Science.)

Many parts of the nervous system participate in storing representations of an event in memory. During an event, visual information is stored in inferotemporal cortex so that the same visual material can later be recognized as familiar. Concurrently, other components of the event—including spatial, temporal, tactile, olfactory, emotional, and other sorts of information—are processed and stored separately. Memory storage in the cerebral cortex thus depends on a fractionation of experience as follows. First, any particular event or learning task is composed of a number of components. Second, each component engages a particular processing site or set of sites. Third, each processing site stores information as an outcome of the processing that is done.

Thus, memory is both distributed and localized in the nervous system. It is distributed in the sense that, as Lashley concluded, there is no unitary cortical center dedicated solely to the storage of memories. Yet, memory is localized in the sense that different aspects or dimensions of events are stored at specific cortical sites—the same regions specialized to analyze and process those particular aspects or dimensions of information.

INSIGHTS FROM AMNESIA

The idea that the functional specialization of cortical regions governs both information processing and information storage is important, but it does not provide a complete account of the organization of memory in the brain. If it did, then particular cortical injuries would disrupt only particular domains of learning and memory (i.e., visual memory or spatial memory) and no global disruption of memory would occur. Brain injury would always produce a difficulty in learning a restricted type of new information along with a loss of previously learned information of that same type. Yet common neurological syndromes of memory impairment conflict with these expectations.

The hallmark of neurological memory impairment is a profound anterograde amnesia, or loss of new learning ability, that extends across all sensory modalities. Typically, this occurs together with retrograde amnesia, a memory loss for information acquired prior to the onset of amnesia. The retrograde deficit often has a temporal gradient, such that recall for recent events is impaired, but recall for remote events is intact. Other cognitive functions are preserved, including attention, immediate memory, personality, and social skills.

The selectivity of the memory deficit in amnesia implies that the brain has isolated intellectual and perceptual functions from the ability to lay down a record of information processing. The cognitive dysfunction experienced by amnesic patients affects memory storage but does not affect a wide range of other intellectual capabilities. The fact that memory storage is affected for all sensory modalities without a parallel disruption of perception implies that the memory function is superimposed on normal cortical processing. The fact that anterograde amnesia often occurs together with intact remote memory implies that viable retrieval mechanisms are intact, and also that the brain structures damaged in amnesia are not the ultimate repositories of memory. Detailed studies of amnesic patients and models of amnesia in nonhuman animals have illuminated these issues considerably.

Specialized Memory Function Amnesia results from damage to either of two brain regions: the medial temporal lobe or the midline diencephalon. Early studies of a severely amnesic patient known as HM markedly stimulated investigation of the role of the medial temporal lobe.

H.M. became amnesic in 1953, when he sustained a bilateral resection of the medial temporal lobe to relieve severe epilepsy. The removal included approximately half of the hippocampus, most of the amygdala, and the neighboring entorhinal and perirhinal cortices. Following the surgery, H.M.'s seizure condition was much improved. Moreover, he retained normal language, normal intellectual functions, and normal immediate memory (e.g., as tested with a digit span test). However, he exhibited profound forgetfulness, and this deficit has persisted for more than 40 years.

Extensive investigations of other amnesic patients have also been used to explore the memory functions of the medial temporal lobe. For example, patient R.B. became amnesic following an episode of global ischemia. He suffered from a moderately severe anterograde amnesia with minimal retrograde amnesia. After his death 5 years later, extensive histological study of his brain revealed a circumscribed bilateral lesion of hippocampal field CA1, whereas the minor additional pathology that was found could not reasonably explain the memory impairment. Similar pathological findings in the hippocampus have also been observed in other amnesic patients (Fig. 3.4-4). Magnetic resonance imaging (MRI) with high-resolution protocols can reveal pathology in the hippocampal region of amnesic patients in vivo. Two conclusions about the anatomical correlates of amnesia follow. First, damage limited to the hippocampus itself can result in clinically significant memory impairment; second, medial temporal regions in addition to hippocampal field CA1 also make a critical contribution to memory.

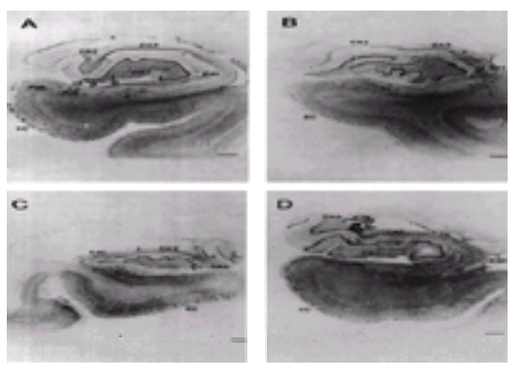

FIGURE 3.4-4 Coronal sections through the hippocampal region stained with thionin in a normal subject (**A**) and three amnesic patients with bilateral damage to the hippocampal formation (**B-D**). The hippocampus proper can be divided into three distinct fields, designated *CA1, CA2*, and *CA3*. The CA1 field extends to the subiculum (*S*). Other structures include the dentate gyrus (*DG*), presubiculum (*PrS*), parasubiculum (*PaS*), and entorhinal cortex (*EC*). In patient GD (**B**), damage included CA1; in patient LM (**C**), damage included CA1, CA2, CA3, DG, and EC; in patient WH (**D**), damage included CA1, CA2, CA3, DG, S, and EC. For additional details, see Rempel-Clower N, Zola SM, Squire LR, Amaral DG: Three cases of enduring memory impairment following bilateral damage limited to the hippocampal formation. J Neurosci *16:*5233, 1996. (Reprinted with permission from Squire LR, Zola SM: Memory, memory impairment, and the medial temporal lobe. In *Cold Spring Harbor Symposia on Quantitative Biology*, vol 61. Cold Spring Harbor Laboratory Press, Plainview, New York, 1996.)

The findings from human amnesia inspired the development of models of amnesia in experimental animals. Early animal studies yielded contradictory findings that could not be easily related to memory impairment. In part, the difficulty was that human amnesia itself was poorly understood. Memory is now known to be a collection of different abilities and not a unitary mental faculty. Human amnesia does not affect all kinds of memory. Until researchers understood this, selecting memory tasks for making comparisons across species was problematic. Indeed, obtaining memory performance measures that reflect parallel memory functions in humans and experimental animals requires a high degree of control over the cognitive strategies used.

Nonetheless, a model of human amnesia in the nonhuman primate became available in the early 1980s, and subsequent investigations identified the crucial structures and connections. In the medial temporal lobe, these include the hippocampus proper (CA fields, dentate gyrus, and subiculum) and adjacent regions of entorhinal, perirhinal, and parahippocampal cortex. Monkeys with surgical damage to specific structures were trained to perform tasks analogous to tasks sensitive to memory impairment in humans. Large medial temporal lesions intended to approximate the damage that occurred in patient H.M. caused monkeys to exhibit many features of human amnesia. For example, the impairment occurred in more than one sensory modality, short-term memory was intact, the deficit was enduring, skill learning was preserved, and retrograde amnesia was temporally graded.

Within the medial temporal lobe separate contributions can be identified for memory and emotion. The participation of the medial temporal lobe region in emotional expression was first studied systematically in 1937 by Heinrich Kluver and Paul Bucy, who found that monkeys with bilateral temporal lobectomy became tame, approached animals and objects without reluctance, examined objects by mouth instead of by hand, and exhibited abnormal sexual behavior. Subsequent studies have indicated that emotional behavior is related not to the hippocampus but to the adjacent set of nuclei known collectively as the amygdala. In addition, other work has shown that the amygdala is part of a set of structures essential for fear conditioning.

Amnesia can also result from circumscribed damage to structures of the medial diencephalon, including the mammillary nuclei, the dorsomedial nucleus of the thalamus, the anterior nucleus, the internal medullary lamina, and the mammillothalamic tract. Korsakoff's syndrome is the best studied example of diencephalic

amnesia. Patients with alcoholic Korsakoff's syndrome typically have frontal lobe pathology in addition to diencephalic damage. Frontal lobe pathology produces a pattern of cognitive impairment that is dissociable from amnesia itself. In the case of the patient with Korsakoff's syndrome, frontal lobe pathology is superimposed on severe memory impairment (Table 3.4-1).

Test	Amnesia	Korsakoff's Syndrome	Frontal Lobe Damage
Delayed recall	+	+	–
Dementia rating scale: memory index	+	+	–
Dementia rating scale initiation/ perseveration index	–	+	+
Wisconsin Card-Sorting Test	–	+	+
Temporal order memory	+	+ +	+ +
Metamemory	–	+	+
Release from proactive interference	–	+	–

Table 3.4-1 Associated and Dissociated Deficits in Amnesia

One limitation of conventional methods for assessing neuropathology is that remote functional damage may be overlooked. For example, standard MRI scans may show structural damage limited to a particular region, but this damage may lead indirectly to disrupted functioning in other regions. Accordingly, functional neuroimaging may be useful for characterizing more fully the neural dysfunction responsible for amnesia. In Korsakoff's syndrome, results from positron emission tomography (PET) have revealed functional damage in widespread cortical regions (Fig. 3.4-5). Accordingly, diencephalic amnesia may often reflect a disruption of thalamocortical connections that are critical for memory storage.

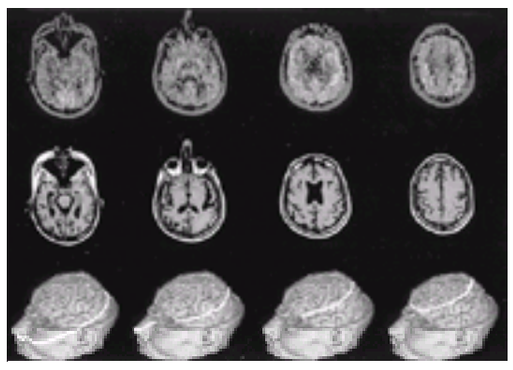

FIGURE 3.4-5 PET and MRI scans in a patient with Korsakoff's syndrome. Neural dysfunction was evident as reduced glucose utilization in multiple cortical regions in the frontal and parietal lobes, and in the cingulate. Functional neuroimaging can reveal brain dysfunction that might otherwise not be evident if limited to structural neuroimaging results. In Korsakoff's syndrome, the memory impairment probably reflects a disruption of thalamocortical circuitry. (Reprinted with permission from Paller KA, Acharya A, Richardson BC, Plaisant O, Shimamura AP, Reed BR, Jagust WJ: Functional neuroimaging of cortical dysfunction in alcoholic Korsakoff's syndrome. J Cogn Neurosci *9:*277, 1997.) (See Color Plate 5.)

Although amnesia can result from damage to either the medial temporal lobe or to the diencephalon, the distinctive functions of these two regions have been difficult to elucidate. It may be reasonable to expect the medial temporal lobe and diencephalic brain regions to make different contributions to normal memory, but there is currently no compelling evidence for a corresponding qualitative difference in memory impairment. This could be because the two regions function together as one system that facilitates the formation of links between neocortical storage sites, or because the two regions function separately but each makes an essential contribution to linking neocortical storage sites. In any event, memory clearly relies on an elaborate complex of neural circuits extending across multiple brain areas; Figure 3.4-6 shows the chief components of this circuitry. Ongoing research continues to improve our understanding of the neuroanatomy of amnesia and the normal functions of this neural circuitry.

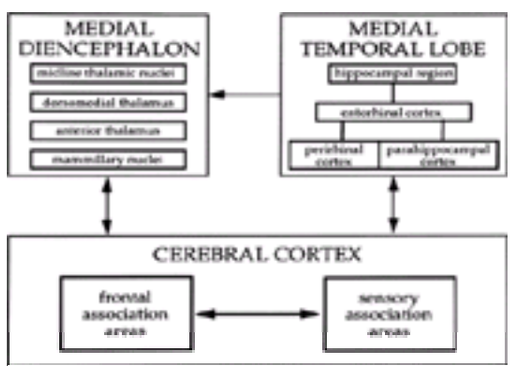

FIGURE 3.4-6 A schematic view of some of the chief brain regions critical for declarative memory. The entorhinal cortex is the major source of projections to the hippocampus, and nearly two thirds of the cortical input to the entorhinal cortex originates in the perirhinal and parahippocampal cortex. Entorhinal cortex also receives direct connections from cingulate, insula, orbitofrontal, and superior temporal cortex.

Retrograde Amnesia Memory loss in amnesia typically affects recent memories more than remote memories (Fig. 3.4-7). Temporally graded amnesia has been demonstrated retrospectively in studies of amnesic patients and prospectively in studies of monkeys, rats, mice, and rabbits. These findings have important implications for understanding the nature of the memory storage process. Memories are dynamic, not static. Apparently, memory storage can become more robust over time. As time passes after learning, some memories are forgotten while others become stronger because of a process of consolidation that depends on cortical, limbic, and diencephalic structures. The limbic-diencephalic contribution diminishes over time such that the neocortical component of the memory eventually becomes self-sufficient. In other words, the limbic-diencephalic structures are needed at the time of learning and during this gradual process. After sufficient time has elapsed, long-term memories can be retrieved whether or not limbic-diencephalic structures are intact. Thus, the permanent repositories of memory are the distributed neocortical regions, not diencephalic or hippocampal regions.

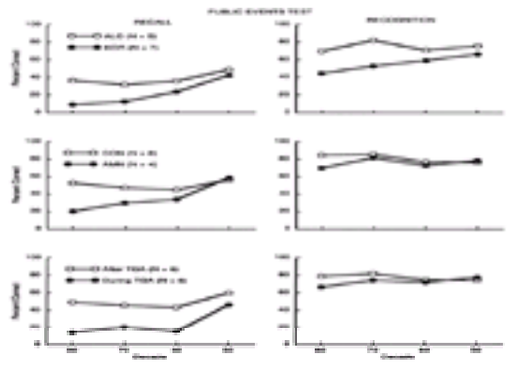

FIGURE 3.4-7 Remote memory performance of amnesic patients with Korsakoff's syndrome (KOR), alcoholic control subjects (ALC), amnesic patients with confirmed or suspected damage to the hippocampal formation (AMN), healthy control subjects (CON), and patients with transient global amnesia (TGA). The left column shows recall scores for past public events that had occurred in one of the four decades from 1950 to 1985. The right column shows performance on a multiple-choice test (four alternatives) involving the same public events. (Reprinted with permission from Kritchevsky M, Squire LR: Transient global ischemia: Evidence for extensive, temporally graded retrograde amnesia. Neurology *39:*213, 1989 and Squire LR, Haist F, Shimamura AP: The neurology of memory: Quantitative assessment of retrograde amnesia in two groups of amnesic patients. J Neurosci *9:*828, 1989.)

Atypical patterns of amnesic impairment have also been reported. Patients have been described with substantial retrograde impairments together with little or no impairment in new learning ability, a pattern termed *focal retrograde amnesia*. Evidence that focal retrograde amnesia can result from damage to portions of the anterior temporal lobes or possibly other neocortical areas has important implications for specifying the neuroanatomical substrates of memory. A likely explanation is that these neocortical areas comprise memory storage sites responsible for critical aspects of certain memories for facts and events. In some cases, retrograde deficits have been reported to span exceedingly long time periods, perhaps most of a patient's life. It thus appears possible to disrupt memory for events that occurred many years prior to the brain insult while retaining the ability to form memories for new events. The minimal problems with new learning in focal retrograde amnesia presumably relate to continued functioning in hippocampal and diencephalic regions as well as the availability of storage sites in intact parts of the cerebral cortex.

MEMORY SYSTEMS

Many kinds of memory remain intact in amnesia. The kind that is impaired is termed *declarative memory*. Declarative memory makes possible the conscious recollection of facts and events. A deficit in declarative memory presents itself as a global disorder of impaired memory for routes, lists, faces, melodies, objects, and other verbal and nonverbal material, regardless of the sensory modality in which the material is presented. This amnesic impairment typically occurs in conjunction with the preservation of a heterogeneous set of other memory capabilities, collectively termed *nondeclarative memory*. Nondeclarative memory includes skill learning, habit learning, conditioning, and the phenomenon of priming. Ample evidence has shown that, for these types of memory, amnesic patients can perform normally. A variety of skills, including perceptual, perceptuomotor, and cognitive skills, can be acquired by amnesic patients and normal subjects at equivalent rates. For example, amnesic patients can learn to read mirror-reversed text normally, they exhibit the normal facilitation in reading speed with successive readings of normal prose, and they improve as rapidly as normal subjects at speeded reading of repeating nonwords. In addition, amnesic patients can, after seeing strings of letters generated by a finite-state rule system, classify novel strings of letters as rule-based or not rule-based. Classification performance is normal despite the fact that amnesic patients are impaired at remembering the previously studied items or the events of training, which rely on declarative memory. Amnesic patients can also learn about categories by abstracting prototype information, even though they forget the examples from which the category was built.

Priming refers to a facilitation of the ability to detect or identify stimuli based on recent experience with those stimuli. Priming is another type of memory that occurs at full strength in amnesia. In one type of priming test, amnesic patients exhibited the normal tendency to complete three-letter stems with previously encountered words when they were instructed to produce the first word to come to mind (e.g., MOT__ completed to MOTEL). In another test, amnesic patients studied a list of words and then exhibited preserved priming with respect to their accuracy at identifying briefly presented words and with respect to their estimates of how long each word was presented (Fig. 3.4-8). Yet patients' ability to recognize the same words when presented later was severely impaired. Amnesic patients also exhibited priming for object names, novel objects, and novel faces. For example, in one experiment patients named pictures of previously presented objects reliably faster than they named pictures of new objects, even after a delay of a week. This facilitation occurred at normal levels, despite the fact that amnesic patients were markedly impaired at recognizing which pictures had been presented previously.

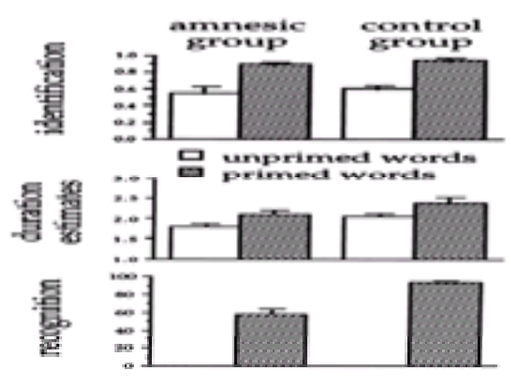

FIGURE 3.4-8 Preserved priming and impaired recognition in amnesic patients. The top graph shows the proportion of briefly presented words identified correctly by a group of amnesic patients and an age-matched control group. The priming effect took the form of more accurate identification for words presented in an earlier study phase (primed words) compared to other words (unprimed words). In the middle panel, both groups showed priming of duration estimations made on an arbitrary four-point scale, in that primed words were rated as having been presented for a longer duration compared to unprimed words. In the bottom panel, recognition performance on a forced-choice, three-alternative recognition test was impaired in the amnesic group (lower percent correct). Values are means plus standard errors of the mean. (Adapted from Paller KA, Mayes AR, McDermott M, Pickering AD, Meudell PR: Indirect measures of memory in a duration-judgment task are normal in amnesic patients. Neuropsychologia *29:*1007, 1991.)

Results from PET studies in normal volunteers suggest that priming reflects changes in early stages of the cortical pathways that participate in perceptual processing (Fig. 3.4-9). With stem-completion priming, both PET and divided visual field studies have implicated visual processing systems in extrastriate cortex, especially in the right hemisphere. In contrast, conscious recollection of remembered words normally engages a larger set of brain areas. Neural correlates of this processing have been observed as blood flow changes in hippocampal, frontal, and other brain areas. This processing simultaneously produces brain electrical activity (event-related potentials) that can be measured at the scalp (Fig. 3.4-10). A role for the frontal lobes in declarative memory has been substantiated both in patients with frontal lesions and in PET studies conducted on normal subjects. Patients with frontal lesions are not globally amnesic but tend to have certain memory problems.

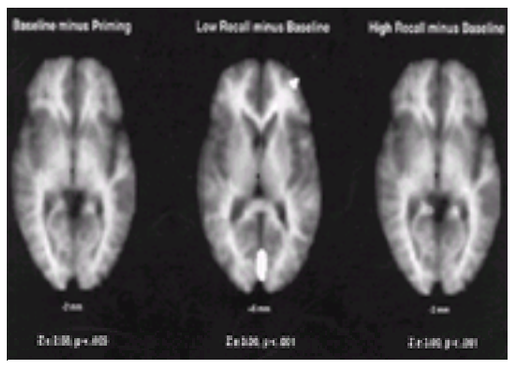

FIGURE 3.4-9 PET activations superimposed over averaged transverse MRI scans with the distance shown representing the distance from the line connecting the anterior and posterior commissure. Words were studied under strong or weak learning conditions (high recall or low recall) and then both declarative memory (cued recall) and nondeclarative memory (priming) were tested. The Baseline minus Priming subtraction showed an area of decreased blood flow (green) in right visual association cortex thought to be related to the greater ease of processing primed words. The Low Recall minus Baseline subtraction showed an area of increased blood flow (yellow) in secondary visual cortex and left prefrontal cortex thought to be related to the effort involved in deliberate, effortful retrieval. The High Recall minus Baseline subtraction showed a region of increased blood flow (red) in bilateral hippocampal regions thought to be related to successful retrieval of recently acquired information. (Reprinted with permission from Schacter DL, Alpert NM, Savage CR, Rauch SL, Albert MS: Conscious recollection and the human hippocampal formation: Evidence from positron emission tomography. Proc Natl Acad Sci USA *93:*321, 1996. ©1996 National Academy of Sciences, U.S.A.) (See Color Plate 5.)

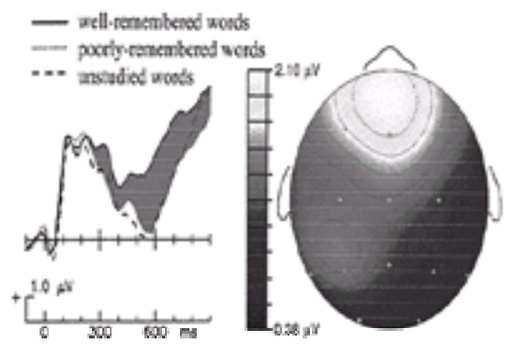

FIGURE 3.4-10 Brain potentials showing a differential response based on the extent to which subjects engaged in recollection following word presentations. Potentials shown at the left were recorded from a frontal scalp electrode. Measurements from multiple electrodes over the 400- to 800-ms latency range were used to generate the topographical map at the right, showing that the neural correlate of recollection was broadly distributed across the scalp, with largest responses over frontal cortex. (Adapted with permission from Paller KA, Kutas M: Brain potentials during memory retrieval provide neurophysiological support for the distinction between conscious recollection and priming. J Cogn Neurosci *4:*375, 1992.) (See Color Plate 6.)

Patient B.G. suffered an infarction restricted to the right frontal lobe, and showed an abnormal tendency towards falsely recognizing as familiar items that had not been presented for study, possibly because of a tendency to rely on a general feeling of familiarity for items rather than specific memories for prior items. By virtue of its connections to posterior neocortical regions, the frontal lobe appears to play a role in the organization of retrieval. In other words, frontal-posterior networks are instrumental both in the on-line processing of information and in the retrieval of declarative memories.

One organizational scheme for categorizing multiple types of memory appears in Figure 3.4-11. Declarative memory depends on medial temporal and midline diencephalic structures along with extensive portions of the neocortex (see Fig. 3.4-6). This system provides for the rapid learning of facts (*semantic memory*) and events (*episodic memory*). Nondeclarative memory depends on several different brain systems. Habits probably depend on both the neocortex and the neostriatum, the cerebellum is important for conditioning of skeletal musculature, the amygdala for emotional learning, and the neocortex for priming. Declarative and nondeclarative memory differ in important ways; declarative memory is phylogenetically more recent than most types of nondeclarative memory. In addition, declarative memories are available to conscious recollection. The flexibility of declarative memory permits the retrieved information to be available to multiple response systems. Nondeclarative memory is inaccessible to awareness and tends to be inflexible, and it is expressed only by engaging specific processing systems. Nondeclarative memories are stored as changes within these processing systems, changes that are encapsulated such that other processing systems have limited access to the stored information.

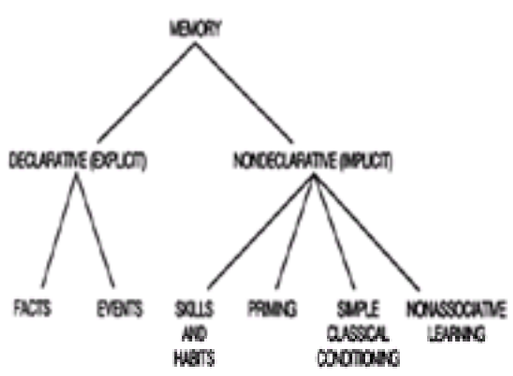

FIGURE 3.4-11 A tentative memory taxonomy. *Declarative memory* refers to conscious recollection of facts and events. *Nondeclarative memory* refers to a collection of abilities wherein performance changes as the result of experience but without affording conscious memory access to the original experience. *Nonassociative learning* includes habituation and sensitization. (Adapted from Squire LR, Zola-Morgan S: The medial temporal lobe memory system. Science *253:*1380, 1991.)

IMPLICATIONS

Current understanding of the biology of memory has significant implications for several fundamental issues in psychiatry. One example is the phenomenon of infantile amnesia, the apparent absence of conscious memory for experiences from approximately the first 3 years of life. Traditional views of infantile amnesia have emphasized repression (psychoanalytic theory) and retrieval failure (developmental psychology). A common assumption has been that adults retain memories of early events but cannot bring them into consciousness. However, another possibility is that the capacity for classical conditioning and skill learning (i.e., nondeclarative memory) emerges early in infancy, whereas declarative memory does not become available until about the third year; limbic and diencephalic structures essential for declarative memory may not be fully developed until that time. According to this view, infantile amnesia results not from the adult's failure to retrieve early memories but from the child's failure to store them in the first place. This is an intriguing suggestion, but recent evidence has not supported it. First, recall-like memory abilities have been demonstrated in young infants. In addition, it now appears that one of the most commonly employed tests of infant recognition memory, the visual-paired comparison task, depends on declarative memory.

What probably limits the development of declarative memory is not the slow maturation of the limbic-diencephalic structures essential for declarative memory, but rather the gradual development and maturation of the neocortex. As the neocortex develops, memories supported and stored there become more complex. Strategies emerge for organizing incoming information, language develops, and declarative memories become more richly encoded and interconnected, and more persistent.

The existence of multiple forms of memory and the gradual maturation of neocortex suggest an alternative to traditional views of infantile amnesia. It is not necessary to suppose that fully formed childhood memories persist but cannot be retrieved. An alternative view is that the capacity to store a viable declarative memory develops only gradually.

The existence of multiple memory systems also has implications for issues in psychoanalytic theory, including the construct of the unconscious. In considering the effects of past experience, it matters what view one takes of the nature of memory. By the traditional view, memory is a unitary faculty, and representations in memory vary mainly in strength and accessibility. According to this view, material that is unconscious is below some threshold of accessibility and could potentially be made available to consciousness. An alternative view begins with the distinction between memory that by its nature can be brought to mind (i.e., declarative memory) and other kinds of memory that are by their nature nonconscious in the sense that the knowledge is expressed through performance without affording any conscious memory content. In this view, early experience might affect later behavior, but the experience can persist to affect behavior without necessarily including a record of the event itself. Behavior can change as experience accumulates in altered dispositions, preferences, conditioned responses, habits, and skills, but these changes do not afford any actual awareness that behavior is being influenced by past experience. Nor is there any necessity that any particular past experience has been recorded. In this sense, the unconscious does not become conscious. Behavioral change can occur when new habits are acquired that supersede old ones or when sufficient awareness of a habit is gained such that it can to some extent be isolated or when the stimuli that elicit it can be processed differently. However, one does not become aware of its content in the same sense that one knows the content of a declarative memory, and one does not become aware of the early experiences that gave rise to the habit.

A better understanding of the biology of memory has also shed light on the imperfect nature of memory retrieval. It is quite possible to remember events that never happened. One way to conceptualize this problem is to consider the phenomenon of source amnesia, which occurs when an individual remembers some information without being able to remember how, where, or when the information was learned. If an individual imagines a certain event, at some later time it is possible to forget the moment when the scene was imagined while still recalling details as if they really happened. In this way, memory distortions can be caused by misattributions of source. Inferences and other thoughts invoked when recalling an experience can also be incorporated into memory such that a subsequent retrieval mistakenly includes the intervening information. Thus, the reconstructive nature of recollection poses problems for interpreting apparently “recovered” memories of traumatic events and emphasizes the importance of corroboration. As documented by experiments in adults and in children, illusory memories can be created, and children appear to be particularly susceptible to these effects. Several lines of evidence suggest that processing in the frontal lobes is essential for accurate source memory. For example, failures of source memory in the elderly appear to be associated with frontal lobe dysfunction. Patients with frontal lobe damage are highly susceptible to source errors, and they also tend to confabulate, sometimes producing bizarre responses that are inaccurate as well as implausible. Convergent results from PET studies in normal subjects imply that frontal regions, especially in the right hemisphere, play a key role in mediating accurate retrieval.

Finally, the biological understanding of declarative memory developed here is important in relation to the topic of consciousness. Declarative memory entails both a lasting influence of prior experience and an awareness of that remembering. The varieties of nondeclarative memory, such as priming, commonly occur without this awareness of remembering. To the extent that this contrast between memory with awareness versus memory without awareness can be understood at the neural level, a neuroscientific foundation can be developed to explain why certain types of neural processing lead to the subjective experience of remembering. Particular combinations of neocortical processing networks working in concert with the medial temporal lobe appear to come into play during the experience of remembering, whereas altered activity in a localized neocortical area can lead to the phenomenon of priming without explicit remembering. In this way, it may be possible to move from probing the neural substrates of declarative memory to addressing the question of why neural processing engenders consciousness at all, a problem that is central to the study of the neural basis of the mind.

ASSESSMENT OF MEMORY FUNCTIONS

A variety of quantitative methods are available to assess memory functions in neurological and psychiatric patients. Quantitative methods are useful for evaluating and following patients longitudinally as well as for carrying out a one-time examination to determine the status of memory function. If a memory problem is detected, it should be determined whether memory is selectively affected or whether memory problems are occurring against a background of intellectual deficits, as occurs in dementia. Although some widely available tests, such as the Wechsler Memory Scale-Revised, are useful measures of memory, most single tests assess memory rather narrowly, and even general-purpose neuropsychological batteries provide for only limited testing of memory functions. A complete assessment of memory usually involves a number of specialized tests that sample intellectual functions, new learning capacity, remote memory, and memory self-report.

The assessment of general intellectual functions is fundamental to any neuropsychological examination. In the case of memory testing, information about intellectual functions provides both information about a patient's general test-taking ability and a way to assess the selectivity of memory impairment. Useful tests include the Wechsler Adult Intelligence Scale-Revised, a test of object naming such as the Boston Naming Test, a rating scale to assess the possibility of global dementia, a test of word fluency, and specialized tests of frontal lobe function.

New Learning Capacity Memory tests are sensitive to impaired new learning ability when they adhere to either of two important principles. First, tests are sensitive to memory impairment when more information is presented than can be held in immediate memory. For example, one might ask patients to memorize a list of 10 faces, words, sentences, or digits because 10 items is more than can be held in mind. The paired-associated learning task is an especially sensitive test of this kind. In the paired-associate task, the examiner asks the patient to learn a list of unrelated pairs of words (e.g., queen-garden, office-river) and then to respond to the first word in each pair by recalling the second word.

Second, tests are sensitive to memory impairment when a delay, filled with distraction, is interposed between the learning phase and the test phase. In that case, examiners typically ask patients to learn a small amount of information and then distract them for several minutes by conversation, to prevent rehearsal. Recollection is then assessed for the previously presented material. Memory can be tested by unaided recall of previously studied material *(free recall)*, or by presenting a cue for the material to be remembered *(cued recall)*, or by testing recognition memory. In multiple-choice tests of recognition memory, the patient tries to select previously studied items from a group of studied and unstudied items. In yes/no recognition tests, patients see both studied and unstudied items one at a time and are asked to say “yes” if the item was presented previously and “no” if it was not. These various methods for assessing recently learned material can be ranked in terms of their sensitivity for detecting memory impairment (from most sensitive to least sensitive: free recall, cued recall, yes/no recognition, multiple-choice recognition). In practice, a cued-recall test can vary widely in its sensitivity, depending on the effectiveness of the cue.

The specialization of the cerebral hemispheres means that left and right unilateral damage to limbic-diencephalic structures is associated with different kinds of memory deficits. Accordingly, different kinds of memory tests must be used when unilateral damage is a possibility. Damage to limbic-diencephalic structures in the left cerebral hemisphere results in difficulty remembering verbal material such as word lists and stories. Damage to limbic-diencephalic structures in the right cerebral hemisphere impairs memory for faces, spatial arrangements, and other material that is typically encoded without verbal labels. For example, left medial temporal lobe damage impairs memory for both spoken and written text; right medial temporal lobe damage impairs the learning of spatial arrays, whether the layouts are examined visually or by touch. A useful way to test for anterograde amnesia for nonverbal material, for example, is to ask a patient to copy a complex geometric figure and then, without forewarning, to reproduce it after a delay of several minutes.

Remote Memory Disorders of memory are frequently accompanied by *retrograde amnesia*, that is, memory loss for events that occurred before the amnesia began. Evaluations of retrograde memory loss should attempt to determine both the severity of the loss and the time period that it covers. Most quantitative tests of remote memory are composed of material in the public domain that can be corroborated. For example, tests have involved questions about former one-season television programs, news events, or photographs of famous persons. An advantage of these methods is that it is possible to sample large numbers of events and target particular time periods. At the least, time periods before which the information could not have been learned can be identified. (For example, knowledge that Sarah Jane Moore tried to assassinate President Ford could not have been acquired prior to the 1970s). However, a disadvantage is that these tests are not particularly useful for detecting memory loss for information learned during the weeks or months immediately prior to the onset of amnesia. Most remote memory tests sample time periods rather coarsely and cannot detect a retrograde memory impairment that covers only a few months.

In contrast, autobiographical memory tests can potentially provide fine-grained information about a patient's retrograde memory. In the word-probe task, first used by Francis Galton in 1879, patients are asked to recollect specific episodes from their past in response to single word cues (e.g., *bird* and *ticket*) and to date the episodes. When normal subjects take the test, the number of episodes recalled is systematically related to the time period from which the episode is taken, and most of the memories come from recent time periods (the past 1 or 2 months). Patients with amnesia often exhibit temporally graded retrograde amnesia, drawing few episodic memories from the recent past, but producing as many remote autobiographical memories as normal subjects (Fig. 3.4-12).

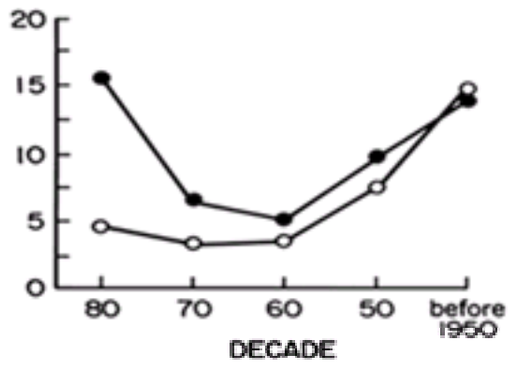

FIGURE 3.4-12 Loss of recent autobiographical memory as measured in five amnesic patients (filled circles) and five normal subjects (open circles). Well-formed memories from specific time periods were recalled in response to 75 single-word cues (e.g., *tree, flag, window*). (Reprinted with permission from MacKinnon D, Squire LR: Autobiographical memory in amnesia. Psychobiology *17:*247, 1989.)

Memory Self-Reports Patients can often supply descriptions of their memory problems that are extremely useful for understanding the nature of their impairment. Tests of the ability to judge one's own memory abilities are called *tests of metamemory*. Self-rating scales are available that yield both quantitative and qualitative information about memory impairment. As a result, it is possible to distinguish memory complaints associated with depression from memory complaints associated with amnesia. Patients with depression tend to rate their memory as poor in a rather undifferentiated way, endorsing equally all the items on a self-rating form. By contrast, patients with amnesia tend to endorse some items more than others; that is, there is a pattern to their memory complaints. Thus, patients with amnesia do not report difficulty in remembering very remote events or in following what is being said to them, but they do report having difficulty remembering an event a few minutes after it happens. Indeed, the self-reports match rather closely the description of memory dysfunction that emerges from objective tests. Specifically, new learning capacity is affected whereas immediate memory and very remote memory are intact. Some patients with amnesia, however, tend to markedly underestimate their memory impairment. In patients with Korsakoff's syndrome, for example, poor metamemory may stem from frontal lobe dysfunction. In any case, querying patients in some detail about their own sense of impairment and administering self-rating scales are valuable and informative adjuncts to more formal memory testing.

Dissociative Amnesia Differentiating dissociative amnesia from amnestic disorder, which results from neurological injury or disease, is less difficult than might be supposed. The two kinds of amnesia have markedly different characteristics. Dissociative amnesias typically do not affect new learning capacity. Patients enter the hospital able to maintain a continuing record of daily events. By contrast, new learning problems are at the core of amnestic disorder, which is much more common than dissociative amnesia. The main positive symptom in dissociative amnesia is extensive and severe retrograde amnesia. Patients may be unable to recall their own name or to recollect pertinent autobiographical information from childhood. However, patients with amnestic disorder never forget their name, and their remote memory for the events of childhood and adolescence is typically normal unless there is brain damage in the lateral temporal or frontal lobes.

Some patients with dissociative amnesia have circumscribed retrograde memory loss that covers a particular time period or that covers only autobiographical memories. One patient was reported to be able to answer questions about past public events but not questions about past personal events. Another patient scored close to zero on a test of famous photographs, far worse than any patient with neurological amnesia would score, and was also unable to identify proper names, such as *Los Angeles* and *Pontiac*. The challenge for the clinician lies not in distinguishing dissociative amnesia from amnestic disorder, but in distinguishing dissociative amnesia from malingering. Indeed, the diagnosis of dissociative amnesia can be difficult to substantiate and may be met with skepticism by hospital staff. Often, the clinical picture remains unclear until the amnesia clears. In some cases dissociative amnesia has been observed to clear after a period of days, but in other cases it has persisted as a potentially permanent feature of the personality.

SUGGESTED CROSS-REFERENCES

Functional neuroanatomy is discussed in Section 1.2; delirium, dementia, and amnestic and other cognitive disorders is discussed in Chapter 10; dissociative amnesia is discussed in Section 18.1; broad issue of neuropsychological and intellectual assessment of cognitive functions is covered in Section 7.4, Section 7.5 and Section 7.6; false memory syndrome is discussed in Section 3.4.

3.5 BRAIN MODELS OF MIND

KARL H. PRIBRAM, M.D., FH.D.

For two centuries brain models of mind have fascinated scientist and the lay public alike. This intense interest began with Francis J. Gall's pioneering correlations between brain pathology and characteristic personality histories of patients. As with every major advance in understanding the mind-brain relationship, Gall's demonstrations became a popular fad in the form of reading bumps on the skull, *phrenology*. Today a similar fad is evident in the application of the findings regarding hemispheric specialization: educators and politicians alike recommend using the right brain more lest the human race fall forever into damnation.

Brain models of mind have shown a remarkable coherence over the nineteenth and twentieth centuries despite the often acrimonious emphasis on this or that phenomenon to the exclusion of a comprehensive analysis. Further, when carefully considered, each of the often opposing views captures important aspects of the issues and that reconciliation devolves on making distinctive definitions and reading the proposals in their original form with these definitions in mind.

One definition of mind was provided by Gilbert Ryle: Mind comes from minding, paying attention. In old English the word is *gemynd*, akin to *remind*, which was derived from terms that meant *to warn* and *to intend*. The Sanskrit word *mynas* means to think.

> As a whole, the human brain is critical to minding; one case history highlights the obvious. A 14-year-old-girl who had fallen out of a rapidly moving automobile had sustained a head injury with multiple scalp lacerations. Transporting her to a hospital several hundred miles away was thought to be too risky to an already traumatized head. Her head was swathed in bandages through which some blood had oozed, making them appear bright red; in contrast, the girl looked green. When addressed: “Hello Cathy, you look like a Christmas package all dolled up in your bandages,” the girl smiled and said, “Hello, doctor.” It was evident that this girl's brain was intact. She minded, and even had a sense of humor. A thorough examination revealed a broken rib with a puncture to one lung, thus her green color. Bandages and a brief time in an oxygen tent quickly allowed healing to commence.

The diagnosis rested on the truism that scrambled brains result in scrambled minds. However, because of its pervasive validity, this truism can blind us to the more subtle aspects of the mind-brain relationship. For instance, the close association of mind to brain might lead us to suspect uncritically that mind and brain are the same, which would be as absurd as stating that the islands of Langerhans of the pancreas are the same as insulin regulation of glucose metabolism. Minding is a function of the entire organism interacting with its environment (just as glucose metabolism is a function of the organism metabolizing environmentally derived nutrients). What is common to brain and mind is their organization, much as what is common to a computer's hardware and the various levels of programming software is the *in*formation (the form within) being processed.

Thus, although the special relation between brain and conscious experience is widely acknowledged, the subtleties inherent in the nature of the relation remain debatable. In this respect apparently no progress has been made in the past two millennia.

The time is ripe for an advance in understanding. Each of the philosophical stances toward the mind-brain relationship has merit as long as it is restricted to the database that defines the stance. The set of problems that characterize the special relation between brain and the variety of mental processes is closely related and the mind-brain analysis must be anchored in an ontological neutral monism. What is ontologically neutral to the material brain and mental (psychological) processes is *order*—order as measured scientifically in terms of energy, entropy, and information.

With respect to the special relation between brain and the variety of mental processes, this ontological neutrality is expressed by showing that conscious (and unconscious) processes are coordinate with identifiable brain processes occurring in identifiable brain systems, that is, at some level the descriptions of brain processes and descriptions of mental processes become homomorphic.

An example from computer science illustrates what is meant by *homomorphic:* the computer is used as a word processor when English words and sentences are typed into it. The word processing system, by virtue of an operating system converts the keyboard input to binary, which is the language of the computer. Nothing in the description of English and of binary machine language appears to be similar, yet by virtue of the various transformations produced in the encoding and decoding operations of the various stages leading from typescript to binary, the information in the typescript is preserved in the binary language of the operation of the computing machine.

In a similar fashion, little in conscious experience resembles the operations of the neural apparatus with which it has such a special relation. However, when the various transformations, the transfer functions, the codes that intervene between experience and neural operations are sufficiently detailed, a level of description is reached in which the *transformations* of experience are homomorphic with the language used by the brain. This language is the language of the operations of a microprocess taking place in synaptodendritic fields, a mathematical language similar to that which describes processes in microphysics that is, subatomic physics.

At this microprocessing level an identity describes the relation between brain and mental processes. At more remote processing levels, encompassing larger event structures (assemblers, operating systems, or their counterparts in brain systems), pluralism, and eventually, at the level of natural language, dualism characterizes the relationship. The special relation between brain and mental processes is thus not identical, except in implementation at the microprocessing level. At the neuronal and even at the neural system level several types of relationship with psychological processes can be discerned.

First, there are neurochemical states operating in the synaptodendritic processing web that determine states of consciousness. The very active field of psychoneuropharmacology is replete with evidence of relations between catechol and indole amines acting in specified brain locations to produce states of consciousness such as wakefulness and sleep, depression, and elation, and perhaps even dissociated states such as those seen in schizophrenia. The relations between relative concentrations of blood glucose and osmolarity and hunger and thirst; between sex hormones and sexually characteristic behaviors; and between peptides such as the endorphins and enkephalins and the experiences of pain and stress are all well documented.

Second, there are detailed descriptions of the relations between the sensory systems of the brain and the sensory aspects of perception: the contents of consciousness.

States of consciousness often determine contents and as often, are determined by them. When hungry one tends to notice restaurant signs; walking past the fresh aromas emanating from a bakery whets the appetite. This connection between states and the contents of consciousness is mediated by the process ordinarily called *attention* (the control of sensory input), by *intention* (the control of motor output), and *thought* (the control of remembering). The understanding of these processes of minding is critical to understanding the special relation between brain states and the contents of conscious experience.

VARIETIES OF BRAIN ORGANIZATION

Localization and Distribution of Function Some models of brain organization are crucial for determining the organization of minding. First is the issue of localization of function. Francis Gall brought this issue to the foreground by correlating different local brain pathologies to the histories of the cadavers he autopsied. Although often wrong in detail, he was correct in the methods he carefully detailed. He was naïve in delineating the faculties of mind for which he sought localization, but systematic classification of mental functions continues to be elusive despite a half-century of operational behaviorism. Today, it is popular to discuss the modularity of mind and component systems of the brain and relate them both in the clinic and in the laboratory by crafting experimental designs and behavioral and verbal testing procedures. The use of these techniques traces its heritage directly to Gall's enterprise.

The excesses of phrenology raised the question of which brain system brought the various faculties together into a conscious self. The unity of being, the soul of mankind, was challenged when mentation was subdivided into a mere collection of faculties. Furthermore, experimental evidence accrued to demonstrate a relation between impairments in complex behaviors and verbally reported experiences and the amount of brain tissue destroyed irrespective of location. In the recent past, Karl Lashley has been an exponent of this mass action view.

However, in a letter to Fred Mettler, Lashley once stated his exasperation at being misinterpreted: “Of course I know the front of the brain does something different from the back. The visual sensory input terminates in the occipital lobes. Electrical stimulations of the pre-Rolandic areas elicit movements and the front parts are more enigmatic in their functions. But this is not the issue.” Elsewhere he states the issue clearly: “. . . certain coordinated activities, known to be dependent upon definite cortical areas, can be carried out by any part (within undefined limits) of the whole area.”

What Lashley emphasized was that certain selected mental functions appeared to be related to brain processes that are distributed. For instance, he pointed out that sensory and motor equivalences could not be accounted for even by a duplication of brain pathways: “Once an associated reaction has been established (e.g., a positive reaction to a visual pattern), the same reaction will be elicited by the excitation of sensory cells which were never stimulated in that way during training. Similarly, motor acts (e.g., opening a latch box) once acquired, may be executed immediately with motor organs which were not associated with the act during training.”

The following is example of motor equivalence: a dog was conditioned to raise his right hind leg to the sound of a tone. After this conditioned response was well established, his right motor cortex (which controls the left side of the body) was exposed. Then during the performance of the conditioned reaction a patty of strychninized filter paper (which chemically excited the cortical tissue) was placed on the area that controls the left forepaw. Immediately the dog switched the responding leg: he now raised his left forepaw to the conditioned signal. A temporary dominant focus of excitation had been established in the cortex by the chemical stimulation. E. Roy John summarizes the experiments that demonstrate such shifts in cerebral dominant foci in Figure 3.5-1.

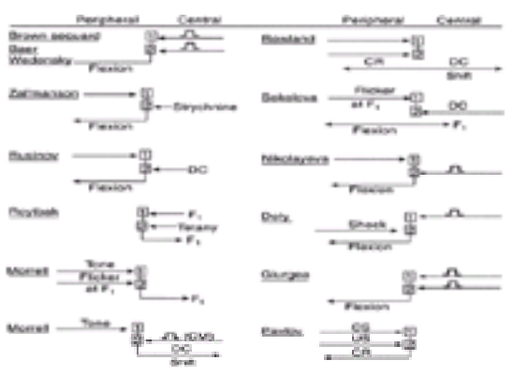

FIGURE 3.5-1 Methods of conditioning that have been used by various investigators to establish and produce shifts in cerebral dominant foci. The example in the text refers to Zal'manson's experiment. (Reprinted with permission from Pribram K: *Languages of the Brain: Experimental Paradoxes and Principles in Neuropsychology*. Random House, New York, 1971.)

The distributed aspect of brain function becomes most evident in memory storage. Even after large deletions of brain tissue such as those resulting from strokes or tumor resections, specific memories, *engrams*, are seldom lost. When amnesias do occur they are apt to be spotty and difficult to classify, which suggests that memory is stored in a distributed fashion. The storage process dismembers the input, which is then re-membered on occasions that necessitate recognition and recall. In contrast to storage, the retrieval processes are localized, at least within systems such as those that are sensory specific. When such systems are damaged, sensory-specific and even category-specific agnosias may result. Thus with regard to memory, both distributed and localized processes can be identified depending on which property of the process is being considered. This principle of analyzing a mental process to identify specific aspects will be useful in other contexts as well.

Systems in the Control of Attention and Intention Brain systems serve as controls on the processes intrinsic to minding in detail. William James noted that the delineation of minding, or consciousness, devolves on processes usually referred to as *attention* and *intention or volition*. Controls on attention determine the span of sensory processing, those on intention determine the span over which action becomes effective, and controls on thought determine the span of memories being considered.

Two decades of investigation into the neural processes involved in the control of attention discerned three such mechanisms: one deals with short phasic response to an input *(arousal)*, a second relates to prolonged tonic readiness of the organism to respond selectively *(activation)*, and a third *(effort)* acts to coordinate the phasic *(arousal)* and tonic *(activation)* processes. Separate neural and neurochemical systems are involved in the phasic (arousal) and tonic (activation) processes: the phasic process centers on the amygdala and the tonic process centers on the basal ganglia of the forebrain. The coordinating system (effort) critically involves the hippocampus, a phylogenetically ancient part of the neural apparatus.

Evidence from the analysis of changes in the electrical activity of the brain evoked by brief sensory stimulation has shown that the arousal and activation systems operate on a more basic process centered on the dorsal thalamus, the waystation of sensory input to the cerebral cortex. Brain electrical activity evoked by sensory stimulation can be analyzed into components. Early components reflect processing via systems that directly (via the thalamus) connect sensory surfaces with cortical surfaces. Later components reflect processes initiated in the thalamocortical and related basal ganglia systems that operate downward onto the brainstem (tectal region), which in turn influence a thalamic “gate” that modulates activity in the direct sensory pathways. It is the activity reflected in these later components of the brain electrical activity that constitutes activation. The thalamic gate is also regulated by input from the system centered on the amygdala—the arousal system. When stimulated, this system produces an effect on the “gate” opposite to that of the activation system.

Evidence also indicates that the coordination of phasic (arousal) and tonic (activation) attentional processes often demands effort. When attention must be paid, the hippocampal system becomes involved and influences the arousal system rostrally through frontal connections with the amygdala system and influences the activation system caudally via connections in the brainstem. At this juncture the relation of attention to intention, that is, to volition or will, comes into focus. Again, William James had already pointed out that a good deal of what is called voluntary effort is the maintaining of attention or the repeated returning of attention to a problem until it yields solution.

William James had apposed will to emotion and motivation (which he called *instinct*). Beginning with Walter Cannon's experimentally based critique of James, followed by Karl Lashley's critique of Cannon, to the anatomically based suggestions of James Papez and their more current versions by Paul MacLean, brain scientists have been deeply concerned with the processes that organize emotional and motivational experience and expression. Two major discoveries have placed the earlier more speculative accounts into better perspective. One such discovery has been of the role of the reticular formation of the brainstem and its chemical systems of brain amines that regulate states of alertness and mood. Donald Lindsley proposed an activation mechanism of emotion and motivation on the basis of the initial discovery and has more recently detailed the pathways by which such activation can exert control over brain processes. The other discovery is of the system of brain tracts that when electrically excited results in *reinforcement* (i.e., an increase in the probability of recurrence of the behavior that has produced the electrical brain stimulation) or *deterrence* (i.e., a decrease in the probability that such behavior will recur) by James Olds and Peter Milner.

To organize these discoveries and other data that relate brain mechanisms to emotion, it is necessary to distinguish clearly between data that refer to experience (feelings) and those that refer to expression, and further to distinguish emotion from motivation. Thus, feelings were found to encompass both emotional and motivational experience, emotional as affective and motivation as centered on a readiness processes. Not surprisingly, the affective process of emotion was found to be based on the process of arousal, the ability to make phasic responses to input that “stop” the motivational processes of activation that maintain selective readiness. Thus, feelings were found to be based on neurochemical states (predispositions or moods) that become organized by appetitive (motivation, “go”) and affective (emotional, “stop”) processes. Feelings of effort often are experienced as anxiety.

A wealth of new data had spawned these insights and made it fruitful to reexamine the Jamesian position with regard to his visceral theory of emotions. James is

almost universally misinterpreted as holding a peripheral theory of emotion and mind. Through his writings he emphasizes the effect that peripheral stimuli (including those of visceral origin) exert on brain processes. Nowhere, however, does he identify emotions with bodily processes; emotions are always the resultant effect on brain states. What James failed to take into account is the role of expectations (the representational role of the organization of familiarity and novelty) in the organization of emotions. It is these “neuronal models” of prior experience that were found to entail the functions of the hippocampus and of the basal ganglia, including the amygdala.

Nonetheless, James is explicit when he discusses the nature of the input to the brain from the viscera. He points out two possibilities: emotions are processed by a separate brain system or they are processed by the same systems as are perceptions. Both possibilities have been realized: parts of the frontolimbic forebrain (especially the amygdala and related systems) process visceroautonomic bodily inputs, and the results of processing become distributed via brainstem systems that diffusely influence the perceptual systems. Additionally, James clearly defines the difference between emotions and motivations (which he calls instincts): emotional processes take place primarily within the organism whereas motivations reach beyond into the organism's environment. James perhaps overemphasized the visceral determination of emotional experience, but he did occasionally include attitudinal factors as depending on sensory feedback from the somatic musculature.

The distinction between the brain mechanisms of motivation and will are less clearly enunciated by James. He grapples with the problem and establishes the questions that must be answered. These questions remained unanswered until the late 1960s when several theorists began to point out the difference between feedback, homeostatic processes on the one hand and programs, which are feedforward, homeorhetic processes, on the other. Feedback mechanisms depend on error processing and are therefore sensitive to perturbations; programs, unless completely stopped, run themselves off to completion irrespective of obstacles placed in their way.

Clinical neurology had classically distinguished the mechanisms involved in voluntary behavior from those involved in involuntary behavior. The distinction rests on the observation that lesions of the cerebellar hemispheres impair intentional (voluntary) behavior whereas basal ganglia lesions result in disturbances of involuntary movements. Damage to the cerebellar circuits are involved in a feedforward rather than a feedback mechanism. Recent microelectrode analyses suggest that the cerebellar hemispheres perform calculations in fast-time, (i.e., they extrapolate where a particular movement would end were it to be continued, and send the results of such a calculation to the cerebral motor cortex where they can be compared with the target to which the movement is directed). Experimental analysis of the functions of the motor cortex had shown that such targets are composed of “Images of Achievement” constructed in part on the basis of past experience.

Just as the cerebellar circuit has been shown to serve intentional behavior, the basal ganglia have been shown to be important to involuntary processes. These structures are also involved in the control of activation, the readiness of organisms to respond. Lesions in the basal ganglia grossly amplify tremors at rest and markedly restrict expressions of motivational feelings. Neurological theory has long held that these disturbances result from interference by the lesion of the normal feedback relationships between basal ganglia and cerebral cortex. Surgical removal of motor cortex has been performed on patients with basal ganglia lesions in order to redress the imbalance produced by the initial lesions; such resections have proved remarkably successful in alleviating the often distressing continuing disturbances of involuntary movement that characterize basal ganglia diseases.

Massively Parallel Distributed Processes Two closely related issues concerning the organization of brain function are often confounded: (1) localization versus distribution of function within each system and (2) whether processing proceeds among different localizable systems in a hierarchical fashion or whether processing proceeds in parallel and thus heterarchically.

The fact that a temporary dominant focus in the cerebral cortex can take control of the expression of a learned behavior indicates that hierarchical control operates in the central nervous system. Equally persuasive is the evidence for control over spinal cord activity by the brainstem and forebrain. Neuronal activity in the spinal cord displays an extremely high rate of spontaneous impulse generation. These generators are modulated by inhibitory local circuit neurons in such a way that the resultant activity can be modeled in terms of coupled ensembles of limit cycle oscillatory processes. In turn, these ensembles of oscillators become organized by brainstem systems that consist of cholinergic and adrenergic neurons. The cholinergic set regulates the frequency of a wide range of tonic rhythmic activities such as those involved in locomotion, respiration, cardiovascular responses, and sleep. This cholinergic system is coupled to an adrenergic set of neurons that segment the rhythmic activities into episodes. Both systems are subject to further hierarchical control by the dopaminergic system of the basal ganglia. Clinically, loss of this hierarchical control is expressed as an exaggeration of the normally present, almost subliminal tremors that under extreme conditions lead to spastic paralysis, hyperreflexia, and uncontrollable fits of oscillatory muscular spasm.

However, the evidence from the experiments that demonstrated temporary dominant foci can be viewed from the perspective: that the flexibility demonstrated by the shift from one controlling locus to another shows the organization of the cortical system to be heterarchial. Any locus within the system can become dominant if sufficiently excited. The following story, attributed to Warren McCulloch, illustrates the nature of heterarchial organization:

> After the battle of Jutland in which the British Navy took a beating, both the British and American navies reorganized to change from hierarchical to heterarchical control. Thus, battleships no longer had to await orders from a central command source to engage in defensive maneuvers. During World War II the Fifth Fleet was stationed in an only slightly dispersed mode of operation somewhere in the Pacific Ocean when it was attacked from two directions by separate air squadrons. Sightings of the attackers were made from different locations in the fleet by observers on the ships closest to one or the other of the attacking planes. The sailor who made the sighting became a dominant focus and his ship and those in his proximity took off to defend against the attackers. However, because the attack came from two different directions, two dominant foci were created, each commanding parts of the fleet to steam away in different directions. This left the ship at the center of the fleet that housed its admiral haplessly unprotected and, since no sightings were made by his ship, at a momentary loss as to what to do. Fortunately, both attacking squadrons were defeated and turned back without any damage accruing to the Fifth Fleet.

There is thus a possible penalty to be paid for the flexibility achieved by temporary dominance over processing as any person who has ever been of two minds knows well.

Ordinarily hierarchical control is conceived of as a serial process. This is because when control is direct, there is a causal connection between the controller and the controlled. Causality implies that the origination of the control signal precedes its effect on the system being controlled. Seriality remains when there are feedback loops. However, when feedforward operations are inserted into the process, seriality is no longer as clearcut. For example, lower the temperature or blood sugar on a thermostat or homeostat and the sensor responds, closes a circuit, and the effector responds; this is a serial process. Now place a control dial or other bias on the process and there are two or more ways for the sensor to become adjusted. The temperature falls, but because the heating bill was too high last month the dial is reset and warmer clothes are worn. There are parallel inputs to the sensor. Herman von Helmholtz is credited with pointing out that voluntary processes such as those by which we move our eyes are constituted of such parallel feedforward corollary discharges to the effectors. Control can be hierarchical yet dependent on a parallel process.

Processing in the cerebral cortex is massively parallel. Simulations of these parallel cortical processes have since the late 1980s become implemented on personal computers to such an extent that the endeavors have been dubbed a cottage industry. These simulations of neural networks are capable of pattern recognition, of language learning, and of decision-making that is remarkably true to life. Single-layered simulations have given way to three-layered computations that involve an input layer, an output layer, and a hidden layer. All the elements of the network are interconnected to one another. In several such simulations the input is fed forward through the net and the output is compared with one that is desired; the difference between the actual and the desired is fed back to the net. The process is repeated until the desired output is achieved. Variations on this theme abound, each variation being better adapted than its alternates for a particular purpose.

One of the most fascinating attributes of these neural networks is that the information contained in the input becomes fragmented and distributed in the elements of the layers. The simulations are therefore said to be massively *parallel distributed processes* (PDP), which makes them akin to optical information processing systems such as holography and tomography from which they were in fact derived.

Cerebral Dominance and the Unity of Consciousness Surrounding the major fissures of the primate cerebral cortex lie the terminations of the sensory and motor projection systems. These systems have been termed *extrinsic* because of their close ties by way of a few synapses with peripheral structures. The sensory surface and muscle arrangements are mapped more or less isomorphically onto the perifissural cortical surface by way of discrete, practically parallel lines of connecting fiber tracts. When a local injury occurs within these systems a sensory scotoma, or a scotoma of action, ensues. A *scotoma* is a spatially circumscribed hole in the field of interaction of organism and environment: a blind spot, a hearing defect limited to a frequency range, a location of the skin where tactile stimuli fail to be responded to. These are the systems where what Henry Head called *epicritic processing* takes place. These extrinsic sensory-motor projection systems are organized such that movement allows the organism to project the results of processing away from the sensory and muscular surfaces where the interactions take place, out into the world

external to the organism. Thus, processing within these extrinsic systems constructs an objective reality for the organism.

Between the perifissural extrinsic regions of cortex lie other regions of cortex variously named *association cortex, uncommitted cortex*, or *intrinsic cortex*. These names reflect the fact that there are few, if any, direct connections between peripheral structures and these regions of cortex that make up most of the convexity of the cerebrum. Thus, on the brain's convexity a three-tiered arrangement for these systems can be discerned. Each ajor sensory apparatus has a fairly direct input to areas in the cortex. Immediately surrounding these areas are others, which when electrically stimulated originate movements of the musculature associated with each of the sense organs (e.g., eye muscles for vision, ear muscles for hearing, and body muscles for somatic sensations). These areas are extrinsically connected to organs in the periphery of the body and therefore provide perspectives relating the body to the world beyond.

Surrounding these extrinsic areas are sensory-specific areas that are primarily connected intrinsically to other brain structures. These areas provide perspectives that are intrinsic to the entities perceived, perspectives such as those provided by color and object constancy. Finally, other areas operate on inputs from a variety of senses and relate their perspectives to each other. All these areas and the brain systems that they represent are involved in organizing phenomenal perceptions or the sensory-driven aspects of perception. Another set of systems, more noumenal in their function, are located frontally and on the limbic medial border of the brain's hemispheres.

Three important discoveries have fueled the current interest in hemispheric lateralization. One of these was actually a rediscovery during the latter half of the nineteenth century of the fact that the speech of most righthanded individuals is usually controlled by the left hemisphere. Hippocrates already knew this and may well have learned it from the Egyptians. Running from back to front, comprehension, grammar, and fluency (*semantics, syntactics*, and *pragmatics*) are affected by lesions centering on the sylvian fissure. However, dominance is not as complete in females as it is in males, nor is it as pervasive in cultures that do not use phonemic writing. It is now known that the non–speech-dominant hemisphere has its own characteristic modes of processing. With the left hemispheres of right-handed persons being taken over by an aural-oral dimension, the right hemisphere is left free to process visual-spatial relations.

A third and most pervasive and persistent focus of interest has been that of the unity of consciousness. When the corpus callosum was severed in patients who had suffered severe unilateral epileptic seizures in order to prevent involvement of the healthy hemisphere, testing revealed that what was sensed by the right hemisphere could only be expressed nonverbally by that hemisphere. The left verbal hemisphere appeared to be ignorant of what had transpired. It seemed as if consciousness had been split when the hemispheres were sundered. The assumption that there is ordinarily a unity to consciousness was bolstered precisely because this unity had been ruptured.

Taken together with the facts of hemispheric specialization and the “dominance” of the left hemisphere for language, these observations were broadened to the conception that human civilization suffered from left brain dominance and that training for greater brain balance would restore balance to civilization. However, innumerable studies have demonstrated that all but the most rudimentary processing involves both hemispheres. Even in language, the appreciation and expression of emotional communication involves the right hemisphere, and extreme specialization is limited to right-handed males raised in a phonemic literary environment.

Although the popular overgeneralization about hemispheric lateralization is to be deplored there was renewed interest in the question of whether consciousness could be divided. Sir John Eccles argued that consciousness is tied to language, an argument also made by Freud, and that therefore the right, speechless, hemisphere was to all intents and purposes essentially unconscious. However, the right hemisphere clearly communicated with left-handed, nonverbal instrumental responses that it had processed the input presented to it: the nonverbal hemisphere obviously had a mind of its own. Conscious minding is of two sorts: *instrumental* and *intentional*; thus, Eccles' proposal is tenable if what is meant is intentional consciousness. Brain facts as they relate to behavior, mind, and consciousness often spring surprises on the unwary.

VARIETIES OF CONSCIOUS EXPERIENCE

Cerebral Cortex and Reflective Consciousness The distinction between the systems that control intentional behavior and those that control involuntary behavior extends to the control of sensory input and the processing of memory. With regard to sensory input, the distinction between the contents of awareness and the person who is aware was delineated by Franz Brentano and called *intentional inexistence*. This dualism of a minding self and objective matter (e.g., brain) was already present in the writings of René Descartes. Although Cartesian dualism is perhaps the first overt nontrivial expression of the issue, the duality between subject and object and some causal connection between them is inherent in language once it emerges from simple naming to predication. John von Neumann and Julian Jaynes have suggested that a change in consciousness (i.e., in distinguishing an aware self from what the self is aware of) occurs somewhere during the eighth century BC between the time of the Iliad and the Odyssey, which links it to the invention and promulgation of phonemically based writing. Prehistory was transmitted orally and aurally; written history is visual and verbal. In an oral and aural culture a greater share of reality is carried in memory and is thus personal; once writing becomes a ready means of recording events, they become a part of extrapersonal objective reality. The shift described is especially manifest in a clearer externalization of the sources of conscience—the gods no longer speak personally to guide individual man.

This process of ever-clearer distinctions between personal and extrapersonal objective realities culminates in Brentano's intentional inexistence, which was shortened by Edmund Husserl to “intentionality.” It is this reading of the subject-object distinction that philosophers ordinarily mean when they speak of the difference between conscious and unconscious processes.

A few years ago during a seminar, the author noted that the left arm of a graduate student was moving somewhat awkwardly while arranging papers on a table in front of us. The author asked the student, Ms. C., if she was alright, while pointing to her left arm. She replied, “Oh, that's just Alice; she doesn't live here anymore.” At the end of the semester, Ms. C. presented a detailed account of her experiences with Alice.

Ms. C. experienced devastations to her locational *integrity*. Other patients, after injuries to their occipital lobes, demonstrate “blindsight,” the ability to visually identify objects in the “blind” field despite the fact that they fail to be consciously aware of these objects. Patients such as those who are blindsighted and Ms. C. who might be considered to have a tactile and kinesthetic blindsight both have damage to the cortex of the posterior convexity of their brains. Thus, they suffer disruption of their egocentric (essentially tactile and kinesthetic) and allocentric (essentially visual and auditory) organization. This is a disruption of “objective” awareness because it relates patients to their impairment as if it were a relationship among objects. The relationship is “intentional” in Brentano's sense of an ability to differentiate the perceiver from the perceived. Note also that the narrative abilities of such patients do not suffer.

In contrast is the case of a boy who was *unable* to recount his experiences. Thus, the case histories present two distinct modes of coping that are disrupted by injury to distinctly different brain systems: one articulates the organism in egocentric space and locates it allocentrically in its environment; the other evaluates and monitors experience.

According to Ms. C.:

I was doing laundry about midmorning when I had a migraine. I felt a sharp pain in my left temple and my left arm felt funny. I finished my laundry towards mid-afternoon and called my neurologist. He told me to go to the emergency room. I packed a few things and drove about 85 miles to the hospital where he is on staff (the nearest was 15 minutes away). In the E.R. the same thing happened again. And again, the next morning after I was hospitalized, only it was worse. The diagnosis of a stroke came as a complete surprise to me because I felt fine, and I didn't notice anything different about myself. I remember having no emotional response to the news. I felt annoyed and more concerned about getting home, because I was in the process of moving.

Not until several days later while I was in rehabilitation did I notice strange things happening to me. I was not frightened, angry, or annoyed. I didn't feel anything—nothing at all. Fourteen days after I was admitted to the hospital, I became extremely dizzy, and I felt I was falling out of my wheelchair. The floor was tilting to my left and the wheelchair was sliding off the floor. Any stimulus on my left side or repetitive movement with my left arm caused a disturbance in my relationship with my environment. For instance, the room would tilt down to the left, and I felt my wheelchair sliding downhill off the floor, and I was falling out of my chair. I would become disoriented, could hardly speak, and my whole being seemed to enter a new dimension. When my left side was placed next to a wall or away from any stimuli, this disturbance would gradually disappear. During this period, my left hand would contract, and the arm would draw up next to my body. It didn't feel or look like it belonged to me. Harrison moved the left arm repeatedly with the same movement, and a similar behavior occurred, except I started crying. He asked me what was I feeling, and I said anger. In another test he started giving me a hard time until the same episode began to occur, and I began to cry. He asked me what I was feeling, and I said anger. Actually I didn't feel the anger inside but in my head when I began to cry. Not until I went back to school did I become aware of having no internal physical feelings.

I call that arm *Alice* (Alice doesn't live here anymore)—the arm I don't like. It doesn't look like my arm and doesn't feel like my arm. I think it's ugly, and I wish it would go away. Whenever things go wrong, I'll slap it and say, “Bad Alice” or “It's Alice's fault.” I never know what it's doing or where it is in space unless I am looking at it. I can use it, but I never do consciously because I'm unaware of having a left arm. I don't neglect my left side, just Alice. Whatever it does, it does on its own, and most of the time, I don't know it's doing it. I'll be doing homework and then I'll take a sip of coffee. The cup will be empty. I was drinking coffee with that hand and didn't know it. Yet I take classical guitar lessons. I don't feel the strings or frets. I don't know where my fingers are nor what they are doing, but still I play.

How do I live with an illness I'm not aware of having? How do I function when I'm not aware that I have deficits? How do I stay safe when I'm not aware of being in danger?

Ms. C. is an obviously intelligent, widowed woman in her mid-50s enrolled in adult education classes and majoring in clinical psychology. She gets around splendidly despite “Alice” and despite a history of a temporary left hemiparesis. The diagnosis was damage of the right temporal-parietal cortex confirmed by an abnormal EEG recorded from that location. The damage was not sufficiently extensive to show up in a PET scan.

Contrast Mrs. C.'s story with the following observations made on an 8-year-old boy:

T.J. had an agenesis of the corpus callosum with a midline cyst at birth. During the first 6 months of his life, two surgical procedures were carried out to drain the cyst. Recently performed magnetic resonance imaging showed considerable enlargement of the frontal horns of the lateral ventricle, somewhat more pronounced on the right. The orbital part of the frontal lobes appeared shrunken as did the medial surface of the temporal pole.

T.J. appears to have no ability to quantify the passage of time and no experiential appreciation of the meaning of time units. For example, a few minutes after tutoring begins, he cannot say, even remotely, how long it has been since the session started. He is as apt to answer this question in years as in minutes. He does always use one of seven terms of time quantification (seconds, minutes, hours, days, weeks, months, or years) when asked to estimate the duration of an episode but uses them randomly. He can put these terms in order, but does not have any sense of their meaning or their numerical relationships to one another.

When T.J. returned from a trip to the Bahamas he did recall that he had been on the trip; however, the details he could recount about the trip numbered fewer than five. His estimates of how long it had been since his trip were typical in that they were inaccurate and wildly inconsistent on repeated trials. Also, on the first five tutoring sessions since his return he stated that he had not been tutored since his trip. He seems unable to place in sequence those few past events that he can recall. Nonetheless, he can answer questions correctly based on his application of general knowledge about development (e.g., he knows he was a baby before he could talk because “everyone starts as a baby”). However, one day he asked his tutor if he knew him when he was a kid, indicating his incomprehension of the duration of each of these developmental periods and his unawareness of what events constituted such a period for him.

T.J. is aware that he has a past, that events have happened to him but he cannot recollect those events. He also spontaneously speaks of events in his future such as driving an automobile and dating and growing a beard. He has playacted on separate occasions his own old age and death. He is capable of excitement about the immediate future. On the very day that he was going to the Bahamas he was very excited as he exclaimed repeatedly: “I'm going to the Bahamas.” But when his tutor asked him when, he said blankly: “I don't know.” He also displayed keen anticipation when he saw a helicopter preparing to take off from the hospital. The helicopter engines revved approximately 13 minutes before it took off and T.J. became increasingly more vocal and motorically active, laughing as he repeated “When's it going to take off?” He also anticipates future punishment when he is “bad.” He is aware, on some level of the immediate future in his constant question “What's next?” which he asks his mother at the end of each activity.

There are a variety of other occasions on which he demonstrated this capacity regarding tempo (as opposed to evaluating the duration of an experience). There have been several breaks in his usual thrice-weekly tutoring schedule. Each of four times this schedule has been interrupted, he has run to meet his tutor when he approached rather than waiting inside as he usually does. Also, on these occasions he has typically asked if his tutor missed him. However, he states he does not know how long it has been since his last session, and there is no evidence that he knew it had been longer than usual.

T.J. can compare who walks faster or who draws faster. He has a basic sense of sequencing as when he says “I'll take a turn and then you take a turn.” He also uses terms like “soon” and “quick” correctly in conversation. For example, when he wanted to do a drawing at the beginning of a session, and his tutor said that they needed begin to work, T.J. countered with “This will be quick.” Unsurprisingly, he finished his drawing at his normal pace. He somehow seems to use such terms correctly without any experiential appreciation of them.

These two case histories illuminate two very important dimensions of self. One dimension, portrayed by Mrs. C., *locates* an objective “me” in the world and with respect to the configural integrity of the body. The other dimension, highlighted by T.J. *monitors* an individual's experience. Without such monitoring, the events comprising the experience fail to be relevant and are not evaluated with respect to an autobiographical self, a narrative “I.” Kempen and van Loon have provided an excellent history of differentiating an objective “me” from a hermauentic “I.”

Location is akin to but more primitive than a spatial dimension; monitoring is akin to but more basic than a temporal dimension. However, the locational dimension includes clock time, what the Greeks called *chronos* and Albert Einstein among others related to space. A moving organism is always located in space-time. Monitoring entails not only the experiencing of duration but also the decisive moment; what the Greeks referred to as *kairos*. The dictionary defines *monitor* as a device to record or control a process; to check for significant content.

Unconscious Processing Freud had training both in medical practice and in philosophy. When he emphasized the importance of unconscious processes, was he implying the medical definition or the philosophical one? Most interpretations of Freud suggest that unconscious processes operate without one's awareness in the sense that they operate automatically much as do respiratory and gastrointestinal processes in someone who is stuporous or comatose. Freud himself seems to have promulgated this view by suggesting a horizontal split between conscious, preconscious, and unconscious processes with repression operating to push memory-motive structures into deeper layers where they no longer access awareness. Still in his “Project for a Scientific Psychology” memory-motive structures are neural programs that are located in the core portions of the brain that access awareness by their connections to cortex, which determine whether a memory-motivated wish comes to consciousness. When the neural program becomes a secondary process it comes under voluntary control, which involves reality testing and thus consciousness. To use language as an example, it is possible to know two languages but at any one time connect only one to cortex and thus the other remains

unconscious and voluntarily unexpressed.

The thrust of most recent psychoanalytical thinking as well as that of experimentalists such as Jack Hilgard is in the direction of interpreting the distinction between the conscious and unconscious in the philosophical sense. For instance, Matte Blanco proposes that consciousness be defined by the ability to make clear distinctions, to identify alternatives. Making clear distinctions would include being able to tell personal from extrapersonal reality. In contrast unconscious processes would, according to Matte Blanco, be composed of infinite sets “where paradox reigns and opposites merge into sameness.” When infinities are being computed, the ordinary rules of logic do not hold. Thus, dividing a line of infinite length results in two lines of infinite length, that is one equals two. Being deeply involved allows love and ecstasy but also suffering and anger to occur. In keeping with this, Carl Jung defined unconscious processes as those that involve feelings.

Bringing the wellsprings of behavior and experience to consciousness means making distinctions, providing alternatives, making choices, becoming informed in Claude Shannon's sense of reduction of uncertainty (Shannon noted that every binary decision reduced uncertainty by half; thus, each such decision provided one bit of information). Clarity regarding the details of how such distinctions are achieved did not come until the late 1960s when several theorists began to point out the difference between feedback, homeostatic processes on the one hand, and programs, which are feedforward, homeorhetic processes, on the other. Feedback mechanisms depend on error processing and are therefore sensitive to perturbations. Programs, unless completely stopped, run themselves off to completion irrespective of obstacles placed in their way. The difference between feedback and feed-forward processing turns out to be the same as the difference Freud drew between primary and secondary processes.

However, unconscious processes as defined by psychoanalysis are not completely “submerged” and unavailable to experience. Rather, unconscious processes produce feelings that are difficult to localize in time or in space and difficult to identify correctly. Unconscious processes construct the emotional dispositions and motivational context within which extrapersonal and personal realities are constructed. As research has shown, feelings are to a large extent undifferentiated, and are recognized and labeled according to the circumstances in which they become manifested.

It is in this sense that behavior is under the control of the unconscious processes. During angry outbursts, individuals are certainly aware of having lost their temper and of the effects of their anger on others. Despite this awareness, the anger may be uncontrolled. Only when the events leading to the anger become clearly separated into alternative or harmoniously related distinctions is the unconscious control converted into conscious control. A person with an obsession or compulsion is not unaware, in the instrumental sense, of his or her experience or behavior. The patient is very aware of it and feels awful; however, without help, he or she cannot differentiate between controls on the behavior generated by feelings.

Consequential Processing As is well known, frontal lesions were produced surgically in order to relieve intractable suffering, compulsions, obsessions, and endogenous depressions. When effective in relieving pain and depression, these psychosurgical procedures established the functional relation between frontal intrinsic cortex and the limbic forebrain in nonhuman primates. Further, frontal lesions can lead either to perseverative, compulsive behavior or to distractibility in monkeys and humans. A failure to be guided by the outcomes, that is, the consequences of behavior, can account for this effect; the opposite—the alleviation of obsessive-compulsive behavior—can also occur. Extreme forms of distractibility and obsession are caused by a lack of sensitivity of the activation (readiness) process to feedback from consequences. The results of experiments with monkeys as well as clinical observations attest to the fact that subjects with frontal lesions, whether surgical, traumatic, or neoplastic, fail to be guided by consequences.

Consequences are the outcomes of behavior. In the tradition of the experimental analysis of behavior, consequences are reinforcers that influence the recurrence of the behavior. Consequences are thus a series of events (Latin *ex-venire*, meaning *outcome*), outcomes that guide action and thereby attain predictive value (as determined by confidence estimates).

Confidence implies familiarity. Experiments on humans have shown that repeated arousal to an orienting stimulus results in habituation, that is, the orienting reaction gives way to familiarization. Familiarization is disrupted by limbic (amygdala) and frontal lesions. Ordinarily, familiarization allows continued activation of readiness; disruption of familiarization (orienting) leads to repeated distraction and thus a failure to allow consequences to form. When the process of familiarization is disrupted, the outcomes of behavior become inconsequential. When the process of familiarization is intact, it is segmented by orienting reactions into episodes within which confidence values can become established.

In such an episodic process the development of confidence is a function of coherences and correlations among the events being processed. When coherence and correlation span multiple episodes, the organism becomes committed to a course of action (a prior intention, a strategy), which then guides further action and is resistant to perturbation by particular orienting reactions (arousals). The organism is now competent to carry out the action; particular outcomes only *guide* competent performance, they no longer *produce* orienting reactions.

This cascade, which characterizes episodic processing, leads ultimately to considerable autonomy of the committed competence. Envisioned events are woven into coherent subjectivity, a story, a narrative, the myth by which the “I” lives. This narrative composes and is composed of an intention, a strategy that works for the individual in practice, a practical guide to action in achieving (temporary) stability in the face of a staggering range of options.

Consciousness is manifest (by verbal report) when familiarization is perturbed and an episode is updated and incorporated into a larger contextual scheme (the narrative) that includes both the familiar and novel episodes. Consciousness becomes attenuated when actions and their guides cohere—actions become skilled, graceful, and automatic.

Transcendental Consciousness The contents of consciousness are not exhaustively described by feelings of familiarity and novelty that are the basis for episodic and narrative consciousness, nor by those of extracorporeal allocentric and corporeal egocentric consciousness. The esoteric tradition in Western culture and the mystical traditions of the Far East are replete with instances of uncommon states that produce uncommon contents. These states are achieved by a variety of techniques such as meditation, yoga, or Zen. The contents of processing in such states appear to differ from ordinary feelings or perceptions. Experiences are described as *oceanic*, a merging of corporeal and extracorporeal reality or as *out-of-body*—that is, corporeal and extracorporeal realities continue to be clearly distinguished but are experienced by still another reality: a *meta-me* alternatively, the “I” becomes transparent, a throughput experiencing everything everywhere; there is no longer any segmentation into episodes nor do events become enmeshed in a narrative structure.

All these experiences have in common a transcendental relationship between ordinary experience and some more encompassing organizing principle. This relationship is ordinarily termed “spiritual.” The spiritual contents of consciousness can be accounted for by the effect of excitation of the frontolimbic forebrain (involved in narrative construction) on the dendritic microprocess that characterizes cortical receptive fields in the sensory extrinsic systems (involved in the construction of objective reality).

In addition to the gross topological correspondence between cortical receptive fields and the organization of sensory surfaces that gives rise to the overall characteristics of processing in the extrinsic systems, a microprocess that depends on the internal organization of each receptive field comes into play. This internal organization of receptive fields embodies, among other characteristics, a spectral domain: receptive fields of neurons in the extrinsic cortex are tuned to limited bandwidths of frequencies of radiant energy (vision), sound, and tactile vibration.

The most dramatic of these data are those that pertain to vision. The cortical neurons of the visual system are arranged, as are the other sensory systems, so as to reflect more or less isomorphically the arrangement of the receptor surfaces to which they are connected. Thus, the homunculi that Wilder Penfield and others have mapped onto the cortical surface of the extrinsic projection systems. However, within this gross arrangement lie the receptive fields of each of the neurons—a receptive field being determined by the dendritic arborization of that neuron that makes contact with the more peripheral parts of the system. Thus, the receptive field of a neuron is that part of the environment that is processed by the parts of the system to which the neuron is connected. Each receptive field is sensitive to approximately an octave of spatial frequency. This frequency-selective microprocess operates in a holographiclike manner.

Processing can thus be conceived to operate somewhat like the production of music by means of a piano; the sensory surface is analogous to a keyboard. Keyboard and strings are spatially related to provide the organization of the process. When individual strings are activated they resonate over a limited bandwidth of frequency. It is the combination of the spatial arrangement and the frequency-specific resonance of the strings that makes the production of music possible.

The gross and microorganization of the cortical neurons in the extrinsic systems resembles the organization of a multiplex hologram. A multiplex hologram is characterized by a Gabor elementary function, which Dennis Gabor called a *quantum of information*. A Gaussian envelope constrains the otherwise unlimited sinusoid described by the Fourier transform to make up the Gabor function. Experiments have shown that electrical excitation of frontal and limbic structures relaxes the

Gaussian constraints that are manifested as inhibitory surround or flanks in the receptive field architecture. When this occurs during ordinary excitation of the frontolimbic systems of the forebrain, processing leads to narrative construction. When frontolimbic excitation becomes overwhelming, experience is determined by an unconstrained holographic process.

Holograms of the type involved in brain processing are composed by converting (e.g., via Fourier transformation) successive sensory images (e.g., frames of a movie film) into their spectral representations and patching these microrepresentations into orderly spatial arrangements that represent the original temporal order of successive images. When such conversions are linear (e.g., when they employ the Fourier transform) they can readily be reconverted (e.g., by the inverse Fourier transform) into moving (i.e., successive) sensory images. The spectral domain is peculiar in that information (in the Gabor sense) becomes both distributed over the extent of each receptive field or quantum and enfolded within it. Thus sensory-image reconstruction can occur from any part of the total aggregate of receptive fields. This is what gives the aggregate its holographic, holistic aspect. All input becomes distributed and enfolded, including the dimensions of space and time and, therefore, of causality. It is this apparently timeless-spaceless-causeless aspect of processing instigated by overwhelming frontolimbic excitation that is responsible for the extrasensory dimensions of experience that characterize the esoteric traditions. Because of their enfolded property these processes tend to swamp distinctions, such as between corporeal and extracorporeal reality. In the esoteric traditions, consciousness is not limited to this type of reality.

An intriguing and related development (because it deals with the specification of a more encompassing, “cosmic” order) has occurred in quantum physics. Over the past 50 years it has become clear that there is a limit to the accuracy with which certain measurements can be made; this limit is expressed as an indeterminacy. In his description of a quantum of information, Gabor showed that a similar indeterminacy describes communication; leads to a unit of minimum uncertainty, the maximum amount of information that can be packed for processing. Thus, there is a convergence of the understanding of the microstructure of communication—and therefore of observation—and the microstructure of matter. The need to specify the observations that lead to inferring the properties of matter has led noted physicists to write representations of the observer into descriptions of the observable. Some physicists have noted the similarity of this specification to the esoteric descriptions of consciousness.

The scientific and esoteric traditions have been clearly at odds since the time of Galileo. Each new scientific discovery and the theory developed from it has thus far resulted in the widening of the rift between objective science and the subjective spiritual aspects of man's nature. The rift reached a maximum toward the end of the nineteenth century: mankind was asked to choose between God and Charles Darwin; Freud showed that heaven and hell resided within people and not in their relationship to the natural universe. However, the discoveries of twentieth-century science do not fit this mold. For once, the recent findings of science and the spiritual experiences of mankind are consonant. This augurs well for the upcoming new millennium because a science that comes to terms with the spiritual nature of mankind may well outstrip the technological science of the immediate past in its contribution to human welfare.

3.6 EMOTIONAL INTELLIGENCE

DANIEL GOLEMAN, PH.D.

To be *emotionally intelligent* is to have the personal skills that characterize a rich and balanced personality. Emotional intelligence includes, as Aristotle put it, the rare ability “to be angry with the right person, to the right degree, at the right time, for the right purpose, and in the right way.” Emotional intelligence is distinct from intelligence quotient (I.Q.), which is the ability to perform cognitive tasks adeptly; each of these kinds of intelligence is based in differing but interlinked neural circuitry, with emotional intelligence largely mediated by limbic and prefrontal areas and I.Q. by neocortical zones alone. Emotional intelligence and I.Q. are not opposing competencies, but discrete and synergistic ones.

The theory of emotional intelligence offers a new psychological framework for primary prevention in psychiatry that integrates recent discoveries in cognitive science, neurological science, and child development. The competencies of emotional intelligence are crucial for the self-management of emotion and for the skillful handling of relationships. These abilities are learned throughout life, with primary learning occurring during childhood. Such learning shapes the underlying neurological circuitry, which continues to mature into adolescence. Emotional intelligence can be enhanced through the systematic offering of beneficial learning experiences as children grow, and deficits can be repaired through remedial learning and coaching.

Those who fail to master the competencies of emotional intelligence face a spectrum of heightened psychiatric risks, such as mood and anxiety disorders, eating disorders, and substance abuse. Because these skills of emotional intelligence are teachable, offering children and adolescents opportunities to strengthen these competencies can act as an inoculation against a spectrum of social and psychiatric risks.

COMPONENTS OF EMOTIONAL INTELLIGENCE

One commonly used version of Peter Salovey and John Mayer's 1990 definition of emotional intelligence includes abilities in five main areas:

1. *Self-awareness:* Recognizing one's feelings as they occur is the linchpin of emotional intelligence. The ability to monitor feelings from moment to moment is key to psychological insight and self-understanding. Being aware of one's emotions makes one more confident when making important personal decisions such as whom to marry or what career path to follow.
2. *Managing emotions:* Having appropriate emotional reactions is a capacity that builds on self-awareness. The ability to modulate negative affects such as anxiety, anger, and depression is a crucial emotional skill. Emotional resilience helps one to prevail over life's inevitable setbacks and upsets; those who lack emotional self-regulation are continually besieged by feelings of distress.
3. *Motivating oneself:* Being able to focus on a goal is essential for a range of accomplishments. Emotional self-control—such as delaying gratification or controlling impulsivity—is crucial in working towards such life goals. Individuals who can harness their emotions, and maintain hope and optimism despite frustrations, are generally more productive and effective in their undertakings.
4. *Recognizing emotions in others:* Empathy, another skill based in emotional self-awareness, is fundamental to interpersonal effectiveness. Those who are well attuned to subtle social cues that indicate what others feel are more successful in personal and professional relations.
5. *Handling relationships:* The art of relationships requires skill in managing others' emotions. Social competence underlies popularity, leadership, and interpersonal effectiveness.

Individuals have a profile of differing abilities in each of these areas; for instance, someone masterful at managing anger may be inept at soothing someone else's upsets. Neurological givens determine initial capacities within each domain of emotional intelligence. Each individual has underlying neurological setpoints that determine temperament—for example, the ability to control emotional impulse, shyness, or irritability. Although the underlying basis for emotional competence is neural, the brain circuitry involved is malleable. To a great extent, each of the five domains represents sets of habit and response that are learned, and so can be improved with appropriate effort.

Using a related measure, Jack Block found that the hallmarks of emotional intelligence are self-assurance, optimism, and social poise. Emotionally intelligent individuals have superior self-control and ability to motivate themselves. Life is meaningful for them; they are principled and responsible. They manage and express emotions appropriately, being assertive but sympathetic and caring in relationships. Their emotional life is rich but balanced; they are comfortable with themselves, others, and the social universe they live in. They manage stress without undue worry or rumination. They tend to be gregarious, spontaneous, playful, and open to sensual experience.

WHAT IS EMOTION?

The root of the word emotion is *motere*, the Latin verb “to move,” plus the prefix “e-” to connote “move away,” suggesting that a tendency to act is implicit in every emotion. *Emotion* refers to a feeling and its attendant thoughts, psychological and biological states, and range of impulses to act. The Oxford English Dictionary defines emotion as “any agitation or disturbance of mind, feeling, passion; any vehement or excited mental state.”

There is a long-standing debate about which emotions should be considered primary—the blue, red, and yellow of feeling from which myriad blends come—or if there are primary emotions at all. The argument for a set of core emotions is based to some extent on studies that suggest there are universally recognized facial expressions for four emotions: fear, anger, sadness, and enjoyment. The universality of facial expressions of emotion was probably first noted by Darwin, who saw it as evidence that these signals have been stamped by evolution into the central nervous system. According to some theorists the following families of emotion are universal:

Anger: fury, outrage, resentment, wrath, exasperation, indignation, vexation, acrimony, animosity, annoyance, irritability, hostility, and, perhaps at the extreme, pathological hatred and violence

Sadness: grief, sorrow, cheerlessness, gloom, melancholy, self-pity, loneliness, dejection, despair, and, when pathological, severe depression

Fear: anxiety, apprehension, nervousness, concern, consternation, misgiving, wariness, qualm, edginess, dread, fright, terror; as a psychopathology, phobia and panic

Enjoyment: happiness, joy, relief, contentment, bliss, delight, amusement, pride, sensual pleasure, thrill, rapture, gratification, satisfaction, euphoria, whimsy, ecstasy, and at the far edge, mania

Love: acceptance, friendliness, trust, kindness, affinity, devotion, adoration, infatuation, agape

Surprise: shock, astonishment, amazement, wonder

Disgust: contempt, disdain, scorn, abhorrence, aversion, distaste, revulsion

Shame: guilt, embarrassment, chagrin, remorse, humiliation, regret, mortification, and contrition

Each of these categories has a basic emotional nucleus at its core, with its variants rippling out in myriad mutations. In the outer ripples are *moods*, which, technically speaking, are more muted and last far longer than an emotion (it is relatively rare to maintain rage all day, for example, but less rare to be in an irritable mood, during which shorter bouts of anger are easily triggered). Beyond moods are *dispositions*, the temperamental proclivity to evoke a given emotion or mood such as melancholy, anxiety, or cheer. Further beyond such inclinations are the *disorders* of emotion such as clinical depressive disorders or generalized anxiety disorder, in which an individual feels chronically trapped in a toxic state.

Emotional intelligence entails the appropriate awareness, management, and expression of the range of these emotions. In this sense, many psychiatric disorders in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV)—such as the anxiety and mood disorders—bespeak a deficit in affective self-regulation, which is a key capacity of emotional intelligence. To the extent that emotional intelligence skills like affective self-regulation can be cultivated, particularly in young people, the risk of developing such psychiatric disorders should be diminished.

EMOTIONAL INTELLIGENCE AND I.Q.

In a sense the human brain contains two minds and two different kinds of intelligence: *rational* and *emotional*. These two fundamentally different modes of consciousness interact to constitute our mental life. The emotional and rational minds are semi-independent faculties, each reflecting the operation of distinct, but interconnected, circuitry in the brain. The complementarity of limbic system and neocortex, particularly of the amygdala and prefrontal lobes, means each is a full partner in mental life.

The emotional and the rational minds operate in tandem for the most part—emotion contributes to and informs the operations of the rational mind, and the rational mind refines and sometimes vetoes the input of the emotions. When these partners interact well, both emotional intelligence and intellectual ability are enhanced.

There is at best a slight correlation between I.Q. and certain facets of emotional intelligence, small enough to make it clear that these are largely independent entities. When people with high I.Q. flounder in life, and those with modest I.Q. do surprisingly well, the difference often may be attributable to emotional intelligence. Those with an extremely high I.Q. but low emotional intelligence—or low I.Q. and extremely high emotional intelligence—are relatively rare; abilities in both domains fit a bell curve.

Unlike the familiar tests for I.Q. there is as yet no corresponding test that measures emotional intelligence, although there is ample research on each of its components. Some aspects of emotional intelligence are best tested by studying an individual's ability at the task. Empathy can be evaluated, for example, by testing an individual's accuracy at interpreting another's feelings from their facial expressions.

In keeping with findings about other elements of emotional intelligence, for instance, research has demonstrated that empathy is independent of academic intelligence. Studies with school children have found only an incidental relationship between scores on measures of empathic acuity and SAT or I.Q. scores or school achievement tests. Children who showed an aptitude for reading feelings nonverbally were among the most popular in their schools, and the most emotionally stable. They did better academically, despite the fact that their I.Q.s were, on average, not higher than those of children who were less able to read nonverbal messages; this suggests that mastering this empathic ability smooths the way for classroom effectiveness (or simply makes teachers like these children more).

PRIOR THEORIES OF EMOTIONAL INTELLIGENCE

Peter Salovey and John Mayer are the first to offer a comprehensive model of emotional intelligence, but others have offered theories that overlap. In the 1920s E.L. Thorndike proposed that *social intelligence*—the ability to empathize and “act wisely in human relations”—was itself an aspect of I.Q. Other psychologists of the time took a more cynical view of social intelligence, seeing it in terms of skills for manipulating other people. Neither outlook on social intelligence convinced theorists, and the theory largely fell into disuse over the next decades. By the mid-1980s, Robert Sternberg's research on correlates of success led him back to Thorndike's conclusion: that social intelligence is distinct from intellectual capacity and is an essential component of what makes people function well in real life.

In 1983 Howard Gardner introduced the concept of multiple intelligences, proposing that rational intellect is just one of seven kinds of intelligence. Gardner's model rejects the traditional concept of I.Q. as a single, immutable factor; it recognizes that a range of skills and abilities matter over and above I.Q. His list includes the two standard academic measures of intelligence: verbal and mathematical-logical thinking, but it also includes the spatial capacity that an outstanding artist or architect might have; the kinesthetic ability necessary for dance or sports; and musical ability. Gardner also includes two facets of what he calls the “personal intelligences”: interpersonal skills—the ability to understand other people and what motivates them, and how to work cooperatively with them; and the capacity for “intrapsychic” awareness—a capacity to form an accurate, veridical model of oneself and to be able to use that model to function effectively in life. The theory of emotional intelligence expands on these two kinds of intelligence.

EMOTIONAL MIND

In recent years a cognitive science model of the emotional mind has been offered independently by Paul Ekman and Seymour Epstein. Their qualitative description sheds light on the underlying neurology; they propose the following qualities that distinguish the “emotional” from the “intellectual” mind.

Unlike the methodical and reflective intellect, the emotional mind reacts immediately, without pausing to consider consequences. Its workings are rapid, outpacing conscious thought and the deliberate, analytical reflection that is the mark of rationality. The emotional mind instantly apprehends potential danger, and can tune in to an emotional reality (e.g., he's angry with me; she's lying; this is making him sad), making snap judgments about whom to be wary of, whom to trust, who's in distress. However, these quick impressions and intuitive judgments can easily be erroneous or distorted, since the emotional mind sacrifices accuracy for speed.

Emotion-driven changes in facial expression begin within thousandths of a second after the event that triggers the reaction. The physiological changes that exemplify a given emotion—such as increased heart rate—also take only fractions of a second to begin. The reaction is particularly swift with intense emotion, like fear of a sudden threat.

This rapid-fire emotional reaction takes over in situations that have the urgency of primal survival, since emotions are a guide to action. The full blaze of intense emotion is technically very brief, lasting mere seconds rather than minutes, hours, or days. For an affect to endure, the original stimulus must be sustained, in effect continually invoking the emotion, as when the death of a loved causes prolonged bereavement. Emotions that persist for longer than a few seconds normally exist in muted forms as moods. Moods set an affective tone, but they do not determine perception or action as powerfully as brief, intense flares of emotion.

The immediate reaction to intense stimulus is emotional rather than logical because the rational mind processes stimuli more slowly than does the emotional mind. Accompanying thoughts are “automatic,” as described by Aaron Beck. However, there is a secondary, slower component to an emotional reaction. This second pathway to emotions is triggered by rumination; it is more deliberate, usually the result of conscious thought. This kind of emotional reaction entails a more extended appraisal in which cognition plays the key role in determining which emotions will be roused. Complex emotions, like embarrassment or apprehension over an upcoming exam, follow this slower route, taking seconds or minutes to unfold—these are emotions that follow from reflective thoughts.

The emotional mind is associative, and looks for symbolic significance. Art, religion, poetry, psychosis, dream, and myth are in the mode of the emotional mind, which Freud described as “primary process” thought. The primary process is the key that unlocks the meanings of art and dreams. In primary process thought, loose associations determine the flow of a narrative; one object symbolizes another; one feeling displaces another and stands for it; wholes are condensed into parts. There may be no coherence of time and no logical cause-and-effect sequence. The psychoanalytic method is in part the art of deciphering and unraveling these

substitutions in meaning.

The emotional mind has childlike qualities that intensify with the strength of the emotion. Categorical thinking typifies this, as does personalized thinking, with events perceived with a bias centering on the self.

Beliefs held by the rational mind are tentative—new evidence can refute one belief and replace it with a new one because the rational mind reasons by objective evidence. The emotional mind, however, is self-confirming, suppressing or ignoring memories or facts that would undermine its beliefs and seizing on those that support it. Emotions are self-justifying, having a set of perceptions and proofs all their own.

The emotional mind can react to the present as though it were the past. An event can bring back associated emotionally charged memories from the past. The emotional mind responds by triggering the feelings that went with the original event, whether or not or to what degree the comparison is warranted. If the evoked emotions are strong, the revived reaction is obvious. If the feelings are subtler, they can influence reactions without breaking into conscious thought. The emotional mind puts the rational mind to use, providing explanations (rationalizations) for emotional reactions without acknowledging the influence of emotional memory.

The emotional mind is largely state-specific in its operations; every strong emotion has its own distinct repertoire of thought, reactions, and memories. These state-specific repertoires become most predominant in moments of intense emotion. Selective memory, attention, or perception may signal that such an emotion-specific repertoire is active.

NEURAL ARCHITECTURE OF EMOTION

The dynamics of the emotional mind as understood through the lens of cognitive science reflect the underlying neural architecture. Understanding the interplay of brain structures that govern moments of acute, intense emotion reveals much about how emotional habits—positive and negative—are learned. The neurological data also suggest a primary prevention window of opportunity for shaping children's emotional habits.

The large size of the human neocortex makes possible the subtlety and complexity of human emotional life; the ratio of neocortex to limbic system is larger in primates than in other species and vastly larger in humans than in primates. Limbic areas that modulate emotion are connected via myriad circuits to all parts of the neocortex. Thus, the emotional centers have immense power to influence the functioning of the rest of the brain, including in its centers for thought. The neocortex, where prefrontal areas modulate emotional impulse, governs much of affective life, although in crucial, extremely emotional moments the neocortex defers to emotional impulse.

When emotions overwhelm concentration, what is being swamped is the mental capacity cognitive scientists call *working memory*, the ability to hold in mind the information relevant to the task at hand. What occupies working memory can be as mundane as the digits that compose a telephone number or as complicated as the intricate plot lines a novelist is trying to weave together. Working memory is the executive function par excellence in mental life, making possible all other intellectual efforts, from speaking a sentence to tackling a knotty logical proposition. Goldman-Rakic finds that the prefrontal cortex is the main site for working memory. When the limbic circuitry that converges on the prefrontal cortex is in the thrall of emotional distress, one cost is in the effectiveness of working memory: thinking, planning, and memory is impeded.

The amygdala is the prime candidate for the site of emotional memory. Antonio Damasio, studying patients with lesions between the amygdala and prefrontal cortex, has demonstrated the role of the amygdala and related limbic circuits in rational decisionmaking. These patients' decisionmaking was typically deeply flawed, despite their showing no deterioration in I.Q. nor in other cognitive abilities like attention and memory. They typically made disastrous choices in their business and personal lives, obsessing over decisions as simple as when to make an appointment.

Damasio argues that in the intact brain, limbic-driven surges from the viscera—“somatic markers”—function as inner alarms, calling attention to potential dangers that may result from a given course of action. These visceral sensations can cause an individual to act decisively and with confidence, immediately dropping or pursuing a course of action, thus paring down the array of choices to a more manageable decision matrix. More often than not these markers occur unaccompanied by conscious memories of the experiences that contribute to form this negative affect.

Although strong emotion can create havoc in reasoning, Damasio argues that the lack of awareness of feeling can also be ruinous, especially in weighing the decisions on which one's destiny largely depends: what career to pursue, whom to date or marry, where to live, and others. Such decisions cannot be made well through sheer rationality; they require the emotional wisdom developed through past experiences. Formal logic alone fails as the basis for deciding, for example, whom to marry or trust or even what job to take; these are realms where reason without feeling is blind.

NEURAL HIJACK

The precise neurological circuitry at play in each emotion has yet to be mapped; so far, the most extensive knowledge is for fear. Joseph LeDoux found the amygdala is central to fear and related acute emotional reactions. The amygdala stages a sort of “neural hijacking” during surges of fear and anxiety. For example, when triggered by fear, it sends urgent messages to every major part of the brain, controlling the secretion of fight-or-flight hormones, mobilizing centers for movement, and activating the cardiovascular system and muscles. Circuits from the amygdala catalyze the secretion of norepinephrine to heighten the reactivity of key brain areas, including those that make the senses more alert, in effect setting the brain on edge. The amygdala also signals the brainstem to fix the face in a fearful expression, cease unrelated muscle activity, increase heart rate and blood pressure, and slow breathing. Other circuits from the amygdala rivet attention on the source of the fear, and prepare the muscles to react.

Simultaneously, cortical memory systems are shuffled to retrieve stored knowledge relevant to the emergency at hand, taking precedence over other strands of thought. The amygdala is able to store memories and response repertoires that are marshaled without conscious thought because a direct circuit from thalamus to amygdala completely bypasses the neocortex. This bypass seems to allow the amygdala to be a repository for emotional impressions and memories that individuals are never fully aware of. Within milliseconds of the perception of something—and before there is conscious awareness of the stimulus—the “cognitive unconscious” produces an awareness of the identity of what we see, and also a liking or disliking for it—another possible indicator of the amygdala's role as a repository for emotional memory.

ROLE OF THE AMYGDALA IN FEAR

Fear is an apt case in point for understanding the neural architecture of emotion. In evolution, fear has a special prominence: more than any other emotion it is crucial for survival. In modern life, misplaced fears cause anxiety, and at a pathological extreme are at play in panic attacks, phobias, or obsessive-compulsive disorder. The neurology of fear highlights the central role of the amygdala as an alarm system.

Given a loud crash in the next room as raw physical data, the sensory circuit from, for example, the ear to the brain stem and then to the thalamus begins the first component of a fear reaction. From the thalamus, LeDoux has discovered, the path branches: a small bundle of projections leads to the amygdala and the nearby hippocampus and another, larger pathway leads to the auditory cortex in the temporal lobe, where sounds are sorted out and comprehended.

The hippocampus, a key storage site for nonaffective memory, quickly compares that “crash” to similar sounds to see if it is familiar—is this “crash” immediately recognizable? Meanwhile the auditory cortex does a more sophisticated analysis of the noise to determine its source—is it the dog? A fallen picture? An intruder? The auditory cortex makes a hypothesis about the source of the noise, and sends that message to the amygdala and hippocampus, which immediately compare it to similar memories.

If the conclusion is reassuring (the cat must have knocked a book off the desk), the general alert does not escalate to the next level. But if the noise remains unexplained, another coil of circuitry between the amygdala, the hippocampus, and the prefrontal cortex further accentuates uncertainty and fixates attention, redoubling the desire to identify the source of the sound. If no satisfying answer comes from this further keen analysis, the amygdala triggers an alarm, activating the hypothalamus, the brainstem, and the autonomic nervous system.

The amygdala's effectiveness as a central alarm system for the brain becomes evident in the ensuing sensations of apprehension and subliminal anxiety. Each of

several bundles of neurons in the amygdala has a distinct set of projections with receptors primed for different neurotransmitters. Discrete areas of the amygdala receive differing information. The amygdala's lateral nucleus receives projections from the thalamus and auditory and visual cortices. The corticomedial area of the amygdala registers smells via the olfactory bulb. The amygdala's central area receives messages from the viscera; this range of incoming signals allows the amygdala to function as a sentinel, scrutinizing every sensory experience.

The amygdala projects to most major areas of the brain. From its central and medial areas a branch goes to the parts of the hypothalamus that secrete corticotropin-releasing hormone (CRH), which mobilizes the fight-or-flight reaction via a cascade of other hormones. The amygdala's basal area sends out branches to the corpus striatum, linking into the brain's system for movement. Via the nearby central nucleus, the amygdala sends signals to the medulla in the autonomic nervous system, activating a wide range of far-flung responses in the cardiovascular system, muscles, and viscera.

The amygdala's basolateral area projects to the cingulate cortex and to the central gray cells that regulate the large muscles. These circuits also tighten the vocal cord muscles, creating the high-pitched voice of fright. Another path from the amygdala leads to the locus ceruleus in the brainstem, which in turn manufactures and disperses norepinephrine throughout the cortex, the brainstem, and the limbic system itself. Norepinephrine increases the overall reactivity of the brain areas that receive it, making the sensory circuits more sensitive.

Most of these changes go on outside conscious awareness. As unconscious anxiety begins to pierce awareness, the amygdala automatically commands a wide range of responses. It signals cells in the brainstem to put a fearful expression on the face, freezes unrelated movements the body's muscles had initiated, speeds heart rate, raises blood pressure, and slows breathing. These are just a few of the myriad changes orchestrated by the amygdala and connected areas as they commandeer the brain through a crisis.

The amygdala and the hippocampus together direct the cells that send key neurotransmitters to trigger releases of dopamine that rivets attention on the source of fear and puts the muscles at readiness to react. At the same time the amygdala signals sensory areas for vision and attention, making sure that the eyes seek out whatever is most relevant to the emergency at hand. Simultaneously cortical memory systems are reshuffled so that knowledge and memories most relevant to the particular emotional urgency will be readily recalled, taking precedence over other less relevant strands of thought.

The result of these many changes is the sensation of full-fledged fear: there is a characteristic tightness in the viscera, the heart speeds, the neck and shoulder muscles tighten, the limbs tremble; the body freezes in place, and the mind races, entertaining a host of possible dangers and appropriate responses. This entire sequence—from surprise to uncertainty to apprehension to fear—can occur within a second or so.

Damage to the amygdala also results in the loss of the ability to produce the acute physical sensation of fear. When a rare brain disease destroyed the amygdala (but no other brain structures) in the patient neurologists call “S.M.,” fear disappeared from her mental repertoire. She became unable to identify looks of fear on other people's faces, nor to make such an expression herself. As her neurologist put it, “If someone put a gun to S.M.'s head, she would know intellectually to be afraid but she would not feel afraid as you or I would.”

The competencies entailed in emotional intelligence reflect the workings of both cortical and subcortical circuits, particularly those that connect the amygdala and related structures with the prefrontal areas. Autopsy studies on children and teenagers have shown that the prefrontal zones, which modulate emotional expression and skill, are among the last parts of the brain to attain anatomical maturity; they do so around mid-adolescence, age 14 or 15.

Neuroplasticity means the brain shapes itself in part through repeated experiences, which strengthen the corresponding neural connections and weaken less used ones. The finding of relatively late maturation of the prefrontal circuitry for modulation of emotion suggests a neurological window of opportunity for helping children learn the best habits of emotional intelligence. If a child learns habits of emotional self-regulation, empathy, social skill and the like, the argument goes, then that will lower the risk of their needing remedial training (such as psychotherapy) later in life.

TRAUMA AND EMOTIONAL RELEARNING

One model for such emotional learning and relearning can be seen in the acquisition of and recovery from posttraumatic stress disorder. In posttraumatic stress disorder a terrifying moment of trauma becomes emblazoned in the emotional circuitry, continuing to trigger an emergency mobilization at the least cue of the original trauma. The acquisition of posttraumatic stress disorder and steps to recovery from it offer a paradigm of emotional learning and relearning with implications that generalize far beyond psychopathology.

Symptoms of posttraumatic stress disorder such as hypervigilance, nightmares, and overreacting to benign stimuli that in some way echo the traumatic event are, in effect, signs of an overaroused amygdala impelling vivid memories of trauma to continue to intrude on awareness. Traumatic memories encoded in the amygdala act as mental hair triggers, ready to sound a physiological alarm at the least suggestion that the original trauma is occurring again—witness the Vietnam veteran who panics at the sound of a car backfiring. This hair-trigger phenomenon may be a hallmark of emotional trauma of all kinds, including repeated physical abuse in childhood. Although posttraumatic stress disorder is typically the result of the impact of a single overwhelming episode, similar results can come from cruelties inflicted over a period of years, as can be the case with children who are sexually, physically, or emotionally abused.

Posttraumatic stress disorder represents a perilous lowering of the neural setpoint for alarm, such that an individual reacts to life's ordinary moments as though they were emergencies. The more brutal, shocking, and horrendous the events, the more indelible the memory. The neural basis for these memories appears to be a transformation in brain chemistry set in motion by a single instance of overwhelming terror. The main symptoms of posttraumatic stress disorder—the most intense kind of learned fearfulness—can be accounted for by changes in the limbic circuitry focusing on the amygdala. Some of the key changes are in the locus ceruleus, a structure that regulates the brain's secretion of catecholamines. These neurochemicals mobilize the body for an emergency; the same catecholamine surge stamps memories with special strength. In posttraumatic stress disorder this system becomes hyperreactive, secreting extra-large doses of these brain chemicals in response to situations that hold little or no threat but somehow trigger memories of the original trauma. The locus ceruleus and the amygdala are closely linked, along with other limbic structures such as the hippocampus and hypothalamus; the circuitry for the catecholamines extends into the cortex. Changes in these circuits are thought to underlie posttraumatic stress disorder symptoms like anxiety, fear, hypervigilance, being easily upset and aroused, readiness for fight or flight, and the indelible encoding of intense emotional memories. One study found that Vietnam veterans with posttraumatic stress disorder had 40 percent fewer catecholamine-inhibiting receptors than did men without the symptoms—suggesting that their brains had undergone a lasting change and that their catecholamine secretion was poorly controlled.

Other changes occur in the circuit linking the limbic brain with the pituitary gland, which regulates release of CRF, the main stress hormone the body secretes to mobilize the emergency fight-or-flight response. The changes lead this hormone to be oversecreted—particularly in the amygdala, hippocampus, and locus ceruleus—alerting the body for an emergency that really does not exist. Hypersecretion of CRF causes an overreactive startle response; individuals with too much CRF do not habituate to stressful stimuli.

A third set of changes occurs in the brain's opioid system, which secretes endorphins to blunt the feeling of pain; it also becomes hyperactive. This neural circuit also involves the amygdala, this time in concert with a region in the cerebral cortex. The opioids are brain chemicals that are powerful numbing agents, like opium and other related narcotics. When experiencing high levels of opioids, people have a heightened tolerance for pain—an effect that has been noted by surgeons who found that severely wounded soldiers needed lower doses of narcotics to handle their pain than did civilians with far less serious injuries.

Something similar seems to occur in posttraumatic stress disorder. Endorphin changes add a new dimension to the neural mix triggered by reexposure to trauma: a numbing of emotion. This appears to explain a set of negative psychological symptoms long noted in posttraumatic stress disorder: anhedonia and a general emotional numbness, a sense of being cut off from life or from concern about others' feelings. Those close to such people may experience this indifference as a lack of empathy. Another possible effect may be dissociation, including the inability to remember crucial minutes, hours, or even days of the traumatic event. The neural changes of posttraumatic stress disorder also seem to make a person more susceptible to further trauma. A number of studies have found that when animals were exposed even to mild stress when young, they were far more vulnerable than unstressed animals to trauma-induced brain changes later in life (suggesting a special urgency to treat children with posttraumatic stress disorder). This seems a reason why, exposed to the same catastrophe, one person goes on to develop posttraumatic stress disorder and another does not: the amygdala is primed to find danger, and when life presents it once again with real danger, its alarm rises to a higher pitch. All these neural changes offer short-term advantages for dealing with the emergencies that prompt them. Under duress, it is adaptive to be highly vigilant, aroused, ready for anything, impervious to pain, with the body primed for sustained physical demands, and—at least temporarily—less reactive to what might otherwise be intensely disturbing events. These short-term advantages, however, become lasting problems when the brain changes so that they become

predispositions, like a car stuck in perpetual high gear. When the amygdala and its connected brain regions take on a new setpoint during a moment of intense trauma, this change in excitability—this heightened readiness to trigger a neural hijacking—means that all of life is on the verge of becoming an emergency, and even an innocent moment is susceptible to an explosion of fear run amok.

In posttraumatic stress disorders spontaneous relearning fails to occur. This may be because of the brain changes of posttraumatic stress disorders, which are so strong that the amygdala hijacking occurs every time something even vaguely reminiscent of the original trauma comes along, thereby strengthening the fear pathway. This means that there is never a time when what is feared is paired with a feeling of calm; the amygdala never relearns a more mild reaction. Extinguishing the fear appears to involve an active adjustment process that is itself impaired in people with posttraumatic stress disorders, leading to the abnormal persistence of maladaptive responses.

But given the right experiences, even posttraumatic stress disorders can lift; strong emotional memories, and the patterns of thought and reaction that they trigger, can change with time. The original fear encoded in the amygdala does not die out completely; rather, the prefrontal cortex seems to actively suppress the amygdala's command to the rest of the brain to respond with fear.

The process whereby something that is not threatening becomes dreaded because it is associated with something frightening is called *fear conditioning*. Animal research indicates that one reason the ensuing fears can last for years is that the fear itself interferes with the ability to learn an alternative, more calm response. The key region of the brain that learns, retains, and acts on this fearful response is the circuit between the thalamus, amygdala, and prefrontal lobe—the pathway of neural hijacking. Judith Lewis Herman's therapeutic work describes distinct stages to recovery from trauma: attaining a sense of safety, remembering the details of the trauma and mourning the loss it has brought, and ultimately reestablishing a normal life. The establishment of a sense of safety as a first step may represent the necessary condition for unlearning fear conditioning. There may be a biological logic to the ordering of these steps as a sequence reflecting how the emotional brain relearns that life need not be regarded as an emergency about to happen.

PSYCHOTHERAPY AS EMOTIONAL RELEARNING

The same circuitry that can be seen so boldly imprinting traumatic memories is presumably at work in life's quieter moments as well. More ordinary childhood travails, such as being chronically ignored and deprived of attention or tenderness by one's parents, abandonment, loss, or social rejection, may never reach the fever pitch of trauma, but still leave their imprint on the emotional brain, creating distortions in intimate relationships later in life. Healing such muted emotional scars is a task of psychotherapy. In learning to deal skillfully with these loaded reactions, emotional intelligence comes into play.

The dynamic between the amygdala and the more fully informed reactions of the prefrontal cortex may offer a neuroanatomical model for how psychotherapy reshapes deep, maladaptive emotional patterns. Given the brain architecture that underlies emotional relearning in fear conditioning, what seems to remain even after successful psychotherapy is a vestigial reaction, a remnant of the original sensitivity or fear at the root of a troubling emotional pattern. The prefrontal cortex can refine or put the brakes on the amygdala's impulse, but cannot keep it from reacting in the first place. Thus while one cannot determine when one will have emotional outbursts, one can gain a degree of control over how long they last. A quicker recovery time from such outbursts may well be one mark of emotional maturity.

Over the course of therapy, what seems to change in the main are the responses that people make once an emotional reaction is triggered, but the tendency for the reaction to be triggered in the first place does not disappear entirely. Lester Luborsky's study of psychotherapy explored the main relationship conflicts that brought dozens of patients into psychotherapy—issues such as a deep craving to be accepted or find intimacy, or a fear of failure or of being overly dependent. Researchers carefully analyzed the typical (always self-defeating) responses the patients made when these wishes and fears were activated in their relationships—such as being too demanding, which created a backlash of anger or coldness in the other person, or withdrawing in self-defense from an anticipated slight, leaving the other person miffed by the seeming rebuff. During such ill-fated encounters, the patients understandably were flooded by upsetting feelings of hopelessness, sadness, resentment, anger, tension, fear, guilt, and self-blame. Whatever the specific pattern of the patient, it seemed to show up in important relationships, whether with a spouse or lover, a child or parent, or peers and supervisors at work.

Over the course of long-term therapy, however, these patients made two kinds of changes: their emotional reaction to the triggering events became less distressing, even calm or bemused, and their overt responses became more effective in getting what they truly wanted from the relationship. What did not change, however, was their underlying wish or fear, and the initial twinge of feeling. By the time the patients had but a few sessions left in therapy, the encounters they talked about showed they had only half as many negative emotional reactions compared to when they first started therapy, and were twice as likely to get the positive response they deeply desired from the other person; what did not change at all was the particular sensitivity at the root of these needs.

In brain terms the limbic circuitry may send alarm signals in response to cues of a feared event, but the prefrontal cortex and related zones would have learned a new, more healthy response. Emotional lessons—even the most deeply implanted habits of the heart learned in childhood—can be reshaped, which may explain why psychotherapy can take so long to change some of these patterns. Luborsky finds that even after successful therapy, core emotional propensities remain, although with an overlay of new insights and relearned responses.

Much successful psychotherapy is emotional relearning, as the posttraumatic stress disorders paradigm suggests. In theory, the behavior changes that ensue from psychotherapy should entail a relearning of emotional repertoires, and might mean a reshaping of the underlying neural circuitry. Suggestive evidence that this is indeed the case comes from a study of patients treated for obsessive-compulsive disorder. Half the study subjects received fluoxetine (Prozac). The other half received no medication, but rather underwent behavior therapy that systematically exposed them to the object of their obsession or compulsion without being allowed to perform it. Patients with hand-washing compulsions were put at a sink, for example, but not allowed to wash. They were taught to question the fears and dreads that motivated their compulsions, such as that failure to wash would mean they would get a disease and die. They were also encouraged to find an activity to do that they enjoyed—like listening to music—whenever they had the compulsion to wash. Over months of such sessions, therapy patients' compulsions faded, just as they did in subjects who received medication.

Positron emission tomography (PET) studies show that people with obsessive-compulsive disorder have greater than normal activity in the caudate nucleus, among other sites. The behavior therapy group had as significant a decrease in the activity of the caudate nucleus as did the patients successfully treated with fluoxetine. Systematic emotional and behavioral relearning had changed brain function and relieved symptoms as effectively as medication had.

ACQUISITION OF EMOTIONAL INTELLIGENCE

Although emotional behaviors are rooted in the operation of neurotransmitter systems, temperament is not destiny; emotional intelligence competencies are largely learned, with experience through childhood shaping and resetting of those neurotransmitter systems. Jerome Kagan proposes that genetically determined neurotransmitter setpoints probably cause individual differences in baseline temperament; for any given emotion, there are differences in how easily it is triggered, how long it lasts, and how intensely it is felt.

For example, Richard Davidson finds that the tendency toward timidity or boldness emerges within the first year of life, a fact that strongly suggests that it is genetically determined. Since the frontal lobes are still maturing in the first few months of life, their activity cannot be measured reliably until about the age of 10 months. But studies of 10-month-old infants have found that activity levels in the frontal lobes predicted whether the infants would cry when their mothers left the room. Of dozens of infants tested, every infant who cried had more brain activity in the right prefrontal area, a center for negative effect, while those who did not cry had more activity on the left; the correlation was virtually 100 percent. Timid children seem to begin life with a neural circuitry that renders them more reactive to even mild stress—from birth, their hearts beat faster than other infants' in response to strange or novel situations. Kagan posits that this signifies “behavioral inhibition,” a lifelong tendency to perceive any new person or situation as a potential threat. At 21 months, when reticent toddlers refrained from playing, heart-rate monitors showed that their hearts were racing with anxiety. This easily aroused anxiety seems to promote lifelong introversion. Middle-aged women who report having been particularly shy as children tend to experience more fears, worries, and guilt, and to suffer more from stress-related conditions such as migraine headaches, irritable bowel syndrome, and other stomach problems throughout life, compared with their more extroverted peers.

Although basic disposition appears to be laid down from birth, or very nearly from birth, those who have a tendency toward inhibition are not necessarily fated to be shy and withdrawn all their lives. The emotional lessons of childhood can have a profound impact on temperament, either amplifying or muting an innate predisposition. The great plasticity of the brain in childhood means that experiences during those years can have a lasting impact on the sculpting of neural pathways for the rest of life. Kagan finds that throughout childhood some timid children grow bolder as experience reshapes key neural circuitry. Subjects who were timid at age 4 were more likely to overcome natural inhibition by age 10 if they had a higher level of social competence: being cooperative; getting along with other children; being

empathic, prone to giving and sharing; being considerate; and being able to develop close friendships. More socially skilled children in this group were far more likely to have a succession of positive experiences with other children. The regular repetition of such social success over many years seems to reduce timidity by making the children more sure of themselves.

Subjects who remained timid at age 10 tended to be less emotionally competent: crying and falling apart under stress more easily; being emotionally inappropriate; displaying fearful, sulky, or whiny behavior; overreacting to minor frustrations; having trouble delaying gratification; being overly sensitive to criticism; or being mistrustful. These emotional lapses are likely to mean their relationships with other children will be troubled, should they be able to overcome their initial reluctance to engage.

Parental style is a powerful modifier of temperament. Kagan reports that “inhibited” children who had become less timid by kindergarten seem to have had parents who put consistent gentle pressure on them to be more outgoing, offering them repeated chances to take social risks despite fears, and so having mastery experiences. Kagan posits this behavioral change toward boldness marks an underlying shift in neurotransmitter setpoints in the amygdala. All learning—emotional, factual, or logical—implies a physical change in the brain, a strengthening of synaptic connection.

One key emotional circuit that continues to shape itself through childhood centers on the vagus nerve, which both regulates the heart and other organs and signals the amygdala via other circuits to secrete catecholamines, which initiate the fight-or-flight response. Research suggests that emotionally adept parenting leads to improved vagal-nerve function in children.

According to John Gottman, parents modify their children's vagal tone with emotional “coaching”: talking to children about their feelings and how to understand them, adopting an uncritical and nonjudgmental stance, helping children to solve emotional predicaments, and offering constructive alternatives to hitting and sulking behaviors. A 4-year longitudinal study found children of parents who did this well were better able to suppress vagal activity, had lower levels of resting catecholomines, and fewer episodes of tantrums and impulsivity.

DEVELOPMENT OF EMOTIONAL INTELLIGENCE

Emotional learning begins in life's earliest moments, and continues throughout childhood and into adulthood. Childhood and adolescence are the most critical windows of opportunity for the establishment of essential emotional habits. The primary skills of emotional intelligence each have critical periods extending over several years in childhood. Each period represents an opportunity for instilling effective emotional habits. The strengthening, sculpting, and pruning of neural circuits throughout childhood may contribute to the enduring and pervasive effects of early emotional hardships and trauma in adulthood.

Hundreds of studies suggest that how parents treat a child—with harsh discipline or emphathy, with indifference or warmth, and so on—has deep and lasting consequences for the child's emotional life. Only recently have there been hard data showing that emotionally intelligent parenting is itself of enormous benefit to a child. The ways parents handle emotions between them—in addition to their direct dealings with a child—impart powerful lessons to their children, who are astute learners attuned to the subtlest emotional exchanges in the family. Gottman's microanalysis of interactions in couples on how the partners handled their children suggested that couples who were more emotionally competent in the marriage relationship were also the most effective in helping children to cope with emotional ups and downs.

All the small interactions between parent and child have an emotional subtext; the repetition of these messages over the years forms the core of a child's emotional outlook and capabilities. These interchanges mold the child's emotional expectations about relationships, which will influence emotional functioning in all realms of life for better or worse.

The risks are greatest for children whose parents are grossly inept—immature, abusing drugs, depressed, chronically angry, or simply aimless and living chaotic lives. Such parents are far less likely to give adequate care, let alone to address their childrens' emotional needs. Simple neglect, studies find, can be more harmful than outright abuse. Studies of maltreated children find that neglected youngsters fare worst of all: they tend to be the most anxious, inattentive, and apathetic, alternately aggressive and withdrawn. In one study the rate among neglected children for having to repeat first grade was 65 percent.

Emotional competence may be decisive in determining the extent to which any given child succumbs to such hardships or responds to them with a core of resilience and thrives despite the odds. Long-term studies of children brought up in poverty, in abusive families, or by a parent with severe mental illness show that those who survive the most severe hardships tend to share key emotional skills. These include social adeptness that draws people to them, self-confidence, persistence, optimism, resilience in the face of upsets, and an easy-going nature.

PRIMARY PREVENTION

The plight of today's children can be seen in day-to-day problems that have not yet blossomed into outright crises. Perhaps the most telling data of all—a direct barometer of dropping levels of emotional competence—are from a national sample of American children, ages 7 to 16, comparing their emotional condition in the mid-1970s and at the end of the 1980s. Based on parents' and teachers' assessments, there was a steady worsening. No one problem stood out; all indicators simply crept steadily in the wrong direction. Children, on average, were doing more poorly in these specific ways:

- Withdrawal or social problems: preferring to be alone; being secretive; sulking a lot; lacking energy; feeling unhappy; being overly dependent
- Anxious and depressed: being lonely; having many fears and worries; needing to be perfect; feeling unloved; feeling nervous, sad, or depressed
- Attention or thinking problems: unable to pay attention or sit still; daydreaming; acting without thinking; being too nervous to concentrate; doing schoolwork poorly; unable to get mind off thoughts
- Delinquent or aggressive: hanging around kids who get in trouble; lying and cheating; arguing a lot; being mean to other people; demanding attention; destroying other people's things; disobeying at home and at school; being stubborn and moody; talking too much; teasing a lot; having a hot temper

No child, rich or poor, is exempt from risk; these problems are universal and occur in all ethnic, racial, and income groups. Thus, while children in poverty have the worst record on indices of emotional skills, their rate of deterioration over the decades was no worse than for middle-class children or for wealthy children: all show the same steady slide. There has also been a corresponding threefold rise in the number of children who have received psychological help, as well as a near doubling of the number of children whose emotional problems warrant help that they have not received—from about 9 percent in 1976 to 18 percent in 1989.

A more careful look at the mechanics of specific problems suggests how given deficits in emotional or social competencies lay the foundation for social or psychiatric problems and how well-aimed correctives or preventives could keep more children on track.

Aggression At the root of aggressiveness lie deficiencies in a triad of emotional intelligence competencies: empathy, self-regulation of anger, and impulsivity. Genetic givens aside, the social shaping of aggression starts early. The family life of aggressive children typically includes parents who alternately neglect their child and administer harsh and capricious punishments, a pattern that can make a child paranoid or combative. Not all angry children are bullies; some are withdrawn social outcasts who overreact to being teased or to what they perceive as slights or unfairness. The one perceptual flaw that such children share is that they perceive slights where none were intended, imagining their peers to be more hostile toward them than they actually are. This leads them to misperceive neutral acts as threatening ones—an innocent bump is seen as intentional—and to attack in return. As a result, other children shun them, isolating them further. Such angry, isolated children are highly sensitive to injustices and being treated unfairly. They typically see themselves as victims and can recite a list of instances when, for example, they were blamed for something they did not do. Another trait of such children is that once they are angry they can think of only one way to react: by lashing out.

These perceptual biases can be seen at work in an experiment in which a bully is paired with a more peaceable child to watch videos. In one video, a boy drops his books when another knocks into him, and children standing nearby laugh; the boy who dropped the books gets angry and tries to hit a child who laughed at him. When the boys who watched the video talk about it afterward, the bully always sees the boy who struck out as being justified. Even more telling, when asked to rate how aggressive the boys were, the bullies see the boy who knocked into the other as being more combative, and the anger of the boy who struck out as being justified.

This jump to judgment testifies to a deep perceptual bias in people who are unusually aggressive: they act on the basis of the assumption of hostility or threat, paying too little attention to what is actually going on. Once they assume threat, they leapfrog to action. For instance, if an aggressive boy is playing checkers with another who moves a piece out of turn, he'll interpret the move as cheating without pausing to find out if it had been an innocent mistake. His presumption is of evil intent

rather than innocence; his reaction is automatic hostility. The knee-jerk perception of a hostile act is accompanied by an equally automatic aggression; instead of pointing out to the other boy that he made a mistake, the aggressive boy begins accusing, yelling, and hitting. The more such children do this, the more automatic aggression becomes for them, and the more the repertoire of alternatives—politeness, joking—shrinks.

Such children are emotionally vulnerable in the sense that they have a low threshold for upset, getting peeved more often by more things; once upset, their thinking is muddled, so that they see benign acts as hostile and fall back on their overlearned habit of striking out. These perceptual biases toward hostility are already in place by the early grades. Most children, especially boys, are rambunctious in kindergarten and first grade, but the more aggressive children fail to learn even a modicum of self-control by second grade. Where other children have started to learn how to settle playground disagreements by negotiation and compromise, the bullies rely more and more on force and bluster. They pay a social price: within 2 or 3 hours of a first playground contact with a bully, other children say they dislike him.

Studies that have followed children from the preschool years into teenagehood find that up to half of first graders who are disruptive, unable to get along with other kids, disobedient with their parents, and resistant with teachers will become delinquents in their teen years. Not all such aggressive children are on the trajectory that leads to violence and criminality in later life. But of all children, these are the ones who are most at risk for eventually committing violent crimes.

The drift toward crime shows up surprisingly early in these children's lives. When kindergarteners were rated for hostility and troublemaking behavior, those whose behavior was most extreme at age 5 already had far greater evidence of delinquency just 5 to 8 years later in their early teens. They were about three times as likely as other children to admit they had beaten up someone who had not done anything to them, to have shoplifted, to have used a weapon in a fight, to have broken into or stolen parts from a car, and to have been drunk—and all this before they reached 14 years of age.

The prototypical pathway to violence and criminality starts with children who are aggressive and hard to handle in first and second grade. Typically, from the earliest school years their poor impulse control also contributes to their being poor students; they are seen as and see themselves as “dumb”—a judgment confirmed by their being shunted to special-education classes. Although such children may have a higher rate of “hyperactivity” or learning disorders, all of them do not. Children who on entering school already have learned a coercive style—that is, bullying—are also written off by their teachers who have to spend too much time keeping these children in line. Defying classroom rules comes naturally to these children, which means that they waste time that would otherwise be used in learning; that they are destined to academic failure is usually obvious by about third grade. While boys on a trajectory toward delinquency tend to have lower I.Q. scores than their peers, their impulsivity is more directly at cause: impulsivity in 10-year-old boys is almost three times as powerful a predictor of their later delinquency as is their I.Q.

By fourth or fifth grade these kids—now seen as bullies or just difficult—are rejected by their peers and are unable to make friends easily, if at all, and have become academic failures. Feeling themselves friendless, they gravitate to other social outcasts. Between grade four and grade nine they commit themselves to their outcast group and a life of defying the law: they show a fivefold increase in their truancy, drinking, and substance use, with the biggest boost between seventh and eight grade. By the middle-school years, they are joined by another type of “late starters,” who are attracted to their defiant style; these late starters are often youngsters who are completely unsupervised at home and started roaming the streets on their own in grade school. In the high-school years this outcast group typically drops out of school in a drift toward delinquency, engaging in petty crimes such as shoplifting, theft, and drug-dealing.

A telling difference emerges in this trajectory between boys and girls. A study of fourth-grade girls who were “bad”—getting in trouble with teachers and breaking rules, but not unpopular with their peers—found that 40 percent had a child by the time they finished the high-school years, which was three times the average pregnancy rate for girls in their schools. In other words, antisocial teenage girls don't get violent—they get pregnant.

There is, of course, no single pathway to violence and criminality, and many other factors can put a child at risk: being born in a high-crime neighborhood where they are exposed to more temptations to crime and violence, coming from a family under high levels of stress, or living in poverty. However, none of these factors makes a life of violent crime inevitable. All things being equal, the psychological forces at work in aggressive children greatly intensify the likelihood of their ending up as violent criminals.

The bent of mind that aggressive children take with them through life is one that almost ensures they will end up in trouble. A study of juvenile offenders convicted of violent crimes and of aggressive high-school students found a common mind set: when they have difficulties with someone, they immediately see the other person in an antagonistic way, jumping to conclusions about the other person's hostility toward them without seeking any further information or trying to think of a peaceful way to settle their differences. At the same time, the negative consequence of a violent solution—a fight, typically—never crosses their mind. Their aggressive bent is justified in their mind by beliefs like, “It's okay to hit someone if you just go crazy from anger”; “If you back down from a fight everyone will think you're a coward”; and “People who get beaten up badly don't really suffer that much.”

Timely help can change these attitudes and stop a child's trajectory toward delinquency; several experimental programs have had some success in helping aggressive children learn to control their antisocial bent before it leads to more serious trouble. One program for anger-ridden grade-school troublemakers conducted training sessions for 40 minutes twice a week for 6 to 12 weeks. The boys were taught, for example, to see that some of the social cues they interpreted as hostile were in fact neutral or friendly. They learned to take the perspective of other children, to get a sense of how they were being seen and of what other children might be thinking and feeling in the encounters that had made them so angry. They also got direct training in anger control through enacting scenes, such as being teased, that might lead them to lose their temper. One of the key skills for anger control was monitoring their feelings—becoming aware of their body's sensations, such as flushing or muscle tensing, as they were getting angry, and to take those feelings as a cue to stop and consider what to do next rather than strike out impulsively.

Many aggressive boys are unhappy that they lose their temper so easily, and are receptive to learning to control it. In the heat of the moment, cool-headed responses such as walking away or counting to ten so the impulse to hit will pass before they react are not automatic; the boys practice such alternatives in role-playing scenes such as riding a bus where other kids are taunting them. They can try out friendly responses that preserve their dignity while giving them an alternative to hitting, crying, or running away in shame.

Three years after the boys had been through the training, a comparison matched these boys with others who had been just as aggressive, but did not have the benefit of the anger-control sessions. It found that, in adolescence, the boys who graduated from the program were much less disruptive in class, had more positive feelings about themselves, and were less likely to drink or take drugs. Also, the longer they had been in the program, the less aggressive they were as teenagers.

Depression International data show what seems to be a modern epidemic of depression; each successive generation worldwide since the beginning of the twentieth century has lived with a higher risk than their parents of suffering a major depression (called major-depressive disorder in DSM-IV)—not just sadness, but a paralyzing listlessness, dejection, and self-pity, and an overwhelming hopelessness—over the course of life. Also, these episodes are beginning at earlier and earlier ages. Childhood depression, once virtually unknown (or unrecognized), is emerging as a fixture of the modern scene.

Although the likelihood of becoming depressed rises with age, the greatest increases are among young people. For those born after 1955 the likelihood they will suffer a major depression at some point in life is, in many countries, three times or more greater than for their grandparents. Among Americans born before 1905, the rate of those having a major depression over a lifetime was just 1 percent; for those born since 1955, by age 24 about 6 percent had become depressed. For those born between 1945 and 1954, the chances of having had a major depression before age 34 are ten times greater than for those born between 1905 and 1914. For each generation the onset of a person's first major depressive episode has tended to occur at an ever-earlier age.

Worldwide, the age when people first experience depression has dropped. The losses of stable sources of self-identification make children more susceptible to depression. A wide-scale reduction of available support from sources such as religious communities and extended families means a broad loss of resources that can buffer against setbacks and failures. Early emotional stressors may affect neuronal development, which could cause depression even decades later. Whatever the cause, depression in the young is a pressing problem. In the United States, estimates of how many children and teens are depressed in any given year vary widely, as opposed to vulnerability over their lifetime. Some epidemiological studies using strict criteria—the DSM-IV diagnostic criteria for depressive disorders—have found that for boys and girls between 10 and 13 the rate of major depressive disorder over the course of a year is as high as 8 or 9 percent, although other studies place it at about half that rate and even as low as 2 percent. Some data suggest that at puberty the rate nearly doubles for girls; up to 16 percent of girls between 14 and 16 suffer an episode of depression, whereas the rate is unchanged for boys.

Among children whose depression was severe enough that they were referred for treatment, three quarters had a subsequent episode of severe depression, according to one study of children diagnosed with depressive disorder when they were as young as 8 years old and assessed every few years until some were as old as 24. Children with major depressive disorder had episodes lasting about 11 months on average, although in one in six of them it persisted for as long as 18 months. Dysthymia, which began as early as age 5 in some children, was less incapacitating but lasted far longer—an average of about 4 years. Children who have a

dysthymia are more likely to have it intensify into major depression—a so-called *double depression*. Those who develop double depression are much more prone to suffer recurring episodes as they grow older. As children who had an episode of depression grew into adolescence and early adulthood, they suffered from a depressive disorder or bipolar I disorder, on average, 1 year in 3.

The cost to children goes beyond the suffering caused by depression itself. The sullenness or sadness such children feel causes them to avoid initiating social contacts, or to look away when another child is trying to engage them—a social signal the other child takes as a rebuff; the end result is that depressed children end up rejected or neglected on the playground. This lacuna in their interpersonal experience means they miss out on what they would normally learn in the rough-and-tumble of play. They become social and emotional laggards, with much catching up to do after the depression lifts. Indeed, when compared to those without depression, depressed children have been found to be more socially inept, to have fewer friends, to be less preferred than others as playmates, to be less liked, and to have more troubled relationships with other children.

Another cost to these children is doing poorly in school; depression interferes with their memory and concentration, making it harder to pay attention in class and retain what is taught. A child who feels no joy in anything will find it hard to marshal the energy to master challenging lessons, let alone experience flow in learning. Understandably, the longer children are depressed, the more their grades drop and the poorer they do on achievement tests, so that they are more likely to be held back in school. There is a direct correlation between the length of time a child had been depressed and his or her grade point average, with a steady plummet over the course of the episode, all of which compounds the depression. Just as with adults, pessimistic ways of interpreting life's defeats seem to feed the sense of helplessness and hopelessness at the heart of children's depression. That people who are already depressed think in these ways has long been known. However, what has emerged only recently is that children who are most prone to melancholy tend toward this pessimistic outlook before they become depressed, which suggests a window of opportunity for inoculating them against depression before it strikes.

One line of evidence comes from studies of children's beliefs about their own ability to control what happens in their lives, such as being able to change things for the better. This is assessed by children's ratings of themselves in such terms as “When I have problems at home I'm better than most kids at helping to solve the problems” and “When I work hard I get good grades.” Children who say none of these positive descriptions fits them have little sense that they can do anything to change things; this sense of helplessness is highest in those children who are most depressed. A telling study looked at fifth- and sixth-graders in the few days after they received report cards. There is a marked consequence in how children assess their role when they get a worse grade than they expected: those who see a bad grade as being caused by some personal flaw (“I'm stupid”) feel more depressed than those who explain it away in terms of something they could change (“If I work harder on my math homework I'll get a better grade”).

Martin Seligman identified a group of third-, fourth-, and fifth-graders whom classmates had rejected, and tracked the ones who continued to be social outcasts in their new classes the following year. How the children explained the rejection to themselves seemed crucial to whether they became depressed. Those who saw their rejection as due to some flaw in themselves grew more depressed. But the optimists, who felt that they could do something to change things for the better, were not especially depressed despite the continuing rejection. In a study of children making the notoriously stressful transition to seventh grade, those with the pessimistic attitude responded to high levels of hassles at school and to any additional stress at home by becoming depressed. The most direct evidence that a pessimistic outlook makes children highly susceptible to depression comes from a 5-year study of children beginning when they were in third grade. Among the younger children, the strongest predictor that they would become depressed was a pessimistic outlook coupled with a major blow such as parents divorcing or a death in the family, which left the child upset, unsettled, and, presumably, with parents less able to offer a nurturing buffer. As the children grew through the elementary school years, there was a telling shift in their thinking about the good and bad events of their lives, with the children increasingly ascribing them to their own traits: “I'm getting good grades because I'm smart”; “I don't have many friends because I'm no fun.” This shift seems to set in gradually over the third to fifth grades. As this happens those children who develop a pessimistic outlook—attributing the setbacks in their lives to some dire flaw in themselves—begin to fall prey to depressed moods in reaction to setbacks. Also, the experience of depression itself seems to reinforce these pessimistic ways of thinking, so that even after the depression lifts, the child is left with what amounts to an emotional scar, a set of convictions fed by the depression and solidified in the mind: that he cannot do well in school, is unlikable, and can do nothing to escape his own brooding moods. These fixed ideas can make the child all the more vulnerable to another depression down the road.

There are signs that teaching children more productive ways of looking at their difficulties lowers their risk of depression. In a study of one Oregon high school, about one in four students had symptoms of subclinical depression. In a special after-school class 75 of the mildly depressed students learned to challenge the thinking patterns associated with depression, to become more adept at making friends, to get along better with their parents, and to engage more in social activities that they enjoyed. By the end of the 8-week program, 55 percent of the students had recovered from their mild depression whereas only about a quarter of equally depressed students who were not in the program had begun to pull out of their depression. A year later a quarter of those in the comparison group had gone on to fall into a major depressive disorder, as opposed to only 14 percent of students in the depression-prevention program. Although the program lasted just eight sessions, it seemed to have cut the risk of depression in half.

Similarly promising findings came from a special weekly class given to 10- to 13-year-old youngsters at odds with their parents and showing some signs of depression. In after-school sessions they learned some basic emotional skills, including handling disagreements, thinking before acting, and, perhaps most important, challenging the pessimistic beliefs associated with depression—for example, resolving to study harder after doing poorly on an exam instead of thinking, “I'm just not smart enough.” Children learn in these classes that moods like anxiety, sadness, and anger do not just descend without warning; they learn that you can change the way you feel by what you think and that disputing the depressing thoughts vanquishes the gathering mood of gloom. These classes lowered depression rates by one half and continued to do so as long as 2 years later. A year after the classes ended, just 8 percent of those who participated scored at a moderate-to-severe level on a test of depression, versus 29 percent of children in a comparison group. After 2 years, about 20 percent of those in the course were showing some signs of at least mild depression, compared to 44 percent of those in the comparison group.

Learning these emotional skills at the cusp of adolescence—a crucial window for risk of depression—may be especially helpful. One experimental program focused on helping adolescent girls to learn how to handle relationships better: how to develop a friendship, how to feel more confident with other teens, how to assert limits on sexual closeness, how to be intimate, and how to express their feelings. In essence, it was a remedial tutorial in some of the most basic emotional skills.

Problems in relationships are a common trigger for depression, particularly in young people. The difficulty is as often in children's relationships with their parents as it is with their peers. Depressed children and teenagers are frequently unable or unwilling to talk about their sadness. They seem unable to label their feelings accurately, showing instead a sullen irritability, impatience, crankiness, and anger—especially toward their parents. This, in turn, makes it harder for their parents to offer the emotional support and guidance the depressed child actually needs, setting in motion a downward spiral that typically ends in constant arguments and alienation.

This new look at the causes of depression in the young pinpoints deficits in two areas of emotional competence: relationship skills and a depression-promoting way of interpreting setbacks. Although the tendency to depression is partially the result of genetic destiny, some of it seems caused by reversible, pessimistic habits of thought that predispose children to react to life's small defeats—a bad grade, arguments with parents, social rejection—by becoming depressed. Evidence suggests that the predisposition to depression, whatever its basis, is becoming ever more widespread among the young and there is a pressing need to introduce children at risk to psychological inoculation.

Eating Disorders The clinical literature on eating disorders offers a multitude of hypotheses about the causes, ranging from ever-younger girls feeling compelled to compete with unattainably high standards of female beauty to intrusive mothers who enmesh their daughters in a controlling web of guilt and blame. Most of these hypotheses suffer from one great drawback: they are extrapolations from observations of patients already diagnosed, rather than from prospective studies conducted on a large cohort before they became symptomatic. Such studies would assess for example, if having controlling parents predisposes a girl to eating disorders. Beyond that, studies can identify the cluster of conditions that leads to the problem, and distinguish them from conditions that might seem to be a cause, but that actually are found as often in people without the problem as in those who come for treatment.

When just such a study was done with more than 900 girls in the seventh through tenth grades, emotional deficits—particularly a failure to distinguish distressing feelings from one another and to control them—were found to be key among the factors leading to eating disorders. By tenth grade 61 girls in an affluent suburban high school already had serious symptoms of anorexia nervosa or bulimia nervosa. The greater the problem, the more the girls reacted to setbacks, difficulties, and minor annoyances with intense negative feelings that they could not soothe, and the less aware they were of exactly what they were feeling. When these two emotional tendencies were coupled with being highly dissatisfied with their body, the outcome was anorexia nervosa or bulimia nervosa. Overly controlling parents were found not to play a prime role in causing eating disorders. Also judged irrelevant were such popular explanations as fear of sexuality, early onset of puberty, and low self-esteem.

Instead, the causal chain this prospective study revealed began with the effects on young girls of growing up in a society that equates unnatural thinness with female

beauty. Well before adolescence, girls are already self conscious about their weight. In one study of 271 young teenagers, half the girls thought they were too fat, even though the vast majority of them were normal in weight. But the Minneapolis study showed that an obsession with being overweight is not in and of itself sufficient to explain why some girls go on to develop eating disorders.

Some obese people are unable to tell the difference between being scared, angry, and hungry and lump all those feelings together as signifying hunger, which leads them to overeat whenever they feel upset. Something similar seems to be happening in these girls. One psychologist who studied young girls and eating disorders, observed that poor awareness of one's feelings and body signals was the strongest single predictor that they would go on to develop an eating disorder within the next 2 years. Most children learn to distinguish among their sensations and can tell if they are bored, angry, depressed, or hungry, which is a basic part of emotional learning. But some have trouble distinguishing among their most basic feelings and may be unable to determine whether they are angry, or anxious, or depressed; they just experience a diffuse emotional storm that they do not know how to deal with effectively. They alleviate these symptoms with food. Other individuals, in an attempt to handle emotional confusion, refuse to eat at all. Anorexia nervosa can be a way to feel one has some control over these overwhelming feelings. The combination of poor inner awareness and weak social skills means that when upset by friends or parents these girls fail to act effectively to improve the relationship or to soothe their own distress. Instead their upset triggers bulimia nervosa, anorexia nervosa, or binge eating. Effective treatments for such girls need to include some remedial instruction in the emotional skills they lack. Researchers find that adolescents with eating disorders need to learn to identify their feelings and ways to soothe themselves or handle relationships better, without developing maladaptive eating habits.

Loneliness Socially rejected children typically are poor at reading emotional and social signals and may have limited repertoires for response. An inability to seize key cues is typical of children who are unpopular. Dropping out of school is a particular risk for children who are social rejects: between two and eight times greater than for children who have friends. One study found, for example, that about 25 percent of children who were unpopular in elementary school had dropped out before completing high school, compared to a general rate of 8 percent.

Two kinds of emotional proclivities lead children to become social outcasts. One is the propensity to angry outbursts and to perceive hostility even where none is intended. The second is timidity, anxiety, and shyness. Over and above these temperamental factors, it is children who are “off”—whose awkwardness repeatedly makes people uncomfortable—who tend to be shunned. When grade schoolers with few friends were asked to match an emotion such as disgust or anger with faces that displayed a range of emotions, they made far more mismatches than did children who were popular. When kindergarteners were asked to explain ways they might make friends with someone or keep from having a fight, it was the unpopular children—the ones others shied away from playing with—who came up with self-defeating answers (e.g., “Punch him” for what to do when both children wanted the same toy), or vague appeals to an adult for help. When asked to role-play being sad, angry, or mischievous, the more unpopular teenagers gave the least convincing performances. It is perhaps no surprise that such children believe that they are helpless to do any better at making friends; their social incompetence becomes a self-fulfilling prophecy. Instead of learning new ways to make friends, they simply keep doing the same things that have not worked for them in the past or make even more inept attempts.

In the lottery of liking, these children fall short on key emotional criteria: they are not seen as fun to be with and they do not know how to make another child feel good. Observations of unpopular children at play show that they are much more likely than others to cheat, sulk, quit when losing, or show off and brag about winning. Most children want to win at a game, but win or lose, most children are able to contain their emotions such that they do not undermine their relations with their friends.

Children who are socially tone-deaf—who continually have trouble reading and responding to emotions—end up as social isolates, but this does not apply to children who go through a temporary period of feeling left out. Those who are continually excluded and rejected feel their painful outcast status clinging to them as they continue their school years. The consequences of ending up at the social margins are potentially great as a child grows into adulthood. It is in the cauldron of close friendships and during the tumult of play that children refine the social and emotional skills that they will bring to relationships later in life. Children who are excluded from this realm of learning are inevitably at a disadvantage.

Understandably, those who are rejected report marked anxiety and are depressed and lonely. How popular a child was in third grade has been shown to be a better predictor of mental-health problems at age 18 than anything else—teachers' and nurses' ratings, school performance and I.Q., and even scores on psychological tests. Later in life people who have few friends and are chronically lonely are at greater risk for medical diseases and an early death.

Most people learn how to negotiate intimate relations—to work out differences and share their deepest feelings—in their first close friendships with same-sex friends. Children who are socially rejected are only half as likely as their peers to have a best friend during the crucial years of elementary school, and so miss out on one of the essential chances for emotional growth. One friend can make the difference even when all others turn away and even if that one friendship is not all that solid.

Friendship coaching sessions for unpopular children have shown some success. Third- and fourth-graders who were the least liked in their classes got six sessions on how to “make playing games more fun” through being “friendly, fun, and nice.” To avoid stigma, the children were told that they were acting as “consultants” to the coach, who was trying to learn what kinds of things make it more enjoyable to play games. The children were coached to act in ways typical of more popular children. For example, they were encouraged to think of alternative suggestions and compromises (rather than fighting) if they disagreed about the rules; to remember to talk with the other child while they play; to listen and look at the other child to see how he's doing; to say something nice when the other person does well; and to smile and offer help or suggestions and encouragement. The children also tried out these basic social skills while playing games such as Pick-up Sticks with a classmate, and were coached afterward on how well they did. This minicourse in getting along had a remarkable effect: a year later the children who were coached—all of whom were selected because they were the least liked in their class—were now solidly average in terms of classroom popularity: neither social stars nor outcasts.

Another program trains social outcasts to hone their ability to read and respond appropriately to other children's feelings. The children, for example, are videotaped while practicing expression of feelings such as happiness and sadness, and are coached to improve their emotional expressiveness. They then try out their newly honed skills with a child they want to make friends with. Such programs have reported a 50 to 60 percent success rate in raising the popularity of rejected children. As presently designed, these programs seem to work best for third- and fourth-graders rather than older children and were more helpful for socially inept children than for highly aggressive ones. But that is all a matter for fine-tuning; the hopeful sign is that many or most rejected children can be brought into the circle of friendship with some basic emotional coaching.

Substance Abuse In the United States the use of most substances among young people generally tapered off in the 1980s, but there is a steady trend toward more alcohol use at ever-younger ages. A 1993 survey found that 35 percent of college women said they drank to get drunk, as compared to just 10 percent in 1977; overall, one in three students drinks to get drunk. That poses other risks: 90 percent of all rapes reported on college campuses happened when either the assailant or the victim—or both—had been drinking. Alcohol-related accidents are the leading cause of death among young people between the ages of 15 and 24. Experimentation with alcohol and other substances might seem a rite of passage for adolescents, but this first taste can have long-lasting results for some. Most alcoholics and substance abusers can trace the beginning of their addiction to their teen years, though few of those who so experiment end up as alcoholics or substance abusers. By the time students leave high school, over 90 percent have tried alcohol, yet only about 14 percent eventually become alcoholics; of the millions of Americans who experimented with cocaine, fewer than 5 percent became addicted. What makes the difference?

One current theory is that those who stay with the habit, becoming increasingly dependent on alcohol or other substances, use these substances as a way to soothe anxiety, anger, or depression. Through their early experimentation they hit upon a chemical fix, a way to calm the feelings of anxiety or melancholy that have tormented them. Thus of several hundred seventh- and eighth-grade students tracked for 2 years, those who reported higher levels of emotional distress subsequently went on to have the highest rates of substance abuse. This may explain why so many young people are able to experiment with alcohol and other substances without becoming dependent, while others become dependent almost from the start: those most vulnerable to dependence seem to find in the alcohol or other substance an instant way to soothe emotions that have distressed them for years. For people who are biologically predisposed, the first drink or dose of a drug is immensely reinforcing; it stabilizes them physiologically, at least in the short term.

Certain emotional patterns seem to make people more likely to find emotional relief in one substance rather than another. For example, there may be two emotional pathways to alcoholism. Someone who was high-strung and anxious in childhood may typically discover as a teenager that alcohol can calm anxiety. Very often they are children—usually sons—of alcoholics who themselves have turned to alcohol to soothe their anxiety. One biological marker for this pattern is undersecretion of g-aminobutyric acid (GABA), a neurotransmitter that regulates anxiety: too little GABA is experienced as a high level of tension. One study found that sons of alcoholic fathers had low levels of GABA and were highly anxious, but when they drank alcohol, their GABA levels rose as their anxiety fell. These men drink to ease their tension, finding in alcohol a relaxation that they cannot seem to get otherwise. Such people may be vulnerable to abusing sedatives as well as alcohol for the same anxiety-reduction effect.

A neuropsychological study of sons of alcoholics who at age 12 showed signs of anxiety such as a heightened heart rate in response to stress as well as impulsivity found that the boys also had poor frontal lobe functioning. Thus the brain areas that might have helped ease their anxiety or control their impulsiveness helped them

less than the brain areas of other boys. The prefrontal lobes also handle working memory—which stores the consequences of various routes of action considered when making a decision—their deficit could cause these boys to slide into alcoholism by helping them ignore the long-term drawbacks of drinking, even as they found an immediate sedation from anxiety through alcohol. This craving for calm seems to be an emotional marker of a genetic susceptibility to alcohol abuse and dependence. A study of 1300 relatives of alcoholics found that the children of alcoholics who were most at risk for becoming alcoholics themselves were those who reported having chronically high levels of anxiety. Indeed, the researchers concluded that alcoholism develops in such people as "self-medication of anxiety symptoms."

A second emotional pathway to alcoholism comes from a high level of agitation, impulsivity, and boredom. This pattern shows up in infancy as being restless, cranky, and hard to handle; in grade school as being fidgety, hyperactive, and getting into trouble, a propensity that can push such children to seek out friends on the fringe and can sometimes lead to a criminal career or the diagnosis of antisocial personality disorder. Such people, who are usually men, cite agitation as their main emotional complaint; their main weakness is unrestrained impulsivity. Their usual reaction to boredom, which they often feel, is to search impulsively for risk and excitement. As adults, people with this pattern (which may be tied to deficiencies in two other neurotransmitters: serotonin and monoamine oxidase inhibitors [MAO]) find that alcohol can soothe their agitation. Not being able to stand monotony makes them ready to try anything; coupled with their general impulsivity, it makes them prone to abusing an almost random list of substances besides alcohol.

Depression can drive some to drink; the metabolic effects of alcohol often simply worsen the depression after a short reprieve. People who turn to alcohol as an emotional palliative do so much more often to calm anxiety than to alleviate depression; an entirely different class of drugs soothes the feelings of people who are depressed, at least temporarily. Feeling chronically depressed puts people at greater risk for dependence on stimulants such as cocaine, which provide a direct antidote to depression. One study found that more than half the patients being treated for cocaine addiction would have been diagnosed with major depressive disorder before they started their habit, and the deeper the preceding depression, the stronger the habit.

Chronic anger may lead to still another kind of susceptibility. In a study of 400 patients being treated for dependence to heroin and other opioids, the most striking emotional pattern was a lifelong difficulty handling anger and a quickness to rage. Some of the patients admitted that opiates made them finally feel normal and relaxed. Although the predisposition to substance abuse may in many cases be brain-based, the feelings that drive people to self-medicate themselves with alcohol or other substances can be handled without recourse to medication, as Alcoholics Anonymous and other recovery programs have demonstrated for decades. Acquiring the ability to handle those feelings—soothing anxiety, lifting depression, calming rage—removes the impetus to use drugs or alcohol in the first place. These basic emotional skills are taught remedially in treatment programs for drug and alcohol abuse; it would be far better if they were learned early in life, well before the habit became established.

PREVENTION

Over the last decade or so "wars" have been proclaimed in turn on teen pregnancy, dropping out, drugs, and violence. These campaigns come too late, after the targeted problem has reached epidemic proportions and taken firm root in the lives of the young. They are crisis intervention, the equivalent of solving a problem by sending an ambulance to the rescue rather than administering an inoculation that would prevent the disease in the first place. Instead of more such wars, the logic of prevention needs to be heeded; children need the skills to face life that will increase their chances of avoiding any of these pitfalls.

The emphasis on the role of emotional and social deficits does not deny the role of other risk factors, such as growing up in a fragmented, abusive, or chaotic family or in an poor, crime- and drug-ridden neighborhood. Poverty itself delivers emotional blows to children: poorer children at age 5 are already more fearful, anxious, and sad than their better-off peers, and have more behavior problems such as frequent tantrums and destructive spells, a trend that continues through the teen years. The press of poverty corrodes family life too: there tend to be fewer expressions of parental warmth, more depression in mothers (who are often single and jobless), and a greater reliance on harsh punishments such as yelling, hitting, and physical threats.

Emotional competence plays a role over and above family and economic forces—it may be decisive in determining the extent to which any given child or teenager is undone by these hardships or finds a core of resilience to survive them. Long-term studies of hundreds of children brought up in poverty, in abusive families, or by a parent who was severely mentally ill show that those who are resilient even in the face of the most grinding hardships tend to share key emotional skills. These include a winning sociability that draws people to them, self-confidence, an optimistic persistence in the face of failure and frustration, the ability to recover quickly from upsets, and an amiable personality. Many of these skills are innate—the luck of genes—but qualities of temperament *can* change for the better. One line of intervention is political and economic: alleviating the poverty and other social conditions that breed these problems; besides these tactics, which seem to move ever lower on the social agenda, there is much that can be offered to help children cope better with debilitating hardships.

One in two Americans experiences a mental disorder over the course of life. A study of a representative sample of 8098 Americans found that 48 percent suffered from at least one psychiatric problem during their lifetime. Most severely affected were the 14 percent who developed three or more psychiatric problems at once. This group was the most troubled, accounting for 60 percent of all psychiatric disorders occurring at any one time, and 90 percent of the most severe and disabling ones. Optimally, these problems should have been prevented in the first place. It is true that not every mental disorder can be prevented, but some, and perhaps many, can be prevented. Early intervention may help to keep one emotional problem from snowballing into a host of others—for instance, a social phobia in the sixth grade can be prevented from becoming a drinking problem in junior high school. By the late twenties, a child may have learned to alleviate her fears with substance abuse—alcohol, drugs, or both—and is liable to become depressed because her life is so messed up. What could have been done early in her life to have prevented this downward spiral?

The same holds true for dropping out, violence, or any of the perils faced by young people today. Educational programs to prevent one or another specific problem such as drug use and violence have proliferated wildly in the last decade, creating a mini-industry within the education marketplace. But many of these programs, including the most slickly marketed and most widely used, have proved to be ineffective. To the chagrin of educators, a few even seemed to increase the likelihood of the problems they were meant to head off, particularly substance abuse and teenage sex.

Active Ingredients A consortium of researchers studied outcome measures of prevention programs and distilled the active ingredients that seemed crucial to the success of those programs that worked. The list of key skills the consortium concluded should be covered, no matter what specific problem it is designed to prevent, reads like the ingredients of emotional intelligence: the skills include self-awareness; identifying, expressing, and managing feelings; impulse control and delaying gratification; and handling stress and anxiety. A key ability in impulse control is knowing the difference between feelings and actions, and learning to make better emotional decisions by first controlling the impulse to act, then identifying alternative actions and their consequences before acting. Many key competencies are interpersonal: reading social and emotional cues, listening, being able to resist negative influences, taking others' perspectives, and understanding what behavior is acceptable in a situation.

These are among the core emotional and social skills for life, and include remedies for most, if not all, of the difficulties discussed in this chapter. The specific problems these skills might prevent are nearly arbitrary; emotional and social skills could also prevent problems such as teen pregnancy and teen suicide.

The causes of all such problems are complex, interweaving differing ratios of biological destiny, family dynamics, the politics of poverty, and the culture of the streets. No single intervention can claim to do the whole job. However, to the degree that emotional deficits add to a child's risk, attention must be paid to emotional remedies, not to the exclusion of other answers, but in concert with them.

School-Based Primary Prevention Pilot interventions designed to target the specific deficits in emotional and social skills that underlie problems such as aggression or depression have been found effective, but have rarely been implemented in schools, where they could reach the maximum number of children. Emotional intelligence skill-building should be used as a primary prevention strategy; the lessons learned from such programs should be generalized and used as a preventive measure for the entire school population and taught by ordinary teachers. This more sophisticated and more effective approach to prevention should include information on acquired immune deficiency syndrome (AIDS), substance abuse, and the like, at the points in youngsters' lives when they are beginning to face these problems. Bringing emotional literacy into schools makes emotions and social life themselves topics, rather than treating these most compelling facets of a child's day as irrelevant intrusions or, when they lead to eruptions, relegating them to occasional disciplinary trips to the guidance counselor or the principal's office.

A list of the contents of an emotional literacy course almost exactly matches the core skills recommended as primary prevention for the range of pitfalls threatening children. The topics taught include self-awareness (recognizing feelings and building a vocabulary for them, and seeing the links between thoughts, feelings, and reactions), distinguishing between thoughts or feelings when making a decision; seeing the consequences of alternative choices; and applying these insights to decisions about such issues as drugs, smoking, and sex. Self-awareness also takes the form of recognizing one's strengths and weaknesses, and seeing oneself in a

positive but realistic light.

Another emphasis is on managing one's emotions: realizing what is behind a feeling (e.g., the hurt that triggers anger), and learning ways to handle anxieties, anger, and sadness. Taking responsibility for decisions and actions, and following through on commitments, is also emphasized. A key social ability is empathy, understanding others' feelings and taking their perspective, and respecting differences in how people feel about things. Relationships are a major focus, including learning to be a good listener and question-asker; distinguishing between what someone else says or does and one's own reactions and judgments; being assertive rather than angry or passive; and learning the arts of cooperation, conflict resolution, and compromise negotiation.

Typical emotional literacy curricula include, for example, learning in the earliest school years to control impulses; children who lack this ability have special trouble paying attention and so fall behind in their learning and grades. Another is recognizing their feelings; one curriculum has fifty lessons on different emotions, teaching the most basic, such as happiness and anger, to the youngest children, and later touching on more complicated feelings such as jealousy, pride, and guilt. The emotional awareness lessons include how to monitor what they and those around them are feeling, and—most important for those prone to aggression—how to recognize when someone is actually hostile, as opposed to projecting one's own hostility onto others.

Parents can benefit from being coached to be emotional mentors to their infants and toddlers, as some home-visit programs do. A strong argument can be made for emphasizing social and emotional skills more systematically in preschool programs such as Head Start; children's readiness to learn depends to a large extent on acquiring some of these basic emotional skills. The preschool years are crucial ones for laying foundation skills, and there is some evidence that, when run well, Head Start can have beneficial long-term emotional and social effects on the lives of its graduates even into their early adult years: fewer drug problems and arrests, better marriages, and greater earning power.

Such interventions work best when they track the emotional timetable of development. The newborn's repertoire of feeling is primitive compared to the emotional range of a 5-year-old, which, in turn, is limited compared to the fullness of a teenager's feelings. The timetable for emotional growth is intertwined with allied lines of development, particularly for cognition and brain and biological maturation. Emotional skills such as empathy and emotional self-regulation start to develop virtually from infancy. The kindergarten year marks a peak ripening of the “social emotions”—insecurity and humility, jealousy and envy, pride and confidence—all of which require the ability to compare oneself with others. On entering the wider social world of school, the 5-year-old also enters the world of social comparison.

David Hamburg, who has evaluated some pioneering emotional-education programs, sees the years of transition into grade school and then again into junior high or middle school as marking two crucial points in a child's adjustment. From ages 6 to 11 Hamburg says:

> School is a crucible and a defining experience that will heavily influence children's adolescence and beyond. A child's sense of self-worth depends substantially on his or her ability to achieve in school. A child who fails in school sets in motion the self-defeating attitudes that can dim prospects for an entire lifespan.

Among the essentials for profiting from school, Hamburg notes, are an ability “to postpone gratification, to be socially responsible in appropriate ways, to maintain control over their emotions, and to have an optimistic outlook”—in other words, emotional intelligence.

The transition to middle school or junior high marks an end to childhood, and is itself a formidable emotional challenge. As they enter this new school arrangement virtually all students experience a dip in self-confidence and a jump in self-consciousness; their very notions of themselves are rocky and in tumult. One of the greatest specific blows is in social self-esteem or confidence that they can make and keep friends. It is at this juncture, Hamburg points out, that it helps immensely to buttress boys' and girls' abilities to build close relationships, navigate crises in friendships, and nurture their self-confidence.

Hamburg notes that as students enter middle school, just on the cusp of adolescence, there is something different about those who have taken emotional literacy classes: they find the new pressures of peer politics, the upping of academic demands, and the temptations to smoke and use substances less troubling than do their peers. They have mastered emotional abilities that, at least for the short term, inoculate them against the turmoil and pressures they are about to face.

As family life no longer offers growing numbers of children a sure footing in life, schools are the one place communities can turn to for correctives to children's deficiencies in emotional and social competence. Since virtually every child goes to school (at least at the outset), school is the place to reach children with basic lessons for living that they may never get otherwise. Emotional literacy implies an expanded mandate for schools, taking up the slack for failing families in socializing children. This daunting task requires two major changes: that teachers go beyond their traditional mission and that people in the community become more involved with schools.

Beyond teacher training, emotional literacy expands our vision of the task of schools themselves, making them more explicitly society's agent for seeing that children learn these essential lessons for life—a return to a classic role for education. Apart from any specifics of curriculum, this enhanced role requires using opportunities in and out of class to help students turn moments of personal crisis into lessons in emotional competence. It also works best when the lessons at school are coordinated with what goes on in children's homes. Many emotional literacy programs include special classes to teach parents about what their children are learning, not just to complement what is imparted at school, but to help parents who want to deal more effectively with their children's emotional growth. The data suggest that although such courses do not change anyone overnight, as children advance through the curriculum from grade to grade, discernible improvements are seen in the emotional competence of the girls and boys who take them (Table 3.6-1).

Table 3.6-1 Outcomes: Social and Emotional Learning

Emotions and Physical Health There is another potential payoff for teaching children the basic skills of emotional intelligence: improved physical health through life. Research over the last two decades has yielded evidence of the emotions' effect on physical health. Medical science could benefit greatly from a broader knowledge and application of recent findings on the myriad ways emotions affect health and medical care.

A new area of medical research, *psychoneuroimmunology* investigates links between the immune system and the central nervous system. Recent research in psychoneuroimmunology suggests that emotions have powerful effects on the autonomic nervous system. The chemical messengers most crucial to the brain and the immune system have been found to be those that are also most dense in neural areas that regulate emotion. There are many physical meeting points where the autonomic nervous system communicates directly with lymphocytes and macrophages in the immune system.

Psychoneuroimmunology is based on a finding in 1974 by Robert Ader, who demonstrated that the immune system, like the brain, is capable of learning. Ader gave white rats a medication that artificially suppressed the quantity of T cells in their blood. The medication was given with saccharin-laced water. When the rats were given saccharin-flavored water alone, without the suppressive medication, their T-cell counts still dropped, to the point that some of the rats died; their immune systems had learned to suppress T cells in response to the sweetened water.

Until Ader's findings the prevailing wisdom had been that only the brain and central nervous system could respond to experience by changing (learning). Ader's finding led to the discovery of the myriad ways in which the central nervous system and the immune system are interconnected: biological pathways that link the mind, emotions, and body.

Research on heart patients has revealed that anger has a significant impact on heart function. When patients were asked to recount incidents that made them mad, the pumping efficiency of their hearts dropped by 5 percent. Some showed a drop in pumping efficiency of 7 percent or greater, thereby falling into a range indicating myocardial ischemia. The heart's pumping efficiency was not affected by other negative feelings such as anxiety, nor during physical exertion. This finding supports a larger network of evidence that suggests that anger can damage the heart. The theory that a hurried, high-pressure type A personality runs a greater risk of developing heart disease has become outdated, but hostility has been found to put the heart at risk.

Another study suggests that a proclivity towards anger is a better predictor of dying young than are other risk factors such as smoking, high blood pressure, and high cholesterol. Physicians who had scored highest on a test of hostility while still in medical school were seven times as likely to die by the age of 50 than those with low hostility scores. Other research has linked an inclination toward hostility in heart patients with the extent and severity of coronary artery disease.

Whereas proclivities toward chronic hostility and anger appear to put men at greatest risk for heart disease, for women the more risk-laden emotion may be anxiety. Research at Stanford University School of Medicine found that of women who had suffered a first heart attack, those who went on to suffer a second heart attack were marked by high levels of fearfulness and anxiety. In many cases the fearfulness took the form of crippling phobias: after their first heart attack the patients stopped driving, quit their jobs, or avoided going out.

An attitude of pessimism has been found to have strong negative effects on patients' recovery, and optimism has been found to offer corresponding benefits. In one study, men who had had a heart attack were evaluated on their degree of optimism or pessimism. Eight years later, of the 25 most pessimistic men, 21 had died; of the 25 most optimistic, just 6 had died. Their mental outlook proved a better predictor of survival than any medical risk factor, including the amount of damage to the heart in the first attack, artery blockage, cholesterol level, or blood pressure. Another study found that artery-bypass surgery patients who were optimistic had a faster recovery and fewer medical complications during and after surgery than did pessimistic patients.

Emotional support offers patients observable and sometimes life-saving benefits. Of bone marrow transplant patients who reported having strong emotional support from spouses, family, or friends, 54 percent were still alive after 2 years, versus just 20 percent of those who reported having little emotional support. Similarly, elderly heart-attack patients who have emotional support are more than twice as likely to survive longer than a year after an attack than are people with no such support.

Emotionally Intelligent Medicine When anger and anxiety are chronic, people are more susceptible to a range of disease. Although depression may not make people more vulnerable to ill health, it does seem to impede medical recovery and heighten the risk of death, especially in frailer patients who are seriously ill.

Medicine's inattention to the impact of emotions on illness neglects a growing body of evidence that indicates that emotions can play a significant role in vulnerability to disease and recovery from disease. Modern medical care too often lacks emotional intelligence. There are many ways medicine can incorporate the new knowledge of the impact of emotions on health into its view of patient care, which could be a new focus for consultation-liaison psychiatry.

SUGGESTED CROSS-REFERENCES

Psychoneuroimmunology is discussed in Section 25.10 on behavior and immunity. Mood disorders and anxiety disorders are covered in Chapter 14 and Chapter 15, respectively. Antisocial behavior, aggression, and violence are covered in Section 27.3. Alcohol and other substance abuse is covered in Chapter 11. School consultation is presented in Section 49.14 and psychiatric prevention in children, in Section 49.15.

CHAPTER 4. CONTRIBUTIONS OF THE SOCIOCULTURAL SCIENCES

4.1 ANTHROPOLOGY AND PSYCHIATRY

ANNE E. BECKER, M.D., PH.D., AND ARTHUR KLEINMAN, M.D.

The fields of social and cultural anthropology comprise the study of various aspects of society, such as kinship, social exchange, and religious experience in the context of politics, economics, and large symbolic systems (e.g., language, aesthetic systems) in order to describe and interpret how the social world is ordered and how it responds to the disordering effects of historical change. Social and cultural anthropology include studies of local worlds—through collection and analysis of ethnographic data—and their cross-cultural comparison. Medical anthropology, a robust and expanding subfield of social anthropology, includes the comparative study of healing systems and the social, economic, political, and cultural contexts of health and health care. This field also encompasses the study of how social processes produce health effects and how cultural processes construct illness experience. This chapter reviews the major contributions of medical anthropological perspectives to psychiatry; these include a set of concepts that enhances communication and service delivery in cross-cultural settings as well as a conceptual framework alternative to biomedical theories of health and disease.

Unfortunately, much of the early interest in cross-cultural studies focused on exotic healing rituals and culture-bound diseases, thereby obscuring anthropology's theoretical and practical relevance to everyday problems and practices. The field's contributions to general medicine—for example, infectious diseases, chronic medical disorders, disability, and public health—have arguably become increasingly visible and relevant since the late 1970s. Whereas the recently emerging paradigm of neurobiological psychiatry increasingly locates mental illness in the brain and favors a universalizing theory of psychiatric illness, anthropology engages the diversity of human experience. Indeed, it is through a cross-cultural lens that universals and diversity in human experience emerge, lending insight into nonbiological factors that affect the pathogenesis, phenomenology, course, response to treatment, outcome, and lived experience of illness.

Anthropology and psychiatry have been historically linked since the late nineteenth century when W.H.R. Rivers, a psychiatrist, was joined by several other physicians on an expedition to the Torres Straits. That research trip to the South Pacific was the source of much empirical research in British social anthropology. Rivers' ethnographic and clinical expertise converged not only in his cross-cultural studies on religious healing and on pain sensation but also in the form of psychotherapy that he later developed to treat soldiers with shell shock during World War I. Cross-fertilization between the fields continued into the next century within the culture and personality school, where studies based on a psychoanalytic conceptual framework and popularized by the American anthropologists, Margaret Mead and Ruth Benedict, brought leading anthropologists and psychiatrists into a productive collaboration. Similarly, French sociologist Emile Durkheim's landmark study on suicide drew attention to the social underpinnings of seemingly individual behavior, and George Herbert Mead, the American sociologist who created the symbolic interactionist theory, created a social science approach to the study of the ways in which personhood and self processes emerge from the social context of language use.

Subsequent interface between the fields explored the phenomenological diversity of mental illness transculturally, with particular interest in culture-bound syndromes and culturally sanctioned altered states of consciousness, such as trance and possession states. These syndromes and states fascinated psychiatrists who were interested in so-called primitive culture (an idea now thoroughly discredited), yet were of only marginal theoretical or practical interest to the clinical practice of psychiatry in Western settings. As the dominant biological paradigm for mental illness emerged, however, so did a keen interest in the cross-cultural epidemiology of psychiatric disorders; indeed, recognition that certain mental disorders appear across cultures strengthened the evidence of their putative biological substrate.

Research in the cross-cultural epidemiology of mental illness has posed theoretical and methodological challenges, calling for the serious engagement of anthropological theory and methodology by the field of psychiatry in addressing the complex interplay of local biologies; the cultural patterning of experience and behavior; and the social, political, and economic contexts of disease. This application of an anthropological perspective to mental illness has illuminated a dialectic between human diversity and universals in light of the cross-cultural data.

The relevance of anthropological contributions to psychiatry is most apparent in three critical areas. First, from a theoretical standpoint, the documentation of particular mental disorders in different sociocultural contexts provides evidence for their syndromal significance and integrity in the absence of biological markers. Second, from a clinical standpoint, the elicitation of explanatory models from and the engagement of the growing number of patients from culturally and ethnically diverse backgrounds play an essential role in formulating illness and responding to it in culturally appropriate ways. Finally, from a public health perspective, understanding the social production and social course of mental illness suggests means of improving outcome or even preventing illness.

CULTURAL PSYCHIATRY

Numerous studies have sought to demonstrate the cross-cultural epidemiology of major mental illness, both to demonstrate the universality of particular syndromes and to investigate how prevalence and phenomenology may differ relative to cultural context. The interpretation of findings, however, has been limited by major methodological pitfalls in conducting transcultural research and a persistent tendency to interpret data as evidence of universality rather than of heterogeneity of disorders. Indeed, such studies have commonly stemmed from the presumption that discrete psychiatric syndromes are identifiable and comparable across varying cultural contexts. This presumption risks creating a *category fallacy*—that is, applying a category that is valid in one cultural context (in this case in Western psychiatric nosology) to a culture in which the category has no local relevance or diagnostic validity. For example, a category fallacy would occur if a Malaysian healer were to study *latah* in Boston. This healer might find fright, echopraxia, or other symptoms associated with *latah* in Malaysia, but the recognition of these symptoms as a particular syndrome with local meaning would be absent in the Boston context. The same caution would need to be exercised by a Western psychiatric researcher in investigating the prevalence of maternity blues, for instance, in Fiji where symptoms of tearfulness and anxiety may be identified in the immediate postpartum period but are not locally marked as an illness. This universalizing approach to exploring the meaning of illness and behavior transculturally contrasts with a *cultural relativist* perspective that posits that cultural values and meanings cannot be measured against a universal system but rather are relative to and fundamentally embedded in their cultural context. For example, particular behaviors (such as trance or possession states) may be judged as deviant in one society but as acceptable in another. Similarly, diverse grieving practices suggest that the duration and form of appropriate bereavement can only be understood within a particular cultural context.

To minimize the risk of creating a category fallacy, it is helpful to draw from the anthropologic concepts of *etic* and *emic* levels of analysis in investigating psychiatric disorders transculturally. *Etic*, in this case, refers to the application of Western categories to another cultural context, whereas *emic* refers to the use of locally meaningful categories. Successful research identifies indigenous syndromes and describes their phenomenology and associated local explanatory models from an ethnographic perspective. Comparison can then be made with Western psychiatric categories of disorder to establish or refute their validity locally. However, translation into the comparative cross-cultural discourse of international psychiatry should be the last, not the first, step, which unfortunately goes against the tide of much psychiatric research.

It is insufficient to use standardized assessment instruments (even if they are translated, backtranslated, and further analyzed and revised) without ensuring that they measure locally valid constructs. Anthropologists have argued that emotions, such as a depressed or anxious mood, are themselves culturally constituted and that the ways in which feelings are experienced, processed, and communicated are constrained and evolved by the cultural milieu. For example, depressed mood among the Flathead Indians of Montana is not only an indicator of distress but is experienced as a positive symbol of belongingness to the community. Among the Ifaluk in the South Pacific sadness and anger are defined as a single, complex emotional state. Soul loss is a moral-emotional state in many non-Western societies. The local meanings attributed to emotional experience and the associated somatic experience may then be recognized and labeled as illness or not, depending on the context. For this reason, assessment instruments are ideally constructed or modified to include culturally local affective terms or idioms incorporating an *emic* approach.

Several investigators have also demonstrated that a cultural response style may skew data toward either an underreporting or an overreporting of symptoms. For example, among Puerto Ricans, one study found that there was an increased tendency to respond in the affirmative to symptoms on a symptom checklist, both because of an increased willingness to report symptoms as compared with other ethnic groups and because the symptoms were judged to be less socially

stigmatizing. The latter may have been true because the symptoms overlapped with culturally appropriate means of expressing distress (ie., *nervios*). Hence, cultural norms in responding to questionnaires as well as within interview settings must be factored into both the development of appropriate instruments and interview questions and techniques and the interpretation of the data in order to enhance the validity of cross-cultural comparisons.

These problems are somewhat attenuated when local ethnopsychological or ethnomedical theories are used to establish illness or emotional categories relevant to the cultural group being studied. For example, the revised second edition of *Chinese Classification of Mental Disorders* (CCMD-2-R) represents an attempt to include Chinese mental illness nosology within a Western psychiatric nosology. The CCMD-2-R includes such illness categories as *shenjing shuairuo* (neurasthenia) and *qiqong*, induced mental disorder—and train or travel psychosis is a candidate diagnosis—while excluding certain Western disorders that hold no local relevance, such as somatoform disorders, pathological gambling, and some personality disorders.

The potential for ethnocentrism in evaluating the presence of psychopathology cross-culturally is particularly heightened in the application of Western constructs of personality. The local cultural context (including means of socialization into language use, child-rearing, adolescent initiation, opportunities for individuation and achievement) not only shapes personality development through culturally specific notions of selfhood, but also determines relative definitions of character pathology. Concepts of self in Western societies are regarded by cultural psychologists and psychological anthropologists as rather intensively *egocentric* in contrast with concepts of selfhood in the majority of other societies, which have been characterized as relatively much more *sociocentric*. In the latter, individual identity is tied to a myriad of social relationships in contrast to personal attributes. Sociocentric societies place a premium on social harmony rather than individual needs or desires. In the same vein, in contrast with Western societies in which status is ideologically *achieved*, many societies *ascribe* status, changing and constraining the landscape of behavioral motivation. Behavior that is undesirable or aberrant in Western contexts is considered appropriate in such contexts. Conversely, behavior that is supported in Western cultures, such as self-assertion or self-cultivation, is potentially problematic or disruptive in a sociocentric society in which status is ascribed.

However, as recent social theory argues, care must be taken in using these categories of cross-cultural difference for several important reasons. First, they tend to represent ideological positions, not necessarily everyday practice. For example, even though Americans, French, Italians, and Greeks may emphasize egocentricity, in actual practice these groups also show considerable sociocentricity. Second, societies are diverse; experience may be (and often is) different owing to gender, age-cohort, ethnic, religious, and class differences. Third, globalization is proceeding at an astonishing rate. Along with changes in dress, diet, entertainment, and lifestyle, the global media and political economy are also changing collective and subjective orientations and practices. A good example of this is the spread of Western fashion ideals and disorders such as anorexia nervosa to areas like China where neither the ideal nor the pathology were previously found.

The bias in cross-cultural epidemiological research in investigating and reporting universals rather than the heterogeneity of illness presentations is exemplified in the International Pilot Study of Schizophrenia (IPSS) and the Determinants of Outcome Study sponsored by the World Health Organization. The IPSS attempted to document core schizophrenic symptoms in diverse cultural contexts. Although it succeeded in establishing clusters of similar symptoms across a variety of Western and non-Western contexts, its rigorous inclusion and exclusion criteria effectively selected for homogeneity and against heterogeneity across cases. Despite this selection bias, the IPSS documented that the course of schizophrenia differed cross-culturally. However, this finding was deemphasized relative to the demonstration of core schizophrenic symptoms across cultures. Similarly, although data generated from the Determinants of Outcome Study showed impressive variation in the cross-cultural prevalence of subtypes of schizophrenia, the authors of the study chose to highlight cross-cultural similarities.

This selective attention to universals in cross-cultural psychiatric research is arguably propelled by the field's enthusiasm for establishing the neuroanatomic and neurophysiological bases of mental illness. The common characterization of mental illnesses as disorders of mind arising in the brain reflects the dominant biological paradigm in the field of psychiatry that mental disorders are grounded in the brain whereas apparent cross-cultural differences are considered mere epiphenomena. This enthusiasm remains untempered by data that continue to support the conclusion that environmental effects can override biological predisposition to illness. Notwithstanding the important advances in neuroimaging, pharmacotherapy, and genetic research that validate a biological understanding of mental illness (albeit in the absence of any biological markers for schizophrenia, depression, or anxiety disorders), the professional culture of psychiatry is itself subject to social pressures (e.g., pharmaceutical industry funding or a managed-care environment that provide incentives for pharmacological management of mental illness) that support a biologically reductionistic approach to mental illness.

Cultural differences in psychiatric illness have been commonly understood as superimposed on biological substrates. Within this model of biological primacy, culture has been conceptualized as contributing only to the particular local manifestations of an underlying disorder rather than as being inherent to the very substrate of the disorder. Anthropological research challenges this perspective by providing data on the dialectical interplay of psychobiological and sociocultural processes in the prevalence, phenomenology, course, and outcome of mental illness.

Culture of Biomedicine The professional culture of biomedicine has also been a focus of inquiry by anthropologists. As within any culture, locally held values and meanings are powerful forces in socializing individuals within the culture—in this case, clinicians. In the course of professional training—medical school, internship, and residency—clinicians learn to recognize and formulate physiological and psychological signs and symptoms into patterns that correspond to culturally salient nosological categories. In Medicine, Rationality, and Experience, Byron Good describes how students of biomedicine are taught to write and speak in ways that construct sick individuals as patients—ways, incidentally, that generally de-emphasize an individual's experience of illness. This reduction of an individual's illness experience to a diagnostic category is also supported within the professional culture of psychiatry for a variety of reasons, including the current dominance of the biological paradigm and the necessity of documenting a diagnosis from the fourth edition of Diagnostic and Statistical Manuel of Mental Disorders (DSM-IV) for reimbursement by third-party payers. The very organization of DSM-IV reflects the professional marginalization of ethnic and cultural dimensions of illness presentation and experience insofar as an outline for the cultural formulation of psychiatric illness is relegated to its ninth appendix.

Culture-Bound Syndromes *Culture-bound syndromes* are illness phenomena that appear to be restricted to a particular cultural context. Numerous culture-bound syndromes that encompass a wide range of psychological and somatic symptoms have been described around the globe (Table 4.1-1). Some examples include acute episodes of psychosis and violence such as *amok* (Malaysia) and *boufée déireante* (West Africa or Haiti), syndromes with prominent anxiety such as *ataques de nervios* (Latin America and the Caribbean), *koro* (Malaysia), or *shin-byung* (Korea), and dissociative events such as *pibloktoq* (Eskimo communities) and *qiqong* induced mental disorder (China).

Table 4.1-1 A Selection of Culture-Bound Syndromes* by Region or Ethnic Group

There has been a tendency within the field of Western psychiatry to interpret these syndromes as exotic manifestations or *formes frustes* of underlying universal disorders rather than as true culturally particular syndromes. Although somewhat controversial, it is illuminating to characterize certain disorders such as chronic fatigue syndrome and dissociative identity disorder that appear to be culturally specific to North American settings as culture-bound syndromes as well. In doing so, it becomes clearer that certain patterns of emotional and somatic experience and behavior are selected and understood as locally meaningful *idioms of distress* within their particular cultural contexts. Particular symptoms are recognized as having salience in signaling distress and channeling experience, thereby organizing a culturally mediated and specific response to distress. Individuals are socialized to attend to and interpret experience in locally meaningful ways, resulting in the culturally distinctive patterning of symptoms and attribution of relevance. This way of looking at illness is now widely accepted by medical anthropologists, whereas for many anthropologists the idea of creating a separate category of culture-bound disorders has come to represent the problem of essentialism in psychiatry, (i.e., a cultural difference is reified as primordial and definitive of some deeply natural source of group difference, when in fact what is seen as a culture is itself a blend of

subgroups and individual differences).

Cultural norms interact with pathophysiological processes not only to pattern illness experience but to sanction or discourage expression of distress in particular ways. However, they do so in ways that are less definitive than earlier believed, and in ways that are modified by intracultural and individual diversity. It is crucial to avoid unidimensional cultural or ethnic stereotypes. In societies that value autonomy, independence, and the pursuit of self-interests (such as in European-American culture), the direct expression of distress is permissible, even encouraged, in the articulation of negative or dysphoric emotional states and often in a psychological idiom; by contrast, in societies in which interdependence and support of familial or community harmony is valued (such as in many Asian societies), distress may be preferentially articulated in an indirect or somatic idiom. However, many European-Americans do not express distress directly and do somatize, and some non-Westerners have traditionally expressed emotion directly and do not somatize. Indeed, using the body as an idiom of distress is a more or less universal social psychological process.

Somatization Research has demonstrated that the somatic expression of distress occurs across all cultural groups studied, although its particular form varies with the local cultural context. The widespread notion that it is a less sophisticated form of distress reflects the western cultural predilection in the second half of the twentieth century to communicate distress in a psychological idiom; it is also a faulty and racist ideological premise in Western thought. In their review of culture and somatization, Laurence J. Kirmayer and Allan Young comment that:

Equating somatization with primitive thinking or communication is based on several doubtful premises: that greater psychological insight necessarily results in fewer somatic symptoms; that psychological idioms are inherently more “advanced” than somatic idioms; that somatic idioms are “less differentiated” and inarticulate; and, finally, that psychological (and by analogy, cultural) development moves along a one-dimensional continuum from primitive to advanced. In fact, the use of a bodily idiom may say more about the social and cultural context of communication than it does about the cognitive limitations of psychological defensiveness of the individual.

What this view fails to mention is the racist potential for deploying this theory in clinical settings; this has actually happened in the way in which ethnic minorities have been labeled by an earlier generation of psychiatrists in America.

A somatic idiom of distress may also be preferentially invoked in contexts in which mental illness is seen as a stigma or in which mental health care is not readily available. Similarly, in contexts in which emotional distress is not culturally marked, the somatic expression of distress can be understood as a means of engaging the social milieu and mobilizing support within the local cultural context. Finally, embodied distress may also have a moral context, signaling complaint, resistance, or profound demoralization in a political or social milieu in which direct articulation is an impossibility.

SOCIOSOMATIC VERSUS PSYCHOSOMATIC ILLNESS Distress may be preferentially articulated in a somatic lexicon in contexts in which a psychological idiom does not have legitimacy or in which embodied illness provides a metaphor for social disharmony. Such an idiom may rapidly mobilize social supports without jeopardizing harmonious social relations or political safety. For example, weight loss (“going thin”) indexes social loss or marginalization in Fiji. Likewise, *na tadoka ni vasucu*, a postpartum somatic syndrome, is attributed to inappropriate physical or emotional exertion by a new mother in Fiji, and is an indirect marker of social neglect. Although the syndrome, which consists of nonspecific aches and pains, commonly coexists with depressed mood, depressed mood is rarely articulated whereas this syndrome rapidly allows the new mother to elicit social supports in the postpartum period. Similarly, individuals suffering from neurasthenia in China have commonly attributed their illness to the political and social upheaval caused by the Chinese Cultural Revolution. Core symptoms of the illness, such as exhaustion and dizziness, resonated with the exhausting and oppressive political changes of that period and became a bodily metaphor for social disorder.

In these examples, pain and suffering are transduced from their social, economic, and political sources and are experienced as physical symptoms. It is arguably most appropriate to understand somatization in such instances as *sociosomatic*—that is, emanating from social contexts—rather than as psychosomatic because it is easier to identify social processes that relate to mind-body processes and because so many psychological formulations of psychosomatic illness ignore the real world of debts, obligations, threats, and opportunities, replacing it with theories like alexithymia that appear to be dubious because they forget that individuals live within a complex social context.

Cultural Construction of Illness Categories It is noteworthy that while the syndromic clustering of particular symptoms and the local attributions of the cause of the various culture-bound syndromes are unfamiliar to Western psychiatric nosology, the symptoms—including anxiety, depressive, dissociative, and psychotic—generally are not. The local interpretation of these symptoms and their formulation as syndromes is culturally constructed according to their salience in their particular context. These syndromes derive their significance from their immediate cultural context and do not necessarily correspond to the illness categories of Western nosology.

It is helpful to depart from the notion that biomedical illness categories described in DSM-IV are somehow more “real” than folk categories that are culture specific. In Medicine, Rationality, and Experience, Good argues that, “medicine formulates the human body and disease in a culturally distinctive fashion.” In other words, medicine does not simply describe biological realities but rather constitutes a particular perspective in attributing meaningfulness to symptoms and symptom clusters. Inasmuch as Western psychiatric nosology organizes disorders categorically despite considerable phenomenological overlap among syndromes, a continuum of severity, high levels of comorbidity among disorders, and the clustering of disorders with particular patterns of social problems, the boundaries between disorders reflect a schema that is culturally derived despite being based in objective symptoms. Both Western psychiatric and culture-bound syndromes are somewhat culturally constructed in that they are characterized by contextual validity and reflect a culturally specific means of organizing symptoms into syndromic significance—this is anthropological commonsense.

Cross-Cultural Variation in Psychiatric Illness Anthropologists and psychiatrists alike have been interested in how illnesses that appear to represent similar processes differ with respect to their cultural contexts. These differences have often been dismissed as relatively superficial influences on, for example, the content of delusions or hallucinations. However, substantive cross-cultural differences have been demonstrated in phenomenological variation of mental illnesses as well as in their prevalence and course. Transcultural comparison can therefore illuminate ways in which the sociocultural environment shapes disease processes, and it is as fundamental a way of knowing as an experiment in the laboratory.

Cross-Cultural Prevalence of Major Mental Disorders The major mental disorders—anxiety, mood, and psychotic disorders—have been identified around the globe but with a wide variation in prevalence. However, methodological constraints have continued to complicate the understanding of their distribution. For instance, cross-national epidemiological research had demonstrated wide variation in rates of major depressive disorder transculturally. Investigators have reported that depression was virtually unreported in China prior to 1981, whereas it has been increasingly reported in the past two decades. Similarly, depression has been documented to be on the increase in a sample of Taiwanese over 15 years. These data suggest that rates of depression may have increased with social risk factors (which almost certainly has happened), that depression has become an increasingly legitimate idiom of distress (which also appears to be the case), or that psychiatric practice may have changed (which again seems true). Thus, a change in prevalence rate is a measure not of one simple thing, but of several processes—cultural, social, and professional.

In one study on the cross-national epidemiology of major depressive disorders and bipolar I disorder, Myrna Weissman and her colleagues reported that lifetime rates of major depressive disorder ranged from 1.5 cases per 100 in Taiwan to 19.0 cases per 100 in Beirut, Lebanon. The authors drew the conclusion that “cultural differences of different risk factor profiles across countries may affect the expression of the disorder.” Indeed, the results of this study imply that either the prevalence of depression varies with culture-specific risk factors or that depression presents differently (even unrecognizably) across cultural contexts. In spite of the simplification of their analytic dichotomy and of particular interest, they also found that in most of the samples studied individuals who were divorced or separated had significantly higher rates of depression than those who were married. These data suggest that marriage may be a virtually universal marker of social support that confers significant protection against depression among the nations studied.

Also, because dysphoric mood was required to meet the criteria of major depressive disorder in this study it is quite likely that locally salient depressive syndromes may have been overlooked (e.g., those in which anhedonia was prominent), so that depression or such local depressive syndromes were underreported. Notably, this study found that the lifetime rates of bipolar I disorder were more consistent across the samples studied, ranging from 0.3 cases per 100 in Taiwan to 1.5 cases per 100 in New Zealand. This intriguing finding may relate to the local cultural response to a manic episode as socially disruptive and thus marked as deviant in contrast to a depressive episode, which may not be expressed in a way that marks it as mental illness. Thus, symptoms may or may not be recognized and labeled as pathological across differing cultural contexts. Dysphoric affect, for example, may be locally understood as emanating from demoralization or grief. This may engender a response from the individual or family to address its existential meanings, but not necessarily to seek medical care. All these possibilities may contribute to the cross-cultural differences in prevalence and presentation of the major mental disorders. The metatheoretical point is that anthropological analysis encourages the

examination and use of multiple frameworks of analysis even if they offer competitive interpretations.

SCHIZOPHRENIA Several large-scale studies have investigated the cross-cultural prevalence of schizophrenia, but interpretation of cross-cultural differences is similarly problematic. Even after the exclusion of cases that represented heterogeneous presentations of schizophrenia, researchers have reported substantial cross-cultural differences in rates of the subtypes of schizophrenia. For example, in the developing world rapid-onset of schizophrenia was more common than insidious onset, whereas in industrialized societies onset with the paranoid type of schizophrenia was more common. Catatonic schizophrenia was also more common and the hebephrenic type less common in developing countries as compared to industrialized societies. Data also reveal major differences in the clinical features and course of schizophrenia across different cultural contexts; specifically, schizophrenia is more likely to present with an insidious mode of onset and follow a worse course in Western countries.

Social Course of Illness The priority placed on identified neurophysiological and neuroanatomical correlates of psychiatric illness obscures the substantial impact of sociocultural context on course and outcome of illness. There is strong evidence that illness follows a social course that interacts with the underlying biology of the disorder to produce a range of severity and outcome. This is perhaps best clarified in data from the International Pilot Study of Schizophrenia and the Determinants of Outcome Study that indicate a more favorable prognosis for schizophrenia in nonindustrialized societies than in industrialized, Westernized societies, which is evidence that the course of schizophrenia unfolds in culturally particular ways.

Psychiatrists and anthropologists have identified several aspects of the sociocultural environment that are likely to improve the course of schizophrenia in developing societies, including the lower likelihood of social isolation and a greater degree of social support. Most developing societies have a higher degree of sociocentrism than Western cultures, placing primacy on social and familial bonds that protect individuals from social isolation. In Western contexts, a familial milieu structured on the nuclear family allows fewer resources than in extended-family situations and may engender greater intrafamilial tension, thereby acting as a potential stressor to an individual with schizophrenia. Reintegrating an individual into occupational or productive roles may be relatively easier in developing countries than in industrialized countries in which unemployment may be high and the job market and milieu may be highly competitive. Moreover, symptomatic individuals may be able to cope with work-related tasks in agricultural or village settings more easily. Furthermore, certain psychiatric symptoms may be less stigmatized in traditional societies in which individuals may be seen as victims of witchcraft or medical illness than in Western societies in which individuals with schizophrenia may be highly marginalized. Finally, the very notion of a desirable outcome is likely to be highly context dependent. Outcome variables in Western, industrialized societies may include frequency of hospitalizations, ability to care for self, or some engagement in productive activities. In developing societies, however, the social environment may provide more flexibility in supporting an individual's ability to engage in meaningful social relationships and productive labor and hence may render the illness less disabling.

Another illustration of the social course that illness takes in relation to local political economy is revealed in the different course acquired immune deficiency syndrome (AIDS) takes in America and Africa. For example, the reason the course of AIDS is several times longer in America than in Africa is not because of the biology of the virus, but because of the absence of new treatments as well as the effect of deep poverty on housing, diet, immunological status, and the presence of high rates of infectious diseases in Africa.

RELEVANCE OF SOCIOCULTURAL FACTORS TO CLINICAL PSYCHIATRIC PRACTICE

Although most practicing psychiatrists are unlikely to encounter psychiatric illness in international contexts, the rapidly expanding percentage of the United States population representing ethnically diverse populations virtually guarantees that ethnic and cultural factors will impinge upon the therapeutic encounter. Whereas only 13 percent of the United States population was comprised of ethnic minority individuals at the beginning of this century, this figure increased to 25 percent by 1990. The minority population is projected to be about one third of the total population by 2010 and to approach one half by 2050. This scenario is already in place in California, the nation's largest state, which records non-Hispanic white Americans as fewer than half the state's population.

A careful sociocultural history provides essential clinical data with which to contextualize how a patient presents with an illness. Specifically, this approach identifies crucial information regarding social supports, relevant psychosocial precipitants and stressors, explanatory models of the illness, and characteristic patterns of help-seeking behavior for a particular illness. It also assists the clinician in distinguishing abnormal from normal presentations relative to the patient's cultural background and attending to culturally salient idioms of distress that may be articulated in unconventional ways and may otherwise confuse diagnosis and delay appropriate interventions.

Ethnicity and Access to Health Care Disturbing trends in diminished access to health care among ethnic minority individuals seriously compromise their ability to receive treatment for mental illness. Some of these barriers to health care are economic; for instance, one study found that a significantly higher percentage of Latino-Americans and African-Americans were without health insurance than white Americans. Because of frequently inadequate reimbursement for mental health care by third-party payers, economically disadvantaged groups are more likely to be unable to pay for care. Other significant impediments to accessing care may include lack of available or conveniently located services; one study found that significantly lower percentages of African-Americans, Latino-Americans, and Asian-Americans had seen a physician in 1987 as compared with all Americans. Also, there is the opportunity cost for poor people to take time off from work and go without wages or to risk losing a job.

Ethnicity and Patterns of Help-Seeking Patterns of help-seeking for health care services—in particular for the treatment of mental illness—differ widely among different ethnic groups. Help-seeking behaviors include willingness to seek and initiate care in professional biomedical settings, folk or so-called alternative settings, or within the popular sector (e.g., family or friends). For example, in Canada a sample of European-Canadian patients were readily self-referred or referred by family members to professional mental health care whereas Chinese psychiatric patients delayed initiation of professional care for protracted periods of time. In this study, mental illness among Chinese patients was kept within the confines of the family, often until the symptomatology was quite advanced. Native-Americans in this study also did not voluntarily seek professional biomedical services, but came into contact passively with various health and social agencies.

Help-seeking patterns for mental illness will be predicated upon identification of symptoms as constituting an illness. The distinction between *disease* and *illness* that is often made in the medical anthropology literature is helpful in illuminating this process further. *Disease* refers to the professional's understanding of the pathophysiological processes constituting signs and symptoms whereas *illness* refers to the patient's and family's recognition, labeling, and experience of these processes as abnormal or as a departure from wellness. Even if symptoms are experienced as *illness*, help-seeking decisions rest upon local explanatory models of what, if anything, constitutes appropriate therapy. For example, an individual may prefer to treat the symptoms with home remedies or folk therapies rather than seek treatment at a biomedical facility. Even when care is sought within the professional biomedical arena, the somatic rather than affective symptoms may be selectively attended to or identified as appropriate for treatment. Additionally, local beliefs that mental illness is a stigma may discourage individuals or families from seeking professional psychiatric care.

Alternatively, persons of color may be dissuaded from seeking professional health care or from effectively engaging in the therapeutic encounter because of past experiences of having been insulted, disrespected, or otherwise discriminated against within professional settings.

Ethnicity and Psychiatric Diagnosis Ethnicity clearly makes a substantial impact upon diagnosis in the clinical encounter. Specifically, indications are that psychiatric misdiagnosis is more likely among minority individuals than nonminority individuals in the United States. A number of studies indicate that African-American patients tend to be overdiagnosed with schizophrenia and underdiagnosed with mood disorders. Some data suggest that in the United States Latinos may also be at elevated risk for a misdiagnosis of schizophrenia. The potential for misdiagnosis among other ethnic minority populations is underresearched.

CLINICIAN BIAS Clinician bias or ethnic stereotyping is likely to account for some of the psychiatric misdiagnosis associated with ethnicity. This is perhaps best evidenced by a study in which 290 clinicians responded to two clinical vignettes describing patients with symptoms, consistent with the undifferentiated type of schizophrenia and dependent personality disorder. In the United States, clinician raters were more likely to (incorrectly) diagnose black males as having paranoid schizophrenia (43 percent compared with 6 percent for white males) and paranoid personality disorder (50 percent of black males as compared with 26 percent of the total sample). In studies in the United Kingdom, persons of Caribbean origin are diagnosed with schizophrenia at least twice as often as whites, whereas the rate of schizophrenia in Trinidad and Jamaica is about the same as that of whites in the United Kingdom. These findings are evidence of racism in psychiatry. Even in the absence of clinician bias, it is important to recognize that racial discrimination in psychiatric service delivery may occur on an institutional level—for example, access to services may be differentially limited because of the distribution of clinicians or facilities or because the organization of health services delivery may favor short-term emergency care rather than preventive care among some socially disadvantaged groups.

CULTURAL FACTORS AFFECTING ACCURACY OF PSYCHIATRIC DIAGNOSIS Psychiatric diagnosis among ethnic minority patients is complicated by a variety of

cultural factors having to do with presentation of illness. Often language or communication styles differ between clinician and patient, increasing the possibility of miscommunication. Similarly, idioms of distress invoked by the patient may be unfamiliar to the clinician. Finally, powerful cultural forces provide a template for the experience of illness and individuals are socialized to attend to or disregard symptoms according to culturally salient concepts of illness. All these factors may also affect assessment of response to treatment and outcome.

For these reasons, ethnic minority patients may present “atypically” in the clinical setting or may selectively emphasize or minimize symptoms in the course of a psychiatric evaluation. In any clinical setting, illness complaints form part of a complex agenda in the negotiation of care from a practitioner. If a patient's explanatory model of the appropriate treatment of the illness diverges from the clinician's—as is more likely in a cross-ethnic or cross-cultural clinical encounter—a clinician may formulate a diagnosis and treatment plan based upon misguided assumptions about the case. A clinician may overlook important symptoms or may overpathologize behavior that is actually not considered deviant within its particular cultural context. This in turn may contribute to situations in which patients may be undertreated or overtreated for their illness, with obviously undesirable consequences. Finally, the evidence of misdiagnosis across ethnic and cultural groups again calls into question the validity of Western psychiatric diagnostic criteria among these groups; even if the illness experience is adequately communicated to the clinician, it may not neatly correspond to DSM nosological categories.

Incorporating a Cultural Formulation of Illness Into Psychiatric Assessment and Treatment Culturally sensitive and competent psychiatric assessment and treatment requires consideration and exploration of the social and cultural world of the patient. Diagnostic accuracy is at stake as is the formulation of the most appropriate treatment plan and the successful engagement of the patient in the therapeutic relationship.

Explanatory Models The concept of *explanatory models* was developed to represent the set of experiences, ideas, and expectations of an illness. Illness experience is nearly always organized around a culturally informed model of what is at stake for the patient's or the family's life and how the illness will evolve within the framework of what matters locally on personal and collective levels. Explanatory models of illness allow individuals to make sense of illness and to integrate it into their lives meaningfully. Such models are often culturally particular—for example, as in a culture-specific illness that is attributed to a spirit visitation or an episode of *nervios* attributed to stress caused by difficult life circumstances—but they also share central themes. These themes include ideas about the nature of the problem (e.g., medical, moral, or religious) and how it affects the body and sense of self (e.g., how serious it is, which parts of the body are involved). Other key questions revolve around expectations and fears regarding course and outcome—that is, what can be expected; will there be associated pain, suffering, or disability; will there be a recovery?

Explanatory models also encompass ideas about appropriate treatment. For example, treatment for an illness may begin within the family setting and only when the patient fails to improve will additional care—folk or biomedical—be sought. Individuals seeking care within a biomedical setting often have specific requests or aversions relating to treatment (e.g., the patient who arrives asking for a selective serotonin reuptake inhibitor [SSRI] but who does not want to talk about problems, the patient who does not want any “chemical” treatment despite a severe depression, the patient who prefers a “natural” remedy such as St. John's wort for depression rather than a drug or the patient who has been brought in reluctantly and who prefers to handle the problem on his or her own). Patients' ideas about appropriate therapies often stem from explanatory models or ethnotheories about illness etiology.

In addition, physical ailments, emotional problems, or unusual behaviors are often not medicalized; that is, they are frequently perceived as existential or moral problems that require intervention in religious or interpersonal realms rather than in clinical settings. In some societies illness is not perceived as a personal crisis but rather as a social indicator of disharmony. For this reason, in some traditional settings illnesses may be preferentially addressed in ritual settings if the problem is understood to emanate from a social conflict or from moral transgressions. This occurs not only in developing societies but also in industrially and technologically advanced societies. The major thematic content of explanatory models is summarized in Table 4.1-2.

What is this problem?
How does it affect the body-self?
What can be expected to happen next?
What will be the long-term outcome?
What is most to be feared about this condition?
What treatment is most appropriate?
What is to be most feared about the treatment?

Table 4.1-2 Illness Concerns and Meanings Addressed by an Explanatory Model

Explanatory Models for Illness Explanatory models of illness causation and appropriate therapy are frequently quite eclectic, incorporating both folk and biomedical therapeutic strategies. These models also often evolve as individuals consult others, build a consensus, or reject ineffective models.

A Fijian mother located in rural Fiji recounted her baby's first seizure and demonstrated her shifting model of etiology of this illness. She explained that her baby had had fever and vomiting for several days when convulsions started in the mid-afternoon. She sought advice from her grandmother, who suggested a traditional herbal remedy, which she prepared for the infant. Despite this therapy, the convulsions continued. At this juncture, her family recalled a recent altercation with a fellow villager who was known for involving evil spirits for revenge and decided that he may be responsible for the child's illness. “Once a while ago, my father and one old man in the village argued with each other,” she explained. Their dispute was on a Monday, and the child fell ill with seizures on that same Friday: “right after the fight, then came the illness.” Her family reached a consensus that they urgently needed to apologize formally for the dispute by making the ceremonial offering of kava root. She recalled that the men had been explicit in relating the argument to the seizure illness: “If [the child's] illness... is due to our argument over the marriage you must drink [the kava] so that [his] sickness will end.” She further recalled that as soon as the kava was accepted and drunk, the child's body relaxed. The child was subsequently taken a considerable distance to the nearest hospital, where he was given an injection. The convulsions finally remitted at about 9 in the evening. Although accepting that her child's epileptic seizures will recur chronically, this mother reports reflecting on her family's relational standing with other villagers with each new seizure episode. In this example, the illness was initially addressed with a popular remedy. When this proved ineffective, however, a new model of causation was formulated by consensus: that the child's seizures were a manifestation of a social conflict that required ceremonial measures. Although this model was retained, the family also sought professional treatment at a Western biomedical facility, where treatment was definitive in eradicating the symptoms. The enduring explanatory model of the illness continued to formulate it simultaneously both as a chronic seizure disorder and as a consequence of social conflict. (Adapted from Beeker AE: *Body, Self, and Society: The View for Fiji*. University of Pennsylvania Press, Philadelphia, 1995).

Patients' explanatory models tend not to be formalized, rigid, or fixed. Rather, they shift to adapt to competing or alternative models or to incorporate new information, experience, or contexts. These models are often negotiated among patients, families, and their communities as decisions about help-seeking and following treatment recommendations are made. Tacit negotiation often accompanies the clinical encounter as well. By contrast, professional explanatory models of illness are more standardized and formal, drawing from a formal body of medical knowledge and theory. However, clinicians also draw their understanding and expectations about an illness from clinical anecdotal experience and personal and cultural backgrounds.

Particularly when a clinician and a patient come from different sociocultural backgrounds, their explanatory models may diverge significantly. Such disparities in explanatory models can seriously complicate the clinical encounter, especially when they are not made explicit. The patient may leave the office with a sense of frustration at not being understood, thus compromising the therapeutic alliance; worse yet, treatment efficacy may be compromised if a patient refuses to adhere to a plan that does not fit with his or her explanatory model or if a patient entirely fails to engage in treatment. A clinician's countertransference in such a situation may include frustration with a patient who may appear to be noncompliant or condescension for unfamiliar folk ideas that do not mesh with professional medical or psychiatric knowledge.

It is common for clinicians to dismiss patients' explanatory models as folk “beliefs” that are inferior to professional clinical knowledge. Such beliefs are frequently

ascribed to mistaken or irrational ideas that can be “corrected” with appropriate education that is based on scientific knowledge. Clinicians should by all means educate patients about professional models of their illness but are strongly cautioned against presuming that patients will easily accept professional explanatory models. It is essential to appreciate that patients' explanatory models reflect a culturally particular form of rationality, one that is quite relevant to their experience of illness. Thus, when viewed anthropologically the role of the physician is to affirm the patient's experience of illness and to listen with respect to the patient and family models. The clinician may not and need not agree with those meanings, but his or her task is to negotiate with them and not to reject or discredit them.

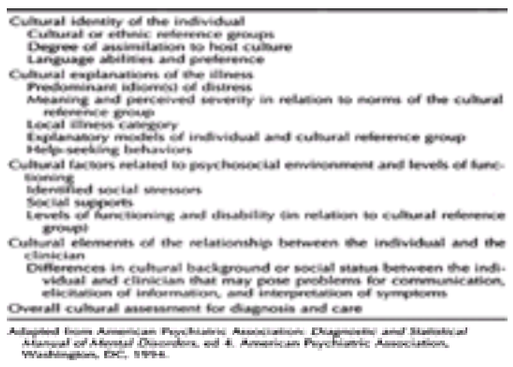
Elicitation of a patient's explanatory models can make discrepancies and common elements in a patient's and clinician's models explicit and allow for an effective negotiation of the meaning of clinical illness and a treatment plan. Exploring a patient's explanatory model is, in effect, a strategic means of anticipating pitfalls in communication and adherence to treatment. In many cases, it is appropriate for the clinician to disclose the clinical explanatory model to allow patients to ask questions that will clarify the treatment plan or, alternatively, to facilitate negotiation of the treatment process.

Illness Meanings In addition to its critical use in psychiatric assessment, exploration of a patient's explanatory model allows a clinician to enter meaningfully into the world of the patient, develop a more empathic connection to the patient's illness experience, and identify and negotiate the most appropriate treatment plan. However, an explanatory model is only a starting point for delving further into a patient's sociocultural background. Beyond the abridged approach of eliciting an explanatory model, more extensive interviewing will be required to gain an appreciation of the social, economic, and political contexts of stressors and the cultural patterning of distress for a particular patient.

Exploring and responding to the many facets of a patient's illness experience is integral to psychotherapeutic work. Illness experience often revolves around what is at stake for a patient in personal, social (e.g., occupational, economic, and political), and cultural contexts. Besides the conventional meanings of particular symptoms and patients' explanatory models for their significance, it is helpful for clinicians to appreciate that illness may take on a variety of meanings particular to personal and cultural contexts.

Chronic mental illness with its exacerbations and remissions may especially take on personal significance for patients as they incorporate it into the trajectory of their lives and reconcile the chronicity of their illness with perceived and actual limitations and suffering. Illnesses are also invested with cultural meanings that substantially impact upon illness experience. For example, some psychiatric disorders are highly stigmatizing (e.g., psychotic disorders or pedophilia in American society) in some cultural contexts, whereas others designate the patient as a victim (e.g., posttraumatic stress disorder). The medicalization or relocation of some illnesses from one social arena to a clinical one (e.g., alcohol use disorders) may diminish their social stigma and allow mobilization of social resources in more effective ways for the patient. On the other hand, the medicalization of posttraumatic response to the violence of political oppression localizes pathology in the individual rather than in the social context that produced the symptoms.

Cultural Formulation in Psychiatric Assessment Notwithstanding the contributions of neurophysiology and psychological development to psychopathology, mental illness always unfolds in a particular social and cultural context that may both precipitate and shape it. Treatment that is decontextualized from these sociocultural influences runs the risk of being insensitive at best and ineffective or harmful at worst. In an effort to promote systematized incorporation of the sociocultural context into psychiatric assessment, DSM-IV includes an outline of the cultural formulation of a patient's illness that is meant to supplement the standard multiaxial system of evaluation. This approach is outlined in Table 4.1-3 and is a starting point for rendering social and cultural factors visible in the clinical encounter.



Cultural identity of the individual
- Cultural or ethnic reference groups
- Degree of assimilation to host culture
- Language abilities and preference

Cultural explanations of the illness
- Predominant idiom(s) of distress
- Meaning and perceived severity in relation to norms of the cultural reference group
- Local illness category
- Explanatory models of individual and cultural reference group
- Help-seeking behaviors

Cultural factors related to psychosocial environment and levels of functioning
- Identified social stressors
- Social supports
- Levels of functioning and disability (in relation to cultural reference group)

Cultural elements of the relationship between the individual and the clinician
- Differences in cultural background or social status between the individual and clinician that may pose problems for communication, elicitation of information, and interpretation of symptoms

Overall cultural assessment for diagnosis and care

Adapted from American Psychiatric Association, Diagnostic and Statistical Manual of Mental Disorders, ed 4, American Psychiatric Association, Washington, DC, 1994.

Table 4.1-3 Outline for Cultural Formulation

Although listed as the fourth component in the DSM-IV cultural formulation, the clinical assessment begins with attention to any cultural and social differences between the clinician and the patient that may introduce barriers to communication. An interpreter's services should be used in cases in which the identified patient cannot be interviewed in English. Structuring the interview setting such that the patient is comfortable may include allowing family members to remain in the room and sometimes even to speak for the identified patient when culturally appropriate. Clinicians should be aware that minority individuals are frequently demeaned or discriminated against, including in clinical encounters. They should make every effort to convey respect for patients' ethnic, cultural, and social backgrounds, particularly when it is obvious that there is a socioeconomic gap or racial difference between patient and clinician. Clinicians are often unaware of ways in which the professional culture has made them unwitting participants in a power differential between themselves and their patients; an awareness of such conventions (e.g., addressing patients by first names instead of surnames, controlling time and space in the clinical setting, limiting telephone access) can allow clinicians to identify and modify behaviors that potentially intimidate patients.

The cultural identity of the individual can be explored by asking about cultural or ethnic reference groups and about the degree of *assimilation* to the local culture. Because there are often vast intergenerational differences in assimilation that can contribute to contested ideas of illness and the need for treatment, it is helpful to ask about the degree of assimilation of family members and any tensions resulting from intrafamilial differences. In addition to assimilating to another culture, the process of *acculturation* includes the discarding of certain cultural practices, values, and traditions in the setting of another (usually more dominant) culture as elements of that culture are incorporated into attitudes and behavior. In some cases highly acculturated individuals may become more vulnerable to conventional stressors because traditional coping mechanisms are no longer available to them.

A cultural context of presenting symptoms is especially important when a patient presents with symptoms that are atypical from the perspective of the host culture. A familiarity with culture-bound syndromes and culturally specific idioms of distress is helpful in evaluating their clinical and cultural salience. Certain culture-specific presentations (e.g., *ataques de nervios* or *zar*) resemble DSM-IV diagnoses, but are not necessarily deemed pathological within their cultural reference group. Explanatory models for the illness as well as culturally salient illness meanings assist the clinician in engaging the patient and negotiating a mutually acceptable treatment plan. Also, an appreciation of the conventional coping styles and help-seeking behaviors of the reference group illuminates the significance of the patient seeking help in a biomedical setting and allows a discussion of alternative therapies a patient may be pursuing concomitant with biomedical therapy. Finally, clinicians should avoid viewing culture, ethnicity, or race as essential characteristics of the individual. Although familiarity with culturally specific idioms of distress and explanatory models of illness is indispensable in contextualizing illness, the clinician should be especially attuned to heterogeneity within the various ethnic and cultural groups and be prepared to engage individual as well as cultural diversity in the clinical encounter. Indeed, individual and cultural diversity need to be viewed as only two kinds of diversity amongst many others: gender, age-cohort, religious, class, and other sources of differentiation contribute to diversity as well.

Assessment of patients' psychosocial environment helps to identify social stressors and supports as well as to formulate what resources may be available. Levels of functioning and disability should be determined with respect to the expectations of the cultural reference group as well as to personal and clinical expectations. Therapeutic goals may differ considerably between clinician and patient and should be explored as treatment unfolds. Clinicians should be cautioned to not rigidly impose their own sociocultural values on a patient's therapeutic goals, but rather should recognize that they may not be appropriate to the patient's cultural background.

Finally, the cultural formulation of the patient integrates elements of the patient's ethnic and cultural identity, social environmental factors contributing to or buffering against distress, and the cultural construct of the illness experience into an assessment of the patient that at once allows application of Western psychiatric nosology and use of biomedical or psychiatric treatment resources in a relevant and appropriate way. Cultural elements of the relationship between the clinician and patient are

also factored into the assessment and the ongoing therapeutic relationship with the patient.

Cultural Considerations in Psychiatric Treatment After assessing and formulating a patient's illness complaint relative to personal, social, and cultural contexts, a culturally informed exploration of the patient's expectations regarding treatment will identify appropriate treatment modalities. If indicated, psychotherapeutic work will ideally integrate personal and cultural agendas for the patient. Whether applying psychodynamic techniques that focus on intrapsychic experience can be successful across cultural groups or whether use of a second or third language in exploring affective experience might affect outcome are underresearched questions. Western psychotherapeutic models assume a rather ethnocentric orientation toward an individuated self that reflects Western notions of selfhood as well as an agenda often derived from white, middle-class, male values. For patients from cultural backgrounds that value social or family harmony over the needs of the individual or that support parental authority over a child's desire to develop an independent agenda, the goals of care must be negotiated between clinician and patient to ensure that they are culturally relevant to the patient.

PSYCHOPHARMACOLOGY Medical management of mental illness takes place in the context of ethnicity-specific biologies. There is evidence that the pharmacokinetics of several psychotropic medications vary among differing ethnic groups. In addition, the volume of distribution, differential brain receptor responsivity, and exposure to environmental factors (such as herbal remedies) that alter drug metabolism may also contribute to interethnic differences in response to psychotropic medications. Specific differences that have been reported in the literature include comparably higher haloperidol plasma concentrations in Asians than in whites with the same dosage of drug and optimal response to lower plasma levels in Asians as compared with whites. Similarly, Chinese patients appear to respond to significantly lower mean lithium concentrations and to be more sensitive to benzodiazepines than whites. Practitioners who are routinely exposed to patients of different ethnic backgrounds are responsible for learning these aspects of the clinical picture.

SOCIAL CONTEXT OF MENTAL ILLNESS

Integral to the cross-cultural and cross-ethnic epidemiology of mental illness are the social, economic, and political factors that create a context for either social supports or stressors that affect risk. Studies have consistently demonstrated an inverse relationship between socioeconomic status and health and mental illness. Although there is some evidence that mental illness sometimes causes downward drift in socioeconomic status (e.g., with schizophrenia), converging lines of evidence implicate social factors in the production of mental illness mediated through social stressors. For example, high rates of suicide and substance abuse have been demonstrated among members of societies such as Native-Americans and Pacific Islanders in which rapid modernization has disrupted social structures and social supports. Powerlessness appears to also pose risk for mental illness along gender, socioeconomic, and ethnic lines. Studies have shown that, globally, women have higher rates of mental illness than men; furthermore, this research shows that women with fewer social supports and greater social stressors are at the greatest risk for depression. Moreover, victims of political violence and oppression are also at increased risk for mental illness, as evidenced by high rates of depression, anxiety, and posttraumatic stress disorder in refugee populations. Unfortunately, economic change in the current era of global capitalism is associated with increasing disparities between the highest and lowest 20 percent of populations and also increased mental health problems.

Suicide The rate of suicide varies dramatically across cultures. Both its varying prevalence and association with varying risk factors suggest that it may be a better marker of social processes than of psychiatric illness. Suicide rates are markedly higher among some age groups in the South Pacific and among women in China than elsewhere in the world. For example, within Micronesia, Trukese 15 to 24-year-old males had an annual rate of suicide of 200 per 100,000 people between the years 1974 and 1983—a rate nearly 10 times that of United States males of the same age. Notably, suicide rates in the Trukese setting underwent an eightfold increase between 1960 and 1980, a time of substantial social change locally. Moreover, precipitants to Trukese adolescent suicide attempts appeared to be related to relatively trivial parent-child conflict rather than to depression or other mental illness; such conflict, however, would have been traditionally resolved with club-houses and men's organizations no longer available in the wake of postwar economic change and restructuring of the family. In other words, social and economic changes that had redefined parenting roles and eliminated particular social supports, in combination with limited legitimate means of expressing anger toward authority figures, created a context for epidemic suicide, apparently unrelated to *psychiatric* illness.

Similarly, the rate of suicide in China, particularly among rural women, has also increased. Forty percent of the world's suicides occur in China, a nation with 21 percent of the world's population. This high rate of suicide cannot be attributed to depression because China has far lower prevalence of depression than many other areas. For example, the point prevalence of depression in China is 3 to 10 times lower than in the United States, yet China's suicide rate is twice that of the United States. Again, suicidal behavior cannot necessarily be linked with mental illness. Rather, these examples suggest that high suicide rates may accompany rapid social and economic change resulting in deep demoralization or eradication of traditional social supports in the context of limited options for resolving distress. In China, for example, rural women aged 16 to 26 years and over the age of 55 have the highest suicide rate. Although a number of social factors contribute to this, it seems as if relative powerlessness in the setting of rising economic expectation and diminishing opportunities for women are instrumental here.

Global Burden of Psychiatric Illness: Psychiatry's International Health Agenda Despite biotechnological advances that have substantially improved the overall health status in developing societies worldwide, studies have shown that there has been a paradoxical increase in the rates of mental illness in low-income societies. This increased prevalence is probably due to a variety of social factors, including rapid social change and economic restructuring that disrupt the integrity of traditional structures of authority and livelihood, thereby increasing the risk of displacement, violence, and poverty. In addition, social structures such as the extended family, which traditionally provide care-taking and other supports for the mentally ill and elderly, are undergoing rapid change in many contexts and thereby decreasing social supports that might either protect against mental illness or buffer its impact on the individual or community. These explanations are supported by the clustering of social and mental health problems. From an anthropological perspective, cases of major depressive disorder or posttraumatic stress disorder rarely occur in isolation; rather they cluster in settings of family breakdown, joblessness, community and domestic violence, and the like. Thus, mental health problems and social problems are largely inseparable.

Care and Treatment for Chronically Mentally Ill Persons in Nepal Nepal is a small, landlocked country of some 23 million people. Given that it is one of the poorest countries in the world—with a gross national product (GNP) per capita of less than U.S. $200—it is not surprising that by most measures, the health and welfare of the Nepalese are far less than optimal. Only 27.5 percent of the population is literate, with a great disparity between literacy rates for men (40.9 percent) and those of women (14 percent). With a growth rate of 2.6 percent per annum, Nepal's population is expected to double in the next 20 years, adding to the problems of an explosion that began at least two decades ago. Life expectancies are low and are at least in part accounted for by high rates of infant mortality (99 per 1000 live births), under-5 mortality (128 per 1000 live births), malnutrition (51 percent of children under 5 are underweight), and maternal mortality (830 per 100,000 live births). Although there has not been extensive psychiatric epidemiological research conducted in Nepal, the research that has been conducted indicates a prevalence rate in the general population of about 2 percent for chronic mental disorders (i.e., roughly the same as has been found elsewhere). Care and treatment services for chronically mentally ill persons in Nepal are virtually nonexistent. Of about 2500 doctors, less than 20 are trained psychiatrists and most of them are in the capital city of Kathmandu: Fewer than 10 nurses have received formal training in psychiatry; clinical psychologists are fewer still. Until recently Nepal had no training programs in psychiatry, psychology, psychiatric nursing, or social work. Individuals who wanted to be trained in these fields had to study abroad (most often in India or Pakistan). Even with the establishment of programs in the Institute of Medicine (IOM) at Tribhuvan University, Nepal's supply of mental health professionals is going to remain inadequate for the foreseeable future. The availability of psychiatric facilities is no better. The National Mental Hospital in Patan has 40 beds and the Psychiatry Department of IOM has 12 beds in the University Hospital. Beyond the Kathmandu Valley the situation is worse. The Western Regional Hospital in Pokhara has 5 psychiatric beds, and the Birendra Army Hospital has 18 psychiatric beds. The director of the National Mental Hospital is planning to open a series of day centers for chronically mentally ill persons in Kathmandu, but in the meantime there is only one rehabilitation facility in the entire country: Asha Deep in Kathmandu, originally established in 1993 by the Sisters of Maryknoll to care for mentally ill persons who had been in jail. Because of the lack of psychiatric facilities and services, many mentally disturbed persons, especially those who are violent, are taken to the police and jailed. There are between 60 and 80 mentally disturbed persons at any given time in the Dhulikhel Jail in Kathmandu where they receive a modicum of treatment. There is no formal information about private psychiatric facilities, but if the anecdotal information is accurate they are no better and some are much worse than the public facilities. Most Westerners would probably be disturbed at the conditions for psychiatric patients in Nepal's hospitals. Running water is still not available in the Mental Hospital. The wards tend to be small and bare; patients mainly stay in bed with nothing more to do than talk to relatives, friends, or one another. Psychopharmacology and electroconvulsive therapy are the primary treatments. However, given the economic constraints under which the health care system functions and the lack of trained staff, conditions in the public hospitals must be considered good. Patients are not abused, the facilities are clean if somewhat dreary, and while better and more comprehensive care can be found in many other countries, what is offered in Nepal is based on modern psychiatric practices. What of care and treatment services for chronically mentally ill individuals in the rural areas? Those who have access to transportation are sent to the hospitals in Kathmandu or Pokhara even though it might take 3 days of rough traveling on a crowded bus. Transportation other than by foot is scarce. Since 1989 His Majesty's Government of Nepal, in collaboration with United Mission to Nepal, has been training rural health care workers in the diagnosis and management of mental disorders. However, this project covers only a small part of the country, and even where it is available, health care workers can only offer a very limited range of psychopharmacological agents as treatment for chronically mentally ill persons. Recognizing the need for mental health services in primary care settings, the government has made a long-term commitment to the mental health project, and for the past decade the project has provided at least some level of treatment for chronically mentally ill persons in rural areas, extended critical knowledge to health care workers in the remote health posts, and helped to spread a concern and better understanding of mental health problems. In addition, if the rehabilitation facilities at Asha Deep are

any indication, there is a much brighter future for those in Nepal who suffer from chronic mental disease. Finally, the lack of formal psychiatric care does not mean that persons with chronic mental illness are abandoned; the great majority of them are cared for by their families. (Courtesy of Alex Cohen, Ph.D.)

In *World Mental Health*, Robert Desjarlais and his colleagues examine the relationships among poverty, urbanization, violence, diasters, displacement, and mental illness in developing societies. They point out that poor countries in Asia, Africa, Latin America, and the Pacific have a disproportionate burden of social problems (e.g., war and natural disasters) that pose risk for mental illness and that they lack adequate mental health services. Furthermore, they illustrate the interpenetration of social and mental health problems (e.g., domestic violence, substance abuse, community disintegration) that perpetuate one another in a vicious spiral in the context of key social forces, such as ethnic conflict, economic inequities, and oppression of women.

Research has shown that psychiatric illness is associated with disability across cultural contexts. Data presented in the *Global Burden of Disease* convincingly demonstrate the impact of global neuropsychiatric illness. For example, five of the ten leading causes of Disability-Adjusted Life Years (DALYs) for 15- to 44-year-olds in the world represent mental illness or self-inflicted injuries: major depressive disorder, alcohol use, self-inflicted injuries, bipolar disorders, and schizophrenia. Furthermore, the leading cause of disability-adjusted life years (DALYs) is major depressive disorder, responsible for over 10 percent of the total (Table 4.1-4). Neuropsychiatric conditions account for 26.4 percent of the total DALYs among 15- to 44-year-olds, and comprise the single largest category of illnesses. (Fig. 4.1-1). This is probably a conservative estimate of the contributions of mental illness to the burden of disease because a proportion of unintentional injuries and cases of cirrhosis of the liver are undoubtedly secondary to substance abuse. Moreover, intentional self-inflicted injuries account for 3.51 of the total DALYs among this group. These percentages reflect the high prevalence of mental illnesses as well as the inadequacy of health resources to address them, often resulting in unnecessarily prolonged disability. The high rates of mental illness and associated disability in the developing world challenge the psychiatric professional community to respond by developing effective treatments that can be applied across cultural contexts as well as by supporting social and public health policies that address the roots of the problem at the population level.

Ranking	Causes	Total DALYs (millions)	% of Total DALYs
	All causes	*419.1*	*100*
1	Unipolar major depression	43.0	10.3
2	Tuberculosis	19.7	4.7
3	Road traffic accidents	19.6	4.7
4	Alcohol use	14.8	3.5
5	Self-inflicted injuries	14.6	3.5
6	Bipolar disorder	13.2	3.1
7	War	13.1	3.1
8	Violence	13.0	3.1
9	Schizophrenia	12.5	3.0
10	Iron-deficiency anemia	12.5	3.0

4.2 SOCIOLOGY AND PSYCHIATRY

RONALD C. KESSLER, PH.D.

Sociology is the study of patterns and structural determinants of social organization. Sociologists presume that there are organizing principles of social life, that these principles can be uncovered by systematic observation, and that the social forces underlying these principles influence both organizational and individual actions. Contemporary sociological studies are interested in psychiatric phenomena in a number of ways. They have focused on the structural determinants of psychiatric disorders, the social consequences of psychiatric disorders, the social factors in psychiatric help-seeking, attitudes toward the mentally ill, and mental health service organization.

SOCIAL AND CULTURAL DETERMINANTS OF MENTAL ILLNESS

Sociological research on social and cultural determinants of psychopathology is varied: one line of research investigates the effects of stressful life experiences on the onset and course of psychiatric disorders; a related line of research studies the extent to which reactivity to environmental stress is mediated or modified by social and cultural forces.

Stress and Mental Health: Effects of Life Events Although the hypothesis that stress can cause mental disorder is an old one, it has been difficult to document causal effects of this sort. Most such work has focused on the putative effects of life events. Although significant associations between presumably stressful events and mental illness have been consistently documented in these studies, the interpretation is ambiguous because this association could reflect an influence of the illness on the event. There is no certain way of discounting this possibility in the nonexperimental studies that are the mainstays of stress research.

Nonetheless, the strength and consistency of the associations documented in this literature are striking. For example, studies of job loss because of plant closings have documented rates of clinically significant anxiety and depression among unemployed workers that are two to three times higher than those found among the stably employed. Furthermore, in a few cases these studies have been able to collect pre-event data that document associations between exposure to stress and the onset of psychiatric disorders, arguing against a selection argument and in favor of the interpretation that stress is a cause of the ill health outcomes.

Elaboration of the stress-illness relationship provides information that is consistent with a causal interpretation. This can be seen in studies that attempt to sort the effects of life events into the dimensions that make them stressful. For example, job loss seems to promote anxiety and depression by increasing financial strain and heightening reactivity to unrelated stresses. As a result, the most serious psychiatric outcomes associated with job loss are found among people who lack financial reserves and who also experience some other major crisis (e.g., a life-threatening illness in a child) during the period of unemployment. Research is ongoing to delineate contextual features of this sort that account for variation in the effects of stressful events.

A recent related line of research involves the determinants of posttraumatic stress disorder following such highly stressful events as rape or combat. Although a substantial proportion of those exposed to such events develop posttraumatic stress disorder or some related anxiety or mood disorder, they typically represent only a minority of those exposed to the events. This has prompted an interest in the protective factors that allow the majority of trauma victims to avoid these disorders, an issue discussed later in this chapter.

Another recent related line of research examines the long-term effects of earlier life adversities in the context of a developmental perspective on psychopathology. Clinical studies clearly suggest that early adversities such as parental death and family violence have lifelong effects on mental health. However, a fairly new development is the systematic investigation of those effects in a representative community sample of adults who are asked retrospectively about childhood experiences. In the 1980s studies largely focused on only one type of childhood adversity, such as death of a parent, childhood family violence, or early sexual abuse, and one clinical outcome (usually major depression). These studies consistently found that the early adversities had significant effects on adult disorders. In the 1990s, however, studies have been concerned with the long-term effects of multiple childhood adversities and have shown that it is much more difficult than previously realized to pinpoint any one particular early adversity as a central risk factor for adult disorders. Instead, it appears that many early adversities cluster in the lives of particular youngsters and that these clusters, rather than the individual adversities of which the clusters are composed, are the most important determinants of psychopathology. It is likely that future work in this area will examine more closely the differential effects of various isolated early adversities and commonly occurring adversity clusters.

Research on Chronic Stress It is easier to study the effects of stressful life events than ongoing chronic stress situations because an event can be dated whereas the onset of chronic stress is more difficult to pinpoint. As a result of this difficulty, research on the effects of chronic stress is less well developed than research on the effects of life events. This does not imply that life events are more important than chronic stresses; indeed, chronic stresses are often more predictive than stressor events of psychological disorders in community surveys. Methodological research is needed before major advances can be made in this area of research.

The most advanced work on chronic stress is concerned with job stress because it is easier to measure than other types of chronic stress. Research on job stress has shown that such indicators as time pressure, closeness of supervision, and job insecurity are all associated with depression, anxiety, and substance abuse. Based on these results, more focused studies of such high-risk workers as assembly line workers and air-traffic controllers have been undertaken. These studies have described particular constellations of job conditions associated with emotional disability. For example, several large studies have linked the combination of high job demands (e.g., a job in which workers must rush to meet important deadlines) with low decision latitude (e.g., low control over the pace or organization of work) to emotional disability and cardiovascular disease. Several major corporations have now agreed to carry out job redesign experiments aimed at modifying some of these health-damaging job conditions. Those efforts, motivated partly by a desire to increase worker productivity, provide an unparalleled opportunity to study the effects of chronic stress. Such experiments should yield important knowledge about the determinants of chronic job stress and about effective strategies for changing work environments to reduce the most pernicious kinds of stress.

Research on Vulnerability Factors Although stress is strongly related to ill health, only a minority of the people who are exposed to stress develop stress-related disorders. Much research has been done on the determinants of this variation in stress reactivity and a number of determinants have been identified. Initial research on vulnerability factors was carried out as part of naturalistic studies of stress effects that focused on the ability of the putative vulnerability factors to exacerbate the impact of stress on health. For example, research showed that the impact of life events in provoking episodes of major depression is reduced among individuals who have an intimate, confiding relationship with a friend or relative. In one study, nearly 40 percent of the stressed women without a confidant became depressed compared with only 4 percent of those women with access to a confidant. This result has been replicated in several community surveys and case-control studies.

Although these studies provide suggestive evidence, methodological problems obscure results. Most seriously, in a naturalistic study the possibility that some predisposition to depression accounts for the presumed exacerbating effects of vulnerability factors cannot be ruled out. Individuals who are predisposed to becoming depressed under conditions of stress may also, for reasons related to this predisposition or its personality correlates, be less likely than others to form close, confiding personal relationships. As a result, more recent research on vulnerability factors has focused on experimental studies.

Experimental Intervention Studies As researchers have come to recognize the methodological shortcomings of naturalistic studies of vulnerability factors, experimental interventions have become popular. Most experimental interventions have examined the effects of attempting to remove vulnerability factors on such outcomes as preoperative anxiety, recovery from surgery, and compliance with medical regimens. Related interventions have also been instituted to facilitate coping with such life crises as widowhood, rape, and job loss. The vulnerability factors manipulated in these experiments have included various types of cognition, coping

strategies, and objective coping resources. The evidence from these studies suggests that a number of presumed vulnerability factors play an important part in protecting against the onset of health problems and serious illness progression. A clearer understanding of these influences will require research advances in conceptualization and measurement as well as the development of more powerful interventions aimed at modifying vulnerability factors.

GROUP DIFFERENCES IN PSYCHIATRIC DISORDER

A large part of sociological research on psychopathology has traditionally been concerned with structural correlates of psychiatric illness such as social class, sex, and age. As shown in Table 4.2-1, the associations between these variables and the prevalence of psychiatric disorders are substantial. The most obvious hypothesis to test in examining such associations is that differential exposure to stress explains group differences in mental illness. It is now clear that this hypothesis can be rejected. Although it is true that people in comparatively disadvantaged positions in society (e.g., women, lower-class persons, nonwhites) are exposed to more stress than their counterparts, differential exposure cannot totally explain their higher rates of anxiety, depression, and nonspecific distress in general population samples. As a result, vulnerability factors have taken center stage in research on group differences; such research has shown consistently that there are group differences in vulnerability to stress and that this plays an important part in explaining differences in rates of psychiatric disorder. Current research on group differences is centrally concerned with the processes that promote vulnerability to stress.

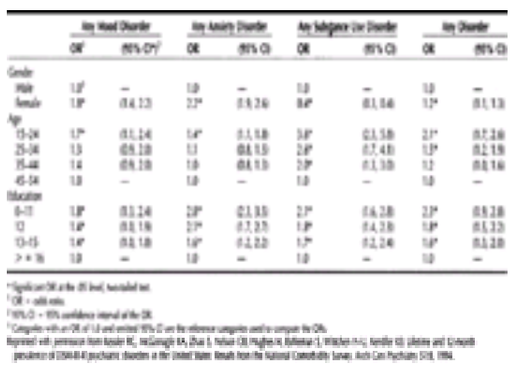

Table 4.2-1 Demographic Correlates of 12-Month DSM-III-R Psychiatric Disorders in a Nationally Representative Epidemiologic Survey of the U.S., 1990

A good example of this new work can be seen in research on the relation between social class and mental illness, one of the oldest and most firmly established associations in psychiatric epidemiology. Socially disadvantaged people have higher rates of psychiatric disorder than their more advantaged counterparts, as measured by treatment statistics, nonspecific distress in community surveys, and clinically significant psychiatric disorders in epidemiological studies. Early work on social class and psychopathology documented that lower-class people have a significantly higher probability of hospitalization and remain hospitalized longer than their middle-class counterparts; subsequent work showed that socioeconomic status is also related to psychopathology in community samples.

Until the early 1970s the dominant line of thinking in the literature on class and mental illness was that lower-class people were exposed to more stressful life experiences than those of more advantaged social status, and that this differential exposure accounted for the negative relationship between class and mental illness. This view was challenged for the first time in the Midtown Manhattan Study, in which an attempt was made to demonstrate empirically that the excess of lower-class mental health problems could be accounted for by greater exposure to stressful life experiences. Although this attempt was unsuccessful, a more complex association was documented: stressful life experiences have a greater capacity to provoke mental health problems in the lower class than in the middle class. Subsequent work has shown that this class-linked vulnerability to stress accounts for the major part of the association between social class and depression and between social class and nonspecific distress.

Differential vulnerability might arise in several ways, one of the most plausible of which is that some type of selection or “drift” of incompetent copers to the lower class might lead to the relationship between class and vulnerability. Another explanation is that one's experience as a member of a particular class leads to the development of individual differences in coping capacity as well as to differences in access to interpersonal coping resources. The available evidence supports both hypotheses. Most of the evidence for the drift hypothesis comes from studies of major mental illnesses, primarily schizophrenia. Those studies show that the early onset of a disorder can reduce one's chances of socioeconomic advancement, which seems true primarily for people who become ill before establishing a career; less severe disorders apparently do not interfere with socioeconomic achievement.

Evidence of the link between vulnerability factors and class is widespread. Lower-class people are disadvantaged in their access to supportive social relationships. Evidence also indicates that personality characteristics associated with vulnerability to stress, such as low self-esteem, fatalism, and intellectual inflexibility, are more common among lower-class people. To date, the major efforts in this area have been confined to the study of social support. The most influential work in this area has been done by the English sociologist George Brown. Brown documented that lower-class people have fewer confidants than those in the middle class, which increases their vulnerability to undesirable life events. This finding has been replicated in several investigations, but more work needs to be done to assess in parallel fashion the importance of coping strategies and personality characteristics. Also, as most investigations of class and stress have focused on life events, a more serious consideration of ongoing stressful situations may help to develop a more complete understanding of the relationship between class and psychopathology.

A related series of studies has been concerned with gender differences in anxiety and mood disorders. Community surveys show that adult women are twice as likely as men to report extreme levels of psychiatric distress and mood disorders. Although other types of psychopathology are as common among men as among women, and still others are more prevalent among men, most research has emphasized mood disorders and nonspecific distress in community samples.

Two lines of research can be identified in research on sex differences in nonspecific distress and mood disorders. The first is based on indirect assessments of role-related stress. Since the late 1980s the dominant perspective has held that women are disadvantaged relative to men because their roles expose them to more chronic stress. Because chronic stress is difficult to measure objectively, empirical analysis has used indirect assessments based on measures of objectively defined role characteristics or constellations of multiple roles to document the relation.

The second line of research on sex differences has examined stressful events. Studies have shown that there is a significant interaction between gender and undesirable events in predicting distress, with women appearing more vulnerable than men to the effects of stressful events. Several different hypotheses have been advanced to account for female vulnerability to stress, including the arguments that females are disadvantaged in access to social support, in the use of effective coping strategies, and in personality characteristics.

Although aggregate analyses of life event inventories show that women are on average more vulnerable than men, there are some events for which this is not true. Research on widows, for example, shows that women adjust to spousal death better than men; women also adjust as well as or better than men to divorce. Furthermore, women cope with financial difficulties better than do men.

A challenge for future research will be to reconcile the discrepancy between these studies of particular life events and aggregate life event surveys. The only such attempt to date, a meta-analysis of several large-scale community surveys in which the effects of different types of events were assessed separately, found no evidence that women are more distressed than men by such major life crises as job loss, divorce, or widowhood. Their greater vulnerability was primarily associated with events that happen to people close to them—death of a loved one other than a spouse being the most commonly reported event in this regard.

The greater impact of network events on women can be interpreted in several ways. One component of the difference is probably linked to the fact that women provide more support to others than men do, creating stresses and demands that can lead to psychological impairment. Also, women might be more empathic than men or might extend their concern to a wider range of people. These and other possibilities need to be investigated in the future because the role played by network events appears to account for a very substantial part of the overall gender-distress relation.

An exciting addition to the investigation of role stress and life event studies of gender difference has recently occurred as part of the larger interest in prior history of disorder. Survey research on the different predictors of onset and recurrence of depression shows clearly that while adult women are twice as likely as men to report a

recent episode of depression, there is no significant gender difference in risk of recurrence. This seeming anomaly can be explained by the fact that women are twice as likely as men to have a lifetime history of depression. Among men and women with such a history, there is no gender difference in recurrence risk; this means that an understanding of gender differences requires an understanding of the determinants of first onset. Analysis of gender-specific age-of-onset curves shows that the 2-to-1 female-to-male ratio of lifetime depression occurs by the mid-20s and that rates of first onset after that age are fairly similar for men and women. Studies of gender differences in depression need to focus not on the mid-life period, where most of the current research on gender roles is concentrated, but on late adolescence and early adulthood.

SOCIAL CONSEQUENCES OF PSYCHIATRIC DISORDERS

Sociologists have traditionally been much more concerned with the social determinants of ill health rather than with its social consequences. However, interest in the consequences of psychiatric disorders has increased over the past decade in response to the changing position of mental health treatment in managed care. Specifically, managed care plans have imposed more severe restrictions on the treatment of psychiatric disorders than physical disorders and have called for the use of evidence-based decision making in the allocation of funds for treatment. These demands necessitate an inquiry into the adverse social consequences of psychiatric disorders as well as a determination of whether these consequences can be ameliorated by treatment.

Part of this investigation has used the methods of social demography, a branch of sociology, to study the effects of early-onset psychiatric disorders on subsequent role transitions. This work has shown that early-onset disorders are powerful predictors of a wide range of adverse social consequences: school failure, teen childbearing, early marriage, marital instability, job instability, and financial adversity.

A second part of this investigation has studied role performance. This work has demonstrated that psychiatric disorders are associated with functional impairments within both family and work roles. It has been shown that people with a history of psychiatric disorders prior to marriage are substantially more likely than others to experience marital distress and marital violence, as well as to have distant or conflictual relationships with their children. As presented in Table 4.2-2, persons with a history of psychiatric disorders miss more days of work and have lower productivity while at work than workers in the same jobs who have never had a psychiatric disorder.

	Sample Distribution		Work Loss Days/100 Worker Months		Work Cut-Back Days/100 Worker Months	
30-Day Disorder	%	(SE)	#	(SE)	#	(SE)
Comorbid disorders	3.7	(0.5)	49*	(15)	144*	(19)
Pure disorder	14.5	(0.8)	17*	(1)	44*	(3)
No disorder	81.8	(1.0)	2	(1)	11	(2)

Table 4.2-2 Multivariate Relationship Between 30-Day DSM-III-R: Disorders and Work Impairment in a Nationally Representative Epidemiologic Survey of the U.S., 1990

The studies of workplace impairments have recently caught the attention of the social policy community. Employers are being asked to reconceptualize treatment of the mental disorders of their workers as investment opportunities rather than workplace costs. Several interdisciplinary interventions are currently under way to investigate the types of workplace stresses and job demands that potentiate the effects of psychiatric disorders on performance decrements and to document the extent to which aggressive outreach and treatment of such disorders can restore productivity. The results of these studies are likely to play an important part in the evolving structure of mental health care benefits offered through the workplace.

PSYCHIATRIC HELP-SEEKING

Needs assessment surveys show that most people with serious emotional problems do not seek professional help. Furthermore, as shown in Table 4.2-3, a person seeking professional help is nearly as likely to turn to a primary care physician as to a mental health specialist. This choice is partly the result of the dearth of mental health specialists in some areas of the country, but other variables are also involved. Most of our direct knowledge about these other determinants comes from general population surveys that ask respondents about emotional problems and whether they sought professional help for these problems. These surveys have documented several consistent attitudinal, demographic, and system-dependent determinants of help-seeking behavior.

	Distribution of Disorders		Probability of Any Service Use		Average Number of Visits Among Users	
12-Month Disorders*	%	(SE)	P	(SE)	#	(SE)
Comorbid disorders	12.0	(0.7)	53.9	(2.4)	23.8	(2.0)
Pure disorder	15.7	(0.6)	18.8	(1.4)	14.0	(1.9)
History of disorders	18.3	(0.7)	11.7	(1.0)	16.9	(2.5)
No history of disorders	54.0	(1.3)	7.6	(1.0)	9.4	(2.1)
Total	100.0	(—)	13.3	(0.7)	16.0	(1.2)

*Respondents who met criteria for two or more disorders at some time during the 12 months prior to interview were classified as having 12-month comorbid disorders, while those who met criteria for only one disorder were classified as having a pure disorder. Respondents who met criteria for no disorder in the past 12 months but had a lifetime history of one or more disorders were classified as having a history, while those who never met criteria for any of the disorders assessed in the survey were classified as having no history.

Sociologists have been particularly interested in structural determinants, the strongest and most consistent of which is social class. A positive correlation between social class and help-seeking persists even though community mental health centers and other inexpensive treatment facilities have reduced the financial barriers to care. In the recent surveys carried out in the 1990s, education emerged as a stronger predictor of help-seeking than income, which suggests that some cultural facilitating factors are more important than financial resources in accounting for the influence of social class.

Women are much more likely than men to seek mental health care, even given the higher prevalence of disorder among women. Sociological research over the past few years has made considerable progress in explaining this gender difference by showing that women are more likely to recognize their problems than men, and that this recognition of a problem is critical in the decision-making process. Once they recognize that they have a problem, men and women do not differ in their likelihood of obtaining professional help. The subject of why women are more likely to recognize their problems is currently under study.

The most recent surveys of help-seeking suggest that the determinants of utilization differ markedly from one community to another, which suggests that local alternatives and barriers play a major part in determining who will seek treatment. It is likely that this result will lead to greater emphasis on comparative case studies of particular communities in the future.

It is interesting to note that most careful case studies of help-seeking document that the critical point in the process is deciding that help is needed. Most people do not know when a personal problem is big enough to warrant professional care. As social scientists come to appreciate the great importance of problem definition,

more sophisticated theories are being developed about how people make sense of symptoms. Recent research has suggested that people operate on the basis of schemas for explaining particular kinds of illnesses. These schemas contain lay accounts of the cause, course, symptoms, and prophylaxis for various illnesses. Research has already shown that a number of different schemas exist for particular medical conditions, and that characteristics of the schema held by a particular person provide important insights into the person's help-seeking and compliance habits.

Although systematic research into schemas for psychiatric disorder is in its infancy, it is likely to become a major area of investigation; this is especially true for research on psychiatric help-seeking. The results of a recent comparative general population survey of the United States and Ontario, Canada, documented that the central role of perceived need explains substantial country-to-country differences in seeking help for emotional problems. This survey found that people in the United States are much more likely than those in Ontario to seek professional help for emotional problems. However, when diagnostic data were used to investigate the relation between objective measures of need and help-seeking, the only significant between-country difference in probability of obtaining treatment was found in the subsample of respondents with low need for services, among whom more than twice as many sought help in the United States as sought help in Ontario. More focused analysis found that this difference is because of a higher level of perceived need for help in the United States than in Ontario among persons with low objective need. This difference was especially pronounced among middle-class people with insurance, raising the possibility that the demand-side controls used to limit access to mental health services in the United States are less effective in controlling unnecessary use of services than the supply-side controls used in Ontario; clearly, more detailed investigation of this possibility is needed.

Persons with comorbid conditions are more likely than those with only a single disorder to seek professional help for psychiatric difficulties. This result is consistent with the more general finding that likelihood of seeking help is positively associated with severity. Persons who have comorbid disorders are more severely distressed than those with only one disorder. Persons with comorbid conditions have a very high probability of having alcohol or drug problems (e.g., substance-related disorders) superimposed on anxiety or depression. Their help-seeking patterns direct them disproportionately to community substance abuse treatment programs where other underlying psychiatric problems are often overlooked and untreated.

Recent commentators have noted that the problems associated with comorbid diagnoses might conceivably be addressed by intervention efforts aimed at attracting psychiatrically disordered persons into treatment before they develop secondary disorders. Early interventions might be effective in preventing the onset of secondary comorbid conditions. The difficulty in implementing that approach is that the motivation to seek help often occurs only in the context of the severe role impairments associated with comorbid conditions. A future challenge will be to devise strategies to attract patients at an earlier stage in their illness, before they develop secondary comorbid disorders. Given recent evidence about the early onset of primary disorders among persons who later develop comorbid conditions, this early intervention work will almost certainly require screening in school-aged populations.

COMMUNITY RESPONSES TO THE MENTALLY ILL

Attitudes Attitudes about the mentally ill have been charted in public opinion surveys since the 1950s and dislike and fear have remained high among the attitudes surveyed. Negative attitudes are particularly pronounced among people who are poorly educated and among the elderly; men consistently report more negative attitudes than do women.

The core concerns about persons who are mentally ill revolve around their presumed unpredictability and dangerousness. These concerns have some basis in reality, as patients released from state psychiatric hospitals have comparatively high arrest rates. However, most crimes committed by released patients are property crimes that do not involve violence. Unfortunately, the mass media typically emphasize cases where violent crimes are committed by people with a history of emotional problems, thus exacerbating the problem of public misperception.

Intensely negative attitudes about the mentally ill may be a part of a larger cluster of beliefs, attitudes, and values characterized by an absence of sympathy for people who need help; a deep-seated distrust of people and institutions who are perceived as different; and a rigid outlook on what is right and wrong. Such people's views are not easily swayed by rational arguments.

Fortunately, most people have much less intensely negative feelings that can be modified on the basis of experience and as they become more knowledgeable and learn to make finer distinctions about kinds of mental illness and treatment. Visits to a psychotherapist, for example, are much less stigmatized than hospitalization for a mental illness and hospitalization in a private facility seems to be less stigmatizing than hospitalization in a public facility. Drug therapies are perceived as evidence of greater disorder and so provoke more fear and distrust of the patient than do talk therapies. For a similar reason, treatment by a psychiatrist involves more negative attitudes than consultation with a psychologist, social worker, or member of the clergy.

Survey data suggest that attitudes of community members can be influenced by contact with the mentally ill. In general, survey respondents who report knowing someone who has a history of mental illness are less negative than people who report no personal contact. It is difficult, however, to sort out cause and effect here, because negative attitudes might be associated with failure to report the mental illness of a close relative.

Family studies and studies of the reintegration of former patients into their old work roles show that contact with former coworkers and associates promotes positive attitudes about the mentally ill. Seeing a former patient perform adequately in a normal role is particularly important in this regard. Self-disclosure by the former patient about what it was like to be mentally ill and to be hospitalized also helps to promote acceptance by reducing the aura of mystery that otherwise surrounds mental illness.

Much less is known about how to change negative attitudes in the general population. Studies of the mass media show that the stereotyped depictions of former patients that commonly appear on television and in movies reinforce negative public perceptions about the mentally ill. Whether sympathetic treatment of mentally ill people in the mass media might change these negative attitudes or whether informational campaigns making use of the mass media could increase public knowledge about mental illness is less well understood.

This last issue is attracting considerable interest because several large mass media campaigns have been launched to increase public awareness, recognition, and treatment of mental illness. One such campaign was developed by the National Institute of Mental Health to increase knowledge about anxiety and depression and to encourage increased voluntary help-seeking for these disorders. Unfortunately, this campaign did not include an evaluation, so it is not known which kinds of message strategies and information channels lead most effectively to attitude and behavior changes among persons with these disorders. Judging by the experiences of health educators in conducting campaigns aimed at other public health problems, information of this sort is vitally important to successful campaign design and implementation.

A more recent related campaign has instituted an annual National Depression Awareness Day in which mass media around the country are mobilized to encourage people who might be depressed to seek treatment. Local screening sites and a toll-free number are used to facilitate screening and to encourage people who screen positively to seek treatment. Evaluations have shown that this growing campaign has been successful in bringing tens of thousands of people into treatment. Comparable programs have been established to create annual national anxiety and eating disorders screening days. Ongoing interdisciplinary research that takes into consideration the importance of social and personal barriers is refining the messages and referral strategies of these campaigns in order to increase their reach and effectiveness.

COMMUNITY REACTIONS TO SHELTER CARE HOMES

Negative attitudes about the mentally ill are important for a number of reasons, including the fact that they inhibit help-seeking for personal problems. The subject of recent sociological attention is the organizational effect of negative attitudes on attempts to establish group homes for the mentally ill.

Sociologists have done a great deal of research on collective action. Community opposition to group homes has become one of the mobilization activities studied by those working in this tradition. Research clearly indicates that middle-class neighborhoods are much more resistant to having group homes in their midst than are working-class neighborhoods; this greater resistance can be traced to effective mobilization efforts. In particular, efforts to meet and organize local opposition are accomplished more quickly in middle-class neighborhoods where a person or a committee is more likely to be selected to act on the neighborhood's behalf and where multipronged political actions are more likely to occur.

Attitudes also play an important role in the success of group homes in fostering readjustment among deinstitutionalized patients. Ethnographic research shows clearly that patients are aware of the climate of acceptance or rejection in their neighborhoods and that this influences their social functioning. The ease with which the

residents of these homes adjust to life in the community depends to a large extent on community acceptance. The conflict that can attend the creation of the home does not make a good foundation on which to build such acceptance. In general, public opinion surveys show that contact with former patients who are strangers exacerbates whatever fears and uncertainties community residents already have, particularly in neighborhoods that had previously opposed the establishment of the group home.

These issues have been neglected in most sociological studies of community opposition to group homes, which generally concentrate on structural determinants of neighborhood mobilization and on strategies available to agencies for defusing this opposition. Research is urgently needed on what happens after the home is opened and the residents must live in the neighborhood. There is evidence that contact with a former mental patient who was known prior to hospitalization can foster positive attitude changes, especially when the former patient can be seen performing adequately in normal roles. One challenge for the future will be to create structured situations that will facilitate contact between residents of sheltered care homes and their neighbors such that positive attitude changes can occur.

ORGANIZATION OF MENTAL HEALTH SERVICES

Interorganizational Coordination Research on complex organizations is one of the liveliest areas in sociology today as a result of the enormous organizational changes in American society and the innovative work of social theorists in developing new frameworks within which to understand these changes. The mental health care delivery system has been a favorite example used by these theorists to test new ideas about interorganizational linkage, because it provides unique opportunities to study a decentralized system consisting of many overlapping organizations that have complex coordinating functions.

One focus has been on the continuing diminution of state mental hospitals and the impact of downsizing on general hospitals and community-based programs. Although there is a general perception that most of the reductions in state mental hospital systems throughout the country occurred in the 1950s and 1960s, up to a 50 percent decrease in the number of inpatients occurred in many state mental health systems during the 1980s. The result has been an increased burden on general hospitals and a revolving-door policy whereby patients are treated during periods of crisis and largely ignored between admissions.

Case studies of community responses to these changes have documented enormous coordination problems and inconsistencies in organizational rationalities. Historical analyses show that these problems result from years of decision-making that lacked any overall plan or purpose. The challenge for researchers is to synthesize these case studies in order to discover the mechanisms that facilitate rationality in the relations among community organizations. Such work is currently the subject of intense interest among organizational sociologists.

A related series of studies has attempted to trace the influence of state and national policy initiatives on community-based organizations and systems. Studies have been done on how strategic decision-making in local organizations is affected by considerations concerning the future actions of state and national funding agencies. The studies show that instability of state and national initiatives to develop community-based programs leads to local processes of adaptation that were not intended by the policymakers who developed the programs. Current research is moving in the direction of comparative studies aimed at isolating characteristics of particular community systems that determine the directions of local responses.

There is also a great deal of interest in designing and evaluating organizational innovations that might improve the quality of care for the chronically mentally ill, particularly for patients unable to afford private care. Capitation programs, managed care programs, and programs that mainstream the mentally ill into existing health maintenance organizations (HMOs) created exclusively for persons with chronic mental illness are among the organizational innovations that are currently being discussed. Criteria for treatment success must be broadened for this population to include fundamental quality-of-life issues such as adequacy of housing, nutrition, employment, social integration, and other topics that are of central concern to sociologists.

Organizational Factors in Service Delivery Another kind of organizational research extends the work on job stress by studying the influence of organizational structure on the health, well-being, and productivity of its members. Some of this research has studied the structural components of mental health care organizations that affect staff satisfaction with their work; a few studies have also examined the impact of organizational structure on patient outcomes. All this work has been naturalistic rather than experimental, and comparative rather than based on case studies of individual treatment settings.

Findings include the fact that staff satisfaction and productivity are positively associated with decision latitude. Patient functioning in long-term mental hospitals is also positively associated with the decision latitude of lower-level staff. Other correlates of good patient functioning include high staff job satisfaction and high staff participation in treatment decisions. Patient functioning in short-term–care inpatient settings is positively associated with an active management style; functioning of patients in community-based shelter care homes is likely to be better when the homes are small, have flexible rules, and require patients to take some responsibility for activities of daily living.

As these results suggest, there is as yet no overarching theoretical framework that integrates the specific findings into a coherent model of organizational influence on staff and patient functioning. Integrative work of this type will be facilitated by job redesign experiments in industrial settings. Similar experiments in treatment meetings are much less common, although innovative experiments are now under way to change the structures of community-based shelter care homes in an effort to reduce the problems of staff burnout and turnover. The success of organizational redesign efforts is likely to determine whether similar experiments are carried out in a wider range of treatment settings.

Evaluation of Community Mental Health Services The development and maintenance of an effective community-based system requires a cyclical process of service planning, implementation, evaluation, and feedback. The first step in this process is usually a needs assessment, which identifies the mental health problems in the community and establishes priorities for the creation of services to address these problems. Such an assessment is vitally important to organizational success because it monitors demand for services and identifies needs not recognized by community residents.

The most direct way to conduct such an assessment is by a large-scale community survey. However, such surveys are very expensive and most local service organizations are unable to afford them. A number of innovative approaches have been devised to obtain more indirect information about need at a lower cost. These techniques include systematic interviews with key informants, the establishment of citizen advisory councils, the use of national statistics on need profiles in conjunction with small-area social indicators on community demographics, and extrapolation from data on demand for services to estimates about need for services.

Once programs are developed, research can also be important in evaluating effectiveness and targeting areas that need to be changed. Program effectiveness relies on at least two levels of research. The first focuses on success in attracting participants to the program; the second focuses on success in helping people with their problems. Behavioral scientists have been more active in the first research area than in the second area.

Research on success in attracting program participants emphasizes acceptability, accessibility, and awareness. Acceptability refers to how willing community residents are to use the new service. Accessibility involves the ease with which the program can be reached; time, distance, transportation, and financial barriers are all important considerations. Awareness relates to community knowledge that the service exists and the particular needs that it is appropriate for. An understanding of local culture is required to develop programs that are sensitive to these issues. Sociological research using ethnographic research tools or other qualitative strategies can increase the sensitivity of program staff to local norms and customs.

Research that evaluates the effectiveness of programs is much less common for several reasons: the substantial costs of implementing a carefully controlled study of treatment effectiveness, the high level of methodological sophistication required to carry out such an investigation, and the potential threat to clinicians and program administrators of openly studying the therapeutic value of their services. Although sociologists and other behavioral scientists have the expertise to do such work, this sadly remains an underdeveloped area of investigation.

Social Context of Professional Activity The medical profession is undergoing enormous changes, engendered by such things as *diagnostic-related groups* and other new payment arrangements, the shifting of care from inpatient to ambulatory settings, diversification of the medical care industry, increasingly overt competition among providers, and the growing importance of third-party payers. These changes are part of broader societal forces that include the aging of our population and cohort shifts, which have led to massive expansion in the plant facilities of the medical care industry and a marked increase in the number of physicians in the marketplace.

Sociologists have been keenly interested in the implications of these trends for the future of medicine. One perspective holds that physician domination of the health care system is too firmly established to be shaken by the changes in social context that are taking place. The legal subordination of nurses, pharmacists, and other medical care professionals to the physician is cited as critical in this regard, as are the exclusive licensing powers granted to physicians as gatekeepers of the

medical care system.

An opposing view is that the medical profession is in a period of declining power as a result of the resurgence of consumerism in medicine. The greater number of medical patients who suffer from chronic rather than acute conditions leads to the creation of interest groups made up of lay people who acquire considerable technical knowledge about their own afflictions and tend to challenge their providers. The technical diversification of medical procedures and the increasingly important contributions to health care by technician-specialists who are not physicians are also believed to play a part. With changes in the organization of professional care, new systems of ownership and management have promoted competition among physicians, which inevitably brings with it increased consumer control. Finally, the more dominant position of large insurers consolidates the bargaining position of consumers in a novel way. All these factors are particularly relevant to psychiatrists because auxiliary mental health specialists, such as clinical psychologists and psychiatric social workers, have no counterpart in the other medical specialties.

Another perspective on the changing nature of medical practice involves the proletarianization of medical work. More and more physicians, especially psychiatrists, are working as salaried employees in large, bureaucratically managed organizations. As those organizations are instituting managerial styles orchestrated by the graduates of business schools rather than of medical schools, changes in procedures for professional control will invariably occur. Formal review procedures are being applied to a wider range of professional behaviors. Within particular institutions, mechanisms are being developed to monitor and control the technical decisions of clinicians. All these trends will result in increasing external control of the domain of professional practice.

The future shape of psychiatric practice is difficult to forecast; social scientists who specialize in such prognostication have conflicting views. A more thorough understanding of the issues discussed in this section may help to modify the role of psychiatrists and future medical care systems.

SUGGESTED CROSS-REFERENCES

Other perspectives on sociocultural influences on psychiatry may be found in Section 4.1 on anthropology and psychiatry, and Section 4.3 on evolutionary biology and its applications to psychiatry. Mental health services research is discussed in Section 5.3.

4.3 EVOLUTIONARY BIOLOGY AND PSYCHIATRY

MICHAEL T. MCGUIRE, M.D., AND ALFONSO TROISI, M.D.

OVERVIEW

Evolutionary studies of human behavior focus on the transmission and modification of genetically influenced behavioral traits and the systems responsible for these traits; development; function; and the environment. Because of the influence of genetic information on traits, humans, like other species, enter the world predisposed to process and interpret information in species-typical ways, to engage in certain behaviors and not others, and to work toward some goals more than others. It is unnecessary to teach infants how to bond; about emotions such as happiness, distress, disgust, anger, and fear; or about language, just as it is unnecessary to teach most adolescents about interest in the opposite sex or male and female mating strategies. This array of traits, rules, motivations, and behaviors is in part a product of the evolutionary past of all human beings, a past that determines much of what humans do, think, and feel.

When evolutionary biologists maintain that behavioral traits and internal systems cannot be adequately explained without taking into account their evolutionary history, nonbiologists often disagree. Some theorists object to what they believe are the deterministic implications of this view and disagree with its disregard for learning and culture; other theorists are concerned with the possible negative social consequences of such a view.

However, in one sense or another all sciences or purported sciences are deterministic. The sociologist who postulates that criminal behavior is caused by peer-group influence, the psychologist who predicts that a child will resent neglectful parents, or the psychiatrist who predicts that changes in central nervous system (CNS) dopamine function will hasten the onset of schizophrenia are using deterministic models in the same way as evolutionary biologists who postulate that genetic information predisposes humans to learn some things rapidly but not others. What is at issue is the *how* and the *why* of determinism and the extent of what is determined.

Concerns about learning and culture are as much a part of evolutionary explanations of human behavior as are genes. Predisposed traits are refined through learning and experience and the degree to which learning and experience influence the expression and form of traits differs across cultures because different cultures differentially value some traits more than others. Biological explanations of human behavior are incomplete unless learning and cultural influences are an integral part of the explanatory calculus—there is simply no ambiguity on this point. Social reformers often worry that if a social behavior is viewed as having genetic origins, efforts at reform will be compromised; however, the opposite is usually the case. The more that is learned about disorder etiology and pathogenesis, the more interventions are possible in the process that leads to illness and functional impairment. Evolutionary studies of human behavior have already demonstrated that a more accurate knowledge of behavior and the needs shaped by natural selection can significantly reduce mental suffering and improve psychological well-being; (e.g., John Bowlby's ethological studies of mother-child attachment have been highly influential in reforming the procedures of pediatric hospitalization).

Much of the understanding of evolution comes from the work of population biologists and their analysis of systems influencing phenotypic variation as well as from evolutionary psychologists who focus on evolved systems that guide behavior. There are important differences in these approaches. Population biologists address issues dealing with the frequency of traits in populations. Their findings permit inferences about interactions between environmental contingencies and both the adaptability and transmission of traits (e.g., walking erect, mother-infant bonding, visual acuity, increased complexity of the brain). To the degree that genetically influenced traits are associated with above-average survival and reproduction, these traits will appear at a greater frequency in subsequent generations. Studies of evolved psychological systems focus primarily on algorithms or information-processing systems that may be the postulated basis of capacities for assessing the costs and benefits of social interactions, devising novel behavioral strategies, anticipating others' needs, and altering behavior in response to self-monitored information. Both these approaches are critical to understanding and treating disorders, and both build on findings from the several branches of evolutionary biology; ethology, behavioral ecology, evolutionary anthropology, evolutionary psychology, and evolutionary psychiatry. A feature common to each of these disciplines is the critical importance placed on the theory of evolution by natural selection for understanding both past and present behavior.

Evolution by natural selection requires three conditions. First, a trait must vary within a population *(phenotypic variation)*. Second, there must be a relationship between the trait and adaptation, such as mating ability, fertility, or survivorship *(fitness variation)*. Third, there must be a consistent relationship, independent of common environmental effects, between parent and offspring for the trait *(inheritance)*. Phenotypic variation, fitness variation, and inheritance are the cornerstones of contemporary evolutionary theory, and interactions between these features are the basis of the cross-generational survival of some genes more than others.

Evolutionary theory does not assume that natural selection has any plans or goals or that the products of evolution are ideal. Environments change; a trait that is advantageous in one environment may be less advantageous in another. Also, some species eventually become extinct. Because numerous factors (e.g., genetic loading for disorders, developmental insults) influence phenotypic outcome, individuals develop variant phenotypes, and some phenotypes fare better than others. Evolutionary theory can accommodate these outcomes because it is as much about normal phenotypes as it is about variant phenotypes, and both types can be understood within the same theoretical framework.

EVOLUTIONARY BIOLOGY OR SOCIOBIOLOGY?

Following the publication in 1975 of E.O. Wilson's *Sociobiology: The New Synthesis*, and the ensuing ideological debate, many social scientists equated the term *sociobiology* with any attempt to explain human behavior using Darwin's theory. This confusion is unfortunate. What Wilson's book did was to bring together in a single volume findings from ethology, behavioral ecology, and evolutionary anthropology and combine them with many of Charles Darwin's ideas as well as refinements and changes to these ideas introduced by later investigators. The debate developed largely because Wilson speculated about the possible evolutionary bases of many human behaviors (e.g., reproduction, rituals, hierarchies) that prior to his book had been explained without consideration of possible evolutionary contributions. Times have changed somewhat since 1975. Although ideas that have their origins in evolutionary theory are now largely accepted within the social sciences, some memories of the debate and its associated confusion remain, which is why the term *evolutionary biology* is preferred over the term *sociobiology*.

KEY POINTS IN EVOLUTIONARY EXPLANATIONS OF DISORDERS

The evolutionary approach to mental disorders is based on concepts and explanations that overlap with and differ from those favored by psychiatry's prevailing explanatory models—biomedical, behavioral, sociocultural, and psychoanalytic.

Ultimate Causation Ultimate causation is the evolutionary concept that explains why in the past some traits were selected in preference to others. Current traits, such as reflexes, emotions, and the capacity to develop contingent strategies, are assumed to have been selected because they were adaptive during prior periods.

Ultimate causes differ from proximate causes such as genetic accidents, dysregulated physiological states, inadequate learning, or intrapsychic conflicts, which are the mainstay of prevailing model explanations of disorders. Ultimate and proximate causal explanations are not contradictory but complementary; both are essential for understanding disorders. For example, proximate explanations of major depressive disorder focus on putative dysfunctional biochemical states (e.g., the norepinephrine hypothesis of depression), and symptoms and signs, such as crying, feelings of despair and hopelessness, withdrawal from social interactions, and somatic indices (e.g., sleep difficulties, lack of appetite). These signs and symptoms are assumed to be the consequences of dysfunctional states. Ultimate cause explanations view many of the same symptoms and signs as evolved traits, such as signals to others that one is distressed, needs help, and is unable to engage in normal social behaviors, as well as a strategy for conserving energy *(social withdrawal)*, which reduces the frequency of costly behavior and allows restorative processes to take effect. The fact that others help those who are depressed, that persons who are depressed are not expected to carry out the normal array of social

behaviors, and that the majority of persons with depression recover on their own not only lends credence to ultimate cause explanations, but also has important therapeutic implications.

Reproduction A central theme of evolutionary theory is that traits and reproduction interact: compared to genetically influenced traits that negatively correlate with reproductive success (e.g., severe physical disabilities, hydrocephalus), traits that positively correlate with reproductive success will be present at greater frequencies in subsequent generations. The importance accorded to reproduction is sometimes taken to mean that evolutionary biologists believe that reproduction is the primary goal of all behavior; this is a misinterpretation. Human behavior (like that of closely related species), is more correctly understood as a set of acts to achieve short-term goals, such as acquiring resources, making friends, finding a mate, and reducing the effects of unpleasant emotions. These are the goals that concern humans and that are responsible for most human behavior. A consequence, often an inadvertent consequence, of successfully achieving short-term goals at a reduced average cost is increased reproduction.

Within this context, proximate factors may or may not influence reproduction and its outcomes; two such factors are of particular interest for psychiatry. First, available data indicate that the majority of persons with disorders have average or close-to-average reproductive success; that is, for most disorders, reproductive rates do not differ significantly from age- and sex-matched individuals without disorders. Disorders thus do not seem to significantly compromise reproductive capacities or reproduction, which means that disorder-influencing genetic information will be transmitted across generations and that human information-processing systems are more variant than human reproductive systems. Second, the findings that reproductive rates are not reduced among persons with disorders would seem to contradict the theory that achieving short-term goals correlates with reproductive success. Several proximate factors may be responsible for this seeming contradiction. For example, studies consistently show that assortative mating (preferential mating among persons with similar traits) occurs among persons with disorders; persons with disorders are known to cluster in enclaves in which mating options may increase; and, compared to females without disorders, those with disorders may be more susceptible to male sexual coercion.

Adaptation According to evolutionary theory any anatomical structure, physiological process, psychological process, or behavior that makes an organism more fit to survive and reproduce in comparison to other members of the same species is viewed as an adaptive trait. However, one's degree of adaptation is relative; no absolute measure exists. Although psychiatrists often use the term *adaptation*, its meaning is usually synonymous with *adjustment*. For example, according to the fourth edition of *Diagnostic and Statistical Manual of Mental Disorder* (DSM-IV) “Adaptive functioning refers to how effectively individuals cope with common life demands...” Coping may or may not be associated with improved survival or reproduction relative to other members of one's species.

Traits and Within-Trait Variation *Traits* are enduring, measurable attributes (e.g., height, baseline measures of serotonin concentration in central nervous system [CNS]) that are influenced by genetic information. *Within-trait variation* refers to the degree to which a given trait varies within a population (e.g., some people are tall, others are short; some are unusually sensitive to criticism, others can emphasize better than others). Most traits can be scaled along a continuum from suboptimal to optimal, when the measure of optimality is taken as the contribution of a trait to achieving short-term goals. Because of the genetic mixing that occurs at conception, the genetic contributions to traits as well as the strength of trait predispositions differ between parent and offspring; such differences are to be expected. Evolution has thrived on trait variation largely because different traits (e.g., sickle-cell trait) and degrees of within-trait variation (e.g., fat distribution) have different survival and reproductive value across environments.

In evolutionary analysis humans are viewed as mosaics of traits, with individual traits ranging from those that are functionally independent (e.g., visual acuity and height) to those that are highly interdependent (e.g., information-processing speed and verbal intelligence). Studies by behavioral geneticists point to three factors that influence traits and are of special interest to psychiatry: genetic predispositions, preferred environments (features of the environment to which persons preferentially respond because of their genetic makeup), and developmental environments, with the first two factors accounting for a significantly greater percentage of phenotypic variance than the third.

Many enduring features of both nondisordered and disordered behavior can be characterized in terms of an individual's location at the extremes of trait continuums: examples include impulsivity, paranoia, shyness, emotional lability, and somatization. Some disorders are best understood as clusters of suboptimal traits: mental retardation and schizoid, schizotypal, and borderline personality disorders are examples. Traits may become more obvious (e.g., impulsivity during a manic episode) or less obvious (e.g., impulsivity, depressive disorders) during disorder exacerbation.

The Social Environment According to evolutionary theory the social environment contributes to the refinement of traits and is the arena in which most short-term goals are achieved. Other individuals are essential for mating, kin investment, and nonkin reciprocal relationships (Fig. 4.3-1). Disorders occur more frequently among persons raised in adverse environments, and persons who have experienced such environments often fail to refine traits essential for social navigation in ways that optimize the achievement of short-term goals. Prevailing model explanations of disorders frequently point to adverse developmental or current environments as disorder-contributing factors. Evolutionary theory does likewise, but it also places strong emphasis on social hierarchies, the turnover rate of individuals in a social environment, and the physiological and psychological consequences of different types of social information. Social hierarchies influence social options and others' expectations of one's behavior. One's position in a hierarchy not only correlates with the type of information one receives and the benefits that accrue from social participation (e.g., high-status individuals receive a surplus of benefits), but also with the frequency of disorders (e.g., low status is associated with a decline in social influence and an increase in the frequency of depression and suicide). Rapid turnover of individuals in one's environment increases the costs and reduces the predictability of achieving goals in which others are essential participants. Social information type (e.g., negative versus positive) has a direct impact on physiological and psychological states, and repeated negative information can trigger the onset of signs and symptoms while repeated positive information can reduce their intensity.

FIGURE 4.3-1 West African Green Monkeys (“vervets”) engaged in a grooming and huddling interaction.

Sex Differences Because of their separate evolutionary histories (e.g., confronting different adaptive problems), males and females differ physically, physiologically, and psychologically in the importance they attach to goals (e.g., caring for offspring) and the strategies they utilize to achieve goals. Sex differences permit predictions about differences in the life prevalence of disorders and their manifestations. Among females disorders should be more frequent when females are unable to achieve goals that are central to female identity, such as attracting faithful mates, reproducing, and developing social support networks. Disorders associated with losses in male-male competition, failure to gain sexual access to females, failure to acquire resources, and declining social status should be more frequent among males. Epidemiological data are consistent with these predictions. Histrionic personality disorder and erotomania have strong male attraction components; anorexia nervosa and depression due to infertility have strong reproductive components. These disorders occur significantly more frequently among females than among males; for example, greater than 90 percent of the cases of anorexia nervosa occur among females, and 37 percent of females experience psychological disruptions in association with marital infertility whereas only 1 percent of males show these disruptions. For males, impulse-related disorders, depressive disorder or suicide following competitive losses, and alcohol have strong male-male competition and resource acquisition components; many types of sexual deviance and spousal abuse have female access components. These disorders are significantly more common among males. A clear implication of this fact is that differences in female-male neuroanatomy, neurochemistry, hormonal activity, goal priorities, and strategy preferences should be consistently integrated into disorder explanations and treatment plans.

Function and Functional Capacities Organisms are designed to do something, and what they do reveals their goals and provides information whereby their efficiency at achieving those goals can be assessed. For example, the function of foraging is to obtain food; the functions of social interactions include recognizing

possible mates and good reciprocators and obtaining information about resources. Some functions, such as mother-infant bonding, are closely tied to specific behaviors whereas others, such as acquiring resources, are associated with a larger number of behaviors.

Functions and the behavioral skills necessary to carry them out (functional capacities) need to be distinguished. Two persons may aspire to gain admission to medical school, yet they may differ in their capacities to achieve the goal. Functional capacities are traits that are influenced by genetic information and are subject to refinement; their goal-achieving efficiency varies across environments. Accurately assessing functions, functional capacities, and short-term goal outcomes requires the moment-to-moment assessment of behavior in the social environments in which it occurs—the success of a social signal is in part defined by the response of the person receiving the signal.

Functions and functional capacities are relevant to discussions of disorders in numerous ways: with a few exceptions, the majority of disorders are associated with both compromised functional capacities and goal achievement and improving function and functional capacities are key objectives of treatment.

Strategies Strategies are the ways in which individuals plan and carry out behavior. For all but the most rudimentary of acts, and especially when others are involved, a person's initial strategies usually require adjustment. When individuals without disorders find that a strategy is inefficient, they may devise alternative strategies. The same is true for persons suffering from minor symptoms, such as depressive disorder and anxiety: they may attempt to reduce their symptoms by avoiding persons or situations that intensify their unpleasant feelings. Both prevailing and evolutionary models of behavior agree on these points. Where evolutionary models differ from prevailing models is in the view that the presence of a disorder does not mean that there is a discontinuation of either the development or use of strategies to reduce symptoms or achieve short-term goals. For all but a few disorders, motivations to achieve short-term goals appear to vary minimally among persons with and without disorders. What often distinguishes persons with disorders is how they go about trying to achieve goals; for example, they frequently use strategies that are counterproductive and they usually have trouble changing strategies that are unproductive.

The evolutionary view that caused motivations remain intact despite the presence of disorders invites alternative interpretations of a wide array of disorder-related behavior. For example, psychic defense or denial may be viewed as selectively attending to and processing external information, while repression is selectively attending to and processing internal information. Rationalization yields self-serving explanations for one's behavior; intellectualization serves to separate emotions from cognition. These defenses take on a new meaning when they are viewed as strategies to facilitate short-term goal achievement. Signs such as social withdrawal, excessive anger, and excessive responses to specific words (e.g., observed among some persons with schizophrenia) may reflect a strategy: withdrawal removes one from painful or frightening situations and excessive anger or excessive emotional responses to normally neutral words usually changes others' behavior.

Emotions In the evolutionary context one function of emotions is as a source of information about short-term goal achievement. Depression informs one that costs have exceeded benefits in past attempts to achieve goals. Anxiety informs one that future goals are unlikely to be achieved or that achievement will result in a negative cost-benefit balance. Frustration informs one that negative cost-benefit balances exist with respect to ongoing goals. Pleasure indicates that goals have been achieved or that they are likely to be achieved with a positive cost-benefit balance.

A second function of emotions is to initiate strategy and behavior change. Evolutionary biologists view emotions as behavior-initiating systems. Pain, anxiety, and anger generally initiate behavioral responses more rapidly than cognitive assessments (e.g., acute fear of a situation triggers rapid flight-or-fight responses whereas cognitive assessments may delay responses). That excessive emotions often exceed the intensity of stimuli is thought to reflect the fact that mankind has evolved to believe that it is better to be safe than sorry.

A third function of emotion is social regulation. Emotions are signals: smiles signal pleasure and usually initiate others' social participation; anger signals that one is displeased and that interpersonal aggression may be forthcoming; depression in response to interpersonal competition signals that one has lost the competition.

More enduring and debilitating emotions require other explanations. In the absence of precipitating causes, debilitating emotions, which are observed in major depressive disorder, manic episode, and panic disorder in part reflect a suboptimal capacity to discontinue (“turn off”) emotion-initiating processes, and in part reflect a compromised ability to act in ways in which benefits exceed costs. In different combinations, genetic information, within-trait variation, physiological dysregulation, and a failure to refine traits may contribute to these types of emotions.

Information Processing Each of the preceding topics involves information processing. A feature common to most disorders is atypical or distorted information processing, such as misinterpreting reality, others' responses and motives, one's own importance, and the meaning of one's symptoms. Another common feature is the compromised ability to correct information misinterpretations. A third feature is the reduced ability to alter strategies on the basis of self-monitored information. Generally, two types of evolutionary interpretations are applied to misinterpretations. One is to ascribe information distortions to dysfunctional algorithms. Viewed this way, distortions are state conditions and they may normalize when disorders remit. The other interpretation emphasizes deficit conditions or the absence of processing capacities. Both views are clinically relevant. Tensions between algorithm capacities and the social environment are observed in highly stressful environments (e.g., dysfunctional marriages, intense parent-offspring conflict), and such tensions can result in dysfunctional algorithms that contribute to depressive disorders, adjustment disorders, amnestic disorders, and anorexia nervosa. Because each of these disorders usually improves, dysfunctionality rather than a deficit condition is implied. In the absence of precipitating causes, deficits are implicated for disorders in which emotions are debilitating and there is functional deterioration relative to predisorder states (e.g., schizophrenia).

Self-Interest and Altruism That individuals have evolved to act in their own interest and not in the interest of the species is a basic premise of evolutionary theory. Sibling rivalry and parent-offspring conflict are examples of self-interest and they illustrate some of the consequences of self-interested behavior in relationships in which genes are only partially shared. For reasons of self-interest siblings compete for parental investment. Parent-offspring conflict occurs because parents tend to limit their investment in offspring in order to achieve other goals, such as attaining resources or maintaining social support networks.

At first glance, self-interested behavior would seem to preclude the possibility of altruism. Yet altruistic behavior does occur (e.g., donating kidneys, helping friends and strangers). How is it possible that individuals have evolved to be both self-interested and altruistic? Evolution-based answers to this seeming paradox are found in the ultimate cause of explanations of kin selection and reciprocal altruism.

Kin selection explains preferential investments in kin (a cost) without an associated immediate benefit. For example, a mother's care for her offspring is both self-interested and altruistic behavior: the mother's investment (the altruistic component) increases the chances that her offspring will mature and reproduce. To the degree that her offspring reproduces, the mother's genes will be replicated in the next generation (the mother's self-interested component as well as the delayed benefit). In more complex situations, one can invest in collateral kin (e.g., sisters and brothers) and increase one's genes in subsequent generations provided that the collateral kin reproduce. *Reciprocal altruism* is defined as an exchange of favors between nonkin separated by a time interval (the time interval distinguishes reciprocal altruism from *mutualism* or *joint cooperation*): one does a favor for another (a cost and the altruistic component) and the favor is reciprocated (the benefit and the self-interested component). On average, the greater the percentage of genes shared by two individuals, the greater the probability of investment; the less offspring appear to be good reproductive bets, the less investment they will receive and nonkin nonreciprocators will be socially ostracized. Data are consistent with these predictions.

Some of the strongest evidence supporting the algorithm concept can be found in the analysis of reciprocal interactions. Most such interactions involve exchanges of different currencies (e.g., a person feeds a neighbor's dog for a week and in return receives a suggestion about how to invest in the stock market; both parties feel that the favor has been repaid). Because most reciprocal exchanges are of this type, and because precedents for specific types of exchanges are often lacking, it can be argued that algorithms are evolved capacities capable of assessing the costs and benefits of different currencies.

Kin selection and reciprocal altruism are both key to describing and understanding disorders in evolutionary context. Nondisordered behavior generally equates with high degrees of kin investment and successful nonkin exchanges. Among persons with disorders, both kin investment and reciprocal relationships are often compromised and counterproductive. For example, persons with disorders frequently seek excessive kin investment. In turn, kin reject such demands and may at times reject the persons making them. Similarly, persons with disorders often fail to reciprocate or they may reciprocate insufficiently; in turn, relationships are likely to be discontinued.

There are multiple reasons for compromised kin investment and reciprocation, including misperceptions, dysfunctional and suboptimal algorithms, as well as the behavior of kin and nonkin. Compromises reflect a breakdown in fundamental social behavior capacities, contribute to disorder onset, and extend disorder longevity by compromising the achievement of short-term goals.

Genetic Contributions to Disorders Multiple genetic factors contribute to disorders. Genes have numerous functions (e.g., structural, regulatory) and these functions may be defective; genomic imprinting (parental determination of gene expression) can occur; genetic deletions contribute to specific disorders (e.g., Prader-Willi and Angelman syndromes); genetic loading occurs for specific disorders (e.g., Huntington's disease, schizophrenia, autistic disorder); and stochastic accidents are also known—deoxyribonucleic acid (DNA) replication is not a perfect process.

The preceding list is only a sampling of possible genetic contributions to traits and disorders. Evolutionary biology introduces other possibilities. *Pleiotropy* is the control of one or more phenotypic characteristics by one gene or a set of genes. Genetic information contributing to minimally adaptive traits may be carried along from generation to generation because such traits are controlled by the same gene or genes responsible for an adaptive trait or traits. Perhaps the clearest example of pleiotropy is that of greater fecundity during reproductive years (the adaptive trait) coupled with postreproductive vulnerability to disorders such as depressive disorder (the minimally adaptive trait). Pleiotropy could qualify as an ultimate cause explanation. *Exaption* is another possibility: a trait was adaptive in the past, but it is not adaptive in the present. This possibility is the basis of what may be called the *genome-lag hypothesis:* the environment changes faster than the species genome, one result of which is that some traits selected in the past are not well adapted to the current environment. *Genetic drift* (change in gene frequencies by chance alone) is also a possibility. The contribution of genetic drift to disorders is not yet clear.

Mutation may be the basis for some disorders. Over the course of evolution, mutations are a source of genetic change and genetic variation, and some traits that currently are viewed as adaptive are possible products of mutations. Sickle cell trait is a frequently cited example of a mutation that became adaptive in malaria-prone areas. However, subsequent migration of persons with this trait to non–malaria-prone areas introduced the sickle cell gene into neighboring populations along with its undesirable consequences. Despite this, and with a few possible exceptions, mutations are an unlikely explanation of most disorders or features of disorders. As a rule, mutations are either neutral or they have deleterious effects and genes that have deleterious effects usually do not remain in populations for more than a few generations. For severely debilitating disorders that are relatively uniformly distributed throughout the world, such as the residual type of schizophrenia for which available evidence does not point to prevalence changes, the possible part played by mutations is more difficult to infer. For example, if schizophrenia is due to a mutation it would be necessary to reason that the disorder-causing mutation is very old (e.g., occurred prior to ancestral migration out of Africa or Asia); the disorder has not negatively affected reproductive success in ways that can be easily demonstrated; and selection against the mutation (if it has occurred or is occurring) is minimally influenced by such factors as the physical environment, cultural variables, or the social consequences of the disorder.

Homozygosity due to inbreeding also needs to be considered. There are a number of reports in which degree and frequency of inbreeding are associated with an increased prevalence of disorders. However, it is doubtful that any of the widely distributed, severely debilitating disorders can be explained by this theory. The near-uniform cross-cultural prevalence of many disorders, when compared to cross-cultural differences in inbreeding practices (e.g., the acceptability versus the unacceptability of marriages between first cousins), suggests as much. Minimal selection pressure is another possibility. Disorders such as reading disorder that go unnoticed in nonliterate societies or disorders that appear after the critical reproductive years, such as dementia of the Alzheimer's type, might be explained in this way. In principle, minimal selection effects are potentially distinguishable from pleiotropy effects because of the absence of associated adaptive traits.

Evolutionary Theory as a General Theory of Behavior When causal formulations are focused upon, there are a number of ways in which evolutionary theory might relate to psychiatry's prevailing models. One is as a competing theory. Viewed this way, evolutionary theory could be compared with one or more prevailing models for its explanatory power, much as the explanatory power of biomedical and psychoanalytic explanations of depression associated with loss can be compared. It is also possible to view evolutionary theory and each of the prevailing models as partial explanations of disorders. Most clinicians tend to explain disorders in this way; for example, primary explanations of bipolar I disorder are usually physiological whereas explanations for drug noncompliance are usually psychological.

A third way is to argue that evolutionary theory is a more general and inclusive explanatory system compared to any of the prevailing theories, and that it can integrate both prevailing model (proximate) and evolutionary explanations (e.g., ultimate causation, sex differences, adaptive strategies, and function). Nothing in evolutionary theory precludes explaining disorders as being partially caused by genetic loading, physiological dysfunction, dysfunctional or inadequate learning, adverse environments, or intrapsychic conflicts. Evolutionary theory can increase the scope and complexity (e.g., the addition of ultimate cause and sex difference explanations) of causal explanations and provide a structure for assessing, interpreting, and testing hypotheses. Physiological mechanisms, psychological processes, and behavioral responses are conceptualized as different components of integrated systems that have evolved because they solved adaptive problems (short-term goals). According to this view, prevailing models are more focused and explain aspects of disordered and nondisordered behavior whereas evolutionary theory integrates these findings and offers novel explanations for disorders within a theoretical framework that is relevant to the species.

IMPLICATIONS OF EVOLUTIONARY THEORY FOR CLINICAL PSYCHIATRY

The preceding discussion has numerous implications for clinical and research psychiatry in the areas of diagnosis, epidemiology, etiology, pathogenesis, and therapy.

Diagnosis The lack of balance between psychological assessment and behavioral analysis in clinical psychiatry is a major obstacle to the development of valid diagnostic criteria. The clinical phenomenology of disorders includes subjective mental experiences and objective behavioral changes, yet the diagnostic process is based primarily on the evaluation of psychological symptoms as revealed by patients. Minimal attention is paid to the detailed description and measurement of behavior and, except for periods of hospitalization, patients are rarely observed in the environments in which they live. Despite the increasing awareness of the inadequacy of disorder-based research (e.g., one disorder, one cause), psychiatry has failed to embrace a valid alternative. A major reason for this failure is that psychiatry lacks a theoretical and methodological framework for studying behavior and function. Evolutionary biology provides such a framework; for example, ethology (the evolutionary study of animal behavior) combines the direct observation of behavior with quantitative recording and a theoretical emphasis on human behaviors that are closely related to social functioning. Since the 1970s, ethological studies addressing numerous areas of ambiguity, such as prediction of drug response and definition of diagnostic boundaries, have appeared in the psychiatric literature.

For example, in 1989 the nonverbal behavior of 22 patients depressive disorders was studied to determine whether their response to antidepressant drugs (50 to 100 mg a day of amitriptyline [Elavil] for 5 consecutive weeks) could be predicted on the basis of ethological profiles at baseline. Patients' behavior during interviews was videorecorded and scored according to an ethological scoring system that included 37 different behaviors, primarily facial expressions and hand movements. For data analysis, these behaviors were combined to form eight functional categories reflecting various aspects of the patients' emotional and social functioning. At the end of the study, patients were divided into two outcome groups on the basis of their final scores on a depression rating scale. At baseline, responders and nonresponders did not differ with respect to sex, age, education; revised third edition of DSM (DSM-III-R) diagnosis, or severity of depression. However, ethological profiles of the two outcome groups did differ, with nonresponders showing significantly more assertive behavior than responders.

In an evolutionary context, suffering, statistically variant behaviors, or organic changes are neither sufficient nor necessary for defining disorders. Persons who have hypomania and antisocial personality disorder do not always suffer; neurofibrils are found at autopsy among persons who had no signs of dementia during their lifetime. Also, statistically atypical physiological measures often are not associated with disorders and statistically normal measures often are; putative atypical genetic profiles do not uniformly correlate with disorder phenotypes (e.g., nonafflicted monozygotic twin of a twin with schizophrenia). Such findings invite consideration of alternative criteria to identify disorders and explain their existence.

If evolutionary theory should be used for developing a taxonomic system for disorders, the system would primarily emphasize function and secondarily emphasize signs and symptoms. This point applies as much to dementia of the Alzheimer's type as it does to residual schizophrenia, reading disorder, amnesia, phobias, adjustment disorders, paraphilian, and mood disorders. This view clearly differs from the thinking between DSM-IV and the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) thinking and its implications are unambiguous. Many persons who suffer from chronic anxiety or intermittent episodes of depression; who somaticize, who have recognizable but mild phobias; or who have mild forms of narcissistic, dependent, or obsessive-compulsive personality disorders function and achieve short-term goals at an average or above-average rate. If compromised function is the primary criterion for disorder identification, such persons would not be viewed as having a disorder, although their symptoms would not be ignored or go untreated. Conversely, many persons who are not strikingly symptomatic experience great difficulty in achieving short-term goals and function well below average; such persons would receive a diagnosis in a functionally oriented taxonomic system.

As regards common final pathways or constraints on phenotypic expression, one can learn only so fast, jump only so high, think only so rapidly, and distort reality in only so many ways. Constraints limit the phenotypic outcomes of genetic mistakes, of genetic loading for disorders, of physiological dysregulation, and of ultimately caused behavior. Social withdrawal, anxiety, depression, fear, concentration difficulties, misperceptions, erratic behavior, and delusions are all present in more than two dozen currently classified disorders. Given that these features are present across a broad array of disorders that are not necessarily obviously related, attempts to

diagnose disorders at the sign-symptom level inevitably lead to porous diagnostic categories, favor comorbidity, and may confuse intervention strategies.

Epidemiology Recent epidemiological studies suggest that the life prevalence for disorders is approximately 50 percent, and it exceeds 50 percent if the upper estimates of the disorder prevalence reported in DSM-IV are totaled. Such percentages have several possible explanations, including that disorder criteria are too broadly defined or that epidemiologists have been overzealous in their attempts to identify disorders. The preferred explanation has two parts. First, current diagnostic practices do not reflect an appreciation of the degree of within-trait variation characteristic of *Homo sapiens* and this variation is often equated with disorders. From an evolutionary perspective, trait variation equates with disorders only if traits are the basis of functional impairment. Second, some disorders and many features of disorders are adaptive and reflect adaptive strategies.

Etiology Evolutionary theories of disorder causation emphasize multiple causes; rarely are disorders explained on the basis of single causes. For example, suboptimal traits resulting from the chance effects of genetic mixing at conception, deficit conditions, genetic loading for disorders, and adverse environments can all be contributing factors to disorders. Chance genetic mixing can partially account for those disorders in which pedigree findings are negative and developmental disruptions have not occurred. The absence of an enzyme, such as monoamine oxidase type A (MAO_A), is an example of a deficit condition; the absence of this enzyme can partially account for the associated mental retardation and increased aggressivity. Genetic loading for disorders can partially account for disorders in which pedigree findings are positive but genetic penetrance is partial, such as schizophrenia, bipolar I disorder, and several personality disorders. Adverse developmental and adult environments can partially explain some features of personality disorders, adjustment disorders, the effects of partner abuse, and stress-related disorders. A lack of fit between ultimately caused behavior and current environments can partially explain childhood and adult phobias. Many of the proximate mechanisms postulated by prevailing models, such as low serotonin activity in the CNS, can partially explain impulsive and aggressive behavior.

In addition, evolutionary theory provides two other etiological explanations: some disorders represent adaptive strategies and many features of disorders are manifestations of adaptive strategies. Time-limited cases of anorexia nervosa (90 percent of which resolve), may be partially understood as an ultimately caused strategy to delay mate selection, reproduction, and maturation in situations where males are perceived as scarce. Antisocial and histrionic personality disorders, a percentage of persons with attention-deficit/hyperactivity disorder, and malingering can be partially understood as evolved, ultimately caused, high-risk strategies that often have high payoffs: for example mate and resource acquisition, reproduction, and social influence may be average or above average. Attempts to adapt are seen among persons with narcissistic and dependent personality disorders, conversion disorder, and other somatoform disorders: information is manipulated in self-interested ways (e.g., excessively personalized); and there is an excessive use of specific strategies (e.g., signaling their distress to alter others' behavior). The social withdrawal and signaling features of major depressive disorder have already been discussed; similar interpretations apply to anxiety. An erotomanic delusion in a postmenopausal single woman may represent an attempt to compensate for the painful recognition of reproductive failure. An extension of this line of reasoning suggests that a detailed ethological assessment of disorder features would reveal important differences in functional behaviors and symptom and sign configurations in association with actual or perceived adaptive problems; data are consistent with this expectation.

Pathogenesis Anyone familiar with psychiatry knows that there are different causal hypotheses for disorders. Psychoanalysts emphasize intrapsychic distortions and conflicts, behaviorists emphasize inadequate or dysfunctional learning, and biomedical psychiatrists emphasize atypical genes and physiology. Often, these hypotheses distinguish between organic and other putative causes of disorders. From an evolutionary perspective, the organic-nonorganic distinction is not useful; until proven otherwise, disorders imply different percentages of genetic, physiology, psychological, trait, and environmental contributions. For some disorders, there is strong evidence favoring the importance of a specific proximate cause. Perhaps the clearest examples are disorders that are caused by genetic mistakes or transmission (e.g., certain forms of mental retardation, Klinefelter's syndrome, Huntington's disease). However, these disorders show a wide array of clinical profiles that require explanation. For other disorders, evidence suggests that genetic information combined with some type of developmental perturbation is associated with an increased probability of disorders: monozygotic twin data addressing the occurrence of schizophrenia, alcohol use disorders, bipolar disorders, and antisocial personality disorder are consistent with this view. For disorders involving risk-taking among adolescent males, trait variation is likely; however, even in these cases there are significant differences in the degree of risk taking.

Causal interpretations become more complex when specific causal variables are considered. Physiological assessments provide a convenient example. Low concentrations of 5-hydroxyindoleacetic acid in cerebrospinal fluid (considered as a measure of serotonin release in CNS and of MAO_A activity) is associated with depression, arson-related behavior, and aggression. Further, because some disorders remit spontaneously, some physiological measures are likely to be indicators of disorder-ameliorating processes. This is also true of molecular biological approaches to disorders: DNA ® ribonucleic acid (RNA) ® protein ® enzyme ® neurotransmitter ® behavior, whereby dysfunctionality can occur at any point in the chain. As regards learning explanations, trouble can occur at any point during development. The influence of environmental information on physiological states and disorder triggering has been established and recent evidence suggests that this influence is stronger than was previously known. If algorithms are seen as evolved information-processing systems, pathogenic explanations are contingent on identifying which algorithms are dysfunctional or suboptimal. Because algorithms are thought to have anatomical, physiological, and psychological properties, it is likely that dysfunctional or suboptimal algorithms will be associated with disorder-related features within each of these parameters. For example, an individual with borderline personality disorder goes from rational reasoning to reasoning that is strongly influenced by emotions, which suggests that reasoning algorithms are unstable and that this instability is reflected in the difficulty such persons experience in their efforts to manage their emotions.

Given the preceding points, it is reasonable to assume that many factors contribute to the vast majority of currently classified disorders, that the timing of and interactions between disorder-contributing factors are crucial in disorder development and type, and that factors such as sex differences, ultimate causation, and within-trait variation can explain the features of many disorders. Postulating multiple causes provides little information on specific causes. However, this view ignores several important facts. Thus far, prevailing models have provided compelling explanations for only a very small percentage of disorders, and for the most part these disorders are caused by specific, identifiable genetic abnormalities or substance abuse. For the majority of disorders, there are simply suggestive correlations between putative causes and outcomes. Further, accepted conventions for testing hypotheses (e.g., the effect of a selective serotonin reuptake inhibitor) favor holding potential contributing or confounding variables constant while exploring the effects of a single independent variable on some outcome measure. Although this approach is methodologically defensible, it often inadvertently leads to reductionistic interpretations of the causes of various disorders.

Therapy In many instances, evolutionary-based interventions do not differ from prevailing therapeutic practices. Not only are there are a limited number of intervention options, but an overlap in interventions would be expected if features of prevailing models could be integrated into an evolutionary framework. Many of the existing therapeutic modalities (drugs, learning, discussion, environmental alterations) will be useful in treating different disorders at different points in the course of disorders. Nevertheless, treating disorders in an evolutionary context has several specific implications and priorities.

Perhaps the most obvious implication is that ultimate causes cannot be treated. However, they can be used, such as placing persons in environments in which there is an increased probability of achieving high-priority goals. Second, traits do not disappear, but in certain instances they can be used to therapeutic advantage, such as in refining suboptimal traits so that they are more useful for social navigation. The priorities of therapy can be outlined as follows: (1) If possible, treat causes, not secondary effects. (2) Improve an individual's capacities to achieve short-term goals. This often necessitates a tradeoff between symptoms and functional capacities. To the degree that immediate symptom relief necessitates the use of drugs that compromise function, function should be favored in preference to symptom reduction because improved function inversely correlates with symptom reduction. Treatment should be aimed at factors that lead to strategy failures. (3) Avoid treating adaptive strategies unless they cause great discomfort to an individual or members of the individual's social environment. Thus, histrionic personality disorder that causes distress to a patient and others would be treated whereas social withdrawal in depressive disorder and schizophrenia, or emotional responses in adjustment disorders, might not be high-priority treatment targets. (4) Optimize environmental conditions; place persons in environments in which they are most likely to achieve high-priority goals. (5) Use multiple therapeutic modalities and change these modalities over the course of treatment.

Evolutionary theory offers a framework for the improved understanding of mental illness as well as a theoretical system that can integrate findings from the neurosciences. The serious introduction of an evolutionary approach into psychiatry would allow for the integration of features of prevailing models, introduce novel causal hypotheses, and provide a structure for interpreting new data and reinterpreting old data. A clear implication of this view is that new and different types of information need to be collected and different types of analyses need to be applied in order to improve the understanding of disorders. Examples include the assessment of function, functional capacities, and strategies; timing details with respect to physiological and behavioral change; detailed assessments of environmental contingencies; and far greater consideration of within-trait variation.

SUGGESTED CROSS-REFERENCES

The neural sciences are covered in Chapter 1, genetics in Section 1.17 and Section 1.18, aggression in Section 27.3, and animal research in Section 5.4. Mood disorders are described in Chapter 14, anxiety disorders in Chapter 15, and personality disorders in Chapter 24.

4.4 CULTURAL PSYCHIATRY

MANUEL TRUJILLO, M.D.

Practicing psychiatrists in the United States are keenly aware of the need for a body of knowledge that allows them to provide state-of-the-art psychiatric services across language and cultural barriers. Clinicians, particularly those who practice in urban settings, will increasingly be called to evaluate and treat patients in the many cultural and linguistic groups that constitute today's multicultural society. In treating a patient who speaks a language other than English and holds beliefs at variance with mainstream culture, the psychiatric knowledge and technical expertise of today's practitioner falls short of the goal of providing optimum psychiatric and psychological care. Different attitudes, knowledge, and skills are needed for the practicing clinician of the next century to provide technically correct and culturally competent services. Cultural psychiatry, thanks to relatively recent explosions of research knowledge, can provide the tools needed to extend accurate diagnoses and effective treatments to patients across linguistic and cultural barriers. Cultural psychiatry aims to define the impact of culture on the diagnosis and treatment of psychiatric disorders and to provide culturally syntonic guidance for the design and implementation of culturally competent systems of psychiatric care.

Cultural psychiatry draws on many basic and applied disciplines to build its essential constructs. Anthropology (both cultural and medical anthropology) supplies cultural psychiatry with essential insights into the behavior of people in their natural habitats, native views on health and illness, descriptions of indigenous healing systems, and the role of the healer and rituals of healing in different ethnic and cultural groups. Sociology elucidates the relation of basic psychological processes and psychiatric disorders to such human universals as age, gender, and social and occupational status. Epidemiology generates data about the differential incidence and prevalence of psychological distress and disorders in different cultural groups as well as comparative studies of the pathogenesis, onset, pathoplasty, course, and outcome of diagnostic entities across diverse cultural groups. Developmental psychology and psychopathology illuminate the impact of culture on normative personality development and its disorders. Cultural psychopathology investigates the various culture-bound or culture-specific syndromes, and finally, ethnic psychopharmacology studies the impact of race and ethnicity on use, metabolism, and differential effects of standard psychotropic medication and expands our knowledge of the biological and psychological effects of ancient systems of diets and curative herbs.

Cultural psychiatry's growth as a scientific discipline parallels the growth of modern clinical psychiatry. Emil Kraepelin, in an expedition to Java to study mental illness in different communities, noted lower rates of bipolar disorder among patients in Java and a lower incidence of “feelings of guilt” in Javanese depressive patients in the early days of the twentieth century. Eugen Bleuler was also keenly aware of culturally generated differences in the expression of psychopathology by English and Irish patients. The steady growth of immigrants and migrants from Hispanic and Asian backgrounds following World War II gave additional impetus to the growth of cultural psychiatry in the United States, since it exposed generations of clinicians to patterns of psychopathology and psychological distress at variance with the standard descriptions provided by emerging classification systems such as the series of diagnostic and statistical manuals published by the American Psychiatric Association.

This may explain why the clinical psychiatric literature of the 1960s and 1970s is filled with anecdotal descriptions of cross-cultural differences in the onset, pathoplasty, course, and outcome of common psychiatric disorders. Simultaneously, as the network of psychiatric services expanded exponentially following passage of the Federal Government Community Mental Health Act in 1963, differential utilization patterns of disadvantaged minorities also became apparent, along with evidence of misdiagnosis of major psychiatric disorders and poorer than expected response to mainstream treatments by socioeconomically deprived, culturally diverse populations who gained access to rapidly growing community-based systems of mental health care.

All these developments, fueled also by considerable advocacy from culturally informed and socially active clinicians and academicians, culminated in the landmark acknowledgment by the American Psychiatric Association in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) of the importance of culture and ethnicity on diagnosis and treatment of psychiatric disorders.

> Special efforts have been made in the preparation of DSM-IV to incorporate an awareness that the manual is used in culturally diverse populations in the United States and internationally. Clinicians are called on to evaluate individuals from numerous different ethnic groups and cultural backgrounds (including many who are recent immigrants). Diagnostic assessment can be especially challenging when a clinician from one ethnic or cultural group uses the DSM-IV classification to evaluate an individual from a different ethnic or cultural group. A clinician who is unfamiliar with the nuances of an individual's cultural frame of reference may incorrectly judge as psychopathology those normal variations in behavior, belief, or experience that are particular to the individual's culture. For example, certain religious practices or beliefs (e.g., hearing or seeing a deceased relative during bereavement) may be misdiagnosed as manifestations of a Psychotic Disorder. Applying Personality Disorder criteria across cultural settings may be especially difficult because of the wide cultural variation in concepts of self, styles of communication, and coping mechanisms.

A final reason for the burgeoning growth of cultural psychiatry is demographic. The U.S. Census Bureau reported in 1996 that 26.7 percent of the U.S. population comprises minorities belonging to four underrepresented racial groups: African-Americans constitute 12.1 percent; Hispanics, 10.5 percent; Asian and Pacific Islanders, 3.4 percent; and Native Americans, 0.7 percent, distributed in more than 500 tribes. Demographers project that by the year 2050, almost 50 percent of the U.S. population will be minorities: Hispanics are projected to grow to 24.5 percent, African-Americans will represent 13.6 percent, and the final 10 percent will comprise Asians, Native-Americans, and others.

These demographic trends ensure that psychiatric clinicians will increasingly face the challenge of evaluating and treating patients from many different cultural and linguistic backgrounds. Key conceptual and technical breakthroughs in cultural psychiatry will enhance their knowledge and skills and move them closer to the goal of meeting this challenge with reasonable clinical competence.

DEFINITIONS AND KEY CONCEPTS

Culture The term “culture,” a key concept for psychiatry, is plagued by lack of clarity and poor agreement by users. The social science literature in English lists over 160 definitions. Probably it was first used in its contemporary anthropological sense by the British anthropologist Sir Edward Tylor, who wrote in 1871 that culture is “the complex whole which includes knowledge, belief, art, morals, law, custom and any other capabilities and habits acquired by man as a member of society,” emphasizing a holistic conception of culture and its bonding power for society. For its application to psychiatric practice, perhaps the best definition of culture is provided by the National Institute of Mental Health's Culture and Diagnosis Group: “Culture refers to meanings, values and behavioral norms that are learned and transmitted in the dominant society and within its social groups. Culture powerfully influences cognition, feelings, and self-concept as well as the diagnostic process and treatment decisions.”

Culture is thus best conceptualized as a totality, composed of a complex system of symbols possessing subjective dimensions such as values, feelings, and ideals and objective dimensions including beliefs, traditions, and behavioral prescriptions, articulated into laws and rituals. This unique capacity of culture to bind the objective world of perceived reality to the subjective world of the personal and intimate lends it its powerful role as expressor, mediator, and moderator of psychological processes and, ultimately, emotional disorders.

A causal chain allows culturally shaped symbols to influence cognition, feelings, self-concept, and the underlying brain functions that control mood and behavior. Since humans do not exist without a culture, cultural perceptions inevitably affect how each person is viewed and what rights and obligations each individual enjoys in the different stages of the life cycle in a given society. Derived from man's unique ability to use symbols and self-awareness to transcend the instinctual biological determinism ascribed to animals, culture becomes according to C. C. Hughes a “learned configuration of images and other symbolic elements (such as language) widely shared among members of a given society or social group which, for individuals, functions as an orientational framework for behavior, and for the group, serves as the communicational matrix which tends to coordinate and sanction behavior.” As such, culture represents a normative framework that defines normality and

deviance and promotes preferred values and behavior while proscribing others and, by such means, facilitates healthy adaptations or hinders development by provoking maladjustment.

Scope of Culture Though the manifestations of culture are broad enough to be considered almost infinite, the noted American anthropologist George P. Murdock listed 68 features considered to be universally present in the hundreds of societies studied by contemporary anthropologists. In alphabetical order, they are "age-grading, athletic sports, bodily adornment, calendar, cleanliness training, community organization, cooking, cooperative labor, cosmology, courtship, dancing, decorative art, divination, division of labor, dream interpretation, education, eschatology, ethics, ethnobotany, etiquette, faith healing, family feasting, fire-making, folklore, food taboos, funeral rites, games, gestures, gift-giving, government, greetings, hair styles, hospitality, housing, hygiene, incest taboos, inheritance rules, joking, kin groups, kinship nomenclature, language, law, luck, magic, marriage, mealtimes, medicine, obstetrics, penal sanction, personal names, population policy, postnatal care, pregnancy usages, property rights, propitiation of supernatural beings, puberty customs, religious ritual, residence rules, sexual restrictions, soul concepts, status differentiation, superstition, surgery, tool-making, trade, visiting, weather control and weaving."

Obviously some of these dimensions are more central than others to the relation of culture to psychology and psychopathology. Among these are rules related to sexuality and reproduction (incest taboo and rules of marriage), community and social organizations (kinship, kin groups, power relations, and division of labor), and cosmological visions (magic, superstition, and creational myths).

Culture, Race, and Ethnicity If *culture* lacks precise definition, the use (often interchangeably) of additional terms such as *race* and *ethnicity* adds considerable complexity to an already confusing semantic field. Traditionally, *race* denotes human groupings that are biologically (and in theory genetically) determined. In fact other contemporary biologists consider race to be poorly correlated with any measurable biological or cultural phenomenon. Although some characteristics of a given "racial" group (e.g., skin color) may appear phenotypically compelling, the use of the *race* to aggregate individuals displaying that characteristic may convey a false sense of distinctiveness and may imply the existence of a biological basis for such classification systems. Such is not the case for any of the phenotypic characteristics used to establish race. On the other hand *ethnicity*, a term increasingly preferred by cross-cultural researchers, connotes groups of individuals sharing a sense of common identity, a common ancestry, and shared beliefs and history. A given patient's ethnicity can be assessed by focusing the clinical history taking on key ethnically shaped developmental experiences, such as special rituals and rites of passage, and adherence to ethnically prescribed family roles, religious observances, food preferences, and the like. Cultural identity denotes the internalized self-definition resulting from the person's selective, developmentally mediated incorporation of values, beliefs, history, and customs from those available in that person's native environment. Typically, it contains many dimensions of self-experience including age, gender, race, sexual orientation, ethnicity, language, class, and religious and spiritual beliefs.

Culture and Psychopathology Culture is an all-pervasive medium for humans. It is driven by the human brain's unique ability to create images and symbols and structure them into complex wholes that in turn can drive brain function to produce defined behaviors and modulate instinctually driven ones. The ability to mediate biological functions via symbolic (and image) representation and manipulation is dramatically expanded in humans by the function of awareness or consciousness leading to the notion of the self.

Humans structure symbols into progressively more complex sequences ranging from basic, simple ideas to complex holistic beliefs, values, and ideals. These in turn are codified by language, images, and other means and shared with others to constitute the building blocks of common culture. Culture thus becomes a hierarchical array of complex symbols that affect the individual's emotions and behaviors and, when communicated to others, affect social and group function.

All cultures develop both processes that facilitate adjustment and conflict resolution and pressures that foster conflict, deviance, and maladjustment. These pressures can act broadly on large social groups and selectively on specific cultural subgroups. All cultures define a spectrum of "normal behaviors" as well as thresholds of tolerance for diverse "abnormalities," imposing different social consequences on different patterns of deviance.

Each culture provides its own unique stresses as well as beliefs and rituals to reduce psychological tension. Ashley Montagu has indicated, for example, that cultures that provide adaptive channels for the expression of aggression and the satisfaction of dependency needs can significantly reduce personal and interpersonal conflict. In the modern era cultures and subcultures change at increasing rates in response to the adaptive demands represented by a global world in increasing economic, political, and social competition. This progressive globalization imposes additional adaptive stresses on individuals and cultural groups.

The relation between culture and psychopathology has changed significantly over the last 100 years of development of culture psychiatry. At the end of the nineteenth century and the beginning of the twentieth, cultural psychiatry was largely concerned with comparative psychiatry studies and the description (from a Western, universalistic viewpoint) of exotic features of clinical syndromes found in Africa, the Philippines, Java, the Indian subcontinent, and other non-Western locations.

During the mid-twentieth century, culture-personality studies became abundant as anthropologists such as Ruth Benedict, Margaret Mead, Bronislaw Malinowski, and others integrated psychoanalytic constructs into their work, an effort finally leading to mixed intellectual results. During the 1970s, 1980s, and in the present, efforts have focused on several fronts; the development of sound, cross-culturally valid instruments for epidemiological research, such as the Center for Epidemiological Studies Depression Scale, and the Composite International Diagnostic Interview, is among the most fruitful. Significant advances have been made in developing measures for culturally specific idioms of distress. This and other efforts may signal a healthy shift from universalistic to culturally specific perspectives.

Insofar as culture exerts broad influence on social and cognitive, affective, communicative, behavioral, and psychophysiological processes, cultural psychiatry must describe pathways through which culture can affect psychopathology, such as the following:

1. Generating psychopathology by presenting adaptive stresses that tax an individual's psychological life and behavior. Chronic social conditions such as poverty, unemployment, and pervasive racism consistently generate high rates of distress and psychopathology in those exposed to them.
2. Reducing psychopathology by enacting protective factors against external or internal stressors. Javier I. Escobar, among others, has called attention to the low prevalence of most psychiatric disorders among low-acculturation Mexican-Americans and recent Mexican immigrants, which may be due to a protective effect of their traditional culture's emphasis on, and pervasive use of, supportive extended family networks.
3. Promoting or modulating social change, thus increasing or reducing the psychological stresses associated with change.
4. Affecting the onset, pathoplasty, course, and outcome of conventional psychiatric syndromes such as schizophrenia or bipolar disorders.
5. Affecting the tolerance for certain behavioral, subjective, clinical symptoms or unusual mental states and thus promoting either pathogenic isolation or healing integration into the wider social group of the individual displaying such signs and symptoms.
6. Patterning culture-specific idioms of distress, sanctioned ways for the individual or group to express subjective distress.

Acculturation Lloyd H. Rogler defined *acculturation* as "the complex process where by the behaviors and attitudes of a significant group change toward the dominant group as a result of exposure to a cultural system that is significantly different." The impact of the acculturation process on the development of stress and psychological disorder has been studied with mixed results. While some studies support the hypothesis that high levels of acculturation decrease psychological stress, others indicate that some form of biculturalism is more conducive to mental health. Recently, studies of immigrant Mexican-Americans have established a relation between increased acculturation and increased psychological distress. Until more-definitive research establishes an empirical basis, culturally competent clinicians should be attuned to the individual experience of their patients' acculturation process. The stress of the process may be revealed by different means: an intense rejection of the subject's original and host cultures, strong resistance to integration into the host culture, or even an excessive, mechanical assimilation into the new setting, with or without rejection of the culture of origin.

GENERAL PRINCIPLES OF CROSS-CULTURAL PRACTICE

DSM-IV's outline for cultural formulation provides a comprehensive framework for the complete assessment of a patient by clinicians from a different cultural or ethnic group and ends with an overall cultural formulation that like the dynamic and psychodynamic formulation in general clinical psychiatry, summarizes the contributions of culturally derived forces and stressors to the specific clinical situation the patient faces. A culturally competent diagnostic interviewer should be aware of the following points.

Interview Across the Cultural Barrier The golden rule for cross-cultural evaluation remains the same as for any diagnostic process used in clinical psychiatry, namely, establish empathy during the clinical interview. To do so one must be aware of cultural diversity preferred communication styles. First-generation Hispanic-American and Asian-American patients may favor less-expressive styles of communication, particularly when talking to authority figures and about content that carries some stigma. Abundant tact is needed when discussing sexual themes and themes of aggression and suicide, in particular with certain Asian and Hispanic groups, if the clinician wishes to get beyond their initial discomfort and denial. Many traditional cultures expect deference and respect to elders and heads of

households and their members may respond with annoyance and emotional withholding to the more-egalitarian, informal ambiance that predominates the mainstream American medical culture.

Assessment Diagnostic assessment of patients across the language barrier is full of opportunities for misunderstanding, over- and underestimation of psychopathology, and consequent misdiagnosis. Luis R. Marcos and others have found that schizophrenic patients of Hispanic origin exhibited higher rates of psychopathology in interviews conducted in English than in interviews held in their native Spanish.

Beyond the language barrier, specific group stressors suffered by certain minority groups may add additional confusion. Cross-cultural clinicians working with refugees, for example, warn the culturally naive evaluator not to mislabel as Axis I psychopathology the sometimes vivid and highly emotional narratives of Southeast Asian and other refugees describing their witnessing or suffering terrible atrocities in their countries of origin or in the process of immigration. Fortunately clinicians practicing today across language and cultural barriers have access to the findings of numerous studies that provide guidance for accurate evaluation and diagnosis and will allow them to correct many distortions and provide culturally syntonic care.

Language Since about 50 percent of patients from different ethnic groups who present to the U.S. health care system for evaluation and treatment are monolingual (with the rest displaying various degrees of linguistic competence), the culturally competent clinician needs to appreciate the impact of language in the evaluation of psychopathology and the possibility, for a given patient, of using language as a vehicle for therapy. Marcos has established the importance of assessing the patient's language proficiency and language independence and has provided evidence of the potentially adverse effect, in the intensive psychotherapy of proficient bilingual persons, of having two relatively separate language systems with unequal access to profound emotions.

The clinician interviewing a patient using a secondary language should also realize that the secondary language is less efficient in evoking and expressing complex emotions, which may result in a more limited and less accurate psychiatric history. The loss of communicative subtleties may lead the clinician to underestimate the patient's adaptive capacity for high-level cognitive functions such as humor and irony. Use of the secondary language may also reduce the patient's ability to establish rapport and emotional communication with the evaluators.

Cultural Consultants When the language barrier proves insurmountable, the clinican may need to resort to translators or interpreters, optimally interpreters specially trained for psychiatric work. Interpretation overcomes the limitations of simple translation by conveying not only the literal meaning of the sentences uttered by the patient (denotative meaning) but also the rich background of affect and meaning accompanying that expression (connotative meaning).

Many authors have described the pitfalls of evaluating monolingual patients by inadequate translation. When relatives or other undertrained translators are used, opportunities for miscommunication are expanded by the patient-translator transference and the translator-patient countertransference, and the expected confidentiality of the clinical interview is broken. These factors may make it desirable in certain settings to have trained translators become part of the clinical multidisciplinary team. Diagnostic accuracy and completeness and culturally syntonic treatment planning often requires the use of cultural consultants familiar with the patient's cultural background, norms, idioms of distress, explanatory models of illness, and family dynamics.

Mental Status Examination The mental status examination, the key component of a psychiatric diagnostic interview, is subject to many distortions when conducted across a language and cultural barrier. The central process of the mental status examination requires observation and interpretation of the patient's appearance, behavior, language, and mental activity, both spontaneous and as elicited by the clinician's questions. In interpreting the patient's appearance, behavior, language, and thought content, the clinician must guard against what has been called “the category fallacy,” the effort to fit all conditions, whatever their cultural context, into the Western diagnostic framework without regard to validating that diagnostic framework in the local culture. Patient responses to specific mental status items are affected by the patient's culture of origin, educational level, literacy, language proficiency, and level of acculturation. Investigators consider the following items of the mental status examination to be more sensitive to cross-cultural misinterpretation.

Appearance and Behavior The mental status sections of psychiatric case reports are often replete with such expressions as “normal,” “attractive,” and “appropriate” and others that are subject to significant cultural variation and must be carefully evaluated by the clinician, with the patient's own development and culturally determined normative framework as a referent.

Relationship to the Evaluator The assessment of a patient's attitude and relationship to the clinician who is performing a psychiatric evaluation is affected by many psychosocial variables, including whether the interview is voluntary and the relative emergency of the clinical situation. Key factors of such an assessment (e.g., maintenance or avoidance of eye contact, deference, reserve, physical proximity, and physical contact) are subject to cultural prescriptions that the clinician should strive to decode.

Motor Behavior The assessment of motor activity is considered a fundamental part of the mental status assessment. In a prior publication, the author and collaborators noted that patients who communicate in a nondominant language may use extra nonverbal activity to facilitate verbalization across the language barrier. This extra activity needs to be carefully evaluated, lest it be attributed to tension, hyperactivity, or other forms of motor psychopathology.

Speech and Thought Patients communicating in a language over which they have a poor command often exhibit a high frequency of speech disturbances such as omissions, incompleteness, long pauses. These must be carefully distinguished from the impact of anxiety, depression, or emotional withdrawal.

Affect In evaluating the range, responsiveness, and quality of a patient's affect, clinicians working across the language barrier must recognize that both the spontaneous and the elicited expressions of affect are deeply patterned by cultural norms and expectations. Culturally sanctioned impassiveness should not be misinterpreted as poverty of affect any more than the ebullience attributed to persons of Mediterranean origin should be evaluated as excessively intense affect. Clinicians need to be equally sensitive to the significance of linguistic factors that may cloud the interpretation of affect.

When a mental status evaluation is performed across language and cultural barriers, certain linguistic problems may be misinterpreted as surplus psychopathology, and clinicians should guard against this error by repeating critical questions, introducing redundancies to facilitate communication, and identifying paralinguistic cues that may cloud their evaluation of mood and emotional expression, and when in doubt they should use trained translators, cultural consultants, or structured, validated interviews.

Cultural Formulation The cultural formulation is as key an instrument in the diagnosis and treatment of culturally diverse individuals as the psychodynamic formulation is for the psychodynamic psychiatrist. DSM-IV provides an outline for its completion and recommends that it includes the following five categories:

1. Cultural identity of the individual
2. Cultural explanations of the individual's illness
3. Cultural factors related to psychosocial environment and level of functioning
4. Cultural elements of the relationship between the individual and the clinician
5. Overall cultural assessment for diagnosis and care

Cultural Identity DSM-IV recommends that in assessing an individual's cultural identity, the clinician should “note the individual's ethnic or cultural reference group. For immigrants and ethnic minorities, they should assess the degree of involvement with both culture of origin and host culture.” Frances G. Lu and coworkers summarized the essential components of cultural identity (Table 4.4-1).

Ethnicity	Gender
Race	Age
Country of origin	Sexual orientation
Language	Religious and spiritual beliefs
Acculturation	Socioeconomic class and education

From Lu FG, Russell FL, Mezzich JE: Issues in the assessment and diagnosis of culturally diverse individuals. In *Annual Review of Psychiatry*, vol 14, J Oldham, M Riba, editors. American Psychiatric Press, Washington, DC, 1995.

Table 4.4-1 Aspects of Cultural Identity Development

To these factors one must add migration history, which is commonly left out of the clinical evaluation of cross-cultural patients. Culturally uninformed clinicians often treat their immigrant patients as if their lives began when they arrived in the United States, and their clinical narratives often lack key data from the patients' preimmigration experience. Careful attention must be paid to the traumas and losses encountered by refugees in their country of origin, often including exposure (as witness or victims) to physical or emotional torture or both. The process of acculturation is once again key to understanding the psychological distress and psychopathology of immigrants. Rogler has identified three major sources of stress in the migration experience: (1) insertion into the host society, frequently at lower occupational and social levels; (2) disruption of primary interpersonal networks; and (3) the stress-inducing acculturation process. The clinician can assess the degree of acculturation and the nature of the acculturation process through many indirect means. Age at immigration, number of years in the United States, occupational status, language proficiency, and participation in the host culture social networks give the clinician some idea of the rate and ease of acculturation for a given patient.

Families can also be classified by degree of acculturation. From this perspective immigrant families may be described along a continuum of acculturation as traditional, transitional bicultural, and Americanized. Each of these family structures presents different assets and vulnerabilities in relation to the immigration experience.

THERAPIES

George L. Engel provided psychiatry with a model for understanding the etiology of psychiatric disorders, the biopsychosocial model. This model emphasizes that understanding and treating psychiatric disorders requires attending to the three levels of human function, biological, psychological, and social, as well as to their systematic interrelations. In a rapidly growing global culture the social component of the biopsychosocial model must include, develop, and elaborate the cultural dimension, including the patient's religious affiliation. Culture is important to psychiatric therapy as it influences, mediates, shapes, or colors beliefs about the cause of psychological distress and preferred modes of intervention. This broad influence of culture applies to somatic interventions such as psychopharmacology as much as to psychological therapies.

The issue of what therapies to apply to patients from different ethnic or cultural groups involves three key questions. (1) can psychoanalytically based and other expressive psychotherapies be applied to patients from all cultures with comparable results? (2) Can culturally specific therapies be devised either by significant modification of mainstream psychotherapy or by crafting therapeutic interventions from the rich lode of culturally syntonic rituals and symbols? (3) Are there psychological therapies that can be specifically focused on the problems and stresses of acculturation?

Critics have argued from several perspectives that psychodynamic psychotherapy is inappropriate and ineffective with nonwhite clients. Empirically, high dropout rates and less than optimal outcomes may have helped buttress that argument. Some medical anthropologists maintain that psychodynamic psychotherapy is itself a culturally syntonic product of middle-class Western minds and as such is inappropriate for patients belonging to different cultural traditions and may even damage the patients' culture-bound view of self and their self-esteem.

Many clinicians, especially those grounded in the experience of providing psychotherapeutic services to socioeconomically deprived ethnic minorities, maintain a more balanced view, noting that psychotherapeutic success is possible and appears to be related to levels of education, acculturation, motivation, and capacity to form a therapeutic alliance. Harvey Bluestone made important recommendations for adjustments in providing psychodynamically based, insight-oriented therapy to poor Puerto Ricans in New York City. In his view, the framework for therapy must be strengthened by explicitly educating patients to keep appointments on time, to change expectations for rapid cures, and to enhance their own active participation in treatment, which challenges the culturally patterned, passive dependence on an authoritative therapist when this pattern exists.

Culturally Specific Therapies The clinical and research literature offers many examples of incorporating specific elements from the patient's native culture into the therapeutic intervention. J. J. Kreisman's account of treating two Mexican-American females with schizophrenia by incorporating folk rituals and native herbs is rather representative. Kreisman advocates integrating the patient's own cultural conceptions of illness into the conventional treatment. Jose Szapocznick has proposed a model of family therapy for Miami's Cuban families, guided by the strong familial affiliation of Cuban families, their preference for hierarchical family structures, and other empirically determined values. His model is especially attractive since it readily lends itself to empirical testing.

Original, culturally sensitive therapeutic modalities have been developed and empirically tested for the treatment of the adjustment problems of vulnerable minority populations. Giusepe Constantino and coworkers demonstrated the superiority of *cuento*, or folktale therapy, over traditional therapy group and nontherapeutic group sessions, in reducing trait anxiety in a sample of over 200 high-risk Puerto Rican children selected for maladaptive school behavior. Repeated exposure to classical Puerto Rican folktales seemed to have provided these vulnerable children with stable, culturally syntonic role models for adaptive internalization of coping skills and positive self-images.

Psychopharmacology The relation between culture and psychopharmacology is as fascinating as it is complex. A web of incompletely understood relations links purely biological factors such as genes to factors deemed more socially generated, such as customary diets, nutrients, and herbs. To complete the picture, the clinician and researcher must consider additional factors such as the patient's culturally based expectations of optimum psychiatric treatment (pharmacotherapy or psychotherapy), expected rate of recovery (fast or slow), target symptoms, and threshold and tolerance for adverse effects. If a Hispanic patient has the culturally shared expectation that psychological disorders are somatically based and best treated by an authoritative physician with medication, alternative treatment recommendations will be met with resistance and reduced compliance, unless extensive psychoeducational efforts are deployed. Alternatively, middle-class, educated, urban professionals may reject psychopharmacological prescriptions for their anxiety or depressive syndromes as simplistic, because they had expected psychotherapy or psychoanalysis. Thus the therapeutic relationship across the language/cultural barrier should be initiated by carefully eliciting the patient's explanatory framework of illness, anticipated path to recovery, and expectations for treatment. Clinicians must spend time and effort in an educational dialogue with patients and their significant others and explain the reasons for an alternative to the patient's preferred course of treatment. Slow onset of action and the frequency of adverse effects interfere with the therapeutic cooperation of some Hispanic and Asian patients who expect rapid relief, fear toxicity, or are concerned with the addictive potential of medications to be taken long term. To obtain adequate compliance across the cultural barrier the clinician must make tactful efforts to know the patient's (and the immediate family's) latent, culturally shaped beliefs about the illness and its normative treatment, to provide therapeutic options compatible with the patient's culturally prescribed explanatory models, lest hidden miscommunication hinder the necessary compliance.

Pharmacogenetics The field of pharmacogenetics grew out of observations of significant ethnic differences in response to drugs, in differential development, and in side effects profiles, leading to the discovery of defects or deficiencies in the genetically controlled activity of enzyme systems responsible for the metabolism of psychotropic medications and toxins such as alcohol.

Acetylation Status Observations of ethnic differences in the side-effects profile of the antituberculosis drug isoniazid (Nidrazid, Rifamate) led to the classification of people as slow or rapid acetylators, which, among other biological effects, determines their metabolism of psychotropic medications such as clonazepam (Klonopin) and phenelzine (Nardil).

Alcohol Metabolism P. H. Wolf, while studying racial differences in alcohol sensitivity, observed that about 80 percent of Asians and 50 percent of native Americans

exhibited the flushing response to alcohol (compared with 10 percent of whites) and concluded that these differences had a genetic basis. They have been proved to be related to genetic polymorphism of isoenzymes of alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH), enzymes critical for complete metabolism of alcohol and other neurotransmitters and which play a role in development of alcoholism or its avoidance. For example, Asians who are either homozygous and heterozygous for the atypical Asian-type *ALDH*2 gene are alcohol sensitive and have a low risk for alcoholism and alcohol liver disease.

Native Americans have a high frequency of both alcohol flushing and alcohol-related problems. Akira Yoshida's research team reported in 1993 that they had practically no detectable Asian type *ADH*2 and *ALDH*2 genes, a major alcohol-rejecting genetic factor.

Cytochrome P450 Isoenzymes The cytochrome P450 enzyme system is key in the metabolism of psychotropic and nonpsychotropic drugs as well as a great variety of environmental toxins that find their way into the diets of animals and humans. The genetic defects that render these enzymes less effective and make humans poor metabolizers are unequally distributed among ethnic populations. This is particularly the case for two cytochrome P450 (CYP) isoenzymes: CYP 2D6 (debrisoquin hydroxylase), and CYP 2Cmp (mephenytoin hydroxylase). The percentage of CYP 2D6 poor metabolizers is lower for Asians (0.5 to 2.4 percent), and higher for whites (2.9 to 10 percent). Similar interethnic variance exists in the frequency of poor metabolizers of CYP 2Cmp, low among whites (3 percent), intermediate for African-Americans (18 percent), and higher (up to 20 percent) in Asian and Japanese populations.

These interethnic differences in the P450 isoenzymes are of great importance in psychiatry and psychopharmacology because of their role in the metabolism of antipsychotics, antidepressants, sedatives such as barbiturates and benzodiazepines, and b-adrenergic receptor antagonists (beta-blockers) such as propranolol (Inderal).

Environmental Factors In addition to being genetically regulated, enzymes that participate in the metabolism of psychotropic medications respond to environmental variables such as diet, alcohol, smoking status, and caffeine intake. All these factors are capable of accelerating or slowing the metabolism of drugs through enzyme induction or inhibition.

Herbal Medicines In parallel with available Western medicine–oriented psychiatric services, immigrants often retain their loyalty to ethnically based folk medicine systems. Accounts by Vivian Garrison and Allan Hardwood document extensive use of folk healers by Puerto Ricans in New York City. Other investigators have reported that Mexican-Americans are willing to accept prescribed medications from psychiatrists and herbs from a community healer, just as mainstream, young, urban professionals use natural serotonin-enhancing herbs such as St. John's wort in addition to, or instead of, the more conventional psychotropics prescribed by their psychiatrists. Culturally competent psychopharmacologists need to inquire about their patients' use of the traditional herbal medicines of Asian, African-American, Hispanics, and other immigrants living in the United States. Many of these herbs posseses high levels of psychoactive activity, such as anticholinergics (*Swertia japonica* used by Japanese patients or *Datura candida* used by Cubans), stimulants (the caffeine-loaded *Ibexguazusa* of Latin America), sedatives (*Schumanniophyton problematicans* of the Nigerians). Others, such as ginseng and glycyrrhiza, may stimulate cytochrome P450 or inhibit it.

Specific Psychoactive Medications

Antipsychotics Clinical lore has it that Asian patients require lower dosages of dopamine receptor antagonist (typical antipsychotic) medications than comparable white patients to achieve a similar clinical outcome and that when treated on a fixed-dosage schedule, Asians seem to develop significantly greater extrapyramidal adverse effects. These reports were corroborated by S. Potkin in a 1983 study that found a 52 percent higher plasma concentration of haloperidol (Haldol) in Chinese schizophrenia patients living in China than in non-Asian schizophrenia patients residing in the United States when both groups received treatment on a fixed-dosage schedule. Other investigators demonstrated that Chinese schizophrenia patients residing in Taiwan and Taipei achieve haloperidol plasma concentrations comparable to those of white, African-American, and Hispanic patients hospitalized in San Antonio while using significantly lower daily dosages of haloperidol. From their data, the authors suggest that dosages above 30 mg a day might not be necessary in Chinese patients to obtain the 20 to 25 mg/mL currently considered the upper therapeutic plateau for haloperidol plasma concentration. Dosages above 50 to 60 mg a day might not be needed in non-Chinese patients.

Survey reports indicate that African-Americans and blacks elsewhere receive significantly higher doses of antipsychotics and receive antipsychotic drug treatments significantly more often than whites, regardless of diagnosis. This fact may be explained by diagnostic and prescription biases that ascribe more psychopathology to blacks, or it may have a pharmacokinetic explanation. One study found African-American patients to have the highest concentration of plasma-reduced haloperidol for a given plasma concentration of haloperidol. Reduced haloperidol lacks antipsychotic activity and has lower binding affinity than haloperidol for the dopamine type 2 (D_2) receptor.

Tricyclic Drugs Once the cornerstone of treatment of depressive disorders, use of tricyclic drugs has been expanded considerably beyond these boundaries to include anxiety, panic disorder, obsessive-compulsive disorder, other behavior disorders, and various pain syndromes. Their cross-cultural utility has been extensively studied. As is the case with neuroleptics, studies with tricyclic drugs have shown that average dosages prescribed for Asians are significantly lower (up to 50 percent lower) than dosages prescribed in the United States for non-Asians, results that cannot be explained by ethnic differences in protein binding alone.

Ethnic psychopharmacologists have proposed that Chinese patients may respond to lower tricyclic drug dosages. Although the reason for this responsiveness has not been clearly established, preliminary evidence suggests differential responsiveness of relevant receptors, differences in plasma concentrations, or both.

Although less extensively studied, similar conclusions (equal therapeutic response to half the standard white dose) have been reached for depressed Hispanic women and African-American patients, who are reported to respond faster and more completely, albeit with higher rates of adverse effects. Sensitivity to development of anticholinergic adverse effects is important to both compliance and morbidity in accidental or intentional overdoses. Researchers have reported that delirium as a complication of tricyclic drugs appears more frequently among African-Americans than among other ethnic groups.

Benzodiazepines Studies of prescription patterns as well as those comparing the pharmacokinetics and pharmacodynamics of benzodiazepines across ethnic groups have established the enhanced sensitivity of Asians to the effects of benzodiazepines, accounting for the typically prescribed doses one half to two thirds those of similar nonminority populations. These ethnic differences in benzodiazepine metabolism are most often linked to polymorphisms in the *(S)*-mephenytoin phenotype, yielding a higher percentage of poor metabolizers in the Chinese ethnic group. Additional mechanisms, both genetic and environmental, have been invoked by other investigators.

Few studies are available to guide clinical practice with benzodiazepines in African-Americans, Hispanics, and Native Americans.

Lithium Lithium salts (Eskalith, Cibalith) are extensively used in clinical psychiatry since their clinical efficacy for the treatment of mania was first established by John Cade in 1949. Besides its core indication for the treatment of bipolar disorder, lithium is currently used for the treatment of other psychiatric disorders (e.g., intermittent explosive disorder), to treat symptoms (e.g., impulsivity of any cause), and to augment conventional strategies in the treatment of schizoaffective disorders and refractory depression.

Many studies have documented lithium's differential pharmacokinetics and pharmacodynamics in different ethnic populations. For African-Americans, in 1980 S. Okpaku and colleagues demonstrated a slow lithium efflux in red blood cells (RBCs) following laboratory loading of RBCs, as well as a higher RBC to plasma ratio, a finding later confirmed by many other investigators. Since RBC lithium concentrations are believed to be correlated with intraneuronal lithium concentration and with the incidence of adverse effects, African-Americans may need lower dosages of lithium than those currently recommended.

As with trycyclic drugs, antipsychotics, and benzodiazepines, Asians seem to achieve clinical responses comparable to those of non-Asian patients using significantly lower dosages and serum concentrations of lithium; 0.5 to 0.7 mEq/L versus the 0.8 to 1.2 mEq/L generally required by white populations.

In addition to these kinetic and dynamic factors, clinicians working across the cultural barrier need to carefully avoid the problem of misdiagnosis. Abundant evidence indicates that minority patients with bipolar disorders are at greater risk for receiving a diagnosis of schizophrenia at some point in their clinical course, and receive antipsychotic medication rather than mood stabilizers for their treatment. To avoid potential misdiagnosis, clinicians need to be especially alert to minority patients diagnosed with schizophrenia who have an atypical course, poorer than expected antipsychotic response, prominent affective symptoms, or a cyclically fluctuating course. The use of structured interview instruments may be necessary to refine the diagnosis.

CULTURE-BOUND SYNDROMES

The culture-bound syndromes have not received much attention by mainstream psychiatry in the United States. When mentioned at all, these syndromes are often discussed as exotic disturbances of thought, mood, or behavior displaying dramatic presentation, occurring in the context of specific local cultures, and at least partially understood through the lens of the psychosocial forces—often conflictual—relevant to that particular culture. For example, *taijin kyofusho*, a syndrome of some prevalence in Japan, whose sufferers have an intense concern that their body may be offensive to others because of appearance, body odor, or any other characteristic, can be best understood against the background of intense Japanese emphasis on proper social behavior and the shame attending transgressions of decorum.

The interpretation of culture-bound syndrome must be tempered by the following observations:

1. Psychiatry's neurobiological knowledge base has not developed firm predictive biological indicators, even for the major psychiatric disorders such as schizophrenic and bipolar disorder.
2. Definitions of syndromes are thus by necessity phenomenologically based and have imprecise boundaries.
3. In defining clinical syndromes, psychiatry depends on subjects who present for medical attention, a process influenced by many psychosocial and socioeconomic variables. Of all people suffering a psychological distress or disorder, only the minority who seek and find access to the health care system are represented in the official definition of the disorders.

Even in the most advanced societies, a considerable lag exists between the emergence of new forms of psychological distress or disorder and the health care system's ability to recognize, properly label, diagnose, and effectively treat it. During this time, there is frequently intense popular interest in the evolving disorder. It took time and considerable popular pressure before psychiatry was ready to respond to disorders such as the bulimia nervosa plaguing young females or the posttraumatic stress disorder of returning Vietnam veterans.

SUGGESTED CROSS-REFERENCES

Anthropology and psychiatry are discussed in Section 4.1, and sociology and psychiatry in Section 4.2. Examination of psychiatric patients is covered in Chapter 7. Psychotherapies are presented in Chapter 30 and psychopharmacological therapies in Chapter 31.

CHAPTER 5. QUANTITATIVE AND EXPERIMENTAL METHODS IN PSYCHIATRY

5.1 EPIDEMIOLOGY

DARREL A. REGIER, M.D., M.P.H., AND JACK D. BURKE, JR., M.D., M.P.H.

Psychiatric epidemiology has contributed to a broad range of clinical, research, and health policy fields. Recent findings provide data on the course and co-occurrence of psychiatric disorders, identify their possible risk factors, measure the functional impairment they cause, establish a basis for policy decisions on mental health, and set a starting point for analyzing access to care and use of mental health services.

Results from epidemiological studies are routinely included in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) to describe the frequency and correlates of mental disorders. In developing the diagnostic criteria themselves, secondary analyses of many epidemiological studies assessed the frequency with which discrete symptoms appeared together, to define syndromes in large community and clinical populations. Epidemiological studies that demonstrate the significance of depression as a risk factor for death in people with cardiovascular disease and for premature death in people with breast cancer have engendered new interest in pathophysiological mechanisms that might account for the relation between these disorders.

One of the most visible indicators of the policy use of epidemiological data is found in the joint publication by the World Bank and the World Health Organization (WHO), The Global Burden of Disease. Based on data developed over the past two decades, mental disorders have been found to be among the leading causes of disability worldwide, with major depression currently the fourth leading cause of disability.

But one principal goal of epidemiology, finding ways to lessen the occurrence of new illnesses, is still in an early stage of investigation. Although some types of dementia and mental retardation caused by viral exposure (e.g., measles), toxins (e.g., lead), or metabolic or nutritional deficiencies (e.g., cretinism, pellagra) can be prevented, wide-scale prevention of other mental disorders will depend on identifying effective interventions and on closer ties to findings in basic and clinical research on mental disorders. At present the most effective methods for reducing prevalence rates of acute disorders involve early detection and treatment to reduce duration of episodes and improved maintenance treatment of chronic disorders to prevent relapse or recurrence.

Definition Mental disorder epidemiology is the quantitative study of the distribution and causes of mental disorder in human populations. This definition has several important components, including a population focus and a reliance on statistical methods to assess significant differences among population groups in their risk for developing mental disorders.

Epidemiological research focuses on population groups rather than individuals. Although individuals within population groups must be accurately diagnosed, the unique scientific questions addressed by epidemiology begin with descriptions of how mental disorders are distributed across different population subgroups. By providing a scientific method for assessing the relative health status of communities and different population groups, epidemiology serves as the basic science of public health. An observation that disease rates in one population group significantly exceed expected or average rates is the basis for identifying an epidemic within the population. Such assessments require accurate diagnosis of all cases of illness within the population and the use of statistical methods to assess differences in the frequency of disorders in population groups studied.

Identifying different rates of illness in population groups is only the first step in epidemiological investigations. Both clinicians and epidemiologists rely on observations that pathological states are differentially associated with physical, biological, social, and temporal characteristics of human beings and their environments. Where causal mechanisms are not yet clearly defined, epidemiologists attempt to identify characteristic factors that define populations with excessively high rates of illness, including mental disorders. By narrowing the range of characteristics associated with a disorder, the ultimate aim is to identify specific correlates or risk factors whose alteration will interrupt the causal network that produces a disorder.

Special Methodological Issues Advances in any field of epidemiology depend on developing methods to measure, detect, and characterize risk factors associated with specific illnesses. Such methodological issues affecting research on mental disorders include the following.

Nosology Grouping morbidity states for quantitative analysis requires explicit classification of disorders reliably applied across large populations. If mixed conditions are included in one diagnostic category, the statistical association of risk factors associated with one of the component disorders will be diluted and, thus, fail to be recognized by the epidemiological method. Psychiatric nosology has been limited by the heavy reliance on manifestational criteria (e.g., signs, symptoms, clinical course, and treatment response) rather than causal criteria (e.g., toxins, trauma, genetic vulnerability, and metabolic defects). Dependence on manifestational criteria in the absence of convincing causal factors increases the likelihood that heterogeneous groups will be combined in one diagnosis. This problem is shared by the rest of clinical medicine, which attempts to move beyond a diagnosis based on symptoms such as fever to a specific etiological agent or anatomical defect. The relatively new descriptive approach to psychiatric nosology is an important intermediate stage that will facilitate more-rigorous investigations of causal factors in clinical and epidemiological studies.

Case Identification Methods One difficulty resulting from this limitation in nosology involves developing a technique to obtain standardized psychiatric assessments of a large sample of individuals to detect clinically meaningful mental disorders. Without clearly defined nosological categories, it is difficult both to define a case and to develop case identification (diagnostic) techniques that are appropriate for large-scale population studies. Such techniques require explicit criteria if clear communication to other researchers and if reliability in administration is to be feasible. In the absence of reliably administered assessment methods, epidemiologists have often used self-report questionnaires that assess the dimensions of psychological and psychophysiological symptoms. Cutoff scores on various symptom scales have been calibrated with symptom profiles of patients under treatment. Thus, subjects in the general population could be assessed in terms of their probability of having disorders similar to those seen in clinical settings. The lack of face validity for many such questionnaires, the lack of diagnostic specificity, and the tautological assumption that mental disorders under treatment should define the full spectrum of all types of mental disorder led to clinician apathy about earlier epidemiological survey results. However, development of standardized clinical interviews for clinicians and highly structured diagnostic assessment instruments for trained survey interviewers has enabled many advances in psychiatric epidemiology.

Risk Factors At a more advanced level of investigation, another difficulty involves determining the psychosocial and biological factors likely to identify high-risk groups for particular psychiatric disorders; once identified, these factors must also be measured objectively as part of an epidemiological study. The relative paucity of clearly defined and modifiable risk factors available for study has led to overdependence on associations with descriptive and relatively unmodifiable factors such as age, gender, and ethnic status. Although presumably modifiable factors such as stressful life events have recently emerged and there is increasing evidence of molecular genetic linkage with some disorders, the mechanism of multifactorial interaction between individual susceptibility and stress or other environmental variables has not yet been fully explicated.

Chronic Disease Epidemiology Paradigm Other difficulties in psychiatric epidemiology are shared with the epidemiology of chronic medical diseases. These characteristics include a dependence on manifestational criteria and incomplete information on the subsequent temporal aspects of clinical course, uncertainty about when causative factors may have affected the individual, an undefined lag time between the onset of a pathogenic influence and the occurrence of the disorder, and the absence of any generally accepted concept of when the disorder may be considered to be eradicated in a patient with a history of the illness. Although these characteristics do not apply to all mental disorders, they are shared by many within the fields of cancer, cardiovascular disease, and rheumatological disease

epidemiology.

USES OF EPIDEMIOLOGY

The various applications of epidemiology depend on three levels of investigation that can be grouped according to their basic intent as follows:

1. *Descriptive*—studies that produce basic estimates of the rates of disorder in a general population and its subgroups
2. *Analytic*—studies that explore the basis of variations in illness rates among different groups, to identify risk factors that may contribute to development of a disorder
3. *Experimental*—studies that test the presumed association between a risk factor and a disorder and seek to reduce the occurrence of illness by controlling the risk factor

Each level of investigation yields information that can be used to improve clinical practice and plan public health policies. Addressing past difficulties with nosology, case-identification techniques, risk-factor specification, and chronic-disease paradigms has led to better action of the potential applications of epidemiology that were identified by J.N. Morris. Relating these seven basic uses to the three stages of epidemiological inquiry demonstrates the important applications of epidemiological knowledge, even in the earliest studies at the descriptive level of investigation.

DESCRIPTIVE LEVEL

Community Diagnosis Epidemiological research starts by estimating rates of illness in a defined population. This community diagnosis provides a baseline for understanding the burden of illness in the population, the mix of disorders present, and the extent to which untreated cases exist in the population. These basic rates are needed before more elaborate studies of risk factors can be undertaken, and they are important for health planners who want to know what kind of treatment services may be needed in the community, especially if untreated patients are to be brought into the health care system in the future.

Over the past 20 years, two national prevalence studies of mental disorders in the United States greatly expanded our understanding of the burden that mental disorders place on the population. The Epidemiologic Catchment Area (ECA) study in the early 1980s was a multisite, 1-year, prospective study (three interviews at 6-month intervals) of mental disorder prevalence, incidence, and mental health service use among over 20,000 adults, age 18 years and older in communities and in nursing homes, prisons, and long-stay psychiatric hospitals. It provided the first estimates of mental disorder and service use rates according to the type of explicit diagnostic criteria that were pioneered by the third edition of DSM (DSM-III) and continued in subsequent editions and in the 10th edition of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10). This study was followed by a cross-sectional (single interview) National Comorbidity Survey (NCS) of over 8000 adolescents and young adults (age 15 to 54 years) in the early 1990s, which was designed to update information on prevalence rates of disorders in the revised third edition of DSM (DSM-III-R) disorders and to clarify the sequence and duration of co-occurring mental and addictive disorders in a younger population group, in which comorbid disorders were more prevalent.

Although the study designs, diagnostic criteria, diagnostic instruments, and population age groups differed somewhat in the ECA and NCS studies, the 1-year community prevalence rates for any mental and addictive disorder were remarkably similar. In the ECA this 1-year prevalence rate for any mental or addictive disorder was 28.1 percent of the population; the NCS rate was 29.5 percent.

Completing the Clinical Picture More-precise answers to such questions about community diagnosis and basic rates of illness can be obtained only with a standardized assessment procedure that can ascertain the diagnostic status of a large number of individuals. If this case ascertainment can be done well, then epidemiological studies will benefit clinical understanding and public health. The full clinical picture of the disorder can be studied by characterizing subclinical or mild cases, by studying relatives to determine the familial occurrence of the condition, and by following the further progression of the illness to determine its course and prognosis. The value of this effort rests on the fundamental rule of epidemiology, which is to sample individuals from a geographically defined population without the bias that may occur with a sample drawn only from patients seen in particular treatment settings. For example, with the new structured interviews that permit classification of anxiety disorders such as posttraumatic stress disorder by both DSM-IV, which requires a numbing criterion and ICD-10, which has no similar requirement, it will be important to determine the associated features for each definition, along with the prevalence, the prognosis, and the course of the illness in longitudinal studies.

Identification of Syndromes Similarly, some conditions may occur in a population sample that were not detected in studies with samples drawn only from clinical populations. The opportunity to identify new syndromes in the population is provided by both representative sampling from the population and the application of thorough, standardized assessment procedures for all individuals in a sample. One example is agoraphobia without prior panic disorder, which appears to occur more commonly in the general population than in clinical samples.

ANALYTIC LEVEL

Assessing Individual Risks Once the basic rates of illness are established, one can identify groups in the population with unusually high rates of illness. This comparative analysis provides a variety of hypotheses for testing to see if some characteristics of the more commonly affected group can be linked to a causal chain for the illness. For example in the 1930s psychiatric epidemiology found apparent higher rates of schizophrenia among low-income, inner-city residents. The first problem in assessing such a finding is to determine whether it reflects a potentially higher risk of developing schizophrenia among those who live in such conditions, or whether those who have schizophrenia move into such areas through downward social mobility. Recent studies by Bruce Dohrenwend and colleagues indicate that downward mobility, or social selection, is the most likely explanation for the higher rates of schizophrenia in those with lower socioeconomic status. In contrast to schizophrenia studies, studies of depression among women and of substance use and antisocial personality disorders among men have shown stronger support for social causation hypotheses.

Even if the place of residence seems to precede rather than follow the disorder, investigators must still pursue the study of risk factors that may underlie the apparent association between this group characteristic and the disorder. Some particular features of poverty, poor housing, or population density may be risk factors; genetic, nutritional, or other familial risks may be higher in persons who live in such areas; or toxic or infectious agents may be the true contributors and occur more commonly in such areas. Moving from demonstrating higher rates in a particular group to more-targeted studies of putative risk factors for individuals is an essential but difficult step in the progression of epidemiological investigations.

Historical Study Risk factor identification may be easier if some historical variation can be shown. This type of evidence may help strengthen the arguments for studying one or another putative risk factor. For example, a 25-year study of one community population in Sweden suggests that depression may be increasing and dementia may be decreasing in an industrialized Western society. Other epidemiological studies have shown that depression and drug abuse or dependence may be occurring at higher rates and with earlier onset in more recent generations.

EXPERIMENTAL LEVEL

Identifying Causes As risk factors are demonstrated, epidemiologists can help reduce the contributing causes of the disorder by intervening in the causal chain that links a risk factor to occurrence of the disorder. Studies that modify a risk factor and assess the impact of this intervention in reducing onset of illness are the long-term goal of epidemiologists. This type of investigation promises to elucidate opportunities for primary prevention of mental disorders by intervening to reduce the chances that high-risk individuals will develop an illness. Quantitative, population-based epidemiological investigation can be used to measure the impact of preventive interventions being tested. Such assessment is important both to determine the benefits of the intervention for high-risk individuals and to assess any unintended negative effects of the program.

Working of Health Services The epidemiological method is usually taken as a guide to primary prevention of disorders, but it can also be used for secondary prevention, early diagnosis, and prompt effective treatment of individuals who have already developed signs of the illness. Although the contribution of epidemiology to understanding the working of health services is often thought to refer to the descriptive level of study—with estimates of treatments provided and unmet need for service—a wider perspective demonstrates that the three-stage epidemiological method can be applied to both patient populations in clinical settings and general populations in the community.

With a parallel to primary prevention based on assessment and reduction of risk factors, a scheme for secondary prevention can also be devised. Once the prevalence of clinical disorders is determined (e.g., as with depression among primary care patients), one can assess the extent of early diagnosis and prompt, effective treatment. Although depressive disorders are common in primary care patients, recent studies in this country and abroad suggest that these disorders are not often diagnosed or treated. Interventions to improve clinical practice through secondary prevention can be tested, just as primary prevention intervention efforts would be tested in the traditional epidemiological model. Research of this type, with application of the three stages of epidemiological research to clinical populations, is known as clinical services research.

EPIDEMIOLOGICAL METHODS

Understanding the conceptual framework for applying epidemiologic methods helps one understand the findings and appreciate the potential benefits of epidemiologic research. Epidemiology has several important characteristics, including a population-centered research strategy that requires an adequate sampling plan. Especially in psychiatry, epidemiological research also required advances in the nosology of mental disorders before acceptable case-identification instruments could be developed. With these prerequisites met, quantitative research in psychiatric epidemiology has become possible.

Sampling The epidemiological method requires two desirable conditions in the sample of people under study: a suitable reference population or universe can be defined, and individuals in the study can be related to this defined universe in a specified way. If these conditions are satisfied, then results of the study can be generalized to the universe.

The *universe* is the hypothetical population to which the investigator wishes to generalize results; the study population is the operational equivalent of the universe, which is actually studied by the investigator. A universe may be all residents of a delimited area, while a study population may consist of those listed as customers of a local electric utility. The study population should be as equivalent to the specific universe as possible.

Once the study population is defined and judged equivalent to the universe, its members can be assessed to determine their risk or illness status. All members of the study population can be assessed in a total count, if money, time, and other resources permit. Usually, few representative members of the study population form the study sample.

Sampling Design The fundamental principle of sampling is to select subjects so that the sample results represent the entire study population and ensure equivalence to the intended universe. To ensure that the sample does represent the entire study population, the members of the sample must be selected without bias and with a known probability of selection. The basic case is the simple random sample: all members of the study population are listed, and a sample is selected randomly.

Sample Selection Consider, for example, a study population of 3000 people who can be listed individually. The investigator plans to examine about 300 subjects, a 10 percent sample of the study population. Using a random selection procedure (e.g., a table of random numbers), the investigator can select on average 1 in every 10 individuals to be in the study. In simple random samples, every member of the population has an equal and known probability of being selected, in this case a 1 in 10 chance. With large numbers chosen, random selection tends to produce a sample that in the aggregate reflects the composition of the study population. In this example, if the distribution of females in the 3000 population members is 60 percent, it will be roughly the same in the sample; the larger the number of people chosen for the sample, the more likely it is to reflect the characteristics of the study population.

Sample Size The drive to reproduce overall population characteristics in the sample by random selection is one reason why large sample sizes are desirable. Estimates of rates or other statistics are more precise when a large number of individuals are used in the estimation.

Point Estimate Study sample A, drawn by the investigator as described above, is clearly not the only one that could be drawn from the study population. With a different starting point in the table of random numbers, a different series of 300 individuals would be selected, called B. Its composition will also roughly reflect the characteristics of the overall population of 3000. The proportion of females in sample B will also be about 60 percent, but it probably will not be exactly the same as in sample A. If the investigator drew repeated samples and continued to calculate the proportion of females in each sample, these various estimates of the proportion of females in the overall population would form a range of values tending to center around the true population of value of 60 percent. The estimate produced from a sample is called a point estimate of the proportion of females in the study population.

Standard Error Although this repeated sampling of 300 individuals from the total population of 3000 is easily described, it is almost never feasible in a world of limited time, money, and researchers. If the first sample was drawn at random, one can calculate a statistic—the standard error of the proportion—that describes how much variation exists in a large series of repeated samples composed of 300 subjects that could theoretically be selected from a given population. With this standard error, which is easily calculated using data from one sample, one can calculate the range of values that allows investigators to say that they are 95 percent confident that the true proportion of females lies between these estimates. This range is known as the 95 percent confidence interval, and authors customarily report this range along with the point estimates of characteristics they have assessed in their samples. Larger numbers of individuals permit more-stable point estimates, which means that the confidence interval is smaller than it is with only a few subjects in the study.

Confidence Interval Uses Confidence intervals are quite helpful in comparing rates of illness. Suppose that in this sample of 300 subjects the investigator assessed the presence of major depression and wanted to compare rates for all high-school graduates with rates for those with less education. The point estimates may look different (e.g., 3.0 percent for graduates and 9.5 percent for nongraduates). A valid comparison requires considering how well these point estimates reflect the true population-based rates of illness.

Calculating 95 percent confidence intervals helps the investigator determine whether the apparent difference in rates reflects rough point estimates or is a true difference. With such a small sample the confidence intervals may be large, say 0.3 to 5.7 percent for graduates and 4.8 to 14.2 percent for nongraduates; there is an overlap, so the differences may be due to variability of point estimates associated with sampling from the population. Because the 95 percent confidence intervals are large enough to overlap, it may not be possible to say that the difference in point estimates of 3.0 percent and 9.5 percent is real. When confidence intervals overlap, a definitive comparison of point estimates can be made by a statistical test such as the chi-square (c_2) test. Larger numbers of subjects in the sample lead to smaller confidence intervals around point estimates, so there is a premium on having enough subjects. Statistical power analysis allows investigators to plan their studies so that they can be sure of a reasonable chance of having enough subjects to support confidence intervals that are smaller than the anticipated differences in the most important rates that will be compared.

Stratified Sampling In many cases, unfortunately, simple random sampling is not useful. In the example being considered, suppose that the investigator wanted to look at subgroups (e.g., college graduates) that occurred in the population much less commonly than high-school graduates and nongraduates. Rather than collapsing the college graduates into a category with all who finished high school, the investigator may want to be sure that the study sample includes enough subjects who are college graduates. With the equal probability of selection entailed in simple random sampling, college graduates would only be as common in the sample as they were in study population.

A more complicated approach to sampling lists the 3000 individuals in three separate groups, or strata, rather than in a single listing, and then samples each stratum separately. The investigator could decide to have 100 subjects from each educational stratum. If the study population contained 1500 nongraduates, the probability of selecting any one of them for the study would be 100/1500, or about 0.07. If the college graduates numbered only 500, the probability of selection would be 100/500, or 0.20.

This type of sampling is called stratified random sampling, and it requires slightly more complex statistical techniques than simple random sampling does to calculate point estimates and confidence intervals for proportions. In stratified random sampling, each subject is weighted according to the selection probability; estimates can be obtained for specific strata as well as the total study population.

Cluster Sampling One problem with these sampling strategies is that individual members of the study population must be listed to be sampled. Listing all potential subjects may be possible for small populations whose members can be identified (e.g., patients seen in a clinical setting) but is usually not possible or economically feasible for large populations, especially of community residents. An alternative is to use lists of groups, or clusters, of individuals. The only roster of units that can be sampled in a community may be a list of census tracts or a map of city blocks. Once a sample is chosen, all households within the selected block can be listed, and a sample of households can be selected. After the households are chosen, individuals who live there can be entered into the study. Cluster sampling is often the only feasible method, because lists of individuals in a population cannot always be obtained, and it is more efficient than simple or stratified random sampling of individuals

in enrolling a large sample. It produces less precise estimates, however (i.e., larger confidence intervals).

In studies of the total population, cluster sampling can become quite complicated. Clusters can be selected within several different types of strata—households and institutions, urban and rural—and some individuals can be sampled at higher rates (e.g., elderly, adults or children). In these cases, calculation of selection probabilities and the associated efforts to produce confidence intervals and more sophisticated statistical comparisons become highly complex.

Nosology Development of acceptable case-identification instruments for epidemiology requires diagnostic criteria that can be unambiguously interpreted. Once clear, explicit statements of the requirements for each disorder are available, examination protocols can be created. Proposed sets of explicit criteria for psychiatric diagnoses were first published in the 1970s, with the St. Louis research criteria and Research Diagnostic Criteria (RDC). In 1980 DSM-III adopted explicit criteria to use as the basis for clinical practice and for epidemiological and other research; this proved useful for researchers and clinicians and was extended in DSM-IV and on an international basis in ICD-10. Although major advances were made in the international standardization of explicit diagnostic criteria, substantial discrepancies in prevalence rates between similar population surveys have exposed the sensitivity of these criteria and assessment instruments to relatively small changes in content and assessment methods. Alternate approaches to adding additional information on disability and role impairment to assess the clinical significance of syndromes in community populations are now being explored.

Case Assessment Information about a subject can be collected in several ways. Medical records, often used for patients seen in clinical settings, provide essential documentation about prior course of the illness, other disorders or preexisting risks, and the type and course of treatment provided. For some studies, the diagnoses shown in these records are used to identify patients with rare disorders.

Records in central data banks can be important both for very rare disorders and for studying patterns of treatment in a defined area. Case registers are now maintained on a national basis for specific types of cancer. They provide a roster of patients with the disorder and also information that can be used to test hypotheses about risk factors or other features of the illness in the future. For more-common disorders, geographically based case registers provide a record of all those in the population who received treatment for the disorder on a longitudinal basis. For three decades, a register of all patients seen in mental health treatment facilities in Monroe County, New York, has been used to describe population treatment patterns in an urban community. With the recent rise of managed behavioral health care companies in the late 1990s, responsible for both public mental health services and large private insurance contracts, their routine clinical records may be a new source of case-register type research information.

The most important source of information about a subject in the study is often the direct interview or examination. Until the late 1970s the major obstacle in psychiatric epidemiology was the lack of an acceptable case-assessment instrument to identify subjects with mental disorders who could be used in studies of the total area population. The National Institute of Mental Health (NIMH)–Diagnostic Interview Schedule (DIS) and more recent versions of the World Health Organization Composite International Diagnostic Interview (CIDI) are now accepted for use in epidemiological studies involving over 30 countries throughout the world.

Criteria for Assessment Instrument An assessment instrument must satisfy several criteria before it can be used successfully in studies of human subjects.

Safety Assessment should not cause subjects harm; if risks do exist, the benefits of the study must outweigh the potential harm. Anyone participating in such a study must do so voluntarily after being informed of the nature and extent of potential risks and must be able to withdraw at any time. These requirements are enforced by institutional review boards for the protection of human subjects at an investigator's institution. At present, there is no reason to believe that participating in epidemiological studies that include a diagnostic psychiatric interview harms either adults or children.

Feasibility With research funds becoming more limited, it is increasingly important to develop assessment procedures that yield adequate information about large numbers of subjects without being unduly time consuming, burdensome for subjects, or dependent on a highly skilled examiner whose services are expensive. For population surveys that assess large samples, it has become prohibitively expensive to use highly trained mental health clinicians to perform psychiatric interviews. Alternatives have been needed before such major studies could begin.

Reliability and Validity One of the most important psychometric properties of assessment instruments is reliability. Although it has several aspects, reliability usually refers to the assessment instrument's capacity to give consistent results when used by different examiners or at different times. An instrument that has acceptable levels of interrater and test-retest reliability can be assessed to determine if it is measuring what it intends to measure. This property is called validity. Reliability and validity are so important that a more extensive discussion of their role in evaluating case-identification instruments is provided.

Reliability The property of yielding equivalent results when used by different examiners with the same subject is known as interrater reliability. The property of producing equivalent results when used for the same subject on different occasions is called test-retest reliability. Although these two properties are necessary, they are not sufficient for an instrument. For example, at least hypothetically a diagnostic interview could show high interrater and test-retest reliability but give consistently wrong results. Accuracy would be attenuated without consistency, however, so acceptable levels of reliability must usually be demonstrated before any assessment instrument can be used in an epidemiological study. Several measures of reliability are available; choice of the proper measure largely depends on the type of information the assessment instrument uses. In the simplest case, consider an interrater reliability pretest of a diagnostic interview that used two examiners to assess presence or absence of a disorder in a series of 100 individuals. A two-way table can be used to summarize the results from the two interviewers:

Proportion of Subjects Classified by Two Raters

		Examiner A: Present	Examiner A: Absent	Total
Examiner B	Present	$a = 0.07$	$b = 0.08$	$B_1 = 0.15$
	Absent	$c = 0.11$	$d = 0.74$	$B_2 = 0.85$
		$A_1 = 0.18$	$A_2 = 0.82$	1.00

Po = proportion of agreement observed = $a + d = 0.81$
Pc = proportion of agreement by chance = $A_1 \times B_1 + A_2 \times B_2 = 0.724$
$\kappa = (Po - Pc)/(1 - Pc) = (0.81 - 0.724)/(1 - 0.724) = 0.31$

A simple measure of agreement for these dichotomous data is proportion of observed agreement, or the percentage of patients on whom the two examiners agreed that the disorder was present or absent. In this instance, the results indicate 81 percent agreement; however, this measure is not recommended.

In comparing two judgments, some agreement can be expected to occur by chance alone, no matter how consistent the interview is. To adjust for the potential contribution of these chance agreements, a better measure of agreement is kappa. Calculation of kappa as shown in Table 5.1-1 yields a value of 0.31. Another advantage of kappa is that its confidence interval can be calculated to determine how stable the point estimate of kappa's true value is.

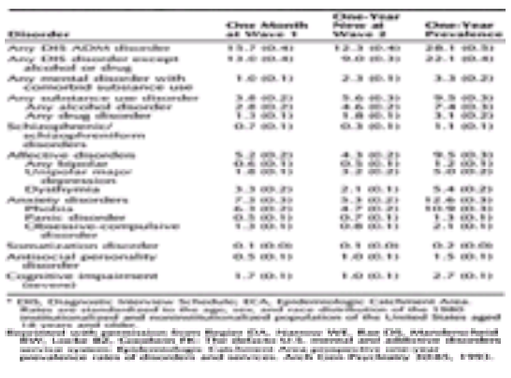

Table 5.1-1 Prevalence per 100 Persons 18 Years and Older: Five ECA Site Combined Community and Institutionalized Population* (Standard Error in Parentheses)

The kappa statistic can be used to measure agreement between the raters at different levels of information. Judgments about any disorder considered in the interview, about just one of the specific disorders (as in the example), or about an individual item for a specific disorder can be described using kappa. As the levels become broader, the reliability is likely to improve, because there are more ways to qualify as having any disorder than there are as having an individual symptom. The value of kappa depends on how common the particular condition is in the study sample. For disorders with a frequency below 5 percent, kappa's value will be so low in most cases that some investigators suggest not calculating it for these conditions.

For data expressed as ratings on an ordinal scale, other statistical measures are appropriate, including an intraclass correlation coefficient using analysis-of-variance techniques. Kappa can also can be calculated for such complex situations as shifting numbers of multiple examiners and weighted items.

Acceptable reliability has become an expected feature of psychiatric assessment instruments, especially diagnostic interviews, because substantial research has demonstrated that routine clinical diagnoses are not reliable. The classic demonstration of this inconsistency was made in the U.S.-U.K. Diagnostic Project, which showed that psychiatrists in New York and London used the same diagnostic terms in widely varying ways, both for their own patients and for patients interviewed on videotape and shown to both groups. One result of this study was to produce standardized interview schedules designed to reduce the most important sources of inconsistency in diagnostic assessments.

1. *Information variance*—examiners collect different types of information about patients
2. *Observation variance*—examiners interpret the subject's answers and nonverbal behavior in different ways
3. *Criterion variance*—examiners evaluate information about the subject according to different diagnostic rules

Standardized interviews reduce, but do not eliminate, these sources of inconsistency. Two other sources of variance remain: (1) subject variance, when the subject has different conditions at different times, and (2) occasion variance, when the subject is in a different stage of the same condition or at least reports different information about it.

Validity Reliability is assessed by comparing agreement between examiners or between examinations. Validity testing requires demonstrating that the test results are accurate, ideally by comparison with a well-known standard of truth. Naturally, a new field that uses descriptive criteria for diagnosis and has just begun developing standardized instruments because clinical examinations are unreliable has no gold standard to use as an absolute measure of truth in diagnostic assessment. In practice, choosing acceptable criterion instrument to use as a standard of comparison in validity testing of a new diagnostic instrument is one of the most difficult aspects of the study.

A simple validity study involves administering the test instrument and the criterion instrument to each subject independently, with the order of administration changed randomly so that one instrument does not influence the results of the other. Different statistical measures are calculated to measure validity than are used for reliability. Reliability tests do not assume that one examiner is more likely than the other to obtain the true answer, so a simple comparison of their agreement is made. In validity testing, however, the criterion instrument is assumed to produce the truth, and the measures calculated are designed to indicate how well results from the new instrument being tested match the results from the criterion instrument. A two-way table is constructed.

		Truth (Criterion Instrument Results)		
		Disorder Present	Disorder Absent	Total
New Instrument	Disorder present	$a = 35$	$b = 8$	$a + b = 43$
	Disorder absent	$c = 5$	$d = 52$	$c + d = 57$
		$a + c = 40$	$b + d = 60$	100

$$\text{Sensitivity} = \frac{a}{a + c} = \frac{35}{40} = 0.875$$

$$\text{False negative} = \frac{c}{a + c} = \frac{5}{40} = 0.125$$

$$\text{Specificity} = \frac{d}{b + d} = \frac{52}{60} = 0.87$$

$$\text{False positive} = \frac{b}{b + d} = \frac{8}{60} = 0.13$$

Sensitivity is a measure of the new instrument's ability to detect those with true cases of disorder identified by the criterion instrument. The *false-negative rate* is the proportion of those with true cases who are missed by the new instrument. *Specificity* is a measure of the new instrument's ability to identify those with true noncases who are identified by the criterion instrument. The *false-positive rate* is most commonly measured as the proportion of those without the disorder who are mistakenly detected as having the disorder by the new instrument.

These measures allow the investigator to judge the new instrument's ability to identify the cases it is designed to identify. Higher sensitivity and specificity values are always desirable. For a given instrument, there are trade-offs between these two values. The only way to improve both sensitivity and specificity without a trade-off is to improve the instrument itself.

Another useful measure related to validity is the proportion of those with apparent cases, as detected by the new instrument, who truly have the disorder as determined by the criterion measure. This proportion is the positive predictive value (PPV). Of the 43 individuals who appeared to have cases in the example, only 35 had true cases, so the PPV = 35/43 = 0.814. This measure is affected by the base rate, so it is especially difficult for diagnostic tests to achieve a high PPV with rare disorders.

Criterion Validity These measures are all based on a type of validity known as criterion validity because results of the test instrument are compared with results of a similar, but presumably more accurate, instrument. If the new instrument is compared with a criterion administered later, the method is called predictive criterion validity.

Face Validity Other types of validity have been described. The simplest is face validity, which refers to a judgment that the new instrument makes sense to an investigator. Standards for this type of validity are usually not clear; however, it can increase clinician and subject acceptability of a new, and otherwise unusual, instrument.

Content Validity *Content validity* refers to a systematic examination of the new instrument by an expert in the area to ensure that it covers the types of information needed for later interpretation and scoring; such instruments as standardized diagnostic interviews that are intended to collect information must be used with a set of explicit diagnostic criteria.

Procedural Validity The term “procedural validity,” recently introduced, refers to whether a particular type of examiner (e.g., nonclinicians) can use the new instrument and produce the same results as a skilled examiner (e.g., a research psychiatrist). Because this concept involves both a comparison between examiners as in reliability testing and a comparison with a criterion as in criterion validity testing, investigators have reported both kappa and sensitivity-specificity measures for

these studies.

Construct Validity The most important concept of validity is construct validity, which is the demonstration that the thing being measured exists the way the instrument assumes it does. Establishing construct validity for a mental disorder is difficult.

Ideally, safety, feasibility, reliability, and validity are examined before an instrument is used to assess subjects in an epidemiological study. In practice, the difficulty in picking a criterion instrument with established validity means that only safety, feasibility, and reliability can be well studied for psychiatric assessment instruments. In an effort to establish at least minimum standards, new instruments can be assessed for content and procedural validity and compared with similar instruments. Although these other instruments cannot be used as legitimate criterion instruments, they can provide useful comparisons if they have met the same standards, including reliability and content validity, as the new instrument being studied.

Descriptive Studies Once an appropriate sampling plan and acceptable assessment instruments are available, epidemiological investigations can begin to explore the distribution of disorders in the population. For rare disorders, a total area population survey may be unrewarding, but for most psychiatric illnesses, the starting point is an area survey to determine basic measures of frequency of the illness.

In epidemiological studies with an emphasis on careful sampling to produce results that can be extended to the universe of interest the results based on number of persons with a disorder are expressed not in raw numbers, but in terms of population rates. In general these rates are proportions that require both a numerator, the number of cases, and a denominator, the total number in the population (with or without the disorder).

$$\text{Rate} = \frac{\text{Persons with the disorder (in the population)}}{\text{Total population}}$$

This rate is actually a proportion, a fraction that includes cases in both the numerator and the denominator. Some writers reserve the term “rate” for an instantaneous change and express it using methods of calculus. To simplify that concept, the term “average rate” can be used for measures that involve rates over specified time periods.

Point Prevalence Most surveys in psychiatric epidemiology have examined the prevalence of disease in the population. The term “prevalence” encompasses several types of rates but always refers to persons who have the disorder at a specified time, regardless of when the disorder started. The basic measure is a point prevalence rate, that is, the proportion of individuals in the population who have the disorder at a specified point in time; this point can be a calendar date, such as April 1, 1990—as in the national census—or it can be defined in relation to the study assessment, such as day of interview, regardless of the calendar date.

$$\text{Point prevalence rate} = \frac{\text{Cases at } t_0}{\text{Population at } t_0}$$

Although a day is often used as the point in time, the use of diagnostic criteria that require multiple symptoms to cluster, with a minimum duration of symptoms, has led some to extend the point measure backward in time to the previous week or previous month. Moving the concept of a point to include a period longer than 1 month prior to interview is not advisable, because it can lead to confusion and raises methodological problems discussed in relation to lifetime prevalence.

To establish a point prevalence rate for depression, an investigator might sample the residents of a defined area, administer an assessment instrument that detects a current depressive illness at that time, and calculate the rate as the proportion of the sample with current depression. Because conducting such a study would likely take several weeks or months, if the sample size is large, the rate would probably be based on the time of interview rather than asking subjects to report their symptoms retrospectively for the starting date of the field survey. (Unless a simple random sample was chosen, the investigator would also need to weight the sample results to reflect the overall population figures according to an individual's probability of selection.)

Incidence In epidemiological research, *incidence* refers to a rate that includes only those whose illness started within a clearly defined time period. The most common time period is 1 year; thus, the annual incidence is usually reported. A study of incident cases is more difficult than a study of prevalent cases. To be done most carefully, a study of incidence requires at least two examinations of each subject in the sample, one at the start and one at the end of the designated time period.

The initial assessment is needed to determine which members of the sample already have the disease; they are not eligible because they already have the illness, so they omitted from the numerator (those with new disorders) at the end of the study. They are also excluded from the denominator, because they are not part of the population considered at risk of developing a new case of the disorder. At the start of the study, the numerator is set to zero; at the end of the study, individuals who have developed the illness will be counted as having new cases. If, at the second examination, the assessment instrument cannot provide retrospective coverage of the entire time period being used (e.g., 1 year), the population at risk must be surveyed more often than just at the end of the period.

For some disorders that have recurrent episodes, it is useful to use an incidence figure that includes both first-episode and later episodes of illness (e.g., a second major depressive episode). A broader concept of total incidence includes those with a new episode of illness, regardless of whether there have been previous episodes. This approach is illustrated in Table 5.1-1, in which new and recurrent episodes are combined for a 1-year total incidence rate, which when added to the point prevalence rate produces a 1-year period prevalence rate.

An alternative way to study incidence is to conduct a single examination of subjects, as if it were the end of the time period chosen for study, and ask them to recall their disease status at the beginning of the time period. Besides problems of recall, this simpler design systematically omits some categories of new cases, including those who died during the time period and cannot be sampled and those who left the circumscribed geographic area for other reasons.

This description of incidence rates is the traditional one, but more-precise concepts of incidence have been developed that take account of change over time and the possible loss to follow-up of individuals in the at-risk population. *Incidence density* (ID) refers to an average incidence rate over the time period of interest.

$$\text{ID} = \frac{\text{Number of incident cases in 1 year}}{\text{Population-time (person-years of observation)}}$$

Because some members of the at-risk population sample will develop the disease and some will drop out of the study (e.g., by moving without a forwarding address, or by dying from an unrelated illness), the denominator is calculated as a person-time figure (e.g., person-years of observation) until the individual leaves the at-risk population. This calculation depends on knowing when during the year an individual develops an illness or otherwise leaves the at-risk population. If for 1000 people being followed the only changes occur at the end of 6 months of follow-up, when 20 are lost to follow-up and another 100 develop disease; then the person-time figure for observation of at-risk, disease-free individuals is (880 × 1 year) + (20 × 1/2 year) + (100 × 1/2 year) = 940 person-years and

$$\text{ID} = \frac{100 \text{ persons}}{940 \text{ person-years}} = 0.1064 \text{ per year}$$

A contemporary example is provided in the Baltimore ECA follow-up survey conducted between 1993 and 1996 by William Eaton and coworkers, with a median time of 12.6 years after the initial interview in 1981. An incidence analysis of DSM-IV major depression identified 71 new cases among 1920 respondents with a total 23,698 person-years of exposure. An incidence density rate of 0.003 per year, or 3.0 per 1000 per year was determined for major depression. This incidence rate is considerably lower than that found during the 1-year follow-up interview in 1982, when 24 new cases were identified with 2550 person-years of exposure—resulting in an incidence density of 9.4 per 1000 per year, three times higher than the rate obtained from an interview requiring a 12.6-year median recall period. When the authors of the Baltimore analysis compared their 1-year incidence rates for major depression with those found in four of the five ECA sites, they found that the average total ECA 1-year incidence rate was 15.9 per 1000 person-years of follow-up.

The problem of recall in psychiatric evaluations is illustrated by the finding that only 5 of the 22 persons with new cases (23 percent) identified in 1982 who could be located for the 1993–1996 interviews confirmed that they had ever had a major depressive episode. Adding the 17 “forgotten” cases to the 71 identified cases would have increased the incidence rate to 3.7 per 1000 per year, and adding a similar number of presumed forgotten cases to the numerator for each year of follow-up

would match the 9 per 1000 found in the 1-year Baltimore follow-up.

One advantage of this more precise approach is that in stable populations the point prevalence rate bears a simple relation to the incidence density: Prevalence = ID × the average duration of illness before termination (e.g., death from the illness or recovery). Here, a stable population is stable in size and age distribution and has constant incidence and prevalence rates. Assuming the total ECA estimates for major depression incidence density of 15.9 per 1000 population per year and the 1 month (point) prevalence of 18 per 1000 yields an average duration of major depression of 18 ÷ 15.9 = 1.1 years. Results of the direct examination of subjects in the Baltimore study demonstrated that the median time to an episode-free year was 1 year for prevalent cases and 2 years for incident cases. Calculation of incidence density rates of mental and other disorders together with mortality, duration, and associated disability was integral to the development of disability adjusted life years (DALYs) for the World Bank and WHO Global Burden of Disease study.

Incidence rates are clearly more difficult to calculate, and they require more extensive data collection than point prevalence rates. Point prevalence rates reflect the accumulated burden of chronic cases of long duration, however, so incidence figures based on new cases in a specified time period are more useful in analytic studies of risk factors. Point prevalence surveys are most useful for descriptive purposes, as in portraying the frequency of illness in a community population and relating disease frequency to potential need for services.

Other Prevalence Rates Although point prevalence and annual incidence rates are the fundamental measures used for descriptive and analytical studies in epidemiology, other types of prevalence figures also have some usefulness.

Period Prevalence *Period prevalence rate* refers to the number of people who have a disorder at any time during a specified period. Its numerator includes any existing cases at the start of the period, plus any new cases that develop during the time period. For a 1-year period, the annual period prevalence rate is approximately equal to the point prevalence rate (existing cases/population at the start) plus the annual incidence rate (new cases in a year/population at risk). In the example of major depression noted above, the point prevalence was 1.8 percent (18 per 1000) and the new plus recurrent incidence was 3.2 percent, for a total 1-year prevalence of 5.0 percent. The period prevalence measure is less valuable than the separate expression of its two components—point prevalence and annual incidence rates. It may be useful, however, for services research studies in which annual treated prevalence rates are contrasted with annual true prevalence rates. Analyses of the ECA study have used each of these measures to describe the de facto U.S. mental and addictive disorder service system.

Lifetime Prevalence The lifetime prevalence rate is a measure of individuals considered at a point in time who have ever had the illness under study. From a clinical perspective, it may best be viewed as equivalent to a past medical history in which the patient is asked to recall any previous health-related conditions, faulty as the person's memory may be. The examiner may only be sure that the patient is most likely to recall the most salient conditions—some of which may be useful in interpreting the present illness. It may be particularly useful to describe conditions that remit but can often recur (e.g., major depression). However, from an epidemiological research perspective, at least three potential problems exist with lifetime prevalence:

1. It is almost always based on subject recall, which can be inaccurate. In addition to the recall problem noted above in the Baltimore ECA incidence study, there was a substantial difference in the reported 7.2 percent lifetime rates for major depression from the total ECA first-wave interview and the 12.5 percent rate obtained when data from both the first- and second-wave interviews are included. The use of a modified interview in the NCS with some memory-enhancing techniques produced a lifetime prevalence rate of 17.3 percent for major depression. Although the Baltimore analysts suggested that the more-severe disorders are the ones most likely to be remembered in long-term recall (lifetime prevalence studies), additional questions are raised about the clinical significance of some disorders identified even in the short-recall periods using existing diagnostic criteria and case-identification techniques in community populations.
2. It covers subjects over the full age range represented in the study population, including many who have not yet completed the age period of highest risk for onset of the disorder. Lifetime rates can be reported separately for specific age groups. This figure may be misleading, however, for some purposes, if no provision is made for the fact that people with the disease at earlier ages may have experienced different death rates than those without the disease.
3. Used in a summary way, it does not allow for the fact that incidence rates may have changed over the years. Therefore, different age groups may have true differences in rates that are obscured both by using an overall rate and by the possible differences in mortality between those with and without the disorder.

Several alternatives to the lifetime prevalence rate, as determined from a point prevalence survey, have been described. One method uses a life table approach to estimate age-specific lifetime rates based on age-specific incidence and mortality figures. This detailed age-specific information is rarely available for psychiatric disorders. Another method calculates lifetime risk by including persons in a birth cohort (with and without the disorder) who died or otherwise dropped out before the cutoff age. This latter method also can be used to ascribe probable risk to those without illness who are below the cutoff age. This approach is the most useful expression of risk, rather than actual development of illness, and is especially important for genetic studies, which must include children and deceased relatives.

Treated Prevalence Treated prevalence usually refers to either a point prevalence or an annual period prevalence rate that is determined by counting all residents in a defined geographical population who receive treatment for a given disorder.

Administrative Prevalence A more restricted form of treated prevalence has been used for studies that use registered patients at a clinical facility as their population denominator. Treated prevalence that uses registered patients as the denominator population has been called administrative prevalence. It presents difficulties, because the denominator depends on registration status, rather than being based on those who perceive the study facility as their usual source of care. With the advent of managed behavioral health care programs, treated prevalence has been used to describe the proportion of the covered population that uses at least one mental health service in 1 year. The less descriptive standard industry term has been *penetration rate*. Potential limitations of both administrative prevalence and penetration rate are the probable inclusion of some patients with no mental disorder who are evaluated or treated and the loss of some who receive treatment outside the insurance plan.

Analytical Studies Measures of disease frequency allow comparisons between groups within the study sample. If one group has higher rates of a disorder than other groups, then a search for factors that led to the higher rate can be undertaken. Many studies of disease frequency have shown that women have higher rates of major depressive disorder than men. From this consistent finding, based on group comparisons, investigators can formulate hypotheses about what factors place women at higher risk. Whether these putative risk factors are biological or psychosocial, they can next be studied in targeted investigations to see if women with the presumed risk factor have higher rates of major depressive disorder than women without them. To make comparisons among groups (and later among groups with and without suspected risk factors), investigators have several options for study design.

Cross-Sectional Prevalence Survey To examine the apparent higher frequency of major depression among women, one approach is to conduct a sample survey of the total population in an area, calculate the point prevalence rates for men and women, and compare them. For example, it may be found that women have twice the point prevalence rate of men. If the investigators examined suspected risk factors, (e.g., use of oral contraceptives), they could compare the rates for women who used this medication and those who did not.

Such a design has been used for this purpose, but it has several drawbacks. As shown in the discussion on incidence rates, point prevalence is affected both by the rate of developing an illness, as reflected in the incidence rates, and by the duration of the illness after it develops. If men and women with major depression had different average durations, they would have different point prevalence rates, even with identical incidence rates; the point prevalence rate for women could be twice the rate for men simply because women with major depressive disorder had more-chronic forms and tended to accumulate in the population. A second problem with this cross-sectional design is that it may be difficult to determine whether women with the suspected risk factor, use of oral contraceptives, were using the medication before they became ill, which would be required to show causality.

Incidence Study and Relative Risk To isolate the frequency of onset from the duration once developed and to assess possible risk factors accurately, studies of incidence rates are much more useful. The fundamental measure used to compare two groups is the relative risk (RR), a form of risk ratio:

$$\text{RR} = \frac{\text{Incidence rate in group with risk factor}}{\text{Incidence rate in group without risk factor}}$$

In terms of the usual two-way table, this risk ratio can be expressed as follows:

Incident Series of Cases	New cases	Noncases
With risk factor	a	b
Without risk factor	c	d

$$RR = \frac{a}{a+b} \div \frac{c}{c+d}$$

If the relative risk is greater than 1.0, the group with the suspected risk factor does have a higher incidence rate of the disorder. In this study design, risk factor status (e.g., use of oral contraceptives) can be determined at the start of the time period for all those without the disorder; these subjects could be reexamined during or at the end of, the period (or both) to assess development of the illness and continued use of the medication.

Prospective Cohort Study The prospective cohort study design assesses incidence rates and risk ratios. A *cohort* is a group formed by sampling from a single, well-specified population, such as residents of a circumscribed area. It allows extension of study findings to the universe of interest, and as a prospective study, it allows determination of risk factor status in persons without the disorder who are followed to identify newly developed cases.

Case-Control Study For very rare disorders (or sometimes for exploratory studies of possible risk factors), a study may use identified cases, rather than potential cases. This design is called a case-control study. It recruits patients already diagnosed, usually by monitoring records at clinical facilities such as hospitals; this method of sampling assumes that everyone with the disorder is likely to present for medical attention and to be accurately diagnosed. It also assumes that either all relevant facilities are monitored or that no differences exist in persons who stay at home or use different facilities.

One problem is that the universe from which these cases are drawn cannot be specified, at least in customary terms (e.g., geographical area of residence). Another problem is that a comparison group of persons without the disorder is not easy to specify. To compensate, often a comparison group is drawn from other patients in the same facility, and a second one is drawn from community residents in the area presumably served by the hospital. Either one of these comparison groups could be drawn from a different universe than the hypothesized one reflected in the sample of cases.

In these case-control studies, ascertaining possible risk factors is usually possible only by retrospective report of the subjects, unless prior documentation exists (e.g., in medical records).

Odds Ratio Because incidence rates cannot be calculated in such a case-control design, the typical calculation of risk ratio must be altered. Instead of an RR, the odds ratio is calculated for case control studies:

	Cases	Noncases
Possible risk factor present	a	b
Possible risk factor absent	c	d

$$\text{Odds ratio} = \frac{a}{b} \div \frac{c}{d} = \frac{ad}{bc}$$

Logistic Regression A common analytical technique in epidemiological studies is logistic regression, which provides an estimate of the probability that an event is true or false. For example, it can be used to estimate whether a disease or a treatment response is present or absent. As in multiple regression, logistic regression examines the impact of different characteristics on the outcome of interest, in this case, the probability of the event.

Analysis of data from a study using logistic regression produces a regression equation, of the form

$$Y = a + b_1X_1 + b_2X_2 + \ldots + b_nX_n$$

One goal in analyzing data with this technique is to produce the best model for predicting whether or not subjects in a study have the outcome of interest. A good model provides a statistically acceptable estimate of the probability Y. Investigators consider different characteristics (e.g., age, gender, socioeconomic status, or laboratory values) to see if they meet scientific and statistical criteria for inclusion in the model. For example, data from a survey of current major depression among patients admitted to a general medical service might be used to test a model including age, sex, and marital status in estimating the probability that major depression is present or absent. Once that model was tested, investigators might examine whether adding family history of mood disorder would improve the model's fit to the data collected from those patients.

This same modeling approach is used in other statistical techniques, but the assumptions, calculations, and interpretations of the model differ. In multiple regression, the b_n coefficient represents change in the dependent variable (Y) for each change in the corresponding independent variable (X_n). For example, a study of adult males might examine the change in weight (Y) for each change in height (X).

In logistic regression, which estimates the probability (Y) that the condition is present or not, the coefficients represent the odds of the condition's occurrence. In logistic regression, the coefficient (b_n) is the natural logarithm of the odds ratio for that independent variable (X_n).

$$b_n = \ln(\text{odds ratio } X_n)$$

Thus the odds ratio for an independent variable can be easily derived from the variable's coefficient in logistic regression models.

$$\text{Odds ratio } X_n = e^{b_n}$$

One advantage of logistic regression in estimating an odds ratio for a characteristic is that the odds ratio is adjusted for other terms present in the regression model.

Bias Analytical studies to assess risk factors can be flawed by three types of bias:

1. Selection bias. If a study sample is not drawn properly, it may not accurately reflect the study population; also, the study population may not be equivalent to the universe of interest. In case-control studies the selection of cases may be distorted if the clinical diagnoses used to determine eligibility are not accurate.
2. Observation bias. If the assessment instruments are invalid, information about subjects will be wrong. In case-control studies, examiners who know the case or noncase status of subjects can be influenced in assessing the risk factors being studied.
3. Confounding bias. In a particular study sample, some other causal factors of the disorder may be related to the risk factor being studied. This effect can often be examined, and some adjustments can be made during data analysis.

These potential flaws can affect the validity of a study's findings. A further question is whether the findings considered applicable to this particular universe also apply to other possible universes; for example, does a risk factor studied in one local community have the same association to disease in other types of communities? The answer to this second question is a matter of judgment until equally valid replications are performed.

Risk Factors and Causality Epidemiological data demonstrate an association between risk factors and a disorder. Because an association does not indicate causality in a particular direction, the desire to study human illness has led epidemiologists to consider standards of evidence that may support an interpretation of a causal connection between a risk factor and a disorder.

1. Temporality. Unless the risk factor precedes the disorder, it cannot cause the disorder. Clear demonstration of the prior occurrence of a risk factor strengthens

the possibility of causality.
2. Replication. Repeated, consistent demonstration of a risk factor's relationship to a disorder in multiple studies strengthens the possibility that a risk factor is causative.
3. Magnitude of association. A large risk ratio tends to support an interpretation of causality, as does demonstration of a doseresponse effect.
4. Plausibility. If a possible causal mechanism can be postulated within the framework of existing knowledge, it may lend credibility to the interpretation of a causal relationship; however, in new fields where knowledge is growing, this criterion may not be so relevant.
5. Specificity. If a proposed risk factor can be associated with a single disorder and no others, that association may strengthen belief in a possible causal relationship. Some factors, such as adverse life events, may lead to a variety of disorders, however, so that the failure of specificity does not discredit a potential risk factor.
6. Experimental intervention. Experiments to control a risk factor may support a causal role for the factor if the occurrence of disease is reduced. However, in such an experiment, unintended or unknown factors may have been the true responsible agents and may have been affected by the intervention.

Experimental Studies An important goal of psychiatric epidemiology is to reduce the burden of illness. With a population-based approach, epidemiological investigations are especially well suited to assessing the impact of broad efforts to reduce the occurrence of illness or its duration and associated disability. Such experimental studies are the next logical development for the WHO/World Bank Global Burden of Disease project. Interventions are now being pilot tested to reduce the burden of disease associated with major depression, which is currently identified as the fourth leading cause of disability and projected to be the second leading cause by the year 2020. By increasing screening, diagnosis, and treatment efforts in primary health care settings and using patient coordinators to ensure compliance with evidence-based protocols, changes in symptom and disability levels can be measured in large primary care population groups. The use of such interventions in community-based, rather than in specialty mental health clinical, populations will permit more-accurate assessment of their impact on changes in the burden of illness associated with major depression.

Population Attributable Risk For primary prevention—the effort to reduce onset of a disorder in persons at risk for developing it—a measure of the potential impact of controlling an established risk factor is derived from the attributable risk (AR), the risk difference measure based on incidence rates (IR) for persons with and without the risk factor.

$$\text{AR} = (\text{IR with risk factor}) - (\text{IR without risk factor})$$

The proportion of cases in the group with the risk factor that may be caused by that factor is the population AR:

$$\text{Population AR} = \frac{\text{IR (total population)} - \text{IR without}}{\text{IR (total population)}}$$

When the more precise figures of incidence density are used, this measure has been called the etiological fraction. In some instances, it may be possible to demonstrate that a “protective factor” has caused a lower rate of illness among those persons exposed to it; then the formula is reversed to show the “preventive fraction.” Studies of low dental caries rates in areas with fluoridated water provide the best example. Calculation of the etiological fraction from observational studies indicates the maximum benefit likely to occur with an intervention designed to reduce the pathogenic effect of the risk factor. Demonstration that an intervention has been effective rests on a controlled design, with calculation of a preventive fraction based on persons with a risk factor who received the intervention and those with the risk factor who did not.

Preventive Applications Over the past decade, the Institute of Medicine (IOM) issued a guide for prevention of mental disorders that separates primary prevention approaches into three types: universal, selective, and indicated. Universal interventions are applied to an entire population (e.g., water fluoridation), selective interventions are applied to populations with some risk factors, and indicated interventions are provided to populations at high risk for developing disorders. In the IOM paradigm, indicated interventions may be applied to individuals who are symptomatic but subthreshold for full diagnostic criteria as well as to asymptomatic persons with biological markers indicating a predisposition for a mental disorder. Decisions to implement any of these approaches depend on the strength of the risk factor information for each of these groups and on the power of the proposed intervention to reduce that risk.

In addition to studies that test interventions to prevent a disorder, this method can also be used for secondary and tertiary prevention. Secondary prevention is aimed at reducing the prevalence of illness by reducing its duration in those who have just developed it. Factors that tend to prolong an episode of illness, including inadequate or inappropriate treatment protocols, can be targeted in secondary prevention efforts.

Reduction of disability produced by a disorder, or tertiary prevention, can also be assessed, even if full recovery does not occur. Such studies require instruments that assess severity of illness, not simply a dichotomous present-absent rating for a disorder. Studies with this design are commonly used in controlled clinical trials to assess the effectiveness of new therapies to reduce duration until recovery or reduce severity in persons without full recovery. For more severe disorders such as schizophrenia, programs of assertive community treatment (PACTs) have been tested in many sites and shown to improve the functional capacity of patients living in community settings.

Primary prevention efforts are especially difficult to study because it is not clear how to choose large groups to study, how to demonstrate that they have received the intervention, and how to ensure that no other, unplanned intervention actually produced any improvement that occurred. Even if these conditions are met, it may be difficult to demonstrate that the intervention was effective for the reasons postulated, and that its costs (including any unintended negative consequences) did not overwhelm any benefits that did occur. However, the potential for implementing such studies will improve as more clearly defined psychosocial and biological risk factors are identified for specific disorders.

EPIDEMIOLOGICAL METHOD IN PSYCHIATRY

Special problems have delayed progress in psychiatric epidemiology. Although the general field of epidemiology has advanced to the point of being most concerned about such issues as controlling confounding bias in risk factor studies and developing ways to measure the impact of preventive interventions, methodological concerns for studies of mental disorders are more basic. They have centered on difficulties in applying complex sampling techniques, in developing acceptable case-assessment instruments, and in identifying potential risk factors that merit study in large-scale investigations. The most important of these problems has been development and application of case-assessment instruments for large-scale studies.

Case Assessment Prior to 1980 the major obstacle to valid identification of cases in large samples of nonclinical populations was the lack of a widely accepted explicit set of criteria for diagnostic classification. Researchers who had access only to earlier systems, such as the first edition of DSM (DSM-I), were forced to rely on detailed descriptions of symptom patterns formulated by the investigators to achieve a meaningful classification of cases. During the 1960s and 1970s, this effort to use detailed specifications for disorders led to more-explicit statements of empirically based criteria for specific mental disorders. Until this goal was met in DSM-III and DSM-IV, investigators had only a few alternatives in selecting instruments to identify cases.

The most common approach used a self-report questionnaire, usually with a concentration on psychophysiological symptoms, which could yield a score based on positive answers by the subject. These scores were intended to reflect the probability that a subject had a diagnosable mental disorder, with higher scores indicating a greater likelihood. Usually, a cutoff score was calculated to separate the sample into two groups—cases and noncases. (In some studies, these scales and other information were also reviewed by clinicians, who attempted to give an overall judgment about the subject's psychiatric status.)

The second major effort to develop standardized assessment instruments was to produce diagnostic interview protocols with acceptable interrater reliability. The first of these was the Present State Examination (PSE), an interview form that concentrates mainly on psychotic conditions, which has been used in major international studies, such as the U.S.-U.K. Diagnostic Project, the International Pilot Study of Schizophrenia, and other studies of schizophrenia supported by the WHO and the NIMH. The PSE is intended for use by skilled clinicians, usually psychiatrists, who have been trained in its use; after training, the interviewers are commonly expected to participate in pretesting any investigation for adequate levels of interrater reliability.

The PSE was not designed to yield diagnostic labels according to an established classification system, because the lack of explicit criteria in the early 1970s made it difficult to determine unambiguous standards for a given category. The advent of formal, detailed criteria for a range of psychiatric diagnoses made it possible to construct interviews that attempted a diagnostic assessment and assign subjects to specific categories of disorder. More recently, the PSE was updated to reflect criteria in DSM-IV and ICD-10 as part of the WHO and National Institutes of Health (NIH)–sponsored Schedules for Clinical Assessment in Neuropsychiatry (SCAN).

New versions of PSE (10th edition) and a categorical diagnostic algorithm (CATEGO) scoring program form the core of the modular SCAN examination protocol. The SCAN was recently used in the first national survey of psychiatric morbidity in Great Britain to confirm functional psychosis diagnoses of schizophrenia, manic episode, bipolar affective disorder, and others.

When the St. Louis research criteria and the RDC were formulated in the 1970s, they were accompanied by interview schedules that investigators would use to assess subjects in a study: the Renard Diagnostic Interview (RDI) for the St. Louis criteria and the Schedule for Affective Disorders and Schizophrenia (SADS) for the RDC. Because skilled clinicians had to spend up to 3 months learning these schedules and because epidemiological studies needed a large number of such high-level interviewers, they were not used much in community surveys. An important exception was use of the Schedule for Affective Disorders and Schizophrenia, Lifetime version (SADS-L) in a follow-up study of 511 community residents in New Haven. That study demonstrated that the SADS-L could be used successfully in epidemiological studies of community subjects.

Stimulated by that demonstration of feasibility and usefulness, and aware that DSM-III would adopt operationalized criteria, as in the St. Louis and RDC systems, NIMH epidemiologists sponsored development of a fully structured interview that could be used by nonclinicians to assess a large number of subjects according to DSM-III criteria. This new instrument, the NIMH DIS, was based on the RDI and SADS interviews and was written by authors of those two earlier interviews. Following extensive use of the DIS in the United States and many other nations, the WHO and three NIH Institutes agreed to sponsor international field trials of an updated and slightly modified DIS. This instrument, the CIDI, has the same structural characteristics of the DIS, with new computer scoring programs that use ICD-10 and DSM-IV diagnostic criteria. Multiple international training sites are now available to prepare research investigators for using both the CIDI and the previously described SCAN in epidemiological and clinical research settings.

Structure of the DIS and CIDI To allow nonclinicians to administer the DIS and CIDI reliably, the interview contains the exact wording to be used for each question; examiners only need to read the question aloud for each item being assessed. Once a question is answered positively, several types of probes are used to determine whether the item can plausibly be counted toward a psychiatric diagnosis. A severity criterion, based on having told a physician or other professional about the symptom or on having experienced life interference as a result of the symptom, is used to separate common and insignificant problems from clinically meaningful phenomena. A symptom that has always occurred as a result of physical illness or injury or in relation to medication, alcohol, or drugs of abuse is coded as being explained by those conditions, not by a psychiatric illness. These two features are intended to ensure consistency, accuracy, and selectivity in the assessment of positive reports of symptoms. Interviewer observations are used only for behavior-related psychotic conditions, and extensive use of marginal notes and examples is encouraged to allow editors and reviewing clinicians to judge any uncertain items.

Another effort to achieve reliability and accuracy is the use of a computer program to score the information and make diagnostic assignments; this program is written in a straightforward style, so that clinicians can easily interpret the scoring algorithms. The reliability of the administration, data entry, and scoring of the interview was greatly facilitated by development of computer-assisted interviews such as the CIDI-Auto developed by the Sydney, Australia, WHO collaborating center. Another computer-assisted interview program, using Windows technology (I-Shell), for use with the CIDI, SCAN, and Disability Assessment Schedule (DAS) was recently developed by the WHO Division of Mental Health. The CIDI and SCAN now cover both ICD-10 and DSM-IV.

Unlike the PSE, which concentrates on the 1-month period prior to interview, the DIS and CIDI assess the occurrence of symptoms throughout the patient's lifetime. This lifetime approach allows diagnosis of some disorders in which symptoms accumulate to a threshold (e.g., somatization disorder, antisocial personality), of disorders in which history is important in the diagnosis (e.g., schizophrenia, bipolar disorder), and prior episodes of recurring disorders (e.g., major depression). This approach also permits estimation of age at onset for subjects in a study as well as identification of subjects with a history of multiple disorders. Once a diagnosis is established on the lifetime basis, its most recent occurrence is dated. A modification of the DIS and CIDI permits dating the most recent experience with any positive symptoms.

Several aspects of the DIS and CIDI approach have been noted as potential weaknesses. Because it minimizes examiner observation and judgment, it is largely limited to subject self-report; self-reports may not be adequate for assessment of some disorders, such as schizophrenia and mania. For example, in the NCS, initial positive results on screening of respondents for schizophrenia with the CIDI were followed by a clinical interview using the Structured Clinical Interview for DSM (SCID). Eliciting these self-reports of symptoms on a lifetime basis means that poor recall may also affect the validity of symptom reporting, particularly for subjects with previous psychotic conditions. Although many aspects of the history of an illness can be obtained, such as age at onset and symptoms during the worst episode (for recurrent illnesses), some aspects of the course cannot be determined. Also, inevitable variations in training and editing procedures may place an effective ceiling on the degree of standardization that multisite studies can achieve.

Characteristics of the DIS and CIDI In the large epidemiological study that it was designed to support, the DIS was shown to be feasible and safe. It has been administered to about 20,000 subjects in five parts of the United States, and the refusal and dropout rate for subjects who agreed to start the DIS has been below 1 percent. The CIDI was used in the NCS to interview subjects as a random sample across the United States. Both the DIS and the CIDI have now been used internationally with many thousands of community and clinical-setting respondents.

Because the RDI and SADS interviews have been demonstrated to yield reliable current and lifetime reports by a range of subjects and because the DIS is similar to them but with more structure and a computer program to score information, it was decided to perform interrater reliability studies at a higher level, called procedural validity. In this first test, agreement was measured between two examiners, a nonclinician and a psychiatrist. Acceptable levels of agreement were reached, and further field testing was undertaken in the context of the epidemiological studies. The CIDI has been shown to have high interrater reliability across a multinational field trial conducted in varied languages.

Criterion validity for a diagnostic interview, especially one based on a new classification system, is hard to test, because no other validated interviews exist. The desire to apply a routine clinical judgment by psychiatrists using the clinical methods suffers from the possible effects of information, observer, and criterion variance that led to development of standardized interview schedules 20 years ago. One alternative is to use similar instruments that apply the same standards of evidence and use scoring procedures based on the same system of diagnostic criteria. The purpose of these studies is not to validate any single instrument, but to understand better any discrepancies with the comparison instrument. Studies comparing the CIDI and SCAN, as well as other interviews such as the SCID, are being undertaken for this purpose.

Construct Validity At least theoretically, the most important form of validity for an assessment instrument, *construct validity* shows that instrument measures what it intends to measure, that in fact the entity exists and can be quantified by the instrument. Various proposals in the psychological literature suggest ways to accomplish this task for a range of purposes. In psychiatric epidemiology, the question involves more than whether an instrument detects a given disorder as specified by a classification system's rules. In practice, these rules cannot be applied independently of a specified, reliable assessment instrument; therefore, the construct validity of the diagnostic entities in a system of classification remains to be shown for many categories for DSM-IV.

As psychiatric nosology has advanced, ways to establish validity for a diagnostic entity have been considered. The first requirement suggested was demonstration that a clinical picture with characteristic features could be described for the disorder and that these features could be used to distinguish the disorder from others that may resemble it. The second type of evidence can be derived from external criteria and includes biological variables (e.g., those obtained from biochemical and neuroanatomical studies); psychosocial and personality styles, including methods for coping with adverse life events; familial and genetic variables (e.g., patterns of transmission in relatives); clinical course and outcome variables (e.g., stability of the diagnosis over time); response to treatment; epidemiological variables (e.g., systematic occurrence in certain groups or places); and multivariate statistical analysis to demonstrate separation from, and relationship with, other disorders in terms of these variables or to examine the latent structure of the underlying category.

Unfortunately, psychiatric diagnostic assessment procedures can rarely evaluate patients with the full range of variables identified above. The differentiation of psychopathology from normal human states is usually not based on structural pathology (except for disorders such as Alzheimer's disease), statistical deviance from a physiological norm, an etiological agent, or an unambiguous pathognomonic symptom presentation. Instead, syndromal patterns of symptoms that are observable or reported by a subject are currently the basis for most diagnoses in psychiatry. The symptom clusters must not only be present, but they must be severe enough to be clinically significant. Although most medical pathology assessments can be separated from the impact of the disorder on social functioning constructs, mental disorder diagnosis requires a clinical significance judgment that implicitly includes evaluating impaired functioning.

Multiple assessment procedures are required to address all of the diagnostic dimensions needed to verify construct validity of current mental disorders. However, the future availability of genetic markers, functional imaging of brain pathophysiology, and better measures of functional impairment should greatly improve our current

efforts to separate psychopathology from normal homeostatic variations in human response to internal and external stresses.

STUDIES OF HISTORICAL IMPORTANCE

Results from epidemiological studies can be most usefully reviewed within the framework of the population studied. This framework emphasizes the primacy of the population group as the basic unit of analysis in epidemiology and illustrates that a variety of descriptive, analytical, and experimental studies may be appropriate with any population group, provided that the selection characteristics of the group are clearly defined and considered in the design. The population groups reviewed here include (1) treated populations in specialty mental health settings, (2) patients registered in general medical practice settings, (3) noninstitutionalized community populations, and (4) defined populations containing specific mental disorders.

Definition of the study population group frequency affects decisions on the type of mental disorder criteria used, interviewer selection, interview method, and the descriptive or analytical variables used. Although the public health framework of epidemiological surveys begins with a community population and proceeds to primary care medical practices and then to specialty mental health–treated populations, the reverse order has more frequently been the rule in the development of psychiatric epidemiology. This pattern is found in the rest of medicine, in which the most frequent progression is from clinical observation to the laboratory for more intensive study—laboratory, in this case, being large population groups. The choice of treated populations reflects the relative ease of defining this population group, the availability of highly trained personnel to conduct assessments, and the existence of extensive diagnostic and other related information in the medical records.

The impetus for proceeding from specialty mental health setting surveys to primary care surveys has been to make the population base more representative of the total community. In so doing, one can still retain the availability of highly trained physicians for case identification and longitudinal medical-record data to extend the pool of information about subjects beyond what is obtainable in cross-sectional studies. Selection bias may affect both the dependent variables of syndromes and diagnoses and the associated descriptive and independent risk factor variables that may lead to better understanding of etiology. Narrowing the population base from which the disorders are drawn to a clinical setting limits generalization to different populations. Likewise, the association of causal or descriptive variables with disorders may be confounded by the tendency of some variables to be strongly associated with use of services, as individuals may visit primary care practitioners or psychiatrists for reasons unrelated to whether they have a mental disorder. A few selected studies of historical importance are presented below. More-comprehensive reviews of psychiatric epidemiology studies are found in summary papers and monographs.

SPECIALTY MENTAL HEALTH SECTOR–TREATED POPULATIONS

Social Class and Mental Illness In the early 1950s August De Belmont Hollingshead and Fredrick Carl Redlich conducted one of the most prominent specialty mental health–treated prevalence surveys. By exhaustively surveying every mental health facility and private office practice psychiatrist who treated any patient in the New Haven area, the authors could define an overall mental disorder, 6-month treated prevalence rate of 8 per 1000 population in the community. The rates vary, however, by socioeconomic status. Treated prevalence rates ranged from 5 to 7 per 1000 in social classes I through IV, to a treated prevalence rate of 17 per 1000 in the lowest social class, V. Clinicians assessed these patients with a protocol report form that required unspecified clinical judgment methods and unspecified criteria for specific diagnoses. Social class was a principal descriptive variable used to stratify frequency of diagnoses and the frequency of treatment setting use. Although careful attention was given to controlling for potential confounding variables of age, sex, or mental disorder type, a strong association was found between higher social class, less severe disorders, and private office treatment settings. This association contrasted with the concentration of severe disorders in both the lower social classes and in the long-stay public mental hospitals. New cases coming into treatment settings (treated incidence) accounted for only one-eighth of the total 6-month prevalence, with a much narrower range of about 1.0 per 1000 for classes I through IV to 1.4 per 1000 for social class V. Incidence rates were less discrepant across the social class groups than prevalence rates, which indicates a longer duration of disorders in the lower social classes (prevalence/incidence = duration). This finding could be partially explained by the diagnostic distribution across social classes, which showed a gradient increase in the proportion of psychotic to neurotic disorders from class I through V.

In summary, this study may be seen as a combined descriptive and analytical epidemiological study of treated prevalence and incidence of mental disorders, in which the community population was examined only for social class and other demographic variables. As such it provided treatment rates and showed strong associations between social class and the frequency, severity, and treatment setting of patients with mental disorders. The absence of standardized assessment procedures in the total population made it impossible to determine if diagnoses were reliably assessed across treatment settings; if social class was associated with mental disorders or only with a treatment frequency; or if social class was causally related to presence of mental disorders or merely concentrated more direct risk factors within this population group.

Despite its methodological limitations, this study had a major impact on the collective social conscience of the day, illustrating that simple frequency and descriptive variable associations can have important administrative and health policy impacts while generating, but not testing, hypotheses about etiology. Implications of social class–determined treatment and the possibility that community characteristics might have an etiological role in mental disorders supported major public policy decisions in the United States to expand specialty mental health services and community mental health center legislation.

National Reporting Program Treated prevalence data are also available from the Mental Disorder National Reporting Program (NRP) transferred in 1992 from NIMH to the Center for Mental Health Services (CMHS) in the Substance Abuse and Mental Health Services Administration (SAMHSA). This program complements the U.S. Public Health Service National Health Survey, which consists of periodic health examinations and facility surveys conducted by the National Center for Health Statistics (NCHS) and other Public Health Service agencies. Components of the NRP include the state and county hospital annual census, the inventory of specialty mental health facilities, and the client/patient sample surveys drawn from the universe of facilities. Routine data on office-based psychiatrists are drawn from the NCHS National Ambulatory Medical Care Survey.

The annual census of state and county mental hospitals describes age, sex, and diagnostic composition of patients in these hospitals at the end of each calendar year and admissions during the year. A comprehensive inventory of all mental health facilities records information on their staffing and organizational characteristics of these facilities as well as the caseload and capacity, including number of episodes of care. *Episodes* are defined as residents at year's end, plus all admissions in the year. As some patients may be admitted more than once in a year, this indicator is slightly inflated over annual treated prevalence rates. Finally the sample patient surveys provide more-detailed information on patient characteristics, including diagnoses, length of stay, and type of treatment received.

Besides being the major source of national service use data, the NRP provides an invaluable source of longitudinal trend data on patients under treatment in the specialty mental health sector. For example, it documents the decrease in number of residents in state hospitals during the period of deinstitutionalization, from a 1955 high of 559,000 to a 1995 level of 69,000 (Fig. 5.1-1).

FIGURE 5.1-1 Number of residents in state hospitals (1950–1995). Patients in mental institutions, 1957–1967, NIMH. Additions and resident patients at end of year state and county mental hospitals by age and diagnosis, by state, United States, 1968–1995.

The shift in care from one type of facility to another can also be analyzed. In 1955, 1.7 million episodes of care were delivered, of which 49 percent were inpatient episodes in state and county mental hospitals, while by 1994, 9.3 million episodes were delivered and only 3 percent were inpatient episodes in state and county

mental hospitals; 12 percent were in general hospital psychiatric units, 6 percent in private psychiatric hospitals, 2 percent in veterans affairs v. medical centers, 1 percent in other inpatient settings, and 76 percent in all outpatient psychiatric services (Fig. 5.1-2).

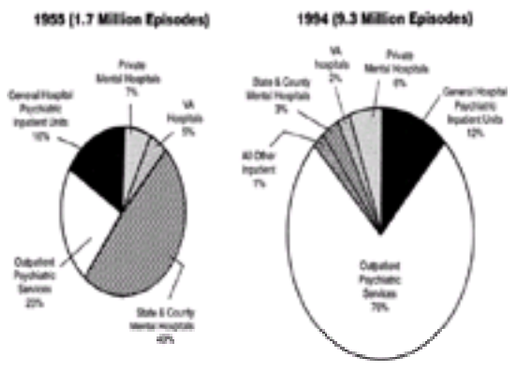

FIGURE 5.1-2 Forty year change in location of mental health treatment episodes (1955–1994). (Reprinted with permission from Redick RW, Witkin MJ, Atay JE, Manderscheid RW: *The Evolution and Expansion of Mental Health Care in the United States between 1955 and 1990*. Mental Health Statistical Note 210, Rockville, MD, 1994.)

Such information illustrates the value of treated prevalence data in describing the workings of the health care system and demonstrates how treated prevalence rates reflect administrative and policy decisions that affect patterns of treatment.

Primary Care Settings Because primary medical care settings reflect a much broader population base than specialty settings and still retain the potential for engaging patients in treatment, many epidemiological investigations have examined mental disorders in general medical populations. Various studies in the United States have indicated that at least 70 percent of the noninstitutionalized population uses general medical services over the course of a year, so general physicians are in a position to screen for mental disorders from a much larger proportion of the population than the 1 to 6 percent who may be seen in specialty mental health services in a year.

Recent studies of mental disorder in primary care patients have used contemporary diagnostic interviews to demonstrate that 15 to 30 percent of patients visiting primary care offices have a current mental disorder. However, some of these same studies suggest that few of these disorders are recognized, diagnosed, or treated by the primary care clinician. Such descriptive epidemiological studies in primary care practice settings have generated remarkable service system responses in the past decade. To address deficiencies in the recognition and treatment of depression, the Agency for Health Care and Policy Research (AHCPR) developed depression treatment guidelines for primary care physicians, and the American Psychiatric Association developed similar guidelines to assist psychiatrists with more complex cases. A promising collaborative primary care/psychiatrist treatment model that includes a patient outcome assessment/treatment compliance coordinator was developed at the University of Washington, Seattle, and the Rand Corporation, Santa Monica, California. The focus on both disability reduction and symptom reduction treatment outcomes may serve as a useful model for addressing the DALYs associated with major depression documented in the World Bank study. A major public health campaign was also developed by NIMH in 1985 to increase the awareness, recognition, and treatment of the most common of these conditions, depression. This effort, known as the Depression/Awareness, Recognition, and Treatment (DART), Project is providing educational materials to the general public, primary care clinicians, and mental health specialists. It has been replicated in the United States by the National Mental Health Association and in other countries such as Great Britain. Similar programs on panic disorder and eating disorders were also initiated in recent years by the NIMH.

Community Population Studies To overcome the problems of selection bias and unreliability of routine clinical diagnosis in treatment settings, epidemiologists rely most heavily on direct surveys of community residents. Prior to World War I, epidemiological studies used institutional records or key informants to generate prevalence estimates of mental disorders. More-recent studies have used direct interviews of community residents, with the information recorded on structured protocols by nonclinicians. Three studies conducted in the 1950s attempted to generate prevalence estimates of mental disorders in accordance with one or more of the major diagnostic practices in use at the time. Two of them (in Stirling County, Canada, and in midtown Manhattan) also examined specific hypotheses about the causal relationship of socioenvironmental factors to the occurrence of mental disorders.

Stirling County The study of Stirling County, directed by Alexander Leighton and continued by Jane Murphy sampled 1010 adults from the 20,000 residents of a rural county in Canada. Independent variables hypothesized to be causally related to mental disorders were cultural and community characteristics. The dependent variables, mental disorders defined in accordance with the newly developed DSM-I, were rated in terms of the presence or absence of 32 detailed symptom patterns, impairment levels, and the need for psychiatric attention. Trained fieldworkers surveyed this population sample with a structured psychiatric interview that was clinically evaluated later by two psychiatrists. Additional information was gathered from all county general practitioners, who supplied more-detailed medical, psychological, and social data about each sample member.

Estimates of the lifetime prevalence of these dependent variables included rates of 57 per 100 population for all DSM-I conditions, 24 per 100 for these conditions associated with significant impairment, and 20 per 100 for these conditions in need of psychiatric attention; this last rate is regarded as the most clinically meaningful estimate. Higher rates of disorders were found in communities characterized by social disintegration, although the exact causal factors within these gross environmental descriptive categories could not be specified.

Midtown Manhattan The midtown Manhattan study of Thomas Rennie, Leo Srole, and colleagues selected a sample of 1660 adult residents from an area of midtown Manhattan that had a population of 110,000 adults. The independent variables included various measures of stress, immigration status, social class, occupation, and marital status; the dependent variables measured impairment in adult life function on a 6-point gradient scale from “none” to “incapacitated.”

Psychologists and social workers used a structured psychiatric interview to obtain information from respondents, which was subsequently rated by two psychiatrists. The most celebrated findings were that 81.5 percent of the population had at least mild impairment from psychological symptoms, whereas 23.4 percent had significant impairment. Although correlations were found between sociodemographic and social stress variables and levels of impairment, one of the most significant results of this study was a debate about the dependent variable measure of mental health status. If less than 20 percent of the population could be identified as mentally healthy, the clinical usefulness of mental disorder definitions was open to question. The importance of using more-rigorous criteria for diagnoses was immediately apparent to other, more medically oriented epidemiologists.

Baltimore A third major study was undertaken in Baltimore, Maryland, where the entire noninstitutionalized population was sampled, including children. This was a two-stage morbidity survey. The first stage, household interviews by census interviewers, was followed by a second-stage clinical examination of 809 subjects, who were stratified by level of disability. General medical internists and pediatricians conducted a medical history and examination, followed by a psychiatrist's rating of all protocols that showed psychological symptoms or impairment related to mental disorders. Because this was a morbidity survey to determine the prevalence of individuals with chronic medical or mental disorders for purposes of improving services, no attempt was made to test etiological hypotheses. Diagnostic categories provided in the ICD were used for all physical and mental disorders, although no effort was made to determine the reliability or validity of assessments. A point prevalence rate of 10.9 percent was found for all ICD mental disorders, with 1.4 percent of the population exhibiting moderate or severe impairment.

Case-Control and Case-Register Studies Population samples are especially important for avoiding selection bias, but they are difficult to use for rare disorders or to generate hypotheses about possible risk factors. Case registers have been maintained for rare disorders that are serious and likely to come to medical attention, such as rare forms of cancer. Over the past three decades, case registers of psychiatric cases have been maintained at great effort in Monroe County (Rochester), New York, and abroad in Copenhagen, Denmark, and Mannheim, Germany. These have been especially useful in providing information about schizophrenia, one of the most difficult disorders to study in population surveys because it is relatively rare and difficult to diagnose accurately. However, privacy concerns and funding difficulties have jeopardized the viability of most total-population psychiatric case registers. Large public systems or private managed care firms with clinical responsibility for treatment may offer epidemiologists a similar research capacity in the future.

Danish Adoption Study One of the most prominent case-control studies in psychiatric epidemiology, that of Seymour Kety and colleagues, began in 1964. They

studied a defined population of 5483 adoptees registered from 1924 through 1947 in the city and county of Copenhagen, Denmark. At that time, the adoptees ranged from 17 to 40 years old. Of the total population, 507 were known to have been admitted to a psychiatric hospital, and 33 of this group were considered to have a diagnosis within a spectrum of schizophrenic disorders. An equal number of matched adoptees who had no history of mental hospitalization were identified for comparison.

A systematic search of available records was conducted to assess the rate of schizophrenia-like conditions in the biological relatives of these patients and comparison adoptees. Of the 150 biological relatives of the schizophrenic adoptees, 8.7 percent had a diagnosis of schizophrenia, compared with 1.9 percent of the 156 biological relatives of the comparison adoptees. The highly significant difference in these rates indicated a genetic contribution to the presence of schizophrenia in those with index cases, since environmental influences had been removed through adoption. This classic study was recently extended by examination of adoptees throughout the rest of Denmark.

An intensive worldwide search is under way for molecular genetic markers associated with schizophrenia in adoptive studies, twin studies, sibling pair studies, and informative pedigree studies. However, no genetic mechanisms that increase passive susceptibility or cause active expression of particular genes have been identified.

Experimental Epidemiology Prospective trials have been used to test the effect of treatments in identified patients, with random assignment of patients to experimental or control groups, to control for possible selection ias. Longitudinal designs allow comparison of expected outcome rates between the control and experimental subjects. Similar clinical trial designs are also being used to test preventive interventions in high-risk populations.

CONTEMPORARY EPIDEMIOLOGICAL STUDIES

Studies Using the Schedule for Affective Disorders and Schizophrenia As the SADS interview was being developed for clinical studies in the mid-1970s and shown appropriate for both patients and normal control individuals in those studies, investigators began testing the feasibility of its use in large, population-based studies of community residents and primary care patients. In a follow-up of 1095 adults first studied in New Haven in 1967, Jerome Myers and Myrna Weissman conducted interviews with 511 who were still available for study in 1975–76 and found that 15.1 percent of the sample had a definite RDC mental disorder at the time of interview. These results attracted special interest in the research community by demonstrating that community-based studies could be conducted using assessment instruments that produced clinically meaningful diagnoses.

Following this successful study, NIMH investigators designed a study for primary care settings, again using the SADS-I. This study demonstrated that nearly 28 percent of patients had a current RDC disorder and that fewer than 1 in 10 of these disorders had been recognized by primary care clinicians. Perhaps equally important, only 14 percent of this primary care population had at least minimal impairment (scored less than 70) on the Global Assessment Scale, and only 9 percent of the 28 percent with a mental disorder (about one-third) had some level of impairment.

Studies Using the Present State Examination Following successful use of the PSE in 12 centers of the WHO's International Pilot Study of Schizophrenia, in both developing and developed countries, European investigators began using the PSE as the core assessment instrument studies of the general population. Although the PSE itself does not generate diagnoses, it provides information that can be related to disease categories in the International Classification of Diseases (ICD) for the month preceding the examination. Some of the larger studies using the PSE as the core assessment instrument have been conducted in the Camberwell section of London; Edinburgh, Scotland; Canberra, Australia; and Athens, Greece.

More recently, the Office of Population Censuses and Surveys carried out the first nationally representative survey of psychiatric morbidity in Great Britain. The survey used a relatively brief (30 minute average) symptomatic screening instrument called the revised version of the Clinical Interview Schedule (CIS-R) to screen 10,000 community residents aged 16 to 64 years. To assess prevalence rates of functional psychosis, a psychosis-screening questionnaire was administered to cover symptoms of mania, thought disorder, paranoia, delusions, and auditory hallucinations in the past year. All respondents who answered this questionnaire positively, stated they or their doctor thought they had a psychotic illness, or were taking any antipsychotic medication were interviewed with the SCAN a few weeks later. To determine 1-year prevalence rates of addictive disorders, subjects were also interviewed with alcohol questions from the 1984 U.S. National Alcohol Survey and the drug use and dependence questions from the ECA study.

One-week (current) point prevalence rates of ICD-10 mood and anxiety (“neurotic”) disorders were determined from scoring algorithms of symptoms assessed by the CIS-R. A hierarchy, used to allocate individuals receiving more than one diagnosis, makes it difficult to identify prevalence rates of individual disorders lower on the following hierarchy which are independent of their co-occurrence with other disorders. The results of this major British National survey included the following diagnostic categories and prevalence rates:

ICD-10 Disorder	Rate per 100 in Past Week
Mixed anxiety and depressive disorder	7.7
Generalized anxiety disorder	3.1
Depressive episode	2.1
Phobias	1.1
Obsessive-Compulsive disorder	1.2
Panic disorder	0.8
Any neurotic disorder	16.0

In addition to the 16.0 percent with 1-week diagnosis identified by the CIS-R, the following 1-year rates were identified by means of the SCAN and separate substance use assessments:

Disorder	Rate per 100 in Past Year
Functional psychoses	0.4
Alcohol dependence	4.7
Drug dependence	2.2

Although much more detailed information is available from a series of surveys of private households, institutions, and homeless people, no annual prevalence rates for all disorders exist for comparison with the annual use of services. In addition, the policy decision to avoid use of the international CIDI instrument in favor of an older and less standardized British CIS-R instrument makes it difficult to make comparisons with U.S. surveys or other international surveys based on the DIS and the WHO CIDI.

NIMH Epidemiologic Catchment Area Program The ECA grew out of a combination of scientific developments and historical events within the mental health field. No scientific development was more critical than the operational criteria for diagnoses that produced the DSM-III and culminated in DSM-IV and ICD-10. A logical extension has used these criteria to construct standardized clinical instruments that reliably elicit information about requisite symptom patterns from research subjects.

In addition to developing operationalized diagnostic criteria and standardized instruments, the 1978 President's Commission on Mental Health demonstrated major gaps in our knowledge of specific mental disorder population rates and how such disorders are treated. Synthesis of information from the NIMH NRP, psychiatric case registers, general practice epidemiological surveys, the Baltimore morbidity survey, and various other data sources provided conservative estimates of overall annual prevalence rates and indicated where individuals with such disorders received care. This analysis of secondary epidemiological and services research data resulted in a mental disorder point prevalence rate estimate of 10 per 100 U.S. population, an annual incidence rate of 5 per 100 population, and an annual period prevalence rate of 15 per 100 population. Treated prevalence data indicated that any mental health specialist in the course of 1 year saw only 3.1 per 100 population and that most (54 percent of the 15 per 100 population) were seen exclusively in the general medical outpatient sector.

Fundamental deficits in knowledge of specific mental disorder frequency rates, the proportion of those treated and untreated, and the locus of treatment became readily apparent. The recommendation to proceed with a new wave of epidemiological and services research studies received favorable response from the NIMH leadership when the need was buttressed with evidence that the new diagnostic criteria and prototype standardized instruments could serve epidemiological

purposes.

Methodology The NIMH ECA program was a multisite epidemiological and health services research study that assesses mental disorder prevalence, incidence, and service use rates in about 20,000 community and institutional residents, using the DIS as a diagnostic assessment instrument. Stratified random probability samples were drawn from geographically defined community populations of at least 200,000 residents to obtain completed interviews from approximately 3000 adult (age 18 and over) community residents and 500 institutional residents. Five participating universities included Yale, Johns Hopkins, Washington University (St. Louis), Duke, and the University of California at Los Angeles. Several of these sites oversampled special populations, including elderly adults and minority groups.

After sample selection, trained lay interviewers used the DIS and service utilization questions to interview each subject. With a longitudinal design, each site conducted wave I and wave II face-to-face interviews (1 year apart) and one intervening telephone or face-to-face interview to assess service use and changes in symptom or diagnostic status. A total of 18,571 persons was interviewed in the first-wave community samples, and the sample was extended to 20,000 by those in prisons, nursing homes, and mental hospitals. U.S. estimates were made by first weighting each person in proportion to their probability of selection in the individual catchment area site and subsequently weighting each person in proportion to their representation in 36 subgroup defined by age, sex, and race-ethnicity characteristics in the 1980 U.S. census of adults age 18 and over.

To illustrate some of the point prevalence, incidence, and period prevalence rate measures discussed above, results are presented here from the two waves of data collection. More-detailed comparisons with data from the NCS are presented to show how different age groups and seemingly minor changes in diagnostic criteria and interview construction can affect community population prevalence rates.

Results The first column of Table 5.1-1 shows 1-month point prevalence from the initial interview, and rates of recurrent and new disorders over the year between initial and follow-up interview are shown in column two. The sum of these two rates (column three) is the 1-year period prevalence obtained from this prospective, longitudinal design. For any alcohol, drug, or mental disorder, 15.7 percent of the adult population had a mental or addictive disorder during the month before the wave-I interview. In the following year, 6.6 percent of this population developed one or more new disorders (none of whom had a lifetime history of a disorder), and 5.7 percent of the population (all of whom had a lifetime history but no current disorder at wave I) developed a recurrent or different disorder at wave II. The sum of incident and recurrent disorders yielded a total incidence rate of 12.3 percent, which combined with the 1-month point prevalence rate to produce an annual period prevalence of 28.1 percent for the adult population. Although the data were obtained from five different cluster areas, they were weighted by age, sex, and ethnicity to reflect the 1980 U.S. Census figures for both noninstitutionalized and institutional populations.

Information on both current prevalence and new and recurrent disorders over the course of 1 year tells more about the course of illness than information obtained from single-wave, cross-sectional designs. For example, the higher rate of new and recurrent disorders (5.6 percent) than current substance use disorders (3.8 percent) indicates a more chronic, relapsing clinical course than that for most other disorders. When the category of any disorder except alcohol or drug is considered, the data show a higher relative proportion of new disorders (6.3 percent) to recurrent disorders (2.7 percent) than that obtained when addictive disorders are included. Other disorders with this pattern include unipolar major depression and antisocial personality disorder; the latter is linked to substance use disorders. The episodic nature of disorders with a relatively low point-prevalence–to–incidence ratio results in significant rates of both incidence/relapse and recovery during the course of a year; thus maintaining a stable point-prevalence rate.

SUBSTANCE USE DISORDERS The 1-year prevalence of any addictive disorder was 9.5 percent, 7.4 percent had alcohol abuse or dependence and 3.1 percent had another drug abuse or dependence disorder. Almost one third of those with an addictive disorder, or 3.3 percent of the population, had a concurrent mental disorder during the same year. This dual diagnosis group has become a source of particular concern for treatment settings that often cannot provide comprehensive care for both conditions. To provide a better scientific base for understanding the relationship between the sequence and timing of the respective onsets of these disorders, the NIMH funded the NCS. Because the ECA had demonstrated that most substance use disorders occurred in the younger age groups, the NCS extended the age downward to 15 years and truncated the upper age range at 54 years. In addition, the NCS used a national probability sample (as opposed to the multisite sample used in the ECA) to obtain closer linkage to institutional and community service settings.

SCHIZOPHRENIA AND SCHIZOPHRENIFORM DISORDEF Either schizophrenia or schizophreniform disorders were identified in 1.1 percent of the population with the DIS approach, which probes each positive symptom answer about interference with life roles, relationship to drugs or alcohol, and help-seeking behavior. This rate is about half that found by the University of Michigan modified CIDI (UM-CIDI) approach of probing severity at the syndrome level rather than the symptom level. However, the NCS provided a clinical evaluation follow-up SCID interview and found a 1-year rate of 0.5 percent for nonaffective psychosis. Using a somewhat different two-stage approach, the Great Britain National Survey, with the SCAN as a follow-up interview, found a 1-year rate of 0.4 percent for schizophrenia. Different diagnostic criteria in the various DSM versions and the ICD-10 provides a source of continuing criterion variance across these studies. Standardizing epidemiological approaches for screening and confirming diagnoses of schizophrenia would be particularly helpful in future international studies. The growing interest in identifying probands for genetic studies has led NIMH-supported investigators to develop an even more comprehensive Diagnostic interview for Genetic Studies for confirmation of the diagnosis before genetic material is obtained and stored for geneotyping analyses.

AFFECTIVE (MOOD) DISORDERS The 1-year prevalence for any affective disorder was 9.5 percent; 1.2 percent met criteria for a bipolar disorder, 5.0 percent criteria for unipolar major depression, and 5.4 percent those for dysthymia. Unipolar depression has the highest annual incidence-or-recurrence rate (3.2 percent) of the affective disorders, compared with a 1.8 percent point-prevalence rate. In contrast, bipolar disorder has about equal rates of point-prevalence (0.6 percent) and incidence or recurrence (0.5 percent). Dysthymia requires a 2-year duration of symptoms and was assessed on a lifetime basis for the ECA study. However, a substantial number of subjects (2.1 percent) developed a new or recurrent episode and were not included among the 3.3 percent of wave-I respondents who were positive. Among the 5.4 percent of the population with dysthymia, 40 percent had a double depression in that they met criteria for another affective disorder during the year. Comparisons of the ECA and NCS rates for mood disorders show similar but slightly higher rates of any mood disorder in the NCS, although the differences in diagnostic interview construction tend to produce a higher proportion of unipolar major depression than dysthymia.

ANXIETY DISORDERS The 1-year prevalence of any anxiety disorder was 12.6 percent, composed primarily of phobic disorders (10.9 percent). More-detailed analyses are also available for the simple phobias, agoraphobia, and social phobia. Panic disorder was found in 1.3 percent of the population, with a slightly higher incidence-or-recurrence rate than point-prevalence rate. Obsessive-compulsive disorder was found in 2.1 percent of the population—a disorder not assessed in the NCS. Since several anxiety disorders, including posttraumatic stress disorder and generalized anxiety disorder, were not covered in all ECA sites, data from these disorders are not part of the public use core data set. However, these disorders were assessed in the NCS with a 1-year prevalence of 3.6 percent for posttraumatic stress disorder, and generalized anxiety disorder was found in 3.4 percent of adults aged 18 to 54 years in an NIMH analysis of the epidemiology of anxiety disorders from both ECA and NCS surveys.

SOMATIZATION DISORDER Somatization disorder is closely related to Briquet's syndrome in the St. Louis research criteria. It was the only somatoform disorder covered in the ECA and was not included in the NCS survey. Found in 0.2 percent of the population in 1 year, it is found predominantly in females who not only visit general medical physicians for physical symptoms, but 70 percent of whom also receive mental health services from either general medical or specialty mental health providers in 1 year.

ANTISOCIAL PERSONALITY DISORDER Antisocial personality disorder, the only Axis II disorder covered in the ECA, was found in 1.5 percent of the population, predominantly males. Criteria for this disorder include the accumulation of some conduct disorder symptoms before age 15 years with other symptom requirements after age 18. Although it is defined as a chronic disorder, there was a relatively high incidence rate, which was most likely linked to a recurrent substance abuse episode that is one criteria of this disorder.

SEVERE COGNITIVE IMPAIRMENT Although cognitive impairment is not a diagnostic category, the prevalence rate of scores between 0 and 17 on the Mini-Mental State Examination was reported to identify populations with a high probability of having organic mental disorders. A 1-year incidence rate of severe cognitive impairment of 1.0 percent provides information on the rate at which the adult population develops cognitive dysfunction in 1 year. Combining this rate with a point prevalence rate of 1.7 percent at the first interview, yields a 1-year prevalence of 2.7 percent. However, separate analyses have shown that only 0.9 percent of the population identified at wave I continued to have severe impairment for 1 year, consistent with chronic dementias such as dementia of the Alzheimer's type or vascular dementia. Slightly less than half of those with severe cognitive impairment at wave I (0.8 percent of the population) showed substantial improvement from more transient conditions.

Services research information, collected concurrently in the ECA with diagnostic information, permits estimates of both 1-year treated prevalence of these disorders and the administrative prevalence (penetration rates), which indicate the proportion of the population using any mental health services regardless of diagnosis. Figure 5.1-3 shows the relationship between the 28.1 percent of the population with any mental or addictive disorder during the year and the 14.7 percent of the population

receiving any mental health services during that year. Of the total number with any 1-year mental or addictive disorder, 28.5 percent (8 per 100 population) received some mental health services during the year. An additional 6.7 per 100 population also received some mental health services during this period, although they were below full diagnostic threshold. Although 45 percent of those using some mental health service during the year did not have a current disorder, 80 percent of the outpatients and 95 percent of the inpatients had a prior lifetime diagnosis subthreshold symptoms of severe disorders associated with significant morbidity or both in other analyses. Hence most of the total 14.7 percent using some mental health services can be considered to have some need for services.

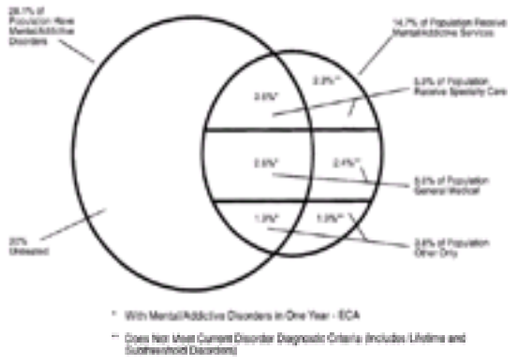

FIGURE 5.1-3 Annual prevalence of mental and addictive disorders and services. (Reprinted with permission from Regier DA, Narrow WE, Rae DS, Manderscheid RW, Locke BZ, Goodwin FK: The defacto U.S. mental and addictive disorders service system: Epidemiologic Catchment Area prospective one-year prevalence rates of disorders and services. Arch Gen Psychiatry *50:*85, 1993.)

Specific detailed information is available from the ECA studies on service use by diagnostic category in various segments of the “defacto U.S. mental and addictive disorders service system.” About 5.9 percent of the U.S. adult population used specialty mental health services, and 6.4 percent sought mental health services from general medical physicians, for an unduplicated total of 10.9 percent using such services in the health system. Other human service professionals from social service agencies and the clergy were contacted by 3.0 percent of the population for “emotions, nerves, alcohol, or drug abuse problems.” A voluntary support network, including self-help groups, family, and friends, was also identified as the source of specific mental health support by 4.1 percent of survey respondents. The hierarchy of services shown in the figure shows that 5 percent of the population received their only mental health services from general medical physicians, and 3.8 percent received their only mental health services from human service professionals or their voluntary support network.

COMORBIDITY

Results from the ECA program demonstrated concomitant disorders were more common than expected from their prevalence rates. Of particular importance was the extensive overlap between mental disorders and alcohol or other substance use disorders. This finding led the three NIH institutes dealing with these conditions to sponsor a national survey of mental disorders co-occurring with alcohol and other substance use disorders, the NCS.

A sample of 8098 respondents aged 18 to 55 years was interviewed from 1990 to 1992 with the UM-CIDI (modified by investigators at the University of Michigan) which reinforced the instructions to subjects to try to recall their past experiences with symptoms relevant to the disorders. Higher rates of disorders resulted from the single interview in the NCS than from the first-wave interview of the ECA. Lifetime rates of mental disorders covered on the UM-CIDI for all respondents were 48.0 percent (versus 32.7 percent in the ECA wave I), and 1-year rates were 29.5 percent (versus 21.8 percent in the ECA wave I). However, when two waves of ECA data were examined and adjustments were made for common age distributions, lifetime rates (46.9 percent) and annual rates (29.8 percent) were more compatible with those found in the NCS.

Despite substantial similarities in the methods and diagnostic criteria of the ECA and NCS studies, discrepancies in prevalence rates between these similar population surveys were observed. These discrepancies and a growing clinical and health policy interest in separating clinically important disorders needing treatment from less severe syndromes prompted a more careful examination of the causes for rate differences between these studies.

A detailed collaborative analysis was undertaken to determine the potential contributions of seemingly minor differences between the two studies in demographic (including age and urban/rural residence) characteristics, use of DSM-III and DSM-III-R criteria, and DIS and UM-CIDI interview construction. By controlling for common demographic variables, standardizing the weighting of respective population groups by age, sex, and ethnicity groups to the 1990 U.S. census, and conducting a detailed comparison of questions in both surveys that addressed DSM-III criteria, rates for any disorder and for selected disorders could be compared. Table 5.1-2 displays the results of this recently published analysis comparing 1-year and lifetime rates for those 18 to 54 years for the ECA I wave, ECA II wave, and NCS I wave.

Disorder	ECA Wave I DSM-III (N = 11,432)	ECA Wave II DSM-III (N = 9,085)	NCS DSM-III-R (N = 7,999)
Any 12-month disorder	24.1 (0.5)	29.8 (0.6)	28.5 (1.0)
Any lifetime disorder	36.1 (0.6)	46.9 (0.7)	48.0 (1.1)
Any substance use or dependence			
12 month	9.5 (0.4)	10.5 (0.4)	11.5 (0.5)
Lifetime	19.9 (0.5)	24.3 (0.6)	28.1 (1.0)
Alcohol dependence			
12 month	4.1 (0.3)	4.4 (0.2)	7.4 (0.5)
Lifetime	8.6 (0.4)	11.3 (0.4)	14.9 (0.7)
Drug dependence			
12 month	2.0 (0.2)	2.4 (0.2)	2.9 (0.3)
Lifetime	4.8 (0.3)	6.4 (0.3)	7.9 (0.5)
Any affective disorder			
12 month	7.0 (0.3)	10.1 (0.4)	11.1 (0.7)
Lifetime	9.3 (0.4)	14.9 (0.4)	19.7 (0.7)
Major depressive episode			
12 month	4.7 (0.3)	6.4 (0.3)	10.1 (0.7)
Lifetime	7.2 (0.3)	12.5 (0.4)	17.3 (0.7)
Dysthymia—lifetime	3.6 (0.2)	5.5 (0.3)	6.7 (0.4)
Any anxiety disorder			
12 month	9.9 (0.4)	11.8 (0.4)	15.3 (0.7)
Lifetime	14.2 (0.4)	19.2 (0.5)	22.8 (0.8)
Panic disorder			
12 month	1.1 (0.1)	1.5 (0.1)	2.2 (0.3)
Lifetime	1.9 (0.2)	2.8 (0.2)	3.6 (0.3)
Social phobia			
12 month	1.6 (0.1)	2.1 (0.2)	7.4 (0.4)
Lifetime	2.5 (0.2)	3.7 (0.3)	13.3 (0.7)

Table 5.1-2 Comparison of One-Year and Lifetime Prevalence Rates Limited to Common Age Range of 18–54 Years (ECA and NCS)

This analysis shows that controlling for common age groups (18 to 54 years) brought results from the two surveys much closer together, despite differences in the diagnostic criteria and assessment instruments. One-year rates for any disorder were 24.1 percent from the retrospective ECA wave-I interview, 29.8 percent from the prospective wave-II ECA analysis, and 28.5 percent from the retrospective NCS single-wave interview. The lifetime rate for any disorder from the two ECA waves combined was 46.9 percent compared with the NCS rate of 48.0 percent. In the context of current health policy issues relating to medical necessity determinations in managed care, these relatively high rates have emphasized the need for greater attention to the clinical significance of these disorders and their implied need for treatment.

The NCS found generally higher rates for both annual and lifetime prevalence, particularly for substance dependence, major depression, and social phobia. However, differences between any affective disorder rate and any substance use disorder rate are not statistically significant. This emphasizes that the NCS instrument identified more symptoms among respondents and tended to move subjects from dysthymia to major depression and from substance abuse into dependence criteria. In the case of social phobia, a clear difference existed in the criteria themselves; DSM-III-R allowed avoidance or distress on exposure, while DSM-III required only avoidance. Because of the somewhat looser diagnostic criteria and additional stem questions for depression and anxiety disorders, the NCS also tended to show more comorbidity between all mental and addictive disorders. This reflects the structural difference in the UM-CIDI which placed stem (criteria A) questions for affective, addictive, and anxiety disorders at the beginning of the entire interview rather than at the beginning of each diagnostic section. This structural change was intended to prevent interviewees from recognizing that a positive response to stem questions resulted in a substantial number of additional questions, which the subject could find fatiguing later in the interview.

As a result of these and other analyses, an international group of investigators is working collaboratively with the WHO to revise the CIDI, standardizing epidemiological assessment techniques to produce more comparable rates in similar population groups. The rate of schizophrenia/schizophreniform disorder from the UM-CIDI was somewhat higher than that found from the ECA. However, a decision was made to reinterview all positive subjects in the NCS with the SCID. The reported 1 year rates of schizophrenia from the reinterview were 0.5 percent for the NCS (versus 2.8 percent who screened positive for possible psychosis on the UM-CIDI, and the 1.5 percent rate reported for the ECA).

An important issue raised by these studies is whether current diagnostic criteria are sufficiently specific to identify the full range of psychopathology—particularly in community settings where perceived disability and need for care are lower than in clinical settings. Approaches to addressing this issue include adding disability assessments to disorder assessments and improving the operational approach to determining the clinical significance of symptom clusters and syndromes. Pressure to address these issues continues from the health policy and insurance fields, which are particularly interested in the epidemiology of clinically significant disorders in need of treatment. However, patients or community residents with less severe disorders or syndromes may continue to be populations for primary or secondary prevention initiatives.

HEALTH POLICY ISSUES

Data from the ECA have been used as a basis for estimating the total direct and indirect cost of mental disorders to the United States. For 1990 the direct (treatment) cost of mental disorders was estimated to be $69.3 billion, with $78.5 billion in indirect (productivity loss) cost for a total cost of $147.8 billion. Although direct treatment cost estimation requires detailed information on service delivery costs, the cost of not treating disorders requires untreated prevalence estimates of the type available only from community population epidemiological studies. Such estimates in the future should require more-precise estimates of treatment need that are not necessarily isomorphic with DSM-IV or ICD-10 disorder prevalence rates.

Direct treatment cost findings can be related to treated prevalence rates and were initially used to estimate the costs of providing parity in coverage of severe mental disorders and physical disorders. Three health policy reports from the National Advisory Mental Health Council to the Senate Appropriations Committee on insurance parity and managed behavioral health care issues have used this epidemiological and services research data.

One of the most significant health policy documents since World War II was the Global Burden of Disease study of the World Bank and WHO, which developed DALYs to assess morbidity and mortality for all illnesses. Estimates of the incidence, prevalence, and duration of mental disorders in the United States and many other countries relied on data derived from studies using the DIS and CIDI. Future confirmation studies must add better measures of disability, such as the WHO DAS, to match prevalence rates of disorders with associated severity, duration, and levels of disability. However, current epidemiological data show the high levels of disability associated with mental and addictive disorders relative to other physical disorders. The use of this common metric for resource allocation decisions affecting services and research funding remains to be seen. Proposals for alerting ministers of health to the importance of such findings appear in World Mental Health, whose endorsement by the United Nations led to WHO sponsorship of a Nations for Mental Health program to destigmatize and increase international funding for mental health services.

Similarly, data on childhood and early adolescent onset of many disorders increased efforts to improve the delivery of mental health services to children and adolescents in the early 1990s. However, definitive epidemiologic data on rates of disorders, service use, and costs remains an unfulfilled research and public policy priority.

FUTURE DIRECTIONS

Recent advances in the fundamental scientific and technical underpinnings of mental disorder epidemiological research include the development of operational criteria that facilitate reliable application in large population groups. Although questions remain about the validity of DSM-IV diagnoses based largely on manifestational criteria instead of causal criteria, the explicit nature of these criteria permits empirical hypothesis testing. Removing presumed etiological criteria from mental disorder diagnoses has facilitated research on etiological hypotheses. Epidemiological studies using DSM-IV criteria will produce external validating criteria to assess the homogeneity of biological, demographic, social, and clinical course characteristics of groups identified with specific disorders. Stability of mental disorder rates in populations with similar characteristics will support the validity of the diagnoses, whereas variations in rates may lead to additional subtyping or even etiological clues.

An excellent cross-cultural epidemiology study was recently conducted by William Vega and coworkers with Mexican immigrants to the United States, native-born adults of Mexican origin, and current Mexican citizens. This Mexican American Prevalence and Services Survey used the UM-CIDI and found a lifetime DSM-III-R mental disorder prevalence rate of only 24.9 percent among immigrants, compared with a 48.1 percent lifetime prevalence among U.S.-born respondents. Although marked differences existed (particularly in substance use disorders), a search for the environmental and cultural causes for such dramatic differences in prevalence rates should provide the basis for careful follow-up investigations.

Improvements in nosological and case-identification tools for epidemiological research will necessitate extending the application of epidemiological methods to new population groups, including those in other cultures. Further refinements in the basic tools for childhood disorders and culture-specific disorders should expand research opportunities in these understudied groups. After 15 years of concentrated effort, investigators collaborating with NIMH have recently developed a Diagnostic Interview Schedule for Children (DISC) and field-tested it in four sites.

When the intrinsic research base of epidemiology is more secure, the interface with such other areas as service systems, clinical services, and clinical and neurobiological research can be extended. Many potential etiological or clinical service–improvement risk factors that emerge from other research areas will require validation in large population studies that use epidemiological research designs.

The full potential of psychiatric epidemiology for public health purposes remains to be realized. Improved understanding of the epidemiology of mental disorders should facilitate allocation of resources to mental health services, broaden the safety and effectiveness of specific treatments for mental disorders, and result someday in effective and reduction in the onset of new cases of these illnesses.

SUGGESTED CROSS-REFERENCES

Other quantitative and experimental methods in psychiatry are discussed in the other sections in Chapter 5. The classification of mental disorders is discussed in Section 9.1. Schizophrenia is the subject of Chapter 12; mood disorders are covered in Chapter 14; anxiety disorders are the focus of Chapter 15; substance-related disorders are discussed in Chapter 11; somatization disorder is discussed in Chapter 16; and personality disorders are the subject of Chapter 54.

5.2 STATISTICS AND EXPERIMENTAL DESIGN

ROBERT M. KAPLAN, PH.D., AND IGOR GRANT, M.D., F.R.C.P.(C)

Descriptive statistics are used to organize, summarize, and describe observations; they might include summaries of symptom checklist scores for a selected group of patients with neuroses, a summary of neuroendocrine data for a group of schizophrenia patients, or a descriptive summary of the correlation between watching television violence and behaving aggressively. In addition to descriptive statistics, *inferential statistics* are required for drawing general conclusions about populations on the basis of samples. There are many uses of inferential statistics. In some cases statistical inference is used to make statements about the eating habits of American citizens on the basis of study of a small fraction of the American people. In other instances, inferential statistics are used to decide whether to attribute differences between two groups to chance or to nonchance factors.

This section is addressed to the "informed consumer" rather than the expert biomathematician, and covers a broad range of topics.

DESCRIPTIVE STATISTICS

Descriptive statistics are used to summarize observations and to place these observations within context. The most common descriptive statistics include measures of central tendency and measures of variability.

There are three commonly used measures of central tendency: the mean, the median, and the mode. The *mean* is the arithmetic average, the *median* is the point representing the 50th percentile in a distribution, and the *mode* is the most common score. Sometimes each of these measures is the same; on other occasions, the mean, the median, and the mode can be different.

The mean, median, and mode are the same when the distribution of scores is normal. The *normal distribution*, shown in Figure 5.2-1, is a theoretical distribution of scores that is symmetrical. Under most circumstances the mean, median, and mode will not be exactly the same. The mode is most likely to misrepresent the underlying distribution and is rarely used in statistical analysis. The mean and the median are the most commonly reported measures of central tendency. The major consideration in choosing between them is how much weight should be given to extreme scores. The mean takes into account each score in the distribution; the median finds only the halfway point.

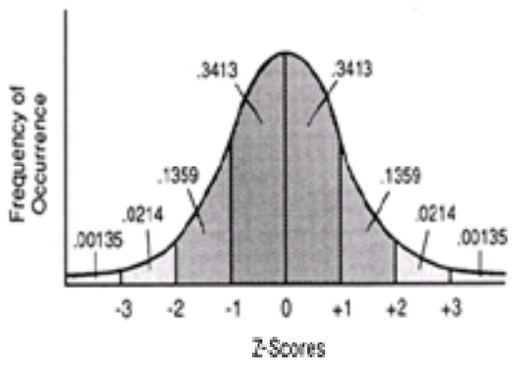

FIGURE 5.2-1 The normal distribution and areas under the normal curve for *Z*-scores from –3 to +3.

Table 5.2-1 shows how the mean and median might have very different values. The table lists the weights of two groups of college women. There are five women in each group, but four of them are in both groups (Sally, Sue, Leslie, and Dana). The fifth member in Group 1 is Allison and in Group 2 is Bertha. These two individuals have very different weights. As the example shows, the median is exactly the same in the two groups. However, the estimation of the mean is affected by the addition of the extreme case. Because the mean best represents all subjects and because of desirable mathematical properties, the mean is typically favored in statistical analysis.

Group 1		Group 2	
Woman	Weight	Woman	Weight
Sally	95	Sally	95
Sue	100	Sue	100
Leslie	105	Leslie	105
Dana	110	Dana	110
Allison	115	Bertha	275
Mean ($\bar{X}$) = 105		Mean ($\bar{X}$) = 137	
Median (Md) = 105		Median (Md) = 105	

Table 5.2-1 Mean and Median for Weights (in Pounds) of Two Groups of College Women

Despite the advantages of the mean, there are also some advantages to the median. In particular, the median disregards outlier cases, whereas the mean moves further in the direction of the outliers. Thus, the median is often used when the investigator does not want scores in the extreme of the distribution to have a strong impact. The median is also valuable for summarizing data for a measure that might be insensitive toward the higher ranges of the scale. For instance, a very easy test may have a ceiling effect but does not show the true ability of some test-takers. A ceiling effect occurs when the test is too easy to measure the true ability of the best students. Thus, if some scores stack up at the extreme, the median may be more accurate than the mean. If the high scores had not been bounded by the highest obtainable score, the mean may actually have been higher.

The mean, median, and mode are exactly the same in a normal distribution. However, not all distributions of scores have a normal or bell-shaped appearance. The highest point in a distribution of scores is called the *modal peak*. A distribution with the modal peak off to one side or the other is described as *skewed*. The word skew

literally means “slanted.”

The direction of skew is determined by the location of the tail or flat area of the distribution. Positive skew occurs when the tail goes off to the right of the distribution. Negative skew occurs when the tail or low point is on the left side of the distribution. Figure 5.2-2 illustrates the normal distribution, a distribution that is positively skewed and one that is negatively skewed.

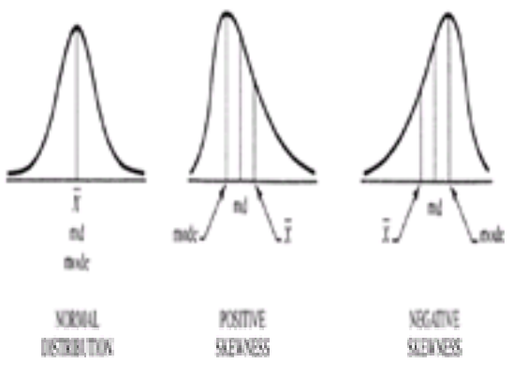

FIGURE 5.2-2 Examples of normal distribution, positive skewness, and negative skewness.

The mode is the most frequent score in the distribution. In a skewed distribution, the mode remains at the peak whereas the mean and the median shift away from the mode in the direction of the skewness. The mean moves furthest in the direction of the skewness, and the median typically falls between the mean and the mode. The relative positions of the mean, median, and mode in normal and skewed distributions are shown in the figure.

Variability Measures of central tendency, such as the mean and median, are used to summarize information. They are important because they provide information about the average score in the distribution. Knowing the average score, however, does not provide all the information required to describe a group of scores. In addition, measures of variability are required. The simplest method of describing variability is the *range*, which is simply the difference between the highest score and lowest score. Another statistic, known as the *interquartile range*, describes the interval of scores bounded by the 25th and 75th percentile ranks; the interquartile range is bounded by the range of scores that represent the middle 50 percent of the distribution.

In contrast to ranges, which are used infrequently in statistical analysis, the variance and standard deviation are used commonly. Since the mean is the average score in a distribution, the sum of the deviations around the mean will always equal zero. Yet, in order to understand the characteristic of a distribution of scores, some estimation of deviation around the mean is important. The sum of these deviations will always equal zero. However, the squared deviations around the mean can yield a meaningful index. The *variance* is the sum of the squared deviations around the mean divided by the number of cases. It is described by the formula:

$$\sigma^2 = \sum \frac{(X_i - \bar{X})^2}{N}$$

where s^2 is the variance, s means sum, X_i is the score of the i_{th} case, ($\bar{X}$) is the mean for the population, and N is the number of observations.

The variance is a very useful statistic and is commonly employed in data analysis. However, its calculation requires finding the squared deviations around the mean rather than the simple or absolute deviations around the mean. Thus, when the variance is calculated, the resulting calculation will be in units that are the natural squared units. Taking the square root of the variance puts the observations back into their original metric. The square root of the variance is known as the *standard deviation*. The standard deviation is an approximation of the average deviation around the mean. Although the standard deviation is not technically equal to the average deviation, it gives an approximation of how much the average score deviates from the mean.

Samples and Populations The methods discussed so far describe populations. *Population* is defined as the entire collection of a set of objects, people, or events, in a particular context. Population refers to the collection of all items upon which statements will be based. This might include all patients with schizophrenia in a particular hospital, or all depressed individuals in a certain community.

In statistics, means and standard deviations for populations are typically estimated from observations taken from samples. A *sample* is a subset of observations selected from the population. It might be unusual for an investigator to describe only patients with schizophrenia in a particular hospital and it is unlikely that an investigator will measure every depressed person in a community. More frequently, statements are made about populations on the basis of samples. Using a random and unbiased sample of individuals from a community, the mean of the population can be estimated. The formulas for estimating the standard deviations for samples differ slightly from those used for populations. The denominator in the radical N-1 is used for sample statistics instead of N, which is used for population statistics. Thus, the definitional formula for the standard deviation of a sample is:

$$S = \sqrt{\frac{\Sigma(X_i - \bar{X})^2}{N - 1}}$$

The computational formula for a sample standard deviation is:

$$S = \sqrt{\frac{\Sigma X^2 - \frac{(\Sigma X)^2}{N}}{N - 1}}$$

The computational formula does not require the calculation of each deviation from the mean. Instead, it uses the sum of the squared scores (å X_2) and the square of the summed scores (åX_2). These can be easily obtained using spreadsheet programs for microcomputers. Notice also that the Arabic “S” is used instead of the Greek “å.” It is customary to use Arabic characters for populations and Greek for samples.

Standardized Scores One of the problems with means and standard deviations is that their meanings are not independent of context. For example, a mean of 57.6 means little unless the score is known. The *Z*-score is a transformation into standardized units that provides a context for the interpretation of scores. The *Z*-score is the difference between the score and the mean, divided by the standard deviation.

$$Z = \frac{X - \bar{X}}{S}$$

In other words, a *Z*-score is the deviation of a score, X, from the mean, $\bar{X}$, expressed in standard deviation units. If a score is equal to the mean, its *Z*-score is zero. Consider the example of a score of 4 taken from a sample with a mean of 5.75 and a standard deviation of 2.11. The *Z*-score would be:

$$Z = \frac{4 - 5.75}{2.11}$$
$$= \frac{-1.75}{2.11}$$
$$= -.83$$

Thus, the observed score (4) is .83 standard deviations below the average score or that the score is below the mean, but its difference from the mean is slightly less than one standard deviation. In other words, it deviates from the mean less than the average deviation.

Now we can consider the standard normal distribution because of its central importance in statistics. The normal distribution is derived from binomial probability. A binomial event has one of two outcomes—like the results of a coin flip. Using an infinite number of binomial events, a probability distribution can be generated. Figure 5.2-1 shows the theoretical frequency distribution of "heads" in an infinite series of coin flips.

Most often, the units on the x axis of the normal distribution are in *Z*-units. Any variable transformed into *Z*-units will have a mean of 0 and a standard deviation of 1. Figure 5.2-1 shows the areas under the normal curve associated with these *Z*-units. For example, 34.13 percent or .3413 of the cases fall between the mean and 1 standard deviation above the mean. Since 50 percent of the cases fall below the mean, if a score is one standard deviation above the mean it will be in the 84th percentile rank (50 + 34.13 = 84.13). A score that is 1 standard deviation below the mean would be in the 16th percentile (50 – 34.13 = 15.87).

Translation of *Z*-scores into percentile ranks is accomplished using a table for the standard normal distribution. Certain *Z*-scores are of particular interest in statistics and psychological testing. The *Z*-score 1.96 represents the 97.5th percentile in a distribution whereas –1.96 represents the 2.5th percentile. A *Z*-score of less than –1.96 or greater than +1.96 falls outside of a 95 percent interval bounding the mean of the *Z*-distribution. Some statistical definitions of abnormality view these defined deviations as cutoff points. Thus, a person who is more than 1.96 *Z*-scores from the mean on some attribute might be regarded as abnormal. In addition to the interval bounded by 95 percent of the cases, the interval including 99 percent of all cases is also commonly used in statistics.

There are a variety of other systems by which raw scores can be transformed to give them more intuitive meaning. One common system sets the mean at 50, to correspond to the 50th percentile, and the standard deviation is set at 10. These scores are usually called *T*-scores the same as standard scores (*Z*-scores), except that the mean in the *T* system is 50 rather than 0 and the standard deviation is 10 rather than 1. Indeed, a *Z*-score can be transformed to a *T*-score by applying a linear transformation.

$$T = 10z + 50$$

The *T*-score system is commonly used in psychological tests. For example, the Minnesota Multiphasic Personality Inventory (MMPI) uses *T*-scores. Thus, a score of 60 on any subscale is one standard deviation above the mean. A score of 60 places an individual in approximately the 85th percentile relative to the standardization sample. The score of 70 or above is more than two standard deviations above the mean and thus might be considered unusual in relation to the normative population. Other simple transformations of the *Z*-score are also in common use, for example, the SAT has a mean of 500 and a standard deviation of 100.

Confidence Intervals In most statistical inference problems the sample mean is used to estimate the population mean. Each sample mean is considered to be an unbiased estimate of the population mean. Although the sample mean is unlikely to be exactly the same as the population mean, repeated random samples will form a sampling distribution of sample means. The mean of the sampling distribution is an unbiased estimate of the population mean. However, taking repeated random samples from the population is also difficult and expensive. Instead, it is necessary to estimate the population mean based on a single sample; this is done by creating an interval around the sample mean.

The first step in creating this interval is finding the *standard error of the mean*. The standard error of the mean is the standard deviation divided by the square root of the sample size. Statistical inference is used to estimate the probability that the population mean will fall within some defined interval. Because sample means are distributed normally around the population mean, the sample mean is most probably near the population value. However, it is possible that the sample mean is an overestimate or an underestimate of the population mean. Using information about the standard error of the mean, it is possible to put a single observation of a mean into context.

The ranges that are likely to capture the population mean are called *confidence intervals*. Confidence intervals are bounded by *confidence limits*. The confidence interval is defined as a range of values with a specified probability of including the population mean. A confidence interval is typically associated with a certain probability level. For example, the 95 percent confidence interval has a 95 percent chance of including the population mean. A 99 percent confidence interval is expected to capture the true mean in 99 of each 100 cases. The confidence limits are defined as the values for points that bound the confidence interval.

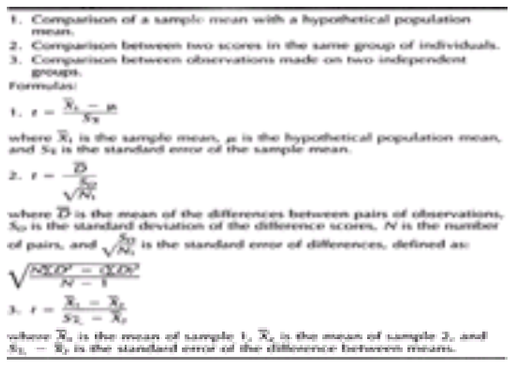
Creating a confidence interval requires a mean, a standard error of the mean, and the *Z*-value associated with the interval. It is accomplished using the formula:

$$CI = \overline{X} \pm Z_{\alpha} S_X$$

Consider the 95 percent confidence interval. This is obtained by taking the mean ± the standard error of the mean multiplied by the *Z*-score for the 95 percent interval, or 1.96.

If smaller sample sizes are involved, it may be advisable to use another sampling distribution instead of the standard normal distribution. For example, it is common to use the t-distribution for creation of confidence intervals for smaller samples.

***t*-tests** In experimental sciences, comparisons between groups are very common. Usually, one group is the treatment, or experimental group, while the other group is the untreated, or control group. If patients are randomly assigned to these two groups, it is assumed that they differ only by chance prior to treatment. Differences between groups after the treatment are usually used to estimate treatment effect. The task of the statistician is to determine whether any observed differences between the groups following treatment should be attributed to chance or to the treatment. The *t*-test is commonly used for this purpose. There are actually several different types of *t*-tests and they are summarized in Table 5.2-2. The table also shows the formulas used to calculate the *t*-values.



1. Comparison of a sample mean with a hypothetical population mean.
2. Comparison between two scores in the same group of individuals.
3. Comparison between observations made on two independent groups.

Formulas:

1. $t = \frac{\overline{X}_1 - \mu}{S_{\overline{X}}}$

where $\overline{X}_1$ is the sample mean, μ is the hypothetical population mean, and $S_{\overline{X}}$ is the standard error of the sample mean.

2. $t = \frac{\overline{D}}{\frac{S_D}{\sqrt{N_1}}}$

where $\overline{D}$ is the mean of the differences between pairs of observations, S_D is the standard deviation of the difference scores, N is the number of pairs, and $\frac{S_D}{\sqrt{N_1}}$ is the standard error of differences, defined as:

$$\sqrt{\frac{N\Sigma D^2 - (\Sigma D)^2}{N - 1}}$$

3. $t = \frac{\overline{X}_1 - \overline{X}_2}{S_{\overline{X}_1 - \overline{X}_2}}$

where $\overline{X}_1$ is the mean of sample 1, $\overline{X}_2$ is the mean of sample 2, and $S_{\overline{X}_1 - \overline{X}_2}$ is the standard error of the difference between means.

Table 5.2-2 Types of *t*-Tests

Most statistical tests have a common logic in that all of them are based on a ratio of observed to expected differences. The top half of the ratio is the observation. For the *t*-test the numerator is usually the observed difference between means. The denominator of the ratio is the standard error for that same observation. This is an estimate of the extent to which the means would be expected to differ by chance alone. The standard error of the mean is the standard deviation of the sampling distribution of sample means. The standard error of the mean is an approximation of the average deviation that would be expected in estimating the population mean

from a sample. Consider the *t*-test for differences between independent means. In this test the numerator is the observed difference between means of independent samples; the bottom half of the equation is the standard error of the differences between means. The observed differences between means are divided by an approximation of the average deviation that would be expected to result from sampling error. If the ratio is large, then the numerator—the observed deviation—is greater than would be expected by chance. If the ratio is small, then the numerator or difference between groups is equal to or less than what might be expected by chance. The rationale is quite similar for other types of *t*-tests. For example, the *t*-test on paired-observations compares the deviations of pairs (numerator) against the standard error for these deviations (denominator).

Analysis of Variance (ANOVA) Psychiatric and psychological studies often require comparison of the means of more than two groups, for example, a comparison of the depression scores of persons in three groups: mood disorder, chizophrenia, and nonpatient controls. The *t*-tests described above are suitable only for two sample problems. When there are three or more samples, and the data from each sample are thought to be distributed normally, *analysis of variance (ANOVA)* may be a technique of choice.

Mathematically, it can be shown that if two or more samples are drawn from the same population, then the variances (S_2) of the several samples will all be estimates of the population variance (s^2). Furthermore, the ratio of the variances derived from two samples of the same population will form a distribution known as the F-*distribution*. The shape of this distribution depends on the size of each sample, or more accurately on $N - 1$ for each sample, which represents the degrees of freedom (df) associated with each sample; df = $N - 1$ because once the mean is known and all but the very last observation is specified, then the very last observation must be invariant.

When two or more samples are being compared, two sources of variance must be considered. For simplicity, in the three-sample problem investigators may wish to compare depression scores of patients with mood disorders (X_m) to those of schizophrenia patients (X_s) and to controls (X_c). Our task is to evaluate the hypothesis (null hypothesis) that the patients with mood disorders, schizophrenia patients, and the controls have been sampled from the same population with respect to depression scores. This population will have a mean depression score X. The mean scores for the three groups will probably not be exactly the same (even if they come from the same population), but they will vary around X. This is termed *between samples variance* and this variance across means is calculated in the ANOVA procedure.

The between groups variance provides an estimate of the difference between group means. How can it be determined whether this variability is meaningful or random? In order to index between groups variance, an independent estimate of variability is used. Within each of the groups, the variability of individual scores around their own group mean provides an estimate of how depression scores are expected to vary by chance. The variance of individual scores around their group, aggregated across group, means becomes an estimate of error. This is called *within samples variance*. The *F*-ratio is a fraction in which the numerator is the between samples variance estimate and the denominator is the within samples variance estimate. The larger the *F*-ratio, the more likely it is that the null hypothesis can be rejected, that is, that the mood-disordered, schizophrenic, and control subjects came from the same population with respect to depression scores. Critical values of *F*, for various degrees of freedom at desired levels of significance, can be obtained from standard *F*-tables.

So far, the discussion of analysis of variance has considered only a one-way classification, that is, only one grouping factor (in the example above, diagnostic classification) has been considered. In much psychiatric research, subjects will actually be classified in several different ways, giving rise to a two-factor model, a three-factor model, and so on. For example, in the analysis of depression scores the subjects might be divided subjects not only by diagnostic classification (mood disorders, schizophrenia, control normals), but also by gender, giving a three-by-two factorial design (three diagnoses times two genders). *F*-ratios can then be computed for each of the two *main effects* (i.e., diagnosis and gender). A main effect is a statistical difference that is independent of the influence of other variables. It is thus possible to determine whether there are significant differences in depression between diagnostic groups and also between men and women. The factorial design allows us to make each of these assessments independently. Typically, studies are designed so that these independent variables are orthogonal or uncorrelated.

When two or more factors or classifications are being considered, an interaction may occur. Interactions are the joint effects of two or more variables. For example, female patients with mood disorders may have higher depression scores than female patients with schizophrenia or controls, but the differences between diagnostic groups may be smaller for males. In other words, some of the variation in depression scores is attributable to unique combinations of gender and diagnosis that can not be explained by either diagnosis and gender. Such a systematic variation in depression scores as a function both of sex and diagnosis is termed an *interaction*. An interaction is literally a difference of differences. In this example, the difference in depression score attributable to diagnostic groupings is larger for female than for male patients; once again, an F-ratio can be computed for the interaction effect.

Table 5.2-3 illustrates the results of a two-way ANOVA. In this study, Beck Depression scores were obtained for 10 patients with mood disorder, 10 with schizophrenia, and 10 controls. Half of the subjects in each group were women. A glance at the raw scores suggests there were differences between patients and controls and between men and women. Are these differences greater than would be expected by chance (defined as occurring less than 5 percent of the time due to chance if the null hypothesis is true)? The ANOVA computation indicates that the *F*-ratio for the diagnosis effect ($F_{2/24} = 100.79$, $p < .001$) is greater than the tabled value of *F* (5.61) at the .01 significance level for 2 and 24 degrees of freedom (df). Thus, there is a "diagnosis main effect." Similarly, for gender, the *F*-ratio exceeds the tabled value for 1 and 24 df at the .01 level (tabled value = 7.82). Finally, the *F* associated with the interaction is also larger than the tabled .05 level (3.40) for 2 and 24 df, demonstrating systematic influence of the combination of gender and diagnosis on Beck scores (i.e., women with mood disorders had significantly higher Beck scores than would be predicted from considering diagnosis and sex alone).

Data	Controls ($N = 10$)	Schizophrenic Patients ($N = 10$)	Mood Disorder Patients ($N = 10$)
	2	8	11
Men	4	9	9
($N = 15$)	3	8	16
	1	7	12
	2	6	10
	4	12	20
Women	4	11	16
($N = 15$)	2	9	18
	3	11	16
	6	13	22

ANOVA Summary Table*

Source	MS	df	F	p
Diagnosis main effect	354.433	2	100.787	<.001
Sex main effect	116.033	1	32.995	<.001
Interaction	18.433	2	5.242	<.02
Error	3.52	24		

* MS, mean square; df, degrees of freedom; F, the F-ratio; p, probability level.

Table 5.2-3 Summary of Two-by-Three ANOVA for Sex by Diagnostic Group

Chi Square The methods covered thus far are *parametric* because they are used to estimate population parameters such as the mean and the standard deviation. Using these methods requires making assumptions about population characteristics. For example, one of these assumptions is that the variable under study is normally distributed within the population from which the sample is drawn. Although for most applications in basic statistics, violations of this assumption have relatively little impact on a statistical test, there are circumstances in which substantial bias will be introduced. To address this problem, there are other statistical procedures that do *not* make assumptions about population distributions. These are called *nonparametic*, or distribution-free techniques. Many research workers prefer nonparametric methods because they rest on fewer assumptions. These techniques are also appropriate to the analysis of data that do not have continuous numerical properties, for example, data that exist as categories, ordinal data (e.g., clinical ratings of severity on a 6-point scale), or ranked data.

The most commonly used nonparametric test for categorical data is the chi-square. The chi-square statistic is used to evaluate the relative frequency or proportion of events in a population that fall into well-defined categories. For each category, there is an expected frequency that is obtained from knowledge of the population or from some other theoretical perspective. There is also an observed frequency for each category. The observed frequency is obtained from observations made by the investigator. The chi-square statistic expresses the discrepancy between the observed and the expected frequency. The formula for chi-square is:

$$\chi^2 = \sum \frac{(O - E)^2}{E}$$

where, *O* is the observed frequency, and *E* is the expected frequency.

An example of a situation in which chi-square is used might be to evaluate the association between gender and diagnosis of major depression. The investigator would consider whether each male and each female in a sample did or did not carry the diagnosis. Under the null hypothesis, the expected frequency for major depression would be assumed to be equal for men and women. The chi-square test would be used to evaluate the two-by-two table.

There are also nonparametric alternatives to problems that suggest the possibility of using a *t*-test or ANOVA, but where the properties of the data render application of parametric statistics inappropriate. For a two-sample experiment the Mann Whitney *U* test may be preferable to the *t*-test, whereas, for problems involving 3 or more samples, the Kruskal-Wallis procedure can replace the ANOVA. Both these nonparametric methods involve transformation of the data into ranks.

ODDS RATIO

One common nonparametric statistic is used for the case-control design. In case-control studies, *cases* are participants classified as having the disease; *controls* are similar individuals but who do not carry the diagnosis. The relative risk may not be an appropriate representation of disease risk because both cases and controls are not representative samples from the general population. The risk of exposure among cases may be quite different from that of the general population for both cases and controls.

In order to represent risks, investigators might consider the odds of exposure to a risk factor among cases and divide it by the risk of exposure among controls. Thus, the odds ratio might be represented as:

$$\text{OR} = \frac{\text{Odds of exposure among cases}}{\text{Odds of exposure among controls}}$$

This can be calculated as:

$$\text{OR} = \frac{a/b}{c/d} = \frac{ad}{bc}$$

The odds ratio is interpreted as the chances of being exposed to a risk among those with the diagnosis divided by exposure to the risk among those without the diagnosis. An odds ratio of >1.0 suggests a positive association between the risk and the diagnosis whereas an odds ratio of <1.0 suggests a negative association with the risk factor. The confidence interval can be interpreted in the same way as the relative risk. If the interval includes 1.0, the odds ratio is assumed *not* to differ from chance.

TYPES OF ERRORS

When the null hypothesis is rejected, the observed differences between groups are deemed improbable by chance alone. For example, if drug A is compared to a placebo for its effects on depression and the null hypothesis is rejected, the investigator concludes that the observed differences most likely are not explainable simply by sampling error. The key word in these statements is *probable*. When offering this conclusion, the investigator has the odds on his or her side. However, what are the chances of the statement being incorrect?

In statistical inference there is no way to say with certainty that rejection or retention of the null hypothesis was correct. There are two types of potential errors. A *type I error* occurs when the null hypothesis is rejected when indeed it should have been retained; a *type II error* occurs if the null hypothesis is retained when indeed it should have been rejected.

Type I Error Type I errors occur when the null hypothesis is rejected but should have been retained, such as when a researcher decides that two means are different. He or she might conclude that the treatment works or that groups are not sampled from the same population whereas in reality the observed differences are attributable only to sampling error. In a conservative scientific setting, type I errors should be made rarely. There is a great disadvantage to advocating treatments that really do not work. The probability of a type I error is denoted with the Greek letter alpha (a). Because of the desire to avoid type I errors, statistical models have been created so that the investigator has control over the probability of a type I error. At the .05 significance or alpha level, a type I error is expected to occur in 5 percent of all cases. At the .01 level, it may occur in 1 percent of all cases. Thus, at the .05 a level, one type I error is expected to be made in each of 20 independent tests. At the .01 a level, one type I error is expected to be made in each 100 independent tests.

Type II Error The motivation to avoid a type I error might increase the probability of making a second type of error. In this case the null hypothesis is retained when it actually was wrong. For example, an investigator may reach the conclusion that a treatment does not work when actually it is efficacious. The probability of a type II error is symbolized by the Greek capital letter beta (*B*). Table 5.2-4 shows four possible outcomes broken down in a 2 × 2 table. The left column shows the decisions the researcher made about the null hypothesis. The hypothesis can be rejected or retained. Across the top of the table is the actual situation. The researcher does not know this, but hypothetically this is the decision that should have been made. In teaching, this is often referred to as “God's model,” implying that there is a correct decision that could have been made but it is beyond human capacity to know what it was.

		“God's Model” What Actually Is True	
		H_0 is True It should have been retained	H_0 is False It should have been rejected
Researcher's Decision	Reject H_0	Type I error $p = \alpha$	Correct decision $p = 1 - \beta$ (also called the power of the test)
	Retain H_0	Correct decision $p = 1 - \alpha$	Type II error $p = \beta$

Table 5.2-4 Four Possible Outcomes of Decisions Concerning the Null Hypothesis

Now consider the entries in Table 5.2-4. The upper-left box shows that the null hypothesis is rejected even though it is true. This is a type I error. It will occur with a probability of alpha (a), or the significance level for the test. For example, at the .05 alpha level, the probability of this type of error is 5 in 100. The other type of error is in the bottom-right box in the table. Here the decision is not to reject the null hypothesis when in actuality the null hypothesis was false. This is a type II error with the probability of beta (*B*).

Not all decisions are incorrect. The table also shows two boxes where the researcher made the correct decision. First there is the lower-left box in which the decision was to retain the null hypothesis when indeed the null hypothesis was true. This is a correct decision, and it occurs with a probability of 1 – a. Finally, there is the situation portrayed in the upper-right box. Here, the investigator decided to reject the null hypothesis when indeed the null hypothesis was false. This is a correct decision with a probability of 1 – *B*. The upper right cell is of particular interest, and defines the power of the test.

Statistical Power There are several maneuvers that will increase control over the probability of different types of errors and correct decisions. One type of correct decision is the probability of rejecting the null hypothesis and being correct in that decision. *Power* is defined as the probability of rejecting the null hypothesis when it should have been rejected. Ultimately, the statistical evaluation will be more meaningful if it has high power. It is particularly important to have high statistical power

when the null hypothesis is retained. Retaining the null hypothesis with high power gives the investigator more confidence in stating that differences between groups were non-significant. One factor that affects the power is the sample size. As the sample size increases, power increases. The larger the sample, the greater the probability that a correct decision will be made in rejecting or retaining the null hypothesis.

Another factor that influences power is the significance level. As significance increases, the power increases. For instance, if the .05 level is selected rather than the .01 level, there will be a greater chance of rejecting the null hypothesis. However, there will also be a higher probability of a type I error. By reducing the chances of a type I error, the chances of correctly identifying the real difference (power) are also reduced. Thus, the safest manipulation to affect power without affecting the probability of a type I error is to increase the sample size. The third factor affecting power is effect size. The larger the true differences between two groups, the greater the power. Experiments attempting to detect a very strong effect, such as the impact of a very potent treatment, might have substantial power even with small sample sizes. The detection of subtle effects may require very large samples in order to achieve reasonable statistical power.

It is worth noting that not all statistical tests have equal power. The probability of correctly rejecting the null hypothesis is higher with some statistical methods than with others. For example, nonparametric statistics are typically less powerful than parametric statistics, for example.

CORRELATION

Clinicians or researchers are often interested not so much in how samples differ, but rather in how variables that represent characteristics of some particular sample or population are related to each other. For example, one might wish to know the relation between oral dose of haloperidol (Haldol) and plasma level, between rapid eye movement (REM) latency and Beck Depression Inventory scores, or between volume of the third ventricle and degree of amnesia. Figure 5.2-3 provides results from a clinical study in which plasma haloperidol was determined 1 hour after each of ten single oral doses of the drug. The distribution of points in the scatter plot suggest that these data could be modeled in terms of a straight line, termed a *regression line*. How well can plasma concentration be predicted from oral dose? How much of the total variation in plasma haloperidol, is attributable to the oral dose and how much can be explained by other factors, (e.g., age, diet, body mass, and so forth)?

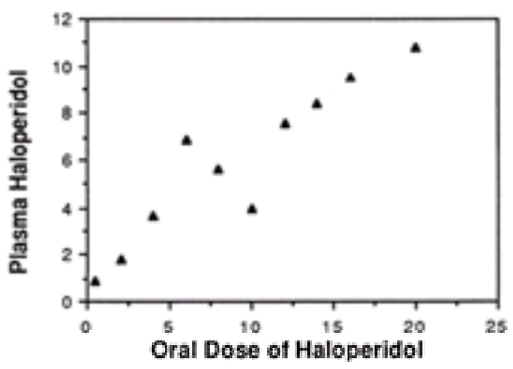


FIGURE 5.2-3 Hypothetical relationship between oral dose of haloperidol and plasma concentration of haloperidol. The linear relationship accounts for 86 percent of the variance.

The regression line that expresses the relationship between plasma haloperidol (*Y*) and oral dose (*X*) can be expressed by the equation: $Y' = a + bx$, where Y' is the predicted value of plasma haloperidol taken from the regression line, *a* is the intercept of the line on the *Y*-axis, and *b* is the slope of the regression line.

Once the regression line has been fitted to the data, what is the strength of the linear relation between plasma haloperidol and oral dose? The strength of the association is expressed as the ratio of the variance in *y* that is attributable to its relation to *x* divided by the total variance in the model. This ratio is called by r^2. In Figure 5.2-3 the r^2 was computed as .86. This means that 86 percent of the total variation in haloperidol plasma concentration can be attributed to its relation to the oral dose, and that 14 percent of the variation is the result of unexplained factors, such as measurement error or characteristics of subjects.

Customarily, the strength of the linear relationship between two variables is actually reported as the correlation coefficient (product moment correlation, Pearson's *r*, or simply *r*). The correlation coefficient is the regression coefficient when both *X* and *Y* variables are expressed in standardized or *Z*-units. The regression coefficient allows a translation between *X* and *Y* in natural units. It is the amount of expected change in *Y* for each unit change in *X*. For example, the equation $Y = 3.25 + .5X$ suggests that each unit change in *X* is expected to correspond with a .5 change in *Y*. The value 3.25 is the intercept. This is the value of *Y* when *X* is 0. The correlation coefficient is also the square root of r^2. In the above example, $r = .93$. To determine whether a product moment correlation falls outside the bounds of chance, one can compute a *t* statistic using a standard formula that takes into account the number of degrees of freedom. In the case of a correlation between two variables, the degree of freedom equals $n - 2$ where *n* is the number of pairs. In the above example *t* was computed as 7.13, which exceeds $t = 2.90$, the critical value of a = .05 for 8 degrees of freedom. Thus, it can be concluded that the *r* is significantly larger than would be expected by chance. The formulas for the correlation coefficient and the evaluation of statistical significance using the *t*-test are:

$$r = \frac{N\Sigma XY - (\Sigma X)(\Sigma Y)}{[N\Sigma X^2 - (\Sigma X)^2][N\Sigma Y^2 - (\Sigma Y)^2]}$$

$$t = r\sqrt{\frac{N-2}{1-r^2}}$$

where *N* is the number of cases and *X* and *Y* are scores on measured variables.

Cautions in Interpreting the Correlation Coefficient Several issues need to be borne in mind in interpreting the correlation coefficient. It is important to inspect the data that are being modeled. For example, the linear correlation between plasma concentration of an antidepressant and score on a symptom checklist is low in Figure 5.2-4; however, this is not because the variables are unrelated. The data are best modeled as a U-shaped function, rather than as a straight line.

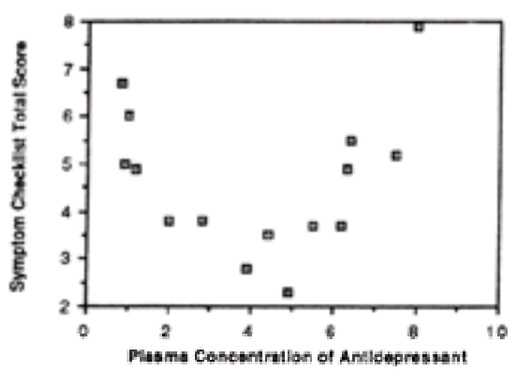

FIGURE 5.2-4 The systematic U-shaped relationship between plasma concentration of antidepressant medication and scores on a symptom checklist is not detected by Pearson product moment correlational methods, which are designed to describe linear relationships.

Correlation coefficients can be biased by a single extreme value. This is illustrated in Figure 5.2-5 and Figure 5.2-6. Figure 5.2-5 shows the correlation between scores on an inventory of life events and a self-rated depression checklist. As the figure shows, there is only a very weak correlation between the scores ($r = -.11$). Figure 5.2-6 displays the same relationship with the addition of a single outlier. This one case had many life events and a high depression score. With the addition of this one extreme point, the correlation is inflated to .97. The example illustrates the sensitivity of correlational methods to extreme scores. Investigators should inspect their data to avoid spurious high correlations caused by outliers.

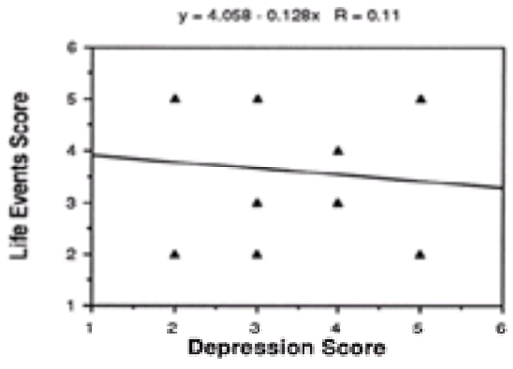

FIGURE 5.2-5 Scatterplot of depression and life events scores.

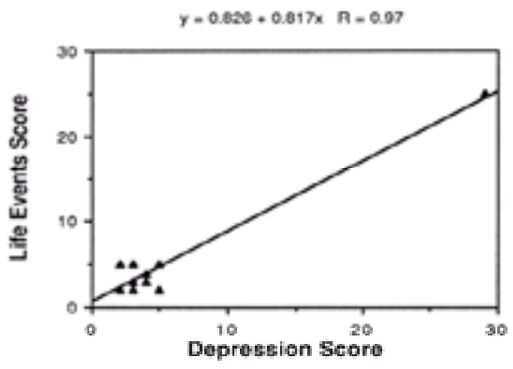

FIGURE 5.2-6 The same data as in Figure 5.2-5, with the addition of one outlier. A single outlier can have a significant effect upon estimates of linear correlation.

Figure 5.2-7 illustrates another problem of interpreting the meaning of the correlation. Here data collected from two samples were pooled and a product moment correlation was computed. This was apparently significant, but an inspection of the scatter plot shows that this apparent linear relationship is explained by the fact that the two samples differed in their mean scores for memory errors and third ventricle width (i.e., the samples came from different populations), but that within each sample there was no relationship between the two variables.

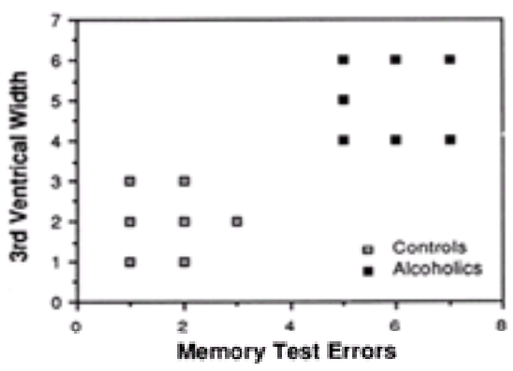

FIGURE 5.2-7 Example of ecological correlation, a correlation that must be interpreted with caution. The correlation between memory and third ventricle width is low within both groups: patients with alcoholism and controls. However, after merging both groups, a significant correlation appears. Just because the correlation from the pooled samples is significant does not demonstrate a true association between ventricle width and memory.

The range of variability in data also will determine the size of the correlation coefficient. For example, if the range of variability is very restricted (i.e., there is not much "play" in the scores), then the observed value of Pearson's r will be constrained near 0. The level of r at which a significant value is attained also depends on the size of the sample. In extremely large samples (e.g., hundreds or thousands of subjects) even tiny values of r (e.g., $r = .1$) may be statistically significant but could have little practical meaning.

Correlation When Variables Are Not Continuous The preceding discussion assumes that the two variables being correlated, x and y, were both continuous. However, correlations can also be computed even if one or both variables are not continuous. It is important to draw the distinction between dichotomous variables that are "true," such as male versus female gender, and those that have artificially been divided to form dichotomies. An artificial dichotomy might be the division of a continuous test score into normal and abnormal categories. The types of correlation coefficients used to find the relationship between dichotomous and continuous variables are summarized in Table 5.2-5. If variable y is continuous (e.g., score on a manual dexterity test), but variable x is a true dichotomy (e.g., sex of children being tested), and if one assigns the value of 0 to one sex and the value of 1 to the other, then computation of the product moment correlation will yield a special statistic called the *point biserial correlation*. The point biserial r can be interpreted in the same way as the standard product moment correlation. The relation between a continuous variable and an artificial dichotomy is evaluated using the *biserial coefficient*.

Variable Y	Variable X		
	Continuous	Artificial dichotomous	True dichotomous
Continuous	Pearson r	Biserial r	Point biserial r
Artificial dichotomous	Biserial r	Tetrachoric r	Phi
True dichotomous	Point biserial r	Phi	Phi

* The entries in the table suggest which type of correlation coefficient is appropriate given the characteristics of the two variables. For example, if variable Y is continuous and variable X is true dichotomous, the point biserial correlation will be used.

Table 5.2-5 Appropriate Correlation Coefficients for Relations Between Dichotomous and Continuous Variables*

The *phi coefficient* (f) is used for correlation's between two dichotomous variables. The phi coefficient is related to the more commonly known chi square described earlier; it can be shown that $c^2 = Nf^2$, where N is the number of cases.

The significance of phi can be determined by computing Nf^2 and referring to a chi-square table with one degree of freedom. When both variables are artificial dichotomies, another coefficient known as the *tetrachoric r* is used.

Rank Order Correlation Sometimes it is difficult to assign precise values to behavioral observations. For example, a clinician might wish to relate the amount of belligerence exhibited by drug-abusing patients to strength of their phencyclidine (PCP) abuse habit. Belligerence may be difficult to quantify, although it might be possible to rank the patients from most to least belligerent. Similarly, the “strength of drug abuse habit” may be difficult to quantify, but it may be possible to order the subjects from heaviest to lightest user. A rank order correlation coefficient, known as *Spearman's rho*, can then be computed. By computing a *Z*-value, using formulas that can be found in standard texts, it is then possible to evaluate the significance of rho for the particular sample size. It should be noted that Spearman's rho may be preferred over the product moment correlation when the variables being related are not normally distributed. For example, the distribution of alcohol consumption among those who regularly drink has a strong positive skew. Rank correlation methods may be preferred in studies of alcohol use because of this nonnormal distribution.

MULTIVARIATE ANALYSIS

Multivariate analysis considers the relation between combinations of three or more variables. For example, the prediction of number of psychiatric readmissions of schizophrenia patients from the linear combination of age, premorbid adjustment, presenting symptoms, and treatment history would be a problem for multivariate analysis. Multivariate analysis is a technical field that requires an understanding of linear and matrix algebra. A schematic representation of the techniques may help place them into context, while showing the basic similarity of approaches that might at first glance appear quite different.

Fundamentally, multivariate techniques involve manipulation of matrix data, that is, data organized in columns and rows. The data in columns are termed *variables* and those in rows are called *observations*. More specifically, multivariate analyses operate on matrix columns.

Figure 5.2-8A,Figure 5.2-8B,Figure 5.2-8C,Figure 5.2-8D,Figure 5.2-8E illustrate how this family of techniques is related. Figure 5.3-8A represents multiple regression. Here, variable Y is predicted from a linear combination (L_x) of variables X_1, X_2, and X_3. In 8b, there are two predictors (X_1, X_2) and also two outcome (dependent) variables (Y_1, Y_2). This illustrates the basis of *canonical correlation*, that is, finding the relationship of the linear combinations of two or more predictors (L_x) and two or more outcomes (L_y) simultaneously. In Figure 5.2-8C there is one outcome (Y) but rather than being continuous, it has discrete levels. This illustrates *linear discriminant analysis*. In Figure 5.2-8D the predictors X_1 and X_2 are dichotomous, but the outcomes Y_1, Y_2, and Y_3 are continuous. This is a representation of *multivariate analysis of variance* with two factors and multiple outcome variables. In Figure 5.2-8E only the relationships among the X variables are being considered, and new linear combinations of these are expressed as the factors Lx_1 and Lx_2. This illustrates *factor analysis*.

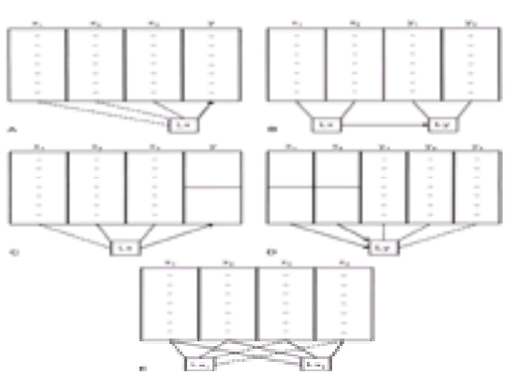

FIGURE 5.2-8 Schematic representations of multivariate models. (Adapted from Van de Geer JP: *Introduction to Multivariate Statistics for the Social Sciences*. Freeman, San Francisco, 1971.)

There is a great deal more to multivariate analysis than this set of schematics has considered. The central point is that what distinguishes these techniques is the *model* being specified more than the statistical theory or computational detail that underlies them. The various methods differ in the number and kind of predictor variables they utilize. They are the same in that they all transform groups of variables into linear combinations. A linear combination of variables is a weighted composite of the original variables. The weighting system combines the variables in order to achieve some goal. The different multivariate techniques differ according to the goal they are trying to achieve.

A linear combination of variables is expressed generally as

$$Y' = a + b_1X_1 + b_2X_2 + b_3X_3 + \ldots + b_kX_k$$

where Y' is the predicted value of Y, a is a constant, X_1 to X_k are variables and there are k such variables, and the b_1 to b_k are regression coefficients. The whole right side of the equation creates a new composite variable by transforming a set of predictor variables.

Example Using Multiple Regression Variables that are important in this combination will be associated with larger regression coefficients. As an example, suppose researchers want to predict the number of psychiatric hospitalizations from three variables: income, rating by psychiatrists, and age. This type of multivariate analysis is called *multiple regression*, and the goal of the analysis is to find the linear combination of the three variables that provides the best prediction of number of hospitalization episodes. The correlation between the criterion (hospital admissions) is found with some composite of the predictors (income plus psychiatrist rating plus age). The combination of the three predictors, however, is not just the sum of the three scores. Instead, a computer algorithm is used to find a specific way of adding the predictors together that will make the correlation between the composite and the criterion as high as possible. A weighted composite might be:

$$\text{Admissions} = .3\ (Z \text{ scores for income})$$
$$+\ .6\ (Z \text{ scores of psychiatrist ratings}) + .03\ (Z \text{ scores for age})$$

This example suggests that psychiatrist ratings are given more weight in the prediction of hospital admissions than the other variables. The rating is multiplied by .6, whereas the other variables are multiplied by much smaller coefficients. Age is multiplied by only .03, which is very close to no contribution. Because any number multiplied by 0 will be 0, age will almost drop out of the equation.

The reason for using *Z*-scores for the three predictors is that the coefficients in the linear composite will be greatly affected by the range of values taken on by the variables. Income is measured on a scale of dollars, while the range in age might be 15 to 70. To compare the coefficients to one another all the variables need to be transformed into similar units. This is accomplished by using *Z*-scores. The standardized coefficients attached to these variable *Z*-scores are termed b or b weights. When the variables are not expressed in *Z*-units, the coefficients or weights for the variables are expressed in their natural units. For example, to find an equation to estimate someone's predicted level of success on the basis of certain personal characteristics, using coefficients that applied to the untransformed values would be

useful. When this is done the weights in the model are called *raw regression coefficients* (sometimes called *b*s).

Interpreting regression coefficients can sometimes be difficult. In addition to being a reflection of the relation between a particular variable and the criterion, the coefficients are affected by the relation among the predictor variables. When the predictor variables are highly correlated with one another, it is difficult to evaluate their individual coefficients. Two predictor variables that are highly correlated with the criterion will not both receive large regression coefficients if they are highly correlated with one another.

For example, suppose that income and psychiatrist's ratings are both highly correlated with readmission. However, these two predictors also are highly correlated with one another. In effect, the two measures seem to be of the same thing (which would not be surprising because the psychiatrist might include income in his or her overall appraisal). So the psychiatrist's rating may get a lower regression coefficient because some of its predictive power is already taken into consideration through its association with income. This is known as the problem of *multicolinearity*. Regression coefficients are most easily interpreted when the predictor variables do not overlap.

The strength of the association between the predictors and the outcome is expressed, as in simple correlation, as a correlation coefficient, usually termed *multiple R*. Note that the upper case *R* is conventionally used in multiple regression rather than the lower case *r* typically used in bivariate correlation. Squaring *R* provides an estimate of the amount of variance in *Y* explained by the predictors *X*s. There are methods for determining the significance of *R*. It is also possible to compute an "adjusted *R*," which takes numbers of subjects and variables into account. This is desirable because the replicability of the regression model becomes less likely if there are too many predictor variables in relation to number of subjects from which such observations derive. Generally speaking, as the ratio of subjects to variables begins dropping below 10:1, confidence in the replicability of the regression should dwindle.

Discriminant Analysis Multiple regression is appropriate when the criterion outcome variable is continuous. However, there are many cases when the criterion is a set of categories. For example, a researcher might want to know the linear combination of demographic, historic, and symptom variables that differentiate positive symptoms and negative symptoms schizophrenic patients. The task is to find the linear combination of variables that provides a maximum discrimination between categories. One appropriate way to model this problem is through application of linear discriminant analysis. The technique attempts to find a linear combination of predictors that achieves best separation between positive and negative symptom cases. A model chi-square can be computed to assess the significance of the solution. If an apparently successful classification is achieved, it is important to determine the generalizability of the model through one of several techniques and cross-validation. *Cross-validation* is a procedure that requires two separate samples; the discriminant function equation is developed for the first sample and then tested for accuracy in the second sample.

Logistic Regression Despite the popularity of multiple regression and discriminant analysis in psychological and psychiatric research, these models have known problems. Both multiple regression and discriminant analysis can be used to predict a binary outcome on the basis of several independent variables. However, when the outcome or the dependent variable has only two values, the statistical assumptions of multiple regression are often violated. One of the most important assumptions is that the distribution of errors is normal. Another assumption, often difficult to meet, is that the independent variables will follow multivariate normality. Logistic regression requires fewer assumptions and provides an excellent alternative for estimating the effect of several independent variables upon a dichotomous outcome. The dichotomous outcome might be a diagnostic category (schizophrenic–not schizophrenic) or a treatment response (responder–nonresponder).

Logistic regression techniques allow the estimation of the probability that an event occurs. The technique differs from multiple regression because it uses the maximum-likelihood method. Linear regression uses the principle of least squares in which regression coefficients are the result of the smallest squared distances between observed and predicted values. The maximum-likelihood method uses a rule that the coefficients are based on the "most likely" result. Logistic regression also allows the characterization of nonlinear relations.

The interpretation of logistic regression coefficients is different from that for multiple regression coefficients. In regression analysis the coefficient gives the amount of change in the dependent variable for each unit change in the independent variable. Coefficients in logistic regression describe the odds of an event occurring. The odds are the probability of an event divided by the probability of no event. Coefficients in logistic regression offer the log-odds or the logarithm-of-the-odds ratio.

Log-Linear Models A variety of multivariate techniques are available for categorical data. Logistic regression is a method for providing linear models of the log-odds of an event. Using these methods the probability of an event is represented as the linear combination of predictor variables. Earlier, the chi-square statistic was described as a method for evaluating the information in contingency tables. In recent years a variety of advanced techniques for analyzing contingency tables have developed. The major limitation of the chi-square test is that it does not provide a systematic evaluation of the relationship between variables. Essentially, chi-square is a test of nonindependence but it does not provide estimates of the relationship between variables. Further, the chi-square test becomes very complicated if more than two variables are in the analysis.

Log-linear analysis allows the construction of systematic models to evaluate the relationship between categorical variables. Complex models can be constructed and specific significance tests can be ordered; tests for hierarchical relationships can also be evaluated. For instance, the relation between employment status and alcohol abuse can be evaluated separately for those with and without a diagnoses of mood disorder.

Factor Analysis and Principal Components Analysis Discriminant analysis, multiple regression, and logistic regression analysis are techniques that find linear combinations of variables that maximize the prediction of some criterion. Factor analysis and principal components analysis are used to study the interrelationships among a set of variables without reference to a criterion. Factor analysis might best be thought of as a data reduction technique. With responses to a large number of items or a large number of tests, it is often desirable to reduce all this information down into more manageable chunks. The task in correlation is to find the best-fitting line through the points created by a two-dimensional scatter diagram. As more variables are added in multivariate analysis, the number of dimensions increases. For example, a three-dimensional plot is shown in Figure 5.2-9. Scatter diagrams for more than three dimensions can only be imagined. Consider that points are plotted in the space created in these many dimensions.

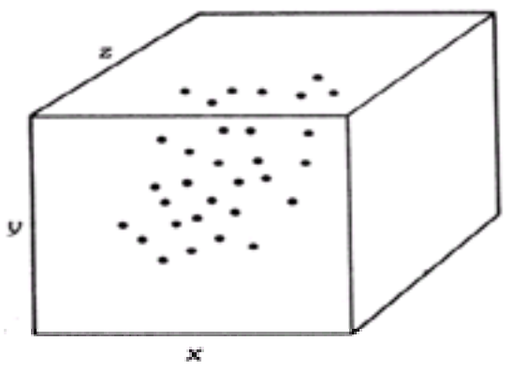

FIGURE 5.2-9 A three-dimensional scatter plot might be represented by this box. In addition to plotting points on the *X* and *Y* axes, they must be located with respect to a third *Z* axis. Although it is hard to show more than two dimensions on a flat page, a three-dimensional figure can be thought of as a box.

In principal components analysis, a matrix of correlations between every variable with every other variable is created. Then the linear combinations of the variables that describe as much of the interrelationships between the variables as possible are obtained. These linear combinations of the variables are called *principal components* and the goal of creating them is to describe as much of the association between the variables as possible. As many principal components as there are variables can be obtained; however, each principal component is extracted according to mathematical rules that make it independent or uncorrelated with all of the other principal components. The first component will be the most successful in describing the variation among the variables, and each succeeding component will be somewhat less successful. Typically, only a few components that account for larger proportions of the variation are extracted for further study.

Once the linear combinations or principal components have been found, the correlations between the original items and the factors are obtained. These correlations are called *factor loadings*. The expression "item 7 loaded highly on factor 1" means there was a high correlation between item 7 and the first principal component. By

examining which variables load highly on each factor, the factors come to be interpreted and named.

Principal components analysis and factor analysis are similar methods that differ in the matrix that is subjected to data reduction. In principal components analysis the initial correlation matrix is made up of raw correlations between variables. Thus, all values on the diagonal of the matrix have the value 1.0. In factor analysis, only the variance that each variable shares with other variables in the data set is used in the analysis. This common variance, known as *commonality*, is estimated using a variety of different methods. Different approaches to factor analysis use different commonality estimates. For example, the *principal factors method* estimates commonalties as the squared multiple correlations of each variable with all other variables. Thus, the diagonal of the initial correlation matrix includes values between 0 and 1.0 that are analogous to R^2 values for independent multiple regressions of each variable with each other variable.

Factor analysis is a complex and technical method, and there are many options the user must consider. For example, investigators frequently use methods that help them get a clearer picture of the meaning of the components by transforming the variables in a way that pushes the factor loadings toward the high or the low extreme. These transformation methods involve rotating the axes in the space created by the factors; they have therefore been labeled *methods of rotation*. These rotation methods can improve the scientific utility of the factor solution. There are several options for methods of rotation, and there are other options concerning the characteristics of the matrix that originally is entered into the analysis.

Survival Analysis Survival analysis evaluates the timing of events. In biomedical research survival analysis is typically used to evaluate life expectancy. However, a whole series of time-dependent questions can be evaluated using survival analysis techniques. For example, survival analysis can be used to evaluate age of onset of psychological illness, time to relapse for those in treatment, or the timing of developmental milestones such as first word, age of initiation of smoking, or age at marriage. Virtually any time-dependent variable can be analyzed such as duration of marriage or duration of employment.

Survival analysis requires the construction of a follow-up life table. Building the table requires a defined starting point. This could be birth, date of initiation of therapy, or date of diagnosis. Next, a follow-up interval, such as a year, is defined. The central focus of survival analysis is the time until a defined event occurs. For each time interval, survival analysis calculates the probability that the event has occurred. The following example illustrates this approach: Alcoholics had previously been reported to experience higher mortality, that is, greater proportions died at a given age compared to nonalcoholics. The alcoholics who achieved long-term sobriety had improved mortality experience compared to relapsed alcoholics. The investigators also wished to compare the mortality of the two groups of alcoholics to that of nonalcoholics. Figure 5.2-10 illustrates the results. The starting point for the analysis was date of entry into the study. The follow-up period ranged from 1 to 11 years. The numbers of deaths in each group is plotted as a function of time. Cumulatively, 19 of 101 relapsed alcoholics died, compared to 4 of 98 continuously abstinent alcoholics and 1 of 92 nonalcoholic controls. The 99 percent confidence intervals were 9.64 to 33.38 for the relapsers, 0.67 to 12.59 for the abstainers, and 0.01 to 7.43 for the nonalcoholic subjects. The confidence interval for relapsers does not overlap with that of the other two groups, so there was 99 percent confidence that these differences were not due to sampling error.

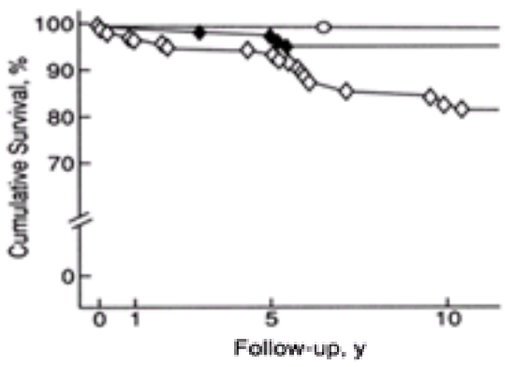

FIGURE 5.2-10 Life table survival experience for all subjects. Open diamonds (à) represent expired relapsed alcoholics (*N* = 19/101); solid diamonds (¨) represent expired abstinent alcoholics (*N* = 4/98); circles (○) represent expired nonalcoholic controls (*N* = 1/92).

Survival analysis can make comparisons between different defined groups. For example, smokers with coaddictions might be compared with those who use tobacco only. For each of these groups a *hazard rate* is created, defined as the estimated probability that an individual who has not experienced an event at the beginning of an interval will experience that event during the interval.

Survival analysis is a complex topic with many attractive features. For example, survival analysis allows the use of time-varying covariates, which means that the influence of a covariate may be different at different points in time. The effects of depression upon substance use, for example, may be stronger at some ages than at others and survival analysis allows the modeling of some of these relations. The example of alcoholic subjects considered factors such as relapse, lifetime alcohol use, neuropsychological status, and personality measures, but relapse was determined to be the only significant predictor. Unfortunately these techniques have received relatively little attention in the psychiatric literature.

EPIDEMIOLOGICAL MEASURES

A variety of epidemiological measures is commonly used in psychiatric research. Epidemiological studies typically focus on outcomes expressed as morbidity and mortality. Morbidity rates are divided into two major types: *incidence* and *prevalence. Incidence* refers to the rate at which new cases are occurring and is defined as the number of new cases that occur within a specific population within a defined time interval. Typically, the incidence rate is expressed per 1000 in the population. Conceptually, it is:

$$\text{Incidence Rate per 1,000} = \frac{\text{New Cases per Unit of Time}}{\text{Persons Exposed or at Risk per Unit Time} \times 1000}$$

Prevalence rates describe the number of diagnosed cases at a particular point in time.

$$\text{Prevalence Rate per 1,000} = \frac{\text{Cases at Specific Time Point}}{\text{Persons in Population at Specific Time Point} \times 1{,}000}$$

Prevalence rate is equal to the incidence rate times the duration of the disease. For example, if the average duration of dementia is 5 years and its incidence is 3 per 1000 per year, the prevalence would be 15 per 1000. Epidemiologists often make the distinction between *point prevalence* and *period prevalence. Point prevalence* refers to the number of cases at a defined time period, such as in the year 1998. *Period prevalence* is relevant to a time interval; it begins with an estimate of prevalence at the beginning of some time period and includes all new cases accumulated until the end of that defined period.

RESEARCH DESIGNS

Virtually all research designs common to clinical and experimental research are used in psychiatry and behavioral sciences.

Observational Studies Observational studies do not attempt to manipulate variables in a systematic fashion; instead, inferences are made on the basis of an ongoing series of observations. Some of the most common observational studies include the cohort study, the panel study, and the case-control study.

Cohort Study In a cohort study groups of people who share some common characteristics are followed over the course of time. These studies, which are often prospective, resample the same population of individuals on repeated occasions. However, the exact participants in the study may not be the same on repeated observations.

Panel Study A panel study is similar to a cohort study; however, it has the stricter requirement that exactly the same individuals who were in the original sample are followed at each repeated assessment.

Cohort and panel studies are considered to be *longitudinal* designs, which make inferences about changes over the course of time.

Cross-sectional studies differ from longitudinal studies in that they examine different groups of individuals at the same point in time. To make inferences about drug use in college, for example, the cross-sectional method would require sampling of each current class such that freshmen could be compared to sophomores, juniors, and seniors. These individuals would not be members of the same class or birth cohort.

Case-Control Study This methodology compares a group of people with a diagnosed disease (cases) with one or more groups that have not been given the same diagnosis. Case-control studies are typically retrospective because they make inferences about events that have caused currently diagnosed cases. Longitudinal studies are often prospective and have the advantage of documenting the antecedents of new cases.

Observational studies often used correlational and multivariate statistical techniques. Variables that are uncontrolled through the experimental design are often adjusted for using statistical methods. In contrast to observational studies in which important variables are not controlled, experimental studies typically involve the systematic manipulation of variables.

Experimental Studies Mental illnesses have a natural history and in most instances their course fluctuates considerably without treatment. One of the difficulties in determining the effects of an intervention is that the intervention may occur at time of crisis. For example, patients with mood disorder might seek psychiatric care on days when they are most depressed. If the exacerbation of the illness is self-limiting (as in the case of mood disorders), the patient's condition will improve spontaneously. A control group can help sort out the effect of treatment from other factors. In this way, a group receiving the intervention under study is compared with the control group to determine whether there are differences attributable to the intervention.

It is widely accepted among medical and biobehavioral scientists that a control or comparison group is required to establish causal inference. In some cases, investigators are willing to accept quasi-experimental data in which an ad hoc control is used, or where there is a stable baseline of observations prior to an intervention. However, several authors have argued that an experiment characterized by a single observation, an intervention, and a second observation is virtually impossible to interpret from a causal perspective.

For experiments using control groups, random assignment to treatment and control conditions is very desirable because randomized clinical trials remove several sources of bias. The value of randomized clinical trials has been emphasized in a series of review articles. In 1982 Harvey Sacks, Thomas Chalmers, and Henry Smith reviewed six therapies for which approximately equal numbers of randomized clinical trials and nonrandomized trials had been reported in the literature. They found that 79 percent of the studies in which patients were not randomly assigned to groups reported that the therapy was better than the control regimen. In contrast, the same therapies were found to be effective in only 20 percent of the studies in which patients had been randomly assigned to the treatment or control condition. In a related review, Chalmers and his colleagues analyzed 145 papers, which were divided into three categories: those in which randomization was blinded, those in which randomization was unblinded, and those in which assignment to treatment or control was by a nonrandom process. Review of these studies suggested that there was a systematic relationship between the rigor of the experimental design and the probability of finding a treatment benefit. There was a significant treatment benefit in 58 percent of the studies in which the subjects were not randomly assigned. The same benefit was observed in 24 percent of the unblinded randomized studies and in approximately 9 percent of the blinded randomized studies.

There are many sources of bias in studies that do not use control groups and the end result is frequently an overestimation of the effects of the therapy under study. These biases are reduced in experimental studies, but the rigor of the experimental design is systematically related to the chances of finding a treatment benefit. Valid scientific inferences must be built upon a solid experimental foundation.

ISSUES IN RESEARCH STUDIES

Reliability Attenuates Relations Reliability is the extent to which the test or measure is free of measurement error. Measurement error is the discrepancy between an observed score and the true value for a particular attribute. Under most circumstances the error is assumed to be random and independent of the true score. Reliability is estimated in a variety of different ways. If the measure is supposed to be stable over the course of time, such as a personality trait, reliability can be assessed by examining the correlation between scores on the same test for the same individuals when the test is administered at two different points in time. Other forms of reliability consider the internal consistency of a test. For example, a measure designed to tap depression may be composed of many items, each of which is an independent assessment of the general depressive attribute. A test is more reliable if responses to these independent items are correlated with one another. Measures of internal consistency, including the Kuder-Richardson 20 and coefficient alpha, are typically correlationlike indexes with ranges from 0 to 1.0. The nearer the reliability coefficient is to 1.0, the higher is the reliability of the test.

The definition of an acceptable level of reliability depends on the purpose of the test. It has been suggested that reliability estimates in the range of .70 to .80 are high enough for most purposes in basic research. In many research studies the investigator only needs an approximate estimate of whether two variables are correlated. If the result looks promising, it then may be worth the extra time and effort to make the research instruments more reliable. Increasing the reliability beyond .90 may increase expense and respondent burden.

In clinical settings, high reliability is extremely important. When tests are used to make important decisions about individual patients, it is essential that classification error be minimized. Thus, a test with a reliability of .9 might not be good enough.

A number of procedures are available to increase the reliability of a test. For example, increasing the number of items tends to increase the reliability of a measure. A prophecy formula is available that permits the estimation of the specific number of items that need to be added in order to achieve a defined level of reliability. A second strategy is to factor analyze the items, thereby obtaining homogeneous subsets of items. Selection of items from these homogeneous subsets increases the reliability of the test.

The effect of low reliability upon correlations has been well documented in the psychometric literature. Observed correlations between two variables are attenuated when either or both variables are measured with error. The expected observed correlation between two variables measured with error is defined as the true correlation times the square root of the product of their reliabilities or

$$r = tr\sqrt{r_{11}r_{22}}$$

where r is the expected observed correlation, tr is the expected true correlation, r_{11} is the reliability of the first measure, and r_{22} is the reliability of the second measure.

Consider the example of the association between a measure of life stress and a measure of social support. The Schedule of Recent Experiences (SRE) has an observed reliability of .55. The Arizona Social Support Interview Schedule has an observed reliability of .52. Suppose that the true correlation between these measures was a substantial .50. Because each measure contains measurement error, the observed correlation between the two measures would be .27. In a study with 50 participants ($r = .27$, $p > .05$), the investigator would fail to find a significant correlation between these two variables, even though there is indeed a substantial association.

Multiple Comparisons Multiple outcome measures are commonly used in psychiatric research. Investigators believe this is beneficial because psychiatric outcomes are complex and a multitude of measures are required to capture them. However, use of multiple measures creates other statistical biases. When multiple comparison are made, the probability of finding at least one difference by chance increases. At the .05 significance level, one significant difference is expected for each 20 independent tests (or 5 percent of all comparisons). Thus, a certain number of significant differences between groups are expected by chance alone. Multiple

comparisons problems occur under two circumstances. First, they may be common when the investigator is comparing multiple groups on the same outcome measure. The number of possible comparisons is equal to

$$j\,(j\,-\,1)/2$$

where *j* is the number of groups.

For example, with six groups the number of comparisons would be 15. This difficulty is avoided by using methods such as ANOVA, with appropriate follow-up tests such as the Neuman-Keuls test. These tests compare pairs of means using adjustments to protect against making a Type I error owing to multiple comparisons.

However, the problem of multiple outcome measures is more difficult. The probability of finding at least one significant difference by chance is defined as:

$$\text{Probability of 1 or more type I errors} = 1 - (1 - \alpha)^C$$

where *C* is the number of tests.

As the number of tests increases, the investigator can expect to find more spurious results. For example, the probability of finding at least one spurious statistical difference in five contrasts is .23. For 10 contrasts, the probability is .40 whereas for 20 tests the probability is .64. In other words, the chances of drawing the wrong conclusion about the null hypothesis can become quite high when multiple comparisons are performed.

There are several remedies for this situation, but the difficulties associated with multiple comparisons tests should always be kept in mind. In order to avoid false conclusions, some investigators adjust the significance level to be more conservative. This is the basis for the Bonferroni inequality, a common procedure to correct for multiple comparisons. Under this procedure, if a was originally set at .05, but 10 comparisons were performed, the adjusted probability of a Type I error would be a/*N* = .005, where *N* was the number of comparisons. However, such adjustments may be problematic because some of the adjustments are so conservative that the null hypothesis is rarely rejected (i.e., a type II error may be introduced). Another approach is to use multivariate techniques that take multiple comparisons into consideration or to reduce the data set to a smaller number of manageable dimensions. For example, if 20 neuropsychological tests were administered to 200 subjects, factor analysis might be used to reduce the neuropsychological domain to three or four factors.

Sample Size Issues Generally speaking, there are fewer biases in studies with large sample sizes in comparison with studies with small sample sizes. However, a large sample size does not necessarily ensure that the conclusions will be meaningful. Further, many studies with small sample sizes have appropriate internal validity. For studies attempting to estimate prevalence or incidence rates, representativeness is more important than sample size. In a famous case, the *Literary Digest* attempted to forecast the outcome of the 1936 presidential election between Franklin D. Roosevelt and Alfred Landon. The magazine drew its sample from its readers, from automobile registrations, and from telephone directories. In 1936, all these sources overrepresented the wealthy, most of them Republicans. The poll showed that Landon (the Republican) would win by a landslide. The results of the elections were, however, just the opposite. Roosevelt won by one of the greatest margins in American history. Thus, survey results are of little value if the sample is not representative of the population. In fact, there was no problem with the sample size in the *Literary Digest* poll; indeed, the sample size was very large. In contrast, election day polls using as few as 2000 respondents to represent all the voters in the United States have been repeatedly shown to be very accurate. Relatively small samples can be of great value if they are drawn in a random and representative fashion.

Most statistical tests take sample size into consideration. Thus, the probability of rejecting the null hypothesis by chance when the sample size is 10 is .05 if the .05 alpha level is used. The probability of rejecting the null hypothesis by chance in a sample size of 10,000 is also .05 at the .05 level. In other words, there is an inherent correction for sample size. It is commonly asserted that studies that reject the null hypothesis but have a small sample size are of little value. However, obtaining a significant difference with a small sample size often requires that the experimental effect is significantly stronger than obtaining the effect at the same alpha level with a larger sample. Thus, demonstrating treatment efficacy with a sample size of 10 per group might require that the treatment effect account for 30 percent or more of the variance in the outcome variable. Obtaining the same significance level with a large sample size (say 300 per group) might only require 1 or 2 percent of the variance to be accounted for.

Power Analysis and Sample Size Planning Many problems in the interpretation of experimental data can be avoided with appropriate planning. Statistical power defines the probability that a statistical test will produce a significant result. Biomedical research now requires sample size planning. In most research studies the investigator evaluates the null hypothesis—that is, the hypothesis of insufficient evidence for the hypothesis of interest. Typically the researcher does not want to accept the null hypothesis but prefers to reject the null hypothesis in favor of the alternative that the investigator hopes to support.

When statistical tests are nonsignificant, the investigator is typically unable to conclude that the null hypothesis is correct. Significant treatment effects can be missed because the experiment does not have sufficient power. For example, if too few subjects are in the study or if there is substantial variability, a potentially beneficial treatment might be overlooked.

In order to avoid making these type II errors, sample size planning is required. This typically requires a power calculation. Formulas for power calculations are available for most types of statistical tests. A common formula for an experiment that compares two groups is:

$$N = \frac{2s^2(Z_\alpha + Z_\beta)^2}{\Delta^2}$$

where *s* is the standard deviation of the outcome, Z_a is the *Z*-score associated with the probability of a type I error, Z_b is the *Z*-score associated with the power of the test, and D is the expected differences between the experimental and control groups.

If an investigator wants to study changes in neuropsychological functioning following the administration of a b-blocker medication. Patients will be randomly assigned to use the drug or to take a placebo. The neuropsychological test expresses outcomes in *T*-scores (mean = 50, standard deviation = 10), and the drug is expected to reduce performance in comparison to placebo by about 5 points. The investigator needs to estimate how many patients would be required to have a 90 percent chance of detecting a difference with the probability of a type I error set at .05.

The *Z*-score for the .05 significance level is 1.96 (Z_a) and the *Z*-score for a power of .90 (Z_b) is 1.28. To estimate this, the following calculations are made:

$$\begin{aligned} N &= \frac{2(10)^2(1.96 + 1.28)^2}{5^2} \\ &= \frac{20(3.24)^2}{5^2} \\ &= \frac{2100}{25} \\ &= 84 \end{aligned}$$

Thus, the experiment would require 84 subjects or 42 in each of the two groups.

Selective Biases A variety of biases are common to psychiatric research, some of which are identified as common flaws.

Selective Attrition Many studies involve follow-up of patients. However, patients may be available for follow-up on a selective basis. For example, it has been demonstrated that in treatment studies those who are available for follow-up are not a representative sample of the original population. It is common for those available for follow-up to be among those who succeeded in the treatment program. This can be a particularly severe problem in studies where the loss to follow-up is

different for treatment and control subjects.

Detection Bias A common problem on etiology studies is that those with the diagnosis may be examined in a different way than those who have not already been so diagnosed. If at all possible, it is valuable to blind the observers.

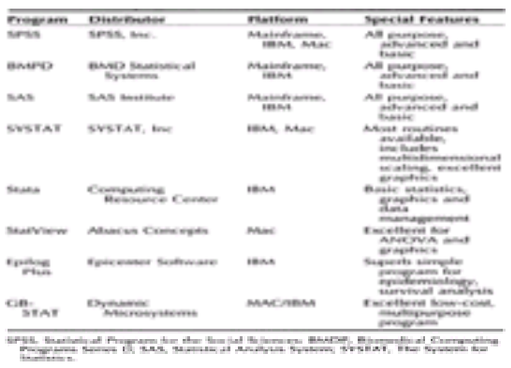
Ex Post Facto Design Problems One of the most common designs in biomedical research is the case-control study. In the research methodology literature, this is known as the *ex post facto design*. In such analyses the investigator already knows that the groups being compared differ in some respect. Typically, individuals who have a diagnosed disorder are compared to a matched group of individuals who have not been placed in the same diagnostic category. The matching occurs for a limited number of variables, and the investigator attempts to determine whether the two groups differ on various prior or current exposures to causal factors. The case-control study is also known as the *case-referent study* or the *case-comparison study* design. An example of this design might be a comparison between patients with a diagnosis of paranoid schizophrenia (cases) with people without schizophrenia (controls). Prior history for the two groups might be compared.

In contrast to true experiments, the case-control or ex post facto method has many deficiencies. In effect, the investigator clearly knows that the two groups differ on at least one variable. The observation that the groups differ on other variables implies relatively little about causation; in effect, these designs represent parallel correlational studies.

Often in case-control studies an investigator matches patients on a particular variable or uses the variable as a covariate or covariable. If the matching variable or covariate fails to change the difference between the cases and controls, it is assumed that the variable does not explain the underlying basis of the condition. However, there are many rival explanations for the failure of covariables to explain an observed relationship. One important explanation is that the covariates were measured with error or that the match was imperfect. To the extent that these problems occur, the effect of adjustment will be greatly attenuated. Thus, the fact that a covariable does not have an effect does not necessarily mean that the covariable is unimportant in the observed relationship.

Computer Applications The availability of computer software has greatly facilitated the execution of most statistical techniques. The many statistical packages run on different types of platforms or computer configurations. There are three main classes of platforms: mainframe, workstation, and microcomputer. Mainframe computers are now used less frequently for data analysis because many complex analyses can be achieved on less expensive work stations and microcomputers. The two most common types of microcomputers are IBM-compatible and Apple-Macintosh. Extensive computer software is now available for each of these platforms. For general data analysis the Statistical Package for the Social Sciences (SPSS), the BMDP series, and the Statistical Analysis System (SAS) are recommended. These are general-purpose statistical packages that perform essentially all the analyses common to biomedical research. In addition, a variety of other packages have emerged. SYSTAT runs on both IBM-compatible and Macintosh systems and performs most of the analyses commonly used in biomedical research. The popular SAS program has been redeveloped for Macintosh systems and is sold under the name *JMP*. Other commonly used programs include Stata, which is excellent for the IBM-compatible computers. The developers of Stata release a regular newsletter providing updates, which makes the package very attractive. StatView is a general-purpose program for the Macintosh computer. Newer versions of StatView include an additional program called Super ANOVA, which is an excellent set of ANOVA routines. StatView is user-friendly and also has superb graphics. For users interested in epidemiological analyses, Epilog is a relatively low-cost program that runs on the IBM-compatible platforms. It is particularly valuable for rate calculations, analysis of disease-clustering patterns, and survival analysis. GB-STAT, is a low-cost, multipurpose package that is very comprehensive.

Historically, a major concern of data analyzers was that each analysis program required its own data format. A software advance helps to alleviate this problem. A program called DBMS/Copy allows the user to move files among a number of spreadsheets, databases, and commonly used statistical packages. DBMS/Copy uses a form of artificial intelligence to create a directory of information about the data. Using this directory it can reformat the data so they can be used in most of the commonly available programs. DBMS/Copy is now distributed SPSS, Inc. of Chicago, Illinois. A summary of some available computer programs is offered in Table 5.2-6.



Program	Distributor	Platform	Special Features
SPSS	SPSS, Inc.	Mainframe, IBM, Mac	All purpose, advanced and basic
BMPD	BMD Statistical Systems	Mainframe, IBM	All purpose, advanced and basic
SAS	SAS Institute	Mainframe, IBM	All purpose, advanced and basic
SYSTAT	SYSTAT, Inc	IBM, Mac	Most routines available, includes multidimensional scaling, excellent graphics
Stata	Computing Resource Center	IBM	Basic statistics, graphics and data management
StatView	Abacus Concepts	Mac	Excellent for ANOVA and graphics
Epilog Plus	Epicenter Software	IBM	Superb simple program for epidemiology, survival analysis
GB-STAT	Dynamic Microsystems	MAC/IBM	Excellent low-cost, multipurpose program

SPSS, Statistical Program for the Social Sciences; BMDP, Biomedical Computing Programs, Series D; SAS, Statistical Analysis System; SYSTAT, The System for Statistics.

Table 5.2-6 Summary of Common Statistical Software

Computer software programs that provide easy access to highly sophisticated statistical methodologies represent both opportunities and dangers. On the positive side, no serious researcher need be concerned about being unable to utilize precisely the statistical technique that best suits his or her purpose, and to do so with the kind of speed and economy that was inconceivable just two decades ago. The danger is that some investigators may be tempted to employ after-the-fact statistical manipulations to salvage a study that was flawed to start with, or to extract significant findings through use of progressively more sophisticated multivariate techniques. Such ex post facto ransacking of data bases does not advance knowledge. Progress in psychiatry will depend increasingly on careful crafting of hypotheses, experimental design, and appropriate statistical modeling. A brief definition of commonly used statistical terms is listed in Table 5.2-7.

5.3 MENTAL HEALTH SERVICES RESEARCH

MARK OLFSON, M.D., M.P.H.

Mental health services research is a broad multidisciplinary field that draws on a variety of methods and approaches to describe and help improve the operation of the mental health services system. Mental health services researchers are interested in defining not only who receives, provides, and pays for care, but also in the combinations of services that are most effective and the costs of these services.

Much remains to be learned about the delivery and effectiveness of mental health services. There are methodological difficulties in defining and measuring the wide variety of financial arrangements, service interventions, and patient outcomes that characterize routine clinical practice. Few randomized controlled effectiveness studies have been conducted on the various emerging forms of service delivery. In several areas, however, experimental and quasi-experimental research provides a rational basis for improving service delivery through public mental health promotion, patient and clinician educational programs, program development, and health care system and policy reform.

Services research has increased the awareness of unmet service needs by revealing that a large number of individuals with mental disorders receive no treatment. Services research has also increased awareness of the factors that govern the flow of individuals into treatment, the pivotal role of primary care providers in mental health care delivery, and the complex treatment needs of severely ill individuals.

In mental health services outcomes research, a tension often exists between “rigor” and “relevance.” Outcome studies that provide the strongest and most scientifically credible findings are often the most difficult to apply to general psychiatric practice where patients present with complex diagnostic problems and treatment needs. However, outcomes research conducted in more naturalistic settings generally yields more readily applicable but uncertain findings. Clinicians face the critical challenge of integrating findings from the full spectrum of psychiatric outcomes research into the ongoing delivery of clinical care.

No well-accepted system exists for classifying the wide array of issues that preoccupy mental health services researchers. This chapter is organized around four general areas: (1) service delivery research, (2) service utilization research, (3) financing of services, and (4) quality of care and outcomes research. Mental health services research activities often span two or more of these areas.

SERVICE DELIVERY RESEARCH

Service delivery research involves the collection, analysis, and interpretation of information from providers concerning the types of services they provide and the patients they treat. Such research uses several approaches, ranging from large-scale surveys of mental health care organizations to detailed studies of individual clinical encounters.

National Perspective A national perspective on mental health service delivery helps to define general trends in health care delivery. Nationally representative service delivery data provide insight into large shifts in practice patterns such as the ongoing decline in public mental hospital-based care, the increasing privatization of mental health services, and the rise of partial care services and other alternatives to inpatient treatment.

In the United States the most extensive national provider-based surveys of mental health services are conducted by the Substance Abuse and Mental Health Services Administration (SAMHSA) National Reporting Program (NRP). This program periodically surveys all the admissions and discharges from state and county mental hospitals. Samples are also drawn from general hospitals, private psychiatric hospitals, and other organizations that provide mental health services. These surveys provide estimates of the volume, diagnostic composition, demographic characteristics, and payment profile of patients treated in different types of mental health organizations.

NRP surveys provide a bird's-eye view of temporal changes in the pattern of service delivery. The findings also allow policy makers and program planners to examine the pattern of mental health services received by special patient groups (e.g., children, adolescents, and persons with severe and persistent mental illness) at a specific point in time.

The NRP does not capture mental health services provided in office-based practice or general medical settings. Some nationally representative mental health services data concerning these settings and providers can be gleaned by surveys conducted by the National Center for Health Statistics.

Resource utilization surveys conducted by the National Center for Health Statistics, together with population-based psychiatric epidemiological studies, have helped to define the extent to which general medical physicians provide mental health services. It is estimated that up to half of all the recipients of professional mental health care in the United States receive it in the general medical sector. This fact has focused attention on the quality of mental health services provided by primary care physicians and other nonpsychiatrist physicians, particularly on how they prescribe psychotropic medications.

Regional Perspective A regional perspective on service delivery emphasizes the composition, range, frequency, and coordination of mental health services provided to patients in a defined region such as a state, county, or catchment area. There is particular interest in measuring the extent to which specific changes in health care policy affect service delivery in a well-defined region.

If a change in policy is planned in advance, such as the scheduled closing of a state mental hospital, data collection can begin before the policy change occurs and can continue after the change in policy. In other cases retrospective designs that rely on data that was originally collected for some other purpose are used. For example, in 1987 New York state enacted triplicate benzodiazepine prescription regulations. Analysis of routinely collected prescription data clearly reveal that this policy was followed by a steep decline in the number of benzodiazepine prescriptions filled in the state.

This study is an example of an interrupted time series design, in which observations are made of a study population before and after the occurrence of a discrete change in the health care environment. Secular change, events that occur separate from the policy change under study, may confound attribution of temporal trends to the policy change.

Regression toward the mean is a second potential limitation of time series studies of policy change. Regression toward the mean is the tendency for observations of populations selected on the basis of exceeding some predetermined threshold level to return toward the mean on subsequent observations. When policies apply to specific patient groups, such as patients with high recent utilization of services, care must be taken to control or adjust for the natural tendency of these patients to return toward mean values of this variable (i.e., lower service utilization).

Policy makers and program planners are particularly interested in whether changes in policy have the intended effects on service delivery. Sections of the Omnibus Budget Reconciliation Act of 1987, for example, were intended to reduce the unnecessary use of antipsychotic drugs in nursing homes. Longitudinal analysis of prescription patterns demonstrates that a substantial decrease in antipsychotic drug use coincided with the implementation of these new federal regulations and provide evidence that the regulations had their intended effect. Detailed clinical studies are needed to evaluate whether this decrease in prescriptions for antipsychotic medications resulted in improved quality of care.

New policies may have the intended effects on service delivery, but these effects may not be sufficient to result in meaningful change in clinical outcomes. An

illustration of the importance of studying patient outcomes together with service delivery variables is provided by the Robert Wood Johnson Foundation Program on Mental Illness. This project examined the hypothesis that strengthening the role of local mental health authorities would make it possible to promote the development of comprehensive mental health care and social welfare services. Greater coordination in service delivery would in turn improve the health outcomes of patients with severe and persistent psychiatric illness. Nine cities were selected for the project. Although the project succeeded in creating structural change through the creation of centralized mental health authorities, these changes were not sufficient to promote improved patient outcomes in such crucial areas as symptomatic distress or quality of life. These findings suggest that structural change in service delivery without a complementary focus on clinical and social service processes may not be sufficient to achieve meaningful improvement in patient outcomes.

The unintended effects of policy change have also been studied. An example of unintended policy effects followed the enactment of state legislation in New Hampshire that limited Medicaid pharmacy reimbursement to three prescriptions per month. This policy sought to lower Medicaid expenditures by reducing discretionary medication costs. Analysis of clinical records revealed that the reimbursement cap led to a prompt decline in the use and costs of psychotropic drugs. However, the three-prescription cap also led to a sharp increase in the use of initial short-term mental health services. The cost of the increase in such mental health services more than offset the savings associated with the decreased use of psychotropic medications. After the reimbursement cap was repealed, use of medications and most mental health services returned to baseline levels.

Program Perspective A programmatic perspective of service delivery considers patterns of service provision from the vantage point of individual mental health programs. Researchers want to learn about the nature, frequency, and range of specific treatments provided by different programs. In some studies it is possible to link observed differences in program service delivery with patient outcomes. Research on assertive public (community) treatment programs offers an example of program level service delivery research.

Assertive public (community) treatment delivers psychiatric, social, and rehabilitative services to severely ill patients through multidisciplinary treatment teams that meet with patients in the community. There is considerable variation in the extent to which individual assertive public treatment programs implement this treatment model; this variation provides an opportunity to examine correlations between program design and patient outcome.

In one study of 18 assertive public treatment programs, total number of patient contacts, daily team meetings, and 24-hour availability were significantly correlated with reductions in number of days of patient hospitalization. Other service elements, including low client-to-staff ratio, small team size, and number of community contacts were not correlated with reduced hospital days. In a second study of three programs, reductions in rehospitalizations were achieved at two of the three programs. The program that did not reduce hospitalizations was distinguished from the other two programs by not having shared case loads, a team nurse, or daily team meetings and by not offering office visits. These observations that link specific service structures to patient outcomes help to inform program planning and development.

Patient Encounter Perspective The most microscopic service delivery research perspective examines specific aspects of individual clinical encounters. An important goal of such research is to define clinician behaviors associated with either positive or negative health care outcomes. There is a long tradition in psychotherapy research of seeking to associate specific therapist behaviors with clinical outcomes.

A related area that has received considerable attention in this regard is the assessment and diagnosis of mental disorders by primary care clinicians. Scales exist to score videotaped patient visits for clinical techniques and behaviors that may either facilitate or impede the recognition of mental disorders by primary care physicians. One study found that only a small proportion of primary care visits with depressed patients include the necessary questions to establish a diagnosis of depressive disorder. Another study found that accurate recognition of the mental disorder was increased by establishing eye contact with the patient at the outset of the interview, clarifying the presenting complaint, responding to verbal and nonverbal cues of psychological distress, and having the capacity to elicit cues from the patient that indicate distress. The results of patient encounter studies can help inform educational efforts to improve the delivery of mental health services.

SERVICE UTILIZATION RESEARCH

Health Care Seeking Service utilization research considers service provision from the perspective of the patient rather than the provider. Service utilization research emphasizes elucidating the range of factors that influence an individual's entry and use of mental health services. One important area in service utilization research concerns health–care-seeking behavior.

It is well established that most people in need of mental health care receive either inadequate professional services or none. This observation has focused attention on the processes that govern the flow of individuals into treatment and the course of patients between different levels of care. Researchers seek to identify and describe factors that either facilitate or impede the use of mental health services by persons with well-defined disorders. An understanding of these processes informs public health efforts aimed at extending treatment access to groups with high rates of unmet need for clinical care.

The main steps in the process of seeking mental health care are recognition of a mental health problem, contact with a general medical provider, and referral to a mental health specialist. In the United States these steps do not necessarily proceed in a orderly or sequential manner because many individuals bypass general medical care and present directly for specialized mental health care, sometimes on an emergency basis.

Individual determinants of the process of seeking health care are commonly conceptualized as involving interactions between health needs, predisposing factors, and enabling resources. Health needs include objective and subjective aspects of mental and physical health status. The assessment of health needs typically includes measures of the type, severity, frequency, and duration of symptoms or distress. Subjective appraisal of mental health is another important dimension of the health assessment.

Predisposing factors relate to willingness to seek care. Norms and beliefs, role obligations, and demographic characteristics are important predisposing factors. Enabling or restrictive influences, on the other hand, reflect the availability of resources that facilitate or impede service utilization. Health insurance, disposable income, and local availability of services are key enabling influences. The operation of predisposing and enabling factors is generally considered to be contingent upon the presence of some underlying clinical need for care.

Beyond individual determinants of health care seeking, health care utilization patterns are determined by provider variables such as the skill, training, attitudes, orientation, knowledge, and behavior of the health care professional; administrative controls over patient access to service are increasingly becoming another important determinant of health care utilization.

Epidemiological data indicate that greater objective illness severity is associated with higher rates of treatment. Among those who receive mental health care, individuals with more severe conditions are disproportionately served by psychiatrists and other mental health specialists as opposed to primary care physicians or other general medical professionals.

Specific aspects of psychopathology influence treatment-seeking behavior. Symptom pattern and severity play important roles in determining the timing of treatment seeking and the pathway to mental health care. In one community study of depression, depressed mood and weight loss, but not sadness or agitation, predicted mental health care from a primary care physician. In another study, chest pain, but not palpitations, during a panic attack was associated with seeking mental health treatment from a primary care physician.

Sociodemographic characteristics have been extensively studied as predisposing or restricting factors in mental health care seeking behavior. Unmet need for mental health service tends to be greatest for children, adolescents, and elderly persons as well as socioeconomically disadvantaged groups including the poor, the uninsured, blacks, Hispanics, and adults with lower levels of formal education. Although women tend to be more likely to use mental health services than men, this effect may be limited to care provided by primary care physicians and other nonmental health specialists.

The basis for the observed lower rates of mental health treatment among racial and ethnic minorities remains an important and poorly understood aspect of service utilization. Although some researchers have suggested that inter-ethnic differences in mental health utilization are largely attributable to socioeconomic differences, research demonstrates that even within privately and publicly insured populations, blacks and Hispanics have substantially lower rates of outpatient mental health service utilization than whites.

Cultural and attitudinal factors may help to explain the lower rates of professional mental health service utilization by blacks and Hispanics in relation to whites. Some

members of ethnic minorities may be reluctant to use specialized services provided by English-speaking whites, whereas others may prefer to rely on traditional, nonmedical care providers. Some racial minorities, for example, have been found to have a stronger belief than whites in the clergy's effectiveness to provide mental health care. Much remains to be learned about the role of race, ethnicity, and culture in the mental health care seeking process.

Recent research suggests that delay in health-care seeking is common and that a majority of people with the common major mental disorders eventially make treatment contact. People with early-onset psychiatric disorders may be at an especially high risk of long delays to first treatment contact.

Long delays in the initiation of treatment are especially common in first-episode schizophrenia and related disorders. Accumulating evidence suggests that failure to treat schizophrenia early in its course adversely affects long-term outcome. Several studies suggest that the duration of untreated psychotic disorders is roughly twice as long for men than women.

Treatment Noncompliance Treatment noncompliance poses a major challenge to the delivery of mental health services. High rates of treatment noncompliance have been observed in a variety of service settings. Following hospitalization, up to one third of psychiatric patients fail to make their first scheduled outpatient visit. High rates of noncompliance have also been found following referral from emergency rooms and primary care practices to outpatient psychiatric services. The literature suggests that across a variety of treatment contexts that active substance use, lack of insight into the need for treatment, and a history of treatment noncompliance—all predispose toward the premature termination of treatment.

A failure to take antipsychotic drugs as prescribed is one of the most important public health aspects of noncompliance with mental health services. In one study almost half of outpatients with schizophrenia stopped taking antipsychotic medications in the first year following hospital discharge. By 2 years following discharge, approximately three out of four outpatients had stopped taking antipsychotic medications. The clinical and public health implications of such widespread noncompliance are underscored by the high rates of relapse following experimental withdrawal of antipsychotic medications and by the close association of noncompliance with antipsychotic medication regimens and rehospitalization as determined by observational studies.

Compliance with mental health treatment is a joint function of the patient's personal characteristics, psychiatric symptoms, prescribed treatment, social context, and access to relevant services. Patient characteristics including demographic, financial, cultural, social, geographic, and attitudinal factors have been shown to influence treatment compliance. In addition, psychiatric symptoms such as pessimism, hopelessness, grandiosity, paranoia, and cognitive impairment may interfere with appropriate adherence to prescribed treatments. In one study of schizophrenia, for example, greater conceptual disorganization, emotional withdrawal, hostility, and grandiosity, but not anxiety or depression, were associated with rejection of antipsychotic medications.

Aspects of the treatment intervention, such as its effectiveness, adverse effects, complexity, and the patient-provider relationship have all been found to influence treatment compliance. Furthermore, characteristics of the service system influence treatment compliance. An increased risk of noncompliance or drop-out has been related to long clinic scheduling delays, restrictive admission and discharge policies, and a lack of access to outreach or emergency services.

Inappropriate Service Utilization Recent growth of prepaid and capitated care has increased efforts to control the costs of care and particularly to reduce care that is deemed unnecessary or inappropriate. This area is marked by considerable controversy as managed-care organizations, third-party payers, service providers, and symptomatic individuals often have very different perceptions of what constitutes inappropriate and appropriate care.

Primary care patients who use very high levels of general medical services have been studied from the standpoint of inappropriate service utilization and accumulating evidence suggests that these patients also have high rates of psychiatric disorder. In one study of distressed high utilizers of primary care, nearly one quarter of the patients met the criteria for current major depression.

It has been hypothesized that appropriate provision of psychiatric care to distressed high utilizers of general medical care will save treatment costs by reducing unnecessary and poorly focused medical expenditures. Thus far, this effect has not been convincingly demonstrated in a well-controlled study. However, a cost-offset effect has been shown following the provision of psychiatric consultation services to inpatients with general medical disorders and medical outpatients with somatization disorder. In addition, a psychiatric consultation–primary care physician collaboration model has been shown to improve the treatment of primary patients with depression.

FINANCING OF MENTAL HEALTH SERVICES

Over the past several years private-sector employers and state Medicaid agencies have increasingly enrolled in companies that provide managed mental health services. The wide appeal of these companies is that they promise to increase the availability of mental health services, contain or reduce costs, and improve the quality of care by integrating the financing and delivery of treatment.

There is general agreement that managed care has been effective in reducing or at least slowing the growth of the costs of providing mental health services. However, there is much less agreement over the effects of managed care on the quality of mental health services. Critics assert that managed care has jeopardized the quality of mental health services by underfunding services, excluding patients with more severe disorders, threatening confidentiality, and relying too extensively on less highly trained health professionals.

The debate surrounding the growth of managed mental health care has been conducted in the near absence of systematic empirical data on its actual clinical effects. Most of the empiric research on managed care has focused on cost-containment issues from the perspective of the payer, insurer, or managed-care organization. Considerably less work has been done on the effects of managed behavioral health care on the quality and effectiveness of clinical services.

In one study Medicaid patients with long-term mental illness were randomly assigned to prepaid care and followed for 1 year. All patients rejoined fee-for-service arrangements following the demonstration project. As expected, patients assigned to prepaid care had lower rates of service utilization in several areas but there were no significant differences between the groups in clinical outcomes. In multivariate analyses, however, patients with schizophrenia in the prepaid group had significantly poorer global functioning once they returned to fee-for-service care. Some indication of the longer-term effects of Medicaid managed care can be gleaned from retrospective analyses of claims data. This research suggests that Medicaid managed care for severely ill psychiatric patients is associated with a slight decreases in the rate and length of inpatient admissions, but an increase in the rate of rapid rehospitalization following hospital discharge.

Insurers and managed-care plans rely on several techniques to control access to care as well as the types, amounts, and costs of care. These include authorizing only selected clinicians to provide care, reviewing decisions concerning service utilization, closely monitoring high-cost cases, and the use of financial incentives. These cost-containment mechanisms are thought to have their greatest impact on patients who are the most severely ill and are therefore the most vulnerable to service reductions. An important challenge is to examine the effects of various evolving managed-care mechanisms on the quality of care and health outcomes of individuals with the most severe mental illnesses.

QUALITY OF CARE AND OUTCOMES RESEARCH

Quality of Care Research *Quality of care* is the degree to which treatment conforms with predefined standards of appropriate or acceptable care. Research on quality of care requires standards of care or treatment guidelines that can be operationally defined and reliably measured. Quality standards are typically developed by experimental or quasi-experimental observation, systematic review of the research literature, or expert consensus.

A distinguishing characteristic of quality-of-care outcomes research is that it does not involve experimental manipulation of service delivery. Instead, quality-of-care research studies the degree, extent, and consequences of naturally occurring variation in the organization, financing, and delivery of mental health services as it relates to adherence or departure from established quality standards. An important consequence of the observational nature of quality-of-care research is that the results readily generalize to broader practice. Three levels of mental health quality-of-care research are briefly described and illustrated.

Practice Variation At the most basic level, quality-of-care research involves documenting the extent to which treatment conforms with or deviates from accepted standards of care. In this type of research investigators observe variations in clinical practice and rely on existing treatment outcome studies to evaluate the clinical significance of the observed practice variations. The results highlight areas of concern in the clinical delivery of care. How physicians prescribe psychotropic

medications is particularly amenable to this approach to quality-of-care research.

The effects of aging on the metabolism of benzodiazepines are well known. Slower hepatic biotransformation and increased volume of distribution prolongs the half-life of long-acting benzodiazepines so drugs with shorter half-lives are recommended for the pharmacological treatment of insomnia in older patients. In one study the prescribing physicians showed little preference or none for shorter-acting agents in elderly patients which suggests that habit rather than sound pharmacokinetic principles may govern the selection of benzodiazepine medications. The findings of this study emphasize the need for targeted physician educational interventions.

Automated pharmacy records have been used to examine and evaluate patterns of psychotropic prescription in relation to established standards. A recent study of lithium (Eskalith) prescribing illustrates this analytic approach. Persuasive evidence exists that lithium has prophylactic mood-stabilizing properties in patients with bipolar I disorder. In one health maintenance organization it was estimated that the median period of continuous lithium use was less than 3 months, far shorter than the recommended duration of mood stabilization prophylaxis recommended by treatment guidelines and experts in the field. The results of this study suggest that detailed clinical studies are needed to evaluate the clinical consequences of this pattern of prescribing.

Practice Variation and Service Structure A second level of quality-of-care research attempts to link variations in processes of care with specific service structures. Service structures include physical facilities, providers, organization of services, and financing mechanisms. In this type of research, investigators seek to uncover clinically significant variations in practice and attempt to explain this practice variation based on some aspect of service structure.

An illustration of linking practice variation to service structure is provided by an analysis of discharge planning activities from a national survey of mental health facilities. It is well established that psychiatric inpatients who receive adequate discharge planning and transitional services are more likely to use outpatient mental health care services and are less likely to require rehospitalization in the months following hospital discharge.

This survey revealed marked unevenness in the availability of transitional-care services. Specifically, lower rates of telephone follow-up, staff assistance with referrals, visits to outpatient providers, and other crucial services were found at general hospitals as compared with specialized psychiatric hospitals. These differences persisted after controlling for case mix, hospital ownership, and other factors. Structural or administrative differences between the psychiatric hospitals and general hospitals might account for the differences in transitional-service availability.

Provider training is an important aspect of service structure and is increasingly becoming a subject of quality-of-care research. In a British study that compared lithium therapeutic drug-monitoring practices of general practitioners and psychiatrists, general practitioners less frequently obtained serum lithium levels from their patients and these patients were more likely to experience lithium levels above the therapeutic range. One third of the general practitioners made no change in the dosing regimen during the 6-week period following high serum lithium levels. These findings point to an area of clinical concern and suggest the need for targeted provider educational interventions.

Practice Variation, Service Structure, and Outcomes The most ambitious quality-of-care studies seek to link structures and processes of care with patient outcomes. Such research seeks to determine the clinical significance of identified practice variation by demonstrating an association between specific aspects of service delivery with patient outcomes.

Such quality-of-care studies resemble traditional epidemiological cohort studies. A well-defined group of patients is identified, receives a differential exposure to key treatment processes followed over time, and is examined for differences in outcome. This type of research tends to be expensive to conduct because very large sample sizes are required to capture sufficient variation in service delivery.

Confounding is an important limitation of research that seeks to link practice variation, service structures, and patient outcomes. It occurs when a variable other than the service and outcome variables under study is independently related to the service and outcome variables. Confounding can create an apparent association between service delivery and outcomes or mask an association that actually exists. For example, a naturalistic study of case management that fails to adjust adequately for initial patient illness severity might spuriously conclude that case management leads to poorer outcomes when in fact this observation may simply be a consequence of more severely ill patients being selectively assigned case managers.

The well-known Medical Outcomes Study provides an illustration of a health services cohort study. The Medical Outcomes Study was designed to compare the naturally occurring processes and outcomes of care for patients with depressive disorders and other chronic illnesses under fee-for-service and various prepaid service arrangements. Over 600 depressed patients of psychiatrists, psychologists, other therapists, and general medical clinicians were followed for 2 years at three urban sites. Among psychiatrists' patients with depression, those who initially received prepaid care acquired significantly more functional limitations than those who received fee-for-service care. Prepaid-plan patients of psychiatrists had fewer mental health visits than their fee-for-service counterparts and experienced a sharper reduction in antidepressant medication use over time.

These findings link treatment differences through financing arrangements to patient outcomes. Such data are valuable in guiding efforts to improve the quality of treatment of depression, particularly in the types of prepaid settings included in this study.

Experimental Outcomes Research Randomized clinical trials remain the most internally valid experimental design from which causal inferences may be drawn. Prospective randomized designs are used to study a range of mental health interventions and treatments. These investigations exist along a continuum from pure efficacy studies to applied effectiveness research. The continuum spans several related dimensions: stringency of patient selection, complexity of the interventions, and breadth of the outcome measures.

Efficacy studies typically select a narrow band of patients who possess characteristics that make them particularly responsive to the treatment and who lack characteristics that limit their responsiveness. The treatments studied in efficacy research tend to be relatively simple, time-limited, and capable of being administered in a highly reliable fashion (e.g., psychotropic medications). Outcome assessment in efficacy research tends to be narrowly focused on specific target symptoms.

Effectiveness research typically employs far less restrictive patient selection criteria and has an overriding interest in studying patients who are representative of broader patient populations. The interventions tend to be more complex and are studied for longer periods of time. Given the complex nature of the interventions studied in effectiveness research, it may be difficult to ascertain which aspects of the intervention are responsible for the observed outcomes. In effectiveness research, outcome assessments are typically broad and may extend beyond clinical symptoms to include social functioning, social relations, treatment and societal costs, work and school performance, family burden, quality of life, satisfaction with care, and other aspects of well-being.

Mental health services that seek to reduce use of acute inpatient psychiatric care have been extensively studied in randomized controlled effectiveness studies. Research has been conducted on the effectiveness of home care, partial hospital care, holding beds, and residential alternatives to inpatient treatment. This literature indicates that for many patients who were previously treated in inpatient settings, less restrictive settings are often feasible alternatives.

A variety of innovative models of continuous mental health service delivery have also been studied in randomized controlled effectiveness studies. The most well studied such model is assertive community treatment. This intervention involves using an interdisciplinary treatment team to provide a broad, individualized, aggressive, and continuous mix of outpatient rehabilitative and psychiatric services. Assertive community treatment staff assume ultimate responsibility for ensuring that patients receive food, shelter, clothing, and medical services and they help patients locate appropriate work and develop recreational interests.

Outcomes research indicates that assertive community treatment consistently increases patient satisfaction with care, usually reduces use of inpatient services, and sometimes reduces clinical symptoms and improves role functioning in relation to traditional outpatient care. The selective use of assertive community treatment has also been associated with savings in total costs. The impressive research findings from assertive community treatment are widely credited for contributing to the dissemination of this treatment model throughout the United States.

SUGGESTED CROSS-REFERENCES

Medicare is discussed in Section 51.5a and managed care is discussed in 51.5b and 52.2. Primary care psychiatry is covered in 28.1, public psychiatry is covered in Section 52.1; emergency psychiatry is covered in Chapter 29; and consultation-liaison psychiatry is covered in Section 25.12. Section 5.1 discusses epidemiology in psychiatry and Section 5.2 discusses statistics. Chapter 11 presents substance-related disorders, and Chapter 12 presents schizophrenia. Discussion of various classes of antipsychotics are found in Section 12.8, Section 31.17, Section 31.26, and Section 51.4e, and benzodiazepines are covered in Section 15.7, Section

31.10, and Section 51.4d; lithium is discussed in Section 14.7 and Section 31.18 .

5.4 ANIMAL RESEARCH AND ITS RELEVANCE TO PSYCHIATRY

WILLIAM T. MCKINNEY, JR., M.D.

Since the previous edition of this textbook the field of psychiatry-related animal research has undergone rapid development despite the continued lack of an effective, organized effort at the federal level. Increasingly attempts have been directed to conceptual clarification of the role of animal models, including their advantages and limitations in the study of human development and psychopathology, and a broader range of animal preparations with important interfaces to the basic and clinical sciences have been developed.

A theme apparent in the field of animal research is that there is no single comprehensive animal model for any clinical syndrome; all proposed animal models have their advantages and limitations. However, there is a range of models for studying specific components or aspects of psychiatric illness, which is a more useful way of viewing animal models (i.e., as experimental preparations developed in one species to understand phenomena occurring in another species).

Cross-species reasoning requires caution and scientific accuracy. Overextended comparisons have no place in comparative psychiatry and have sometimes given the field a bad name. However, certain principles guide attempts to learn something about the behavior or neurobiology of one species by studying another species, and these principles must always be respected.

Most psychiatric illness can be best understood by using a multivariate approach. Animal studies, where variables can be controlled rather precisely, have the potential to permit the study of the main effects of single variables and especially of how they interact. Such approaches are highly relevant to a biopsychosocial view of human psychopathology.

HISTORY

Ivan Pavlov is often said to have been the originator of research relevant to animal modeling of human psychopathology in general. His use of clinical terms as well as the experimental techniques he used, may seem foreign to most psychiatric clinicians. However, the fact that his work represented one of the first moves away from the correlational method of behavioral analysis to the experimental study of psychopathology is of central importance. As H. D. Kimmel has said:

> The significance of this change in direction may best be comprehended in relation to its two most important implications. First, the completely correlational method of behavioral analysis, which was the empirical foundation of all earlier systematic efforts to understand psychological abnormality, including everything from Hippocrates' humors and Franz Gall's prominences to the ingenious psychoanalytic theorizing of Sigmund Freud, could now be supplemented, if not altogether supplanted, by a direct experimental approach which was much less fraught with the dual dangers of loose conjecture and empirical untestability. Second, and historically of possible greater significance, the continuity of animal morphology, physiology, and behavior, already beginning to assume a position on center stage in man's philosophical thinking, received a new extensive thrust from the early Pavlovian findings since for the first time even such uniquely human phenomena as emotional breakdowns were seen to occur in subhuman animals.

Pavlov was followed by a number of other workers, and it is difficult to know what conclusions to draw about the early history of the field of experimental psychopathology research; some have not seen it as a particularly noteworthy beginning. However, the early pioneers may have been more successful than they seem in developing certain principles that are being rediscovered today. These include the following:

1. The demonstration that psychopathology could be experimentally studied in animals as well as in the strictly correlational studies done previously in humans.
2. The demonstration of the importance of careful behavioral observations as well as serendipity. Although most of the early workers did not use the more sophisticated and quantifiable behavioral scoring techniques now available, they were keen observers and literate in their descriptions.
3. The repeated proposal of an interactive model of psychopathology. The role of the temperament of the animals, along with a variety of social and neurobiological variables, was repeatedly stressed in the early literature. The concept of individual variability was part of the early work, and investigation of the sources of such variability continues to be an important area of research.
4. The discovery that a persistent internal response could be present even after the inducing stimulus had been withdrawn remains a major contribution to the understanding of a number of forms of psychopathology.
5. The recognition of the importance of unpredictability and uncontrollability, systematic investigations into which continue today.
6. Experimental paradigms for adaptive behavioral process that provide the foundation on which maladaptive behavior patterns are built in the presence of altered environmental demands. Adaptive mechanisms of animals and humans are fragile and share a tenuous relationship with the environment. Either internal changes in the organism (e.g., with drugs or other altered neurochemistry) or changes in the external environment (e.g., example, separation, the imposition of uncontrollability) can lead to serious behavioral changes, which can in turn lead to neurobiological changes and the establishing of a vicious circle. The study of those interactions has become the cornerstone of animal modeling research in depression and other forms of psychopathology.

One of the problems in early experimental psychopathology was that clinical terms were applied far too loosely and prematurely to a set of behavioral changes induced by methods that seemed to bear only a faint resemblance to inducing conditions for human syndromes. The result was that clinicians viewed the whole field of animal research with a certain amount of skepticism and cynicism.

The work of Harry Harlow, in particular, helped to stimulate clinicians' interest in the field of primate behavioral research. With his passing in 1981 the field of primatology lost one of its most prominent scientists. Harlow's research with primates began in about 1930 with observations at the local zoo. He soon discovered that monkeys and apes were much smarter than rats, and that tests designed to study rodent learning did not begin to tap the primates' intellectual capacities. It became apparent that more challenging or complex learning tasks and a better physical environment in which to test his primates were needed. Harlow addressed these two problems by developing the Wisconsin General Test Apparatus and a primate laboratory.

The Wisconsin General Test Apparatus brought to the study of primate learning capabilities a means by which a large number of discrete learning tests could be rapidly presented in highly standardized fashion to subject after subject. Studies of primate learning proliferated in the following years, and a battery of discrimination learning and memory tasks was developed that provided a standardized intelligence test for monkeys. Harlow then proceeded to study cortical localization of learning capabilities by lesioning different primate brain areas and noting subsequent differential patterns or deficits in their performance on the test battery.

In the late 1940s Harlow achieved a major conceptual and methodological breakthrough with his discovery of learning sets. He showed that rhesus monkeys presented with long series of six-trial, two-choice discrimination problems soon learned to achieve near-perfect performance on the second and subsequent trials of each problem. He was able to demonstrate unequivocally that the monkeys had acquired a strategy for problem solving. What the monkeys had learned was an abstract concept (“learning to learn,” in his words), rather than the product of simple associative learning.

Harlow's interest in the processes underlying primate learning extended to two lines of research. The first line involved motivation. In an effort to understand the factors that influenced learning performance, he discovered major inconsistencies with classic notions of drive reduction. It was not readily apparent why monkeys should solve puzzles more effectively when motivated by mere curiosity than when driven by hunger or thirst, but they did. Convinced that drive reduction and other motivational theories then in vogue in psychology and psychiatry could not possibly account for most of a monkey's behaviors, he began to look for alternative formulations.

At about the same time, Harlow began studies of the ontogenetic development of learning capabilities in rhesus monkeys. The task required devising a new battery of age-sensitive learning tests and acquiring suitable subjects. The latter requirement led to the establishment of a captive breeding colony and a nursery suitable for the hand rearing of large numbers of baby monkeys.

Work from Mortimer Mishkin's laboratory has demonstrated that an experience can enter into memory in monkeys in two ways: (1) as cognitive information stored in a cortico-limbo-thalamocortical system involving higher-order sensory areas of the cortex, amygdala, hippocampus and interrhinal cortex, medial thalamic nuclei, ventromedial prefrontal cortex, and basal forebrain; and (2) as a habit perhaps stored in a cortical striatal system involving sensory cortical areas, caudate, and putamen. The two systems seem to be developmentally dissociable. The system for noncognitive association (*habit system*) seems to develop early in infancy. By contrast, the system for cognitive association (*memory system*) appears to develop late in infancy, presumably because the neural circuit on which it depends has a slow ontogenetic maturation. Neonatal removal of the limbic system (i.e., combined amygdalo-hippocampal removal) produces a severe memory deficit from birth onward that is accompanied by social and emotional abnormalities that are strikingly similar to those seen in children with autistic disorder (i.e., an absence of social interactions, blank facial expression, motor stereotypies, and memory deficits). Thus, neonatal damage that leads to a severe memory disorder can have extremely serious consequences for personality and social development in part because of the cognitive memory impairment that is present from infancy onward, but also because of the direct effect of limbic lesions on mechanisms of emotionality.

Next came the cloth- and wire-covered surrogate mothers and the entrance of primatology into clinical psychiatry. Infant rhesus monkeys reared with the choice between a wire surrogate that fed them and a cloth surrogate that did not overwhelmingly preferred the cloth “mother.” Contrary to prevailing wisdom, *contact comfort*, as Harlow called it, was much more instrumental than feeding in bonding most infants to their surrogates. Harlow's discoveries with the surrogates sounded the end for drive reduction theory and revolutionized thinking about the socialization process in children; they also opened up the field of primate social development to serious scientific inquiry.

Eventually, Harlow shifted the major focus of his research to the study of social behavior and its development, both normal and abnormal. He developed the concept of affectional systems, the idea that social ontogeny involves the establishment of qualitatively different types of social relationships with a variety of others in the social network—parents, siblings, and peers as one grows up. At the same time, he studied the consequences of blocking the formation of different affectional systems through social isolation rearing or disrupting the attachment bonds once formed by experimental separations. Those studies clearly established the overwhelming importance of early social experiences for the development of species-normative adult social activities, including reproduction and maternal behavior.

Harlow spent his last years at Wisconsin expanding on the twin themes of normal and abnormal social behavior. Along with Margaret Harlow he was instrumental in establishing the nuclear family living unit, in which adult male-female pairs and various offspring could live together in a laboratory but in a situation rich in stimulation compared with the more typical laboratory environment. Harlow made a career of using rhesus monkey subjects to study human capabilities and problems not easily researched in humans themselves, and many of the fundamental concepts he developed, the source of considerable controversy at the time, are now fully incorporated into developmental theories.

RATIONALE FOR USING ANIMALS IN PSYCHIATRIC RESEARCH

The following reasons for including animal modeling research as part of a comprehensive psychopathology research program are illustrative rather than comprehensive. Issues concerning the development, practical use, and potential benefits of animal models are also summarized in Table 5.4-1.

Criteria for Development	Use in Research	Benefits
Similarity of inducing conditions	Treatment screens	New treatments
Similarity of behavioral syndromes	Study of developmental determinants	Better definition of syndromes in humans
Similarity of neurobiological mechanisms	Study of underlying mechanisms	Identification of at-risk persons
Similarity in response to clinically effective treatments	Study of interactions between social and biological components	Development of improved diagnostic tests
Other criteria appropriate for the specific model		

Table 5.4-1 Development, Practical Use, and Potential Benefits of Various Types of Animal Models

1. Many critical questions about the origins of human psychopathology cannot be studied directly in humans. By using animal preparations it is possible to control inducing conditions fairly precisely and to study the behavioral and neurobiological effects on a short-term as well as a long-term basis. For example, in the field of depression, prospective studies examining the effects of developmental events on behavior and neurobiology can be done much more easily in animals than in humans. The timing and exact nature of certain alterations in development can be specified, and the short- and long-term consequences studied. That aspect of modeling research is relevant to the question of developmental vulnerability based on early experiences and the mediating mechanisms of vulnerability.

   A particular line of research where animal preparations have a special contribution to make is in prospective studies of the effects of developmental events on behavior and neurochemistry. The interactions between those variables can be studied in a controlled and prospective manner. Animal preparations developing since the late 1980s make such investigations feasible and will facilitate the movement beyond correlation and retrospective analysis to cause-and-effect studies.
2. The underlying mechanisms associated with specific behaviors and patterns of behaviors can be studied more directly in certain animal species. Animal models potentially make possible the dissection of mechanisms in a more direct way than is possible in human clinical research, and they complement ongoing efforts in human protocols. More direct and potentially more invasive studies of neurobiological mechanisms can be performed, although such procedures need to be suited both to the species and the overall purpose of the experimental paradigm. Not all procedures are justified on ethical or economic grounds in all species. The questions have to be clear and specific, especially in proposing such studies in higher-order primates.

   The time is ripe for a vigorous effort in this area. The area of experimental psychopathology in animals has become complex enough to require the involvement of multiple laboratories, much as collaborative human studies of psychopathology often involve many centers. For example, different strategies and approaches need to be employed with several species, and techniques now generally available in only one laboratory need to be applied to many of those preparations. Attention needs to be paid to how to do what kinds of mechanism studies in a given species. Molecular or submolecular studies may be indicated in some preparations, but that may not be the only reasonable way to approach mechanism studies, for example, in a socially behaving species. The issues are complex but probably can be solved with enough discussion and with the development of some collaborative protocols across laboratories that take advantage of complementing expertise.
3. Single variables can be evaluated in terms of their main effects and in terms of the nature of their interaction with each other. For example, the nature of the interactions among genetic, developmental, social, and biological variables can be studied in various combinations in different species. In human clinical research, multiple variables interact simultaneously, and it has been impossible to sort them out in any quantifiable way.
4. The ability to isolate specific behavior patterns in animals and to study their origins, pathophysiology, and responsiveness to treatment techniques is important. Typically, in clinical work one is dealing with a broad range of behaviors that occur together, and it is impossible to study one or two in isolation and to understand them more completely. The many examples include anhedonia, stereotypic rituals, social withdrawal, and altered learning and cognitive abilities. If these and other particular aspects of psychopathological syndromes can be understood better, it might be possible to expand the understanding of situations where they typically occur together.
5. Animal models have played an important role in the preclinical evaluation of drugs. The empirical or predictive validity of animal models will be discussed further with regard to the general kinds of animal models.

   A related aspect of the use of animal models is their contribution to a better understanding of the mechanism of the action of drugs in altering specific behavior

patterns. This assistance goes beyond a mere prediction of whether drugs work or do not work and relates to the behavioral effects of agents with relatively specific mechanisms of action.

6. Animal models can also be used to understand the mechanisms of established treatment techniques. They can make possible the investigation of the mechanisms in terms of pathogenesis and of treatment responsiveness; that is, why do some drugs work whereas others do not? What are the mechanisms of action of electroconvulsive therapy in depression? Why are certain behavioral interventions effective whereas others are not?
7. Animal models also permit the understanding of a specific behavior or set of behaviors in terms of the developmental and social context as well as pathophysiologically. Rather than focusing on global syndromes, the origin, context, and responsiveness of behaviors to certain interventions can be investigated.
8. Animal modeling research, especially with primates, has led to the development of improved behavioral, ethologically based rating methods that can now be used in clinical research settings to evaluate social interactions, as between mother and infant or among peers.

Paul Wilner has described three different concepts of validity of animal models including predictive validity, face validity, and construct validity. He makes the point that, in the case of depression, animal models have been most frequently encountered in the pharmaceutical industry, where they have been used in screening tests in the development of new antidepressants. He indicates that animal models are also being used as simulations for investigating the psychobiology of depression, and that some models have been specifically developed for that purpose.

Predictive validity primarily concerns the correspondence between drug actions in the model and in the clinic. Manipulations that have certain effects in the clinic should have similar effects in the animal model for that model to be valid from this standpoint. Using this criteria, there are likely to be false positives as well as false negatives. Not all agents that work in an animal model will also work in humans and not all drugs that work in human depression will necessarily work in animal models. In terms of evaluating animal models according to this criteria it is the pharmacological profiling that is critical rather than the response to just one drug. No animal model has perfect concordance in this regard. *Face validity* refers to phenomenological similarities between the model and the disorder being studied. Realistically, not all symptoms can necessarily be modeled nor are all symptoms equally important in defining the clinical syndrome. The major point in considering the validity of animal models from this standpoint is the composite patterns of behaviors shown rather than the presence or absence of any one behavior or symptom. *Construct validity* refers to the theoretical rationale for the model, which in turn relates to the theoretical understanding of the clinical condition and its causation. Unfortunately, too many proposed animal models of depression or other psychiatric disorders use single proposed causes rather than operating on the basis of multiple risk factors. However, it should be possible in animal models to evaluate the relative contributions of various risk factors thought to be important in the human syndrome in question.

In a recent review, Mark Geyer makes the point that before criteria can be considered it is important to be explicit about the intended purpose of the model because this will determine in part the criteria that should be used to evaluate its validity. He contends that for a model to be of value in neurobiological research it must only satisfy two criteria: reliability and predictive validity. He does not think that construct validity is essential. He concludes his review by stating that there are no perfect animal models for any condition; each has advantages and limitations that need to be recognized in working with the model.

There are a number of approaches in developing animal models for any psychiatric disorder, and there is no such thing as a best model for any single syndrome. Animal models should be understood as basically experimental preparations that are developed in one species for the purpose of studying phenomena occurring in other species. The concern should be and increasingly is to develop a variety of experimental paradigms in animals to study selected aspects of human psychopathology rather than to attempt to develop a model of a given syndrome. Certain paradigms are suitable for studying certain phenomena whereas others are more suitable for studying other aspects. What is the best model for depression, schizophrenia, other mental disorders depends on what the question is.

CATEGORIES OF ANIMAL MODELS

Animal models can be divided into four categories: (1) those developed to simulate a specific sign or symptom of the human disorder (behavioral similarity models); (2) those developed to evaluate etiological theories (theory-driven models); (3) those developed with the primary purpose of studying underlying mechanisms (mechanistic models); (4) those developed to permit preclinical evaluation of treatment methods (empirical validity models). There is obvious overlap among the categories.

Behavioral Similarity Models Behavioral similarity models are designed to simulate specific symptoms of the human disorder in animals. The primary intent is to produce a particular symptom or set of symptoms, not to evaluate any specific etiological theory or to study underlying mechanisms or treatment responsiveness. The validity is judged by how closely the model approximates the human disorder from a phenomenological standpoint.

Theory-Driven Models In a theory-driven model a theory drives the development of a specific experimental paradigm. It is not necessary to assume the validity of the theory in order to proceed with the research. The attempt is made to operationalize the theory and to develop experimental paradigms to evaluate the effects of such inducing conditions. The approach is sometimes criticized on the basis that because the theory has not been substantiated in humans its use in animals is questionable. The response is that the very reason for developing the paradigm is to test or evaluate the theory. Most etiological theories of psychopathology have developed from studies of sick humans and therefore are retrospective. Using inducing conditions as an independent variable, the effects of specific conditions designed to represent certain causative theories can be evaluated prospectively.

Mechanistic Models The issue of the use of animals to study mechanisms is complex. For some, mechanism studies represent the only reason for developing animal models, which are evaluated by how well they lend themselves to those studies. With the increasing availability of high-technology methods for studying underlying neurobiological mechanisms, many researchers have become preoccupied with the molecular and submolecular basis of the altered behavior seen in many proposed animal models, and they consider useful only a model that permits those types of studies.

One must be careful, however, with the term “mechanisms.” Mechanistic studies certainly include the application of high-technology neuroscience techniques to the study of different mechanisms in the various models, but they also include social, behavioral, and developmental mechanisms. The techniques of mechanism studies cannot necessarily be transposed from rodents to monkeys or vice versa. Mechanisms must be studied as appropriate in a particular species and each approach should be recognized as having certain advantages and disadvantages. Because behavior and psychopathology occur in a social and developmental context the continued study and monitoring of social behavior is essential. A serious challenge that remains for researchers is the development of noninvasive techniques for mechanism studies in socially behaving animals that will be satisfactory to basic neuroscientists as mechanism studies. Compromises between directness of neurobiological studies and sophisticated ongoing assessment of social behaviors may be necessary.

Empirical Validity Models The best known and oldest use of animal models involves the use of animal preparation to develop and test clinically effective drugs. Basically, an ideal animal model would be one in which there are no false positives and no false negatives; that is, when a drug works in animals it is predictive of its clinical effects in humans and vice versa. Unfortunately, there is never 100 percent correspondence between the effects of a drug in an animal model and in a clinical condition, although there are a number of models with established high empirical validity. The establishment of an animal model as valid on empirical grounds (or on any other grounds) does not necessarily establish its validity on other parameters.

Genetic Models In contrast to most animal models that rely on stress-induced changes suggestive of depression, genetic models involve studying strains that exhibit spontaneous behaviors that mimic aspects of psychiatric disorders. Through selective breeding, some investigators have developed animal strains that are especially sensitive on certain tests. One example of this is the Wistar Kyoto (WKY) strain of rats, which are motorically depressed in the open field test, reveal an escape deficit when exposed to inescapable shock, and rapidly acquire a passive avoidance response and freeze in the conditioned defensive burying test. Desipramine (Norpramin) reduces immobility in the forced swim test. These animals are also sensitive to restraint-induced stress ulcer and show higher levels of adrenocorticotropic hormone in response to restraint stress, suggesting that they are hyperresponsive to stress stimulation. Other researchers have also studied various rat strains, especially the Flinders Sensitive Line that are reported to show depressive behaviors on a range of testing procedures and to respond positively to antidepressant medications.

ILLUSTRATIVE ANIMAL MODELS

Mood Disorders

Pharmacological Models In one approach drugs are administered to animals in order to reproduce some of the phenomenology of human depressive syndromes. A related approach is to use certain drugs to produce a set of changes in animals, changes that do not necessarily resemble human depression but have high empirical

validity in terms of predicting clinical drug responses. A third class of animal models is heterogeneous and, although not based on drug-induced changes, has been found useful in predicting and characterizing antidepressant activity. That type of model may have empirical validity in terms of drug screening, but in terms of induction techniques or behaviors, it bears little relationship to human depression (e.g., the bulbectomized rat syndrome and kindled amygdaloid convulsions).

Among pharmacological models, the syndrome induced by reserpine (Serpasil) and related compounds has been the most widely used. When given to animals of various species, reserpine produces a characteristic set of behaviors, including ptosis, hypothermia, inactivity, social withdrawal, and sedation. The interest in this animal model came from the clinical observation that drugs containing reserpine were reported to induce depression in humans who took them for the treatment of hypertension. At least in its initial form, this clinical observation has been called into question on the basis of recent evidence. It appears that humans who become depressed while taking reserpine-containing drugs have a history of depression and are presumably vulnerable in that area.

The reserpine syndrome as an animal model of depression has been reviewed extensively. In addition, a number of related compounds have been used to induce symptoms qualitatively similar to those produced by reserpine, although several factors are different, such as the speed of onset, duration, and central and peripheral effects. Initially most clinically active antidepressant drugs were believed to antagonize some or all of the symptoms induced by reserpine. In general this is true, but there are a number of inconsistencies. The reserpine syndrome is not a unitary entity, but involves many different effects. For example, ptosis antagonism, although probably a peripheral effect, seems to characterize the greatest number of clinically effective antidepressants, including several of the newer ones, some of which are regarded as false negatives in other reserpine procedures. In evaluating the empirical validity of the model, one must be specific about which behavior is involved. Some behaviors could have high empirical validity in terms of predicting clinical drug response, although the mediating mechanism may not even be central in origin. Reserpine has so many different neurochemical effects that one cannot reason directly from such studies to possible mechanisms associated with the behaviors produced, let alone to human depression.

Several other pharmacologically induced models have been developed, one of which is the amphetamine withdrawal model. Animals subjected to repeated amphetamine treatments, which are then stopped, evince a number of effects, including decreases in motor activity and self-stimulation behavior. Those effects have been reported to be reversed to a certain extent by amitriptyline, imipramine, mianserin, and pargyline when given on an initial short-term basis, but especially when given on a long-term basis.

Another proposed pharmacological model is clonidine (Catapres)-induced behavioral depression. Clonidine, an a-adrenergic receptor agonist, is thought to act at presynaptic receptor sites to reduce the release of norepinephrine, resulting in hypothermia, analgesia, and marked sedation. Clonidine-induced hypoactivity has been proposed as a test for antidepressant drugs. Although it is not clear which drugs will work in that model, it may play a role in screening for antidepressants that might be active in other models.

Another class of procedures widely used in pharmacology involves the potentiation by antidepressants of the behavioral and other effects of amines or their precursors. Those procedures do not attempt to mimic the clinical condition, but are based on theories about the role of the amines in depression. Thus, they are designed to show how amines interact with each other and are influenced by antidepressant drugs. By such routes, important information can be obtained that may ultimately have a bearing on mechanism questions, which can be tested in more highly developed behavioral models. Examples of such procedures include the potentiation by antidepressants of the various central effects of amphetamines and yohimbine (Yocon).

Pharmacologically induced models continue to be important for screening clinically effective drugs. Thus, in evaluating them, attention should be paid primarily to their empirical or predictive validity. Each has false negatives and false positives, but by using several such tests in a battery it may be possible to achieve an even higher degree of empirical validity.

In the case of all empirically based tests, it should be kept in mind that the mechanism by which the drug presumably acts in the animal preparation is not necessarily the same as its mechanism of action in human depression. Too many variables can intervene, and additional types of animal preparations may be necessary to assist with mechanism questions.

Separation Models Disruption of attachment bonds, whether in humans or nonhumans, has been established as a very stressful event. Humans and many animal species are in their most stable condition when they have developed secure social attachment systems. Disruption of such systems almost invariably leads to the development of grief reactions and can precipitate clinical depression in some vulnerable individuals. Many developmental, social, and neurobiological variables are known to influence the reaction to separation. However, determining the influence of those variables in humans and of how the variables interact with one another has been extremely difficult. Investigators have therefore turned to animal models for a more systematic study of the effects of separation.

BEHAVIORAL RESPONSES TO MATERNAL SEPARATION The earliest work on separation in animals began in the 1960s at a number of laboratories with the short-term separation of pigtail macaque infants from their mothers at the ages of 5 and 7 months, followed by reuniting them with their own or another mother. The behaviors seen following separation have been divided into two categories, labeled *agitation* or *protest*, and *depression* or *despair*.

The protest and despair response seen in many primate species after maternal separation has been compared with the responses in human children diagnosed with analytic depression or observed in institutions (usually hospitals or nurseries) where they were unavoidably separated from their mothers and families. The stages of response of human infants to maternal separation have been described as *protest, despair*, and *denial* (later changed to *detachment*). These stages have played a key role in the development of the theory of primary separation anxiety. As animal researchers extended the original work on the response to maternal separation, it became apparent that the response of the infants was influenced by a number of parameters, including the species, age, and social conditions.

The reaction to maternal separation in primates represents a true biobehavioral syndrome. Significant behavioral effects occur as described above, as well as major neurobiological changes.

PHYSIOLOGICAL RESPONSES TO MATERNAL SEPARATION Pigtail macaque infants undergoing maternal separation have been studied using totally implanted multichannel biotelemetry systems to monitor heart rate, body temperature, and sleep physiology before, during, and after the separation. In these studies the biological mother was usually removed from a group living situation and the infant was left in the group. Attachment bonds have been found to be as central to the development of monkeys as they are to humans, with disruption of those bonds leading to serious changes. In one study, for example, the infant's heart rate and body temperature increased significantly immediately after maternal separation. The changes were most pronounced early in separation and diminished as the separation continued. Beginning with the first night, both the heart rate and body temperature showed marked decreases from baseline levels and the behavioral patterns became more like depressive states. During reunion, the heart rate and body temperature returned to normal, although some infants exhibited a lower heart rate well into the reunion. An increased incidence of cardiac arrhythmias as a result of maternal separation has also been reported. Significant sleep changes have included increased sleep latency, more frequent arousals, less total sleep, and a disruption of rapid eye movement (REM) sleep.

In other research neurochemical effects were examined in rhesus monkey infants that were in the protest stage following maternal separation. Positive findings included elevated serotonin levels in the hypothalamus and significantly higher levels in the adrenal gland of all the major enzymes involved in catecholamine syntheses. Resting levels of norepinephrine and dopamine were unchanged in any of the brain regions examined. The study measured resting levels of those substances at one point in time and thus gives no information about possible dynamic changes occurring over time. However, it provides additional confirmation of the powerful effects of disrupting the maternal attachment bond; the syndrome is neither transient nor mild.

When separated from their mother or from a surrogate, squirrel monkeys show a marked increase in the pituitary-adrenal response. Initially it was reported that there was an identical physiological response whether the infant was separated from a mother or from a surrogate. The monkey mother also showed an elevated corticoid response to separation. The latter finding is interesting in that the mother's responses to infant removal have been very minimally described in most studies because investigators have been preoccupied with assessment of the infant. The mother has been typically described as acutely upset but as getting over it very quickly. The infant's corticoid response was felt to be caused by the separation itself rather than by the new cage in which it was housed during the separation phase, and this finding has been supported by data from a number of studies. The presence of a familiar animal during the separation phase did not alter the corticoid response, suggesting that the disruption of the specific attachment bond between mother and infant was the main cause of the increased corticoid levels.

Physiological and behavioral changes following separation may not occur simultaneously. For example, separation from the surrogate results in a behavioral response but no corticoid response. Later work shows that infants of highly dominant mothers manifest the greatest adrenocortical response to separation and that they may not always exhibit concomitant behavioral changes. This important research illustrates the complexity of the neurobiological and behavioral changes that

may accompany separation. It is important to obtain adequate baseline behavioral profiles of both the group structure and individual behavioral assessments.

Desipramine has been reported to be effective in preventing the response to maternal separation in primates, and imipramine has a similar therapeutic effect on the responses to peer separation.

OTHER RESPONSES TO MATERNAL SEPARATION When infant lagur monkeys were separated from their mothers at 6 to 8 months of age, all infants showed changes in social behavior, which varied from minimal to severe and included two deaths. All infants sought substitute caretaking during the separation and adopted a major substitute caretaker. Most infants remained with the substitute even when the mother returned. Some researchers have used distress vocalizations in various animals as an index of separation and have studied the effects of many pharmacological agents on those vocalizations. In general, the distress vocalizations are reported to be relieved by morphine and made worse by the narcotic antagonist naloxone (Narcan) when those drugs are given as single injections. A variety of opiate-like peptides have been tested, and all have been reported to be effective in decreasing distress vocalizations in separated animals when injected into the vicinity of the fourth ventricle in quite low doses. Additional maternal separation studies have been done using canine puppies, guinea pigs, and chicks. From those studies researchers have developed the theory that brain endorphins may play a critical role in the mediation of social bonds, and that when those bonds are disrupted by separation, a syndrome similar to that following narcotic withdrawal is produced.

PEER SEPARATION Rhesus monkeys and most other primate species develop strong, complex social bonds, and paradigms have been developed that involve experimental disruption of those bonds in peers of various ages, including adults. In general, the behavioral reaction to peer separation is quite similar to that following maternal separation in terms of the classic protest-despair response. Furthermore, when peer groups are formed and separations are repeated, the response is seen with each separation. Not surprisingly, a number of variables can influence the nature of the response, including age; rearing conditions; housing conditions before, during, and after each separation; and treatment with pharmacological agents. Significant individual variability can be related to a number of developmental and neurobiological variables. For example, the concentration of norepinephrine in cerebrospinal fluid (CSF) appears to be a trait-related marker predicting a more severe response to separation. Animals with lower concentrations of norepinephrine in CSF respond to separation with more huddling and self-directed behaviors than animals with higher concentrations. By contrast, CSF homovanillic acid (HVA) and 5-hydroxyindoleacetic acid (5-HIAA) levels are state-related markers that reflect the behavioral response to separation no matter how the response is obtained.

Pharmacological agents can affect the response to peer separation. Imipramine reverses the reaction to peer separation and prevents the reaction to future separations as long as the monkeys are continually administered the drug. They return to more typical separation behavior when the drug is withdrawn. Amphetamine modifies the behavioral response to separation in a very similar manner to imipramine, but the overall effects of the two drugs on group social behavior can be distinguished. a-Methylparatyrosine, which blocks tyrosine hydroxylase and thereby lowers norepinephrine and dopamine levels, can exacerbate the response to peer separation at doses so low that they have no effect when the monkeys are living as a stable social group. It is only when one combines the stress of separation with low-dose a-methylparatyrosine that one sees other effects of the drug in that paradigm. Parachlorphenylalanine, which blocks serotonin synthesis, has no effect. Low doses of alcohol alleviate the peer separation response whereas high doses make it worse.

During separation, mother-reared monkeys exhibited low and stable levels of disturbance behavior, which did not vary much from separation to reunion conditions. However, peer-reared monkeys exhibited significantly higher disturbance behavior during separations than mother-reared monkeys and the behavior was greater during separations than during reunions. Drug treatment with desipramine blocked the increase in disturbance expected by peer-reared animals during separations. Moreover, the full drug effect was not significant until 5 weeks after administration or 3 weeks after separation challenge. Fluoxetine (Prozac) had a similar effect on the response to repeated peer separation; desipramine and fluoxetine did not differ from each other.

Additional Separation Studies Based on studies in rats it has been reported that recurrent and unpredictable, brief, early maternal separations induce changes in responses to reward in adulthood and that these changes were generally opposite to those induced by isolation rearing. A reduction in the immediate exploratory response to novelty has been reported in both sexes, as well as a blunted locomotor responsivity to compound cues predictive of food reward in females. Early maternal separation did not lead to any overall alteration in consummatory behavior and sucrose preference, but did lead to a definite blunting of the responses to successive positive and negative contrast. The researchers concluded that adverse early experience could induce enduring alterations in the responding of rats to rewarding stimuli in maturity. Given the importance of anhedonia as a core clinical feature of serious depression, early maternal separation could represent a very useful paradigm to explore the neurobiological substrate of reward and of depressive disorders.

Other studies have examined the neuroendocrine correlates of separation stress in the Siberian dwarf hamster (*Phodopus sungorus*). These animals form monogamous male-female pair bonds. Disruption of the pair bond has been shown to result in increases in body mass and behavioral alterations similar to profiles seen in human atypical depression. They found that separation stress was accompanied by increased hypothalamic-pituitary-adrenal axis function, decreased peripheral sympathetic nervous system activity, and decreased reproductive profiles.

Data from a report of free-ranging rhesus monkeys to a more natural form of social separation than that used in the laboratory, namely the decreased amount of time a mother spends with its infant when they have their first postpartum estrus period and resume mating, suggest strong parallels between the behavioral response of rhesus infants to their mother's resumption of mating in the field and to forcible separation from mothers in captivity. In both situations the infants experienced increased separation from their mother and responded with distress and, in the case of a certain percentage, with depression.

RESEARCH APPLICATIONS With regard to proposed depression models, the rationale for separation studies in animals is that the bulk of evidence strongly suggests social separations as risk factors that cut across types of depressions. Animal studies represent one way of studying those risk factors. Although many factors are involved in depression, separations appear to be important events for vulnerable individuals and so are worthy of additional investigation. An even more important context in which to view separation studies is as prototypes for the study of stressful events in general. With the recent advances in the knowledge of developmental and neurobiological influences on behavior, it becomes increasingly important to have experimental paradigms in which the interactions between neurobiological factors and social risk factors can be examined. Such animal preparation provides the opportunity to control social and developmental variables and to conduct prospective studies of behavioral and neurobiological parameters. The long-term effects of early alterations can be examined in a much shorter period of time. Repeated measurements of neurobiological variables, as in the CSF, can be obtained in a way that cannot be done in humans and in relation to specific units of behavior. The effects of drugs on parameters similar to those being studied in humans can be evaluated and what those changes mean with regard to specific social behaviors can be determined. The role that specific neurotransmitter systems play in influencing specific units of social behavior, including responses to separation, can also be clarified. Humans are fundamentally social creatures, and an understanding of the social origins of psychopathology and how they are related to neurotransmitter systems becomes possible in this kind of preparation.

Learned Helplessness The animal model of learned helplessness has been extensively studied for more than 15 years. It relates closely to some important aspects of clinical depression, particularly cognitive aspects, such as a negative conception of the self, negative interpretations of one's experiences, and a negative view of the future. Those cognitive aspects are reflected in feelings of helplessness and hopelessness. Whether the phenomena are primary or secondary is a moot point for the present discussion. The phenomena occur as core aspects of depression frequently enough to be worthy of further study. Etiological theories as well as therapeutic approaches have developed from that cognitive view of depression.

In the original experimental study with animals, dogs were placed in one of three situations. In the first situation they were put in harnesses and subjected to electric shock that they could terminate by touching a panel; not surprisingly, they learned to escape the shock rather quickly. In the second situation the dogs were prepared as in the preceding situation, but when the shock was given, they were unable to terminate it. Finally, to control for the effect of the shock itself, dogs were put in harnesses but were not subjected to shock at all. In Phase 2 of the study, dogs were given electric shock while unharnessed in a shuttle box. Normally, dogs have no difficulty learning to avoid the shock by going to the other side of the box, which proved to be true for the dogs that had been exposed to escapable shock while in the harness. However, the dogs that had been exposed to inescapable shock failed to learn that they could escape from the electric shock in Phase 2 by jumping over a barrier that separated the two sides of the shuttle box. They were described as being initially agitated in reaction to the shock but, rather than to run around frantically until they discovered that they could escape the shock by crossing the barrier, they would sit or lie down, whining quietly—that is, they acted as if they were helpless and incapable of escaping. The interpretation was that the inescapable shock they had experienced earlier made them unable to cope with the present situation. One explanation was that they had learned during their initial experience that outcomes were not contingent on their behavior. No matter what they did, it did no good; they learned to be helpless.

To reverse this state, attempts were made to retain the dogs by trying to coax them across the barrier. This strategy was very difficult, and ultimately it was found that the only effective way was to drag the dogs across the barrier forcibly and thus to terminate the shock. It took many efforts before most of the dogs could learn this response and do it by themselves when placed in the shuttle box.

Recent studies suggest that cortisol may be specifically elevated in helpless animals. One study found that animals showing deficits in escape performance have norepinephrine depletions, specifically in the locus ceruleus, and the researchers have used an antagonist to manipulate that system. They suggest that the a-receptor system is involved, which has been confirmed in mice by other studies on the effects of serotonin and acetylcholine. Other investigators have suggested specific alterations in the hippocampal b-receptors that occur with the development of helpless behaviors. They suggest that those changes are reversed by antidepressant drug treatments, and that serotonin appears to regulate b-adrenergic receptor concentrations in the hippocampus. Along with lesion studies implicating the fornix and septal regions in the behavioral alterations, that study points to the septal-hippocampal pathway as an important site for serotonin regulation of norepinephrine function. The latter group has been successful in selective breeding for learned helplessness through several generations. Thus, use of the learned helplessness model that leads to some detailed hypotheses about the neurological regulation of mood is improving the understanding of human mood disorders.

RESEARCH APPLICATIONS The literature on learned helplessness is enormous and, as in the case of separation models, controversial. However, one set of recent findings merits closer scrutiny and illustrates clearly how experimental paradigms in animals can be used to investigate the interrelations between behavioral events and neurobiology, an interface crucial to understanding human psychopathology. Again, as in the separation models, one does not have to agree with the validity of the model itself to appreciate the value of that kind of work in a spectrum of research approaches aimed at understanding specific aspects of human depression.

Severe, inescapable trauma, for example, has been found to produce a deficiency in central noradrenergic activity, namely, depletion of locus ceruleus norepinephrine levels. However, studies have shown that subjects who were able to control the noxious experiences did not develop the noradrenergic deficiency and were able to respond efficiently. When the drop in noradrenergic activity was prevented by treatment with drugs, the learned helplessness phenomenon did not occur. Unfortunately, those kinds of data have sometimes been cited as evidence that the concept of learned helplessness is not valid.

A major finding, by contrast, has shown that a state that is clearly induced behaviorally is associated with major changes in certain neurobiological systems, and that if those changes can be prevented, the behavioral state that results from certain well-described behavioral manipulations can be prevented or even reversed. It would be interesting to learn if behavioral reversal of the syndrome leads to reversal of the biological changes, or if reversal of the biological changes alone (once the syndrome is set in motion) will reverse the behavioral aspects. Investigators know that in human depression not all of the significant behavioral and cognitive changes are necessarily reversed with drugs, which presumably alleviate whatever underlying biological alterations may be present. One sometimes has to deal directly with the altered cognitions and behaviors, as well as the underlying neurochemistry. The evidence of a complex interplay between a cognitive-behavioral state and neurobiology clearly warrants further investigation.

Other ongoing work in learned helplessness mainly relates to that interface between the behavioral state and neurochemical substrates. Several such substrates may prove to be important, and it will be critical to ascertain their interaction with behavioral variables. For example, the involvement of the opioid system in the learned helplessness models of depression has been investigated. Animals preexposed to inescapable shock and treated with either opioid agonists or enkephalin catabolism inhibitors evidenced a reversed escape deficit that was induced by shock pretreatment. In contrast, nalzone potentiated the effect of inescapable shocks. Imipramine reduced the number of escape failures and this effect was antagonized by naloxone (Narcan). The central histaminergic system has also been investigated in the learned helplessness paradigm. In another series of studies, earlier learned helplessness training was shown to sensitize the hippocampus to increased norepinephrine release during a subsequent less severe stressor.

Chronic Stress Models In chronic stress paradigms rats are subjected to a chronic stress regimen that is designed to be unpredictable with regard to the stimulus properties of the stress, as well as the time of stress delivery. Stressors are administered every 1 to 2 days over a period of 21 days at various points in the circadian cycle. Stressors include switching of cage mates, removal from double housing to single housing for 24 hours, 30 minutes of scrambled unpredictable foot shock, 46 hours of food deprivation, 46 hours of water deprivation, a coldwater swim, shaker stress, and tail pinch. After 21 days, when the rats are tested in an open field test situation, they do not exhibit normal open field activity or the usual response to an acute stress. The decreased exploratory behaviors can be reversed by a variety of drugs, including monoamine oxidase inhibitors (MAOIs) and tricyclic antidepressants, as well as by electroconvulsive therapy (ECT). Amphetamines and scopolamine are ineffective. Thus, the model appears to have good pharmacological specificity and is one in which studies of the neurobiological substrates could readily be done. Such an approach emphasizes the combined influence of chronicity and unpredictability in producing the behavioral alterations.

Changes in Dominance in Hierarchy Another proposed model reflects the importance of dominance in the relationships of many nonhuman primates. It has been postulated that changes in the stability of the dominance arrangement cause behavioral alterations. It is hypothesized that the behavior that occurs in association with gaining higher-dominance ranking may be elation; depression occurs with falls in one's position in the hierarchy. In this theory, depression is postulated to be adaptive because it prevents the descending animal from fighting back. It has been reasoned that, if this is so, depression could be induced by altering the dominance hierarchy in some nonhuman primates. The theory rests on limited data since the evidence for particular behavior patterns occurring in association with specific changes in the hierarchy is fragmentary. Dominance hierarchies are not easy to manipulate. However, work concerning dominance and serotonin metabolism will be interesting to follow. The work is not concerned primarily with animal models of depression, but it does involve manipulation of the dominance hierarchy, careful behavioral observations, and study of the serotonin systems.

Intracranial Self-Stimulation Models Another proposed animal model of depression is the reward-reduction model using self-stimulating animals. The involvement of catecholamines in the mediation of intracranial self-stimulation has been well established, although there is controversy about their relative importance. In general, agents that enhance the effects of catecholamines tend to increase intracranial self-stimulation responding, whereas those that impair catecholamine actions tend to decrease intracranial self-stimulation response rates. However, the actions of tricyclic antidepressant drugs in the model appear anomalous because they do not enhance intracranial self-stimulation responding despite their well-documented antidepressant action and their effects on catecholamine systems. Those drugs tend to decrease the rate of responding and to raise the reward threshold. Attempts have been made to find an animal model in which tricyclic antidepressant drugs potentiate intracranial self-stimulation responding. One such model has been suggested, in which reinforcement requires increasing effort. In those progressive fixed-ratio schedules, responding typically drops gradually to zero. Antidepressants have been reported actually to enhance responding. However, efforts to replicate the work have been unsuccessful. Rats that had electrodes implanted long term in the medial forebrain bundle were trained in progressively increasing fixed ratio schedules. Two tricyclic drugs (imipramine and protriptyline) were given, but neither resulted in response enhancement. Thus, additional work is indicated to evaluate more fully the reward-reduction model involving ICSS as an animal model of depression. It is worth pursuing, however, in view of the important finding that anhedonia is a key feature in many cases of severe depression. It would be valuable to have an animal model in which the mechanism and pharmacology of that sign could be studied.

Conditioned Motionlessness The proposed model involves pairing a buzzer (conditioned stimulus) with a tetrabenazine injection (unconditioned stimulus) for at least 11 trials. Following conditioning, some rats exhibited motionlessness after the presentation of the buzzer alone; imipramine attenuated the conditioned motionlessness. Subsequent neurochemical studies of those rat preparations supported the conclusion that the observed motionlessness was associated with an excess of functional serotonin at the synaptic cleft. Motionlessness after tetrabenazine administration is not blocked by imipramine. When the conditioned response is reversed by imipramine, however, the biochemical data resemble those for control subjects.

Behavioral Despair The model involves the use of a test of behavioral persistence in the context of an inescapable task. The test is based on the observation that when rats or mice are forced to swim in a restricted space from which they cannot escape, they eventually cease their attempts to escape and become immobile. It has been suggested that the characteristic behavioral immobility reflects a state of despair in the rats or mice. The immobility is reduced by most clinically active antidepressant medications, as well as by nonpharmacological treatments such as ECT, REM sleep deprivation, or exposure to an enriched environment. The effects can be seen after initial short-term administration, but more marked effects are seen after repeated treatments with lower doses. The drug effects do not appear to be caused by increased motor activity because the doses used generally decrease motor activity. Antidepressant medications seem to prolong the escape-directed behavior observed at the beginning of a test session, whereas psychostimulants or anticholinergic drugs cause a generalized behavioral stimulation. Those potential false positives can be distinguished from the effects of true antidepressant drugs. However, as with all models, both false positives and false negatives occur. False-positive results have been reported with antihistamines, subconvulsant doses of convulsants, and some neuropeptides. False negatives have been found with clomipramine (Anafranil) in rats and albuterol (Proventil, ventolin) in rats and mice.

The model was developed mainly for drug screening and thus must be evaluated in terms of its empirical validity, which seems at least as good as that of most drug-screening models. At a theoretical level its relationship with learned helplessness or uncontrollability models needs to be clarified and mechanism studies remain to be done. Recent years have seen a major expansion in the number of behavioral paradigms that have been proposed as animal models of depression.

Other Considerations of Animal Models of Mood Disorders Because it is ethically unacceptable to use human subjects to conduct manipulative experimental hypothesis-testing research on major depressive disorder, investigators interested in the depressive disorders have turned to observation of models with humans and to interactive models with animals. The models based on limbic dysfunction could be used to explore specific neurosubstrates of depression. In that context, the rat

with limbic dysfunction induced by olfactory bulbectomy is believed to best fulfill the requirements for a model of depression. Discovery of a genetic strain of animals that show comparable behavioral and neurovegetative deficits and similar selected drug responses to those seen in patients with depression would help to advance the field and increase the understanding of the neurobiology of the limbic system.

Comparatively little work has been done to develop animal models of bipolar disorders. Most work has involved the antagonism by lithium (Eskalith) of drug-induced states in animals and man. Table 5.4-2 summarizes those studies. Some of the newer thinking is represented by an evolutionary model of manic-depressive disorder, the essence of which is that manic and depressive behaviors are evidence of triggered fundamental alpha (a) and omega (w) states of social rank and are not by themselves pathological.

State	Lithium Effect	
	Humans	Animals
Amphetamine (low dose)		
Hyperactivity, activation	Blocked	Reduced
Amphetamine (high dose)		
Stereotypical behavior	Unchanged or prolonged	—
Morphine		
Excitement, euphoria	Reduced or unchanged	Unchanged
DMA plus tetrabenazine		
Hyperactivity	Reduced or unchanged	—
L-Dopa		
Hyperactivity, hypomania	—	Possibly reduced
Ethanol high	—	Unchanged
MAO-inhibitor		
Hyperactivity	Enhanced	—

Table 5.4-2 Antagonism by Lithium of Drug-Induced States of Animals and Humans

SCHIZOPHRENIA Is it possible to produce an animal model for schizophrenia? Several authors have suggested standards that should be satisfied if a particular preparation is to qualify as an adequate animal model. Those criteria have been mostly drug related; for instance, clinically effective antipsychotic drugs should reverse the abnormal behaviors whereas clinically ineffective drugs should not.

There should be no argument about the need for animal models of psychiatric diseases in general and for schizophrenia in particular. Although significant progress is being made in clinical research on schizophrenia, the development and use of suitable animal preparations could facilitate many kinds of studies that, for ethical and practical reasons, are impossible to do in humans.

There are no animal analogues for many of the core signs and symptoms of schizophrenia. Clinicians and animal researchers need to pay careful attention to ways of making schizophrenia's signs and symptoms operational, possibly through a more ethological analysis of human schizophrenia than has so far been done. If different types of human schizophrenia could be analyzed ethologically, the same or a similar system could be applied to the development of animal models and analogues for specific behaviors might then become more feasible. There also needs to be a major conceptual shift away from the idea that an animal model of schizophrenia can be developed. It is more realistic to develop animal preparations for studying specific aspects of schizophrenia and to better understand some fundamental issues. Figure 5.4-1 summarizes some of the existing animal models of schizophrenia along with some future approaches.

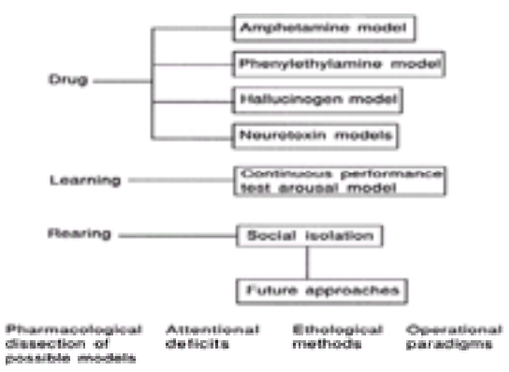

FIGURE 5.4-1 Existing animal models of schizophrenia and future approaches.

Drug-Related Animal Models

AMPHETAMINE MODEL The amphetamine model has attracted a considerable amount of attention in connection with schizophrenia and hyperactivity because amphetamine psychosis in humans can closely mimic paranoid schizophrenia. Do the data indicate, as some investigators have suggested, that animals develop schizophrenia when they are given amphetamine? Clearly, the paranoid delusions have no direct measurable analogue in the animal model, although inferences have been made from certain behaviors. Some investigators have reported that animals are hypervigilant when given amphetamine, as shown by their increased alertness and visual attention to other animals in their environment. Subordinate rats actively withdraw from social interactions, retreat to strategically defensible positions in their environment, and remain hypervigilant; some researchers have theorized that the behavior may be a manifestation of paranoia.

When given to rats, cats, and monkeys, amphetamine produces stereotypical behaviors; stereotypical behavior is not included in any list of major symptoms of schizophrenia in humans; thus, a model is being proposed based mainly on a behavior that is nonspecific and nondiscriminating for schizophrenia. However, from the standpoint of empirical validity, drugs that have antipsychotic properties in humans block the amphetamine-induced stereotypical behavior in both animals and humans. This finding has been related to the possible dopaminergic mechanisms in schizophrenia on the assumption that amphetamine-induced stereotypical behavior in animals is mediated by increased dopamine turnover.

Some investigators have tried to separate the stereotypical behavior from the increased locomotor activity produced by amphetamine by relating the behavior to the release of striatal dopamine, which is significantly increased with repeated amphetamine administration. By contrast, the increased locomotor activity is thought to be mediated by norepinephrine. Tolerance develops in locomotor activity with repeated doses of amphetamine, but not to the effects on stereotypical behaviors. Such an approach attempts to distinguish the different types of amphetamine-induced behavioral alterations in animals and to elucidate the neurochemical mechanisms that may be involved.

Other researchers have examined the effects of amphetamine on a variety of behaviors in rats, especially locomotor activity and stereotypy. A progressive augmentation of both behaviors with repeated drug administration has been reported. The duration of stereotypy was not necessarily increased, but the onset of stereotypy was. Those data were interpreted to mean that long-term amphetamine administration tended to produce increased preservation of progressively more focused and restricted behaviors; a similar phenomenon has been reported in rhesus monkeys.

PHENYLETHYLAMINE MODEL Another proposed drug-induced model of schizophrenia involves b-phenylethylamine, a neuroamine that is an endogenous component of mammalian brain and is most highly concentrated in the limbic system of the human brain; the drug phenylethylamine produces stereotypies that closely resemble those produced by amphetamines.

HALLUCINOGEN MODEL Many animal experiments using hallucinogenic agents have been very productive in promoting the understanding of the behavioral pharmacology of those compounds, but they have not provided convincing animal models of schizophrenia. As the phenomenology of hallucinogenic-induced states

in humans was more carefully compared with the symptomatology of schizophrenia, the proposed behavioral isomorphism became less persuasive.

NEUROTOXIN MODELS One hypothesis is that schizophrenia results from impairment of the structural integrity of the noradrenergic reward mechanism, and that the impairment is chronic and at least partially irreversible. 6-Hydroxydopamine (6-0HDA) is said to be the aberrant metabolite that causes schizophrenia on the basis of the following evidence obtained from animal studies:

1. When injected into certain brain sites in animals, 6-0HDA decreases stimulation and other rewarded behaviors an effect that is long-lasting.
2. Prior treatment with chlorpromazine (Thorazine) blocks the behavioral deficits as well as the depletion of norepinephrine induced by 6-hydroxyclopamine.

Nondrug Animal Models

AROUSAL It has been postulated that patients with schizophrenia operate at excessive arousal levels and that impaired attention resulting from hyperarousal constitutes a major deficit. By training rats on an operant task thought to be analogous to a test of attention (the Continuous Performance Test) used to study schizophrenia patients, attempts have been made to produce an animal model for the attentional deficit. Low levels of electrical stimulation to the reticular formation in rats cause the animals to make errors similar to those made by patients with schizophrenia. In general, antipsychotic drugs are most effective in reversing the deficit.

PRIMATE SOCIAL ISOLATION Isolation seems to share some components with schizophrenia, as illustrated in Figure 5.4-2, but one should be extremely cautions about such linkages until further studies have been done.

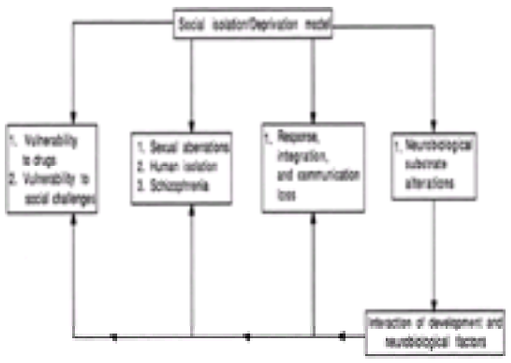

FIGURE 5.4-2 Applications of the social isolation-deprivation model of human psychopathology.

There are two potentially productive approaches toward creating animal models of schizophrenia. The ethological approach would focus on a specific behavioral analysis of schizophrenia and could in turn provide the foundation for comparisons with other species. The second approach would involve creative operational paradigms for animals based on the present level of analysis of human schizophrenia and move away from attempts to develop global models of the disorder.

Sensorimotor Gating Model of Schizophrenia Another proposed animal model of schizophrenia relates to the concept of sensorimotor gating. The background comes from reports of oversensitivity to sensory stimulation in schizophrenia patients that theoretically correlates with stimulus overload and leads to cognitive fragmentation. There have been experimental paradigms using cortical event-related potentials and the prepulse inhibition of startle responses that show that schizophrenia patients have impaired CNS inhibition (*sensorimotor gating*). Animal model studies have shown that sensorimotor gating failure similar to that seen in schizophrenia patients can be reproduced. The time course of the observed schizophrenia and animal model deficits is compatible with a temporal map of monoaminergic neuron functions. The researchers make the point that studies of sensorimotor gating would allow investigators to comment on the spatial and temporal mapping of neurons, trait and state deficits, and vulnerability factors in a schizophrenic spectrum of disorders. Such an approach that studies sensorimotor gating research in schizophrenia patients and related animal model experiments should permit one to understand the functional significance of neurotransmitter abnormalities and the relationship of those abnormalities to cognitive disturbances seen in schizophrenia. Some recent studies have shown that periods of social isolation of rats during development, but not during adulthood, produce deficits in prepulse inhibition that are partially reversible by a dopamine antagonist. Thus, this is a model in which neurodevelopmental factors can be studied in terms of their possible interactive role in schizophrenia.

ANXIETY DISORDERS It is well known to clinicians that anxiety can be either a symptom or a specific syndrome; the literature on animal models is often very confusing in that regard. In some work, anxiety seems to be used synonymously with neurosis; in other paradigms, what is being studied seems more akin to fear or to certain kinds of learning behavior. It is important to keep in mind the core features of the human syndrome.

Proposed models of anxiety must be evaluated according to how they resemble human anxiety behaviorally and how they conform to treatment responsiveness criteria. Neither in itself is completely satisfactory, but investigators do not know enough about the cause, pathogenesis, or mechanisms of human anxiety to use them as validating criteria for animal models. Some of the proposed animal models of anxiety may help to clarify those issues.

Most approaches to animal modeling of anxiety use variations of operant conditioning paradigms, and validity is evaluated on an empirical basis—that is, how well do clinically effective antianxiety agents work in the paradigms and how specific is the response? A number of the approaches have high empirical validity. Although they may not bear any relationship to the etiology or pathogenesis of human anxiety, they may still have merit in the context of that aspect of animal modeling. The assessment of behavior is of vital importance in the development of any animal model, and anxiety is no exception. What defining characteristics of the symptom or syndrome of human anxiety should researchers attempt to measure in animals? The inducing conditions for many forms of human anxiety are unknown, and so it is impossible to use those conditions as criteria. Also, not enough is known about its mechanisms to use anxiety as a criterion.

Operant Conditioning Paradigms The basic strategy is to use operant techniques to elicit a behavior with a high frequency of occurrence. After the response is well established, the behavior is suppressed by punishing it when it occurs. The analogy to fear is the conditioned association between the behavior and the punishment. Potential antianxiety drugs are evaluated according to their ability to restore responding to what it was at presuppression levels.

The Geller Conflict Test, one of the best known of such tests, is widely used to screen for potential antianxiety drugs. In the original Geller paradigm, rats were trained on a multiple variable interval 2-minute continuous reinforcement schedule for milk reinforcement; that is, there was a two-component operant behavior schedule. In the variable interval portion, signaled by one stimulus, bar pressing was reinforced at variable intervals, with the mean interval being 2 minutes. In the continuous reinforcement portion, signaled by a different stimulus, every bar pressing was reinforced. When foot shock was given concurrently with the positive reinforcement, response rates were suppressed.

Drug-induced increases in the rate of punished responding are interpreted as an index of antianxiety activity whereas decreases in unpunished responding are interpreted as indicating depressant activity. The type of behavior that originally occurs frequently but is subsequently suppressed by certain manipulations is highly sensitive to the benzodiazepines and meprobamate (Miltown) but not to chlorpromazine (Thorazine). The test, along with many modifications of it, identifies clinically active anxiolytic agents, predicts their clinical potency, and is generally insensitive to stimulant, antipsychotic, antidepressant, or analgesic drugs. It seems to work in different species and to be relatively independent of the schedules of positive reinforcement or punishment. Thus, the operant conflict approach has high empirical validity in terms of predicting clinical drug responsiveness.

The model, involving conflict behavior, has been used to evaluate several biochemical hypotheses concerning the mechanism of action for the antianxiety, “emotional analgesic” properties of benzodiazepines. With the increasing interest in the possible neurobiological substrates of anxiety, the availability of a paradigm in which the mechanism of drug action can be explored simultaneously with measures of operant behavior is necessary for future research. Over the past few years with the identification of benzodiazepine receptor sites, evidence has begun to accumulate that those receptors may mediate the therapeutic effects of such drugs. The relation of those receptor sites for benzodiazepines to the understanding of the neurobiological mechanisms of anxiety states is complex and remains an active area of investigation. The involvement of various neurotransmitter systems with those receptor sites is important to understand, and the continuing development of experimental systems in which the complex interrelationships can be studied would be helpful. A number of theories, especially with regard to the g-aminobutyric acid

(GABA) and the serotonin systems, purport to explain the effects of the anxiolytic drugs. However, anxiety has many different components, and different neurotransmitters may be involved with each. For example, muscle relaxant or anticonvulsant properties may be neurochemically mediated in one way, but anxiolytic effects as revealed in conflict paradigms may be mediated by other neurotransmitters. It is important to have careful behavioral descriptions available along with the specific neurochemical technology.

Alteration of Locus Ceruleus Function The locus ceruleus is a brain structure with a very high density of norepinephrine-containing neurons and numerous projections to other brain regions. Various techniques to alter its function provide one way to learn more about the function of one noradrenergic system in the brain. The system has been studied in the cat, macaque monkey, and squirrel monkey with such techniques as electrical stimulation, ablation, and pharmacological probes. Significant species differences are found in the catecholamine-containing cells in the brain stem, in addition to significant variations in behaviors. Cross-species reasoning from such studies is difficult, but a recent set of studies in nonhuman primates may be particularly relevant to animal models of anxiety.

Increasing locus ceruleus function, whether by electrical stimulation or with drugs, led to an increase in threat-associated behaviors, whereas decreasing it reduced those behaviors. Those behavioral effects are said to be consistent with the critical role of the locus ceruleus in mediating anxiety and fear.

It has been argued that the behavioral measures associated with the locus ceruleus function in primates are the same ones that change with environmental stimuli associated with fear in humans, and that they are decreased by diazepam (Valium). However, this approach does not permit a distinction between fear as a response to an externally threatening situation and anxiety, which typically is less related to a specific environmental precipitant. The problem arises in much of the literature on animal modeling of anxiety, where the terms “anxiety,” “fear,” and “learning” are often used interchangeably. The locus ceruleus is essential but not sufficient for the behavioral and physiological expression of anxiety and can be likened to an alarm system.

Studies of *Aplysia* It has been proposed that not only anxiety as a general state, but several specific subcategories of anxiety, can be modeled in the sea snail, *Aplysia Californica*, and that the molecular basis of anxiety can be studied in that type of animal preparation because of its relatively simple nervous system. The approach has attracted interest because it offers the possibility of more direct approaches to studying the cellular mechanisms of behavior. Behavior in such a preparation has a very different meaning from that in some of the previous models. It is not social behavior, and it is closest to a variant of conditioning paradigms that has been used for some time in the animal modeling field. In *Aplysia*, classically conditioned fear has been said to model anticipatory anxiety, and what is called long-term sensitization to model chronic anxiety.

Many workers have speculated about the relation of aversive conditioning paradigms in animals to human anxiety. The situation in which the conditioned stimulus serves as a cue for the occurrence of the unconditioned stimulus and various behavioral changes take place, presumably in anticipation of that stimulus, has been likened by investigators to anticipatory or signaled anxiety. In the sea snail, for example, exposure to the extract of shrimp elicits the withdrawal and reflex responses. The term *chronic anxiety of long-term sensitization* has been widely used to describe the state when there is repeated exposure to the unconditioned stimulus alone without any cueing or prior exposure to the conditioned stimulus. Researchers have speculated about the role of the unpredictability or uncontrollability as a factor in mediating that response.

Social Manipulations The initial stage of reaction to separation, historically labeled the *agitation* or *protest stage*, has been more recently conceptualized in the context of anxiety. The first phase is characterized by the infant's being very active behaviorally. Such infants have marked activation of the pituitary adrenal system and an increase in the enzymes involved in catecholamine synthesis. Those findings and others support the view of separation as a very powerful event from both behavioral and neurobiological standpoints, and they are consistent with a large body of literature regarding the behavioral and biological effects of a variety of stressors. To what extent the initial stage of reaction responds to anxiolytic pharmacological agents and how specific the response may be are not known.

Phobias and Other Anxiety Disorders Fear is an emotion produced by present or impending danger; the cause of fear is apparent. Anxiety, on the other hand, is an emotion of which the cause is vague or less understandable. Fear can lead to one's either freezing up or becoming mute. Much literature reports the same thing (e.g., rats freezing up in an open field) as being caused by stress.

The relation between conditioning models and theories, and anxiety and phobia models in animals has a number of shortcomings when extended to human phobias. Many animal experiments that assume conditioned fear, as well as avoidance conditioned by trauma, are models of human phobic (or anxiety) reactions. Although it is true that such induction techniques do produce fear of relatively specific stimuli and enable one to study the variables that are important for learning about fear in humans, rarely can the initiation of a human phobia (or anxiety) be ascribed to a definable event (i.e., to a definable unconditioned stimulus).

It is contended that research on animals has little to impart about human anxiety, which exists internally and symbolically, often without observable motor or autonomic concomitants. Anxiety is difficult to define. Some investigators feel that Pavlovian or Skinnerian conditioning paradigms are useless for modeling human phobias (anxieties) because human phobias and anxiety do not fit into conditioning language or paradigms. It has been argued that the language of conditioning makes assumptions about cause and treatment that are not borne out by clinical events.

One approach to the study of phobias involved the development of two lines of Pointer dogs. One line was bred for fearfulness and lack of friendliness toward people and the other for the opposite characteristics. The basic hypothesis was that heredity would largely determine many behavioral characteristics of the dog, including susceptibility to breakdown under acute and chronic stress. Through the process of selection and inbreeding, it was possible to establish the two lines of dogs and to study their behavior on a number of parameters. Throughout 10 generations, about 80 percent of each litter were similar in temperament to the parents. The phobic line of dogs was extremely timid, avoided humans, and showed decreased exploratory activity. They showed an excessive startle response, and had a slower heart rate and an increased incidence of atrioventricular heart block. Even the dogs with the most severe disturbance could learn operant conditioning bar pressing, but it was necessary to facilitate that process with benzodiazepines—the most efficacious drugs. Both amphetamines and cocaine disrupted the behavioral responses of genetically nervous dogs to a far greater extent than the stable dog.

There has been some recent work relevant to developing animal models of generalized anxiety disorder and panic disorder that should help to clarify the possible roles of neurotransmitter systems as well as to alter developmental experiences and how those two might be related in the causes of these widespread and disabling illnesses. The studies involve use of lactate to induce acute endogenous distress in nonhuman primates. Since lactate has been reported to induce panic disorder in humans, if it also does so in animals it may be possible to do studies that are more directed toward the mechanisms of those disorders. Additional animal models for anxiety have been reported in the context of the increasingly complex serotonergic receptor systems. There has also been animal work relevant to other ethologically based animal models of the various anxiety disorders.

PSYCHIATRY AND ETHOLOGY

Several authors have suggested that work in the biological science of ethology might be useful in psychiatry. John Bowlby has been taking an ethological approach to psychiatry for many years and as early as 1957 suggested that such an approach might be useful in psychiatric research. Other authors who have written about the interface between ethology and psychiatry generally approached the topic by defining ethology, presenting its vocabulary, describing its methodology, and suggesting conceptual and specific applications of ethological findings to psychiatry.

The roots of ethology lie in the natural science of biology, in particular, in zoology. The principal philosophical tenet is a naturalistic one, that is, that studies of behavior should take place in natural settings. Its origin in biology and its emphasis on the study of behavior in context have led to ethology being largely an observational, nonexperimental science. Several authors have contrasted that characteristic with the field of comparative psychology, which has different historical origins and emphases. Research in ethology has at times seemed indistinguishable from research in comparative psychology, as both have used similar techniques, such as studying naturally occurring phenomena, introducing experimental factors into a natural setting, and actually working in a laboratory. Ethology researchers usually consider those occasional excursions into the laboratory as attempts to refine mechanisms of behavior, while always being cognizant of the fact that the behavior evolves in a natural setting. A glossary of some key ethological terms is provided in Table 5.4-3.

Action-specific energy	Energy associated with the innate releasing mechanism, which builds up in a given behavioral pattern when it is not ''released'' by the appropriate releaser, and which builds up in the releasing mechanism in the absence of releasers. The behavior pattern is then said to be ''released'' by spontaneous activity.
Aggression	Intraspecific conflict mediated by physical attack or social signaling.
Appetitive behavior	Phase of behavior governing the active seeking of releasers and thought to be driven by action-specific energy. Also known as ''appetitive'' behavior pattern.
Consummatory response	Phase of behavior whereby the energy driving the appetitive phase is released. Includes the performance of the fixed action pattern (FAP).
Critical period	The time during which imprinting must occur, usually shortly after birth or early in life. Also, ''sensitive period.''
Displacement activity	A set of behavior patterns occurring alongside an unrelated set of behavior patterns. Typically, but not necessarily, these two behavioral systems are motivationally in conflict, and the displacement activity may serve to drive down another behavior system.
Ethology	The biological study of behavior. From the Greek ethos, meaning custom, usage, manner, habit. The study of behavior is considered to have a broader, more rigid concept of meaning.
Fixed action pattern (FAP)	A genetically determined behavior pattern that is released by short particular or by releasers and that consists of species-specific, stereotyped movements.
Imprinting	A specialized form of learning occurring early in life and often subserving both short- and long-term attachment to the parent. Also known as ''filial imprinting.'' The critical period, and the sometimes careful distinction between imprinting and habituation, is controversial. Imprinting is particularly resistant to extinction.
Innate	Usually describing behavior patterns, in theory not influenced by experience.
Innate releasing mechanism (IRM)	Sensory mechanisms selectively responsive to specific external stimuli and responsible for triggering the stereotyped motor responses.
Instinct	A development process resulting in species-typical behavior.
Motivation	The energy or urge that is derived from an organism's state, but simultaneously activated, driven or stimulated by stimuli in object.
Habituation	Process of a habituated pattern being interrupted through repetition itself a primary learning process. Habituation, with sensitization, and modification, is known to also sensitization.

Table 5.4-3 Selected Glossary of Ethological Terms

It has been suggested that psychiatric research and practice might benefit from the careful observational techniques ethologists employ in describing specific behavioral patterns and the context in which the behaviors occur. Those techniques would be applicable to both nonverbal and verbal behavior, as well as to the communicative aspects of each. A more general methodological issue relates to the use of the scientific method in research. In particular, it has been stressed that the ambiguity in the interpretation of findings in psychiatric research could be reduced by a greater use of operational definitions of behavior. One example is the definition of attachment behavior as any behavior that results in an increased proximity between two or more members of a species, rather than its being defined in more global terms that make inferences about the internal states of the individuals involved.

Another aspect of ethology that has been stressed in previous approaches to the interface between psychiatry and ethology is the phylogenetic origins of behavior. Ethologists are involved in the comparative study of behavior and derive hypotheses based on phylogenetic assumptions. In the same way that hypotheses are derived in the comparative study of anatomy, behavior can also be studied using the comparative method. The underlying assumption is that the behavioral patterns being studied have evolved as a result of mutation and natural selection in the same way as anatomical systems.

The more recent use of cybernetics, both control theory and information theory, in the understanding of behavioral systems in ethology has been paralleled to some extent in psychiatry; therefore, the cybernetic approach may be a useful theoretical bridge between the two fields.

The field of attachment systems has been frequently cited with regard to the application of ethological methodology and theory to psychiatry. The research on separation and the relationship between separation and depression is a corollary of the work on attachment systems. Another area of ethological research commonly suggested as potentially useful in psychiatry is that of aggression, particularly in the study of hierarchical and territorial behavior.

A natural relation between psychiatry and ethology results from their parallel positions within their respective broader disciplines. The medical sciences are based principally on the biological sciences. Psychiatry is the area within medicine most concerned with the study of behavior, and ethology has an analogous position in biology. However, ethology is still not commonly taught or used in training programs in psychiatry or child psychiatry in the United States. Nikko Tinbergen has delineated three conditions that have contributed to the relative lack of communication between psychiatrists and ethologists. The first condition is communication difficulties that arise because of differences in scientific language; the second is the obvious differences in the education of students in the two disciplines; the third is the likelihood that the people who study ethology as graduate students are different from those who enter medical school and subsequently train in psychiatry. But even if the people themselves are not particularly different, the stereotypes and the expectations of them by others can inhibit communication between psychiatrists and ethologists.

In 1973 the Nobel Prize in Physiology and Medicine was awarded to three ethologists: Karl von Frisch, Konrad Lorenz, and Nikko Tinbergen. That occasion highlighted the importance of ethology for medicine and its special relevance for psychiatry in a manner not dissimilar to the relation between molecular biology and medicine.

Karl Von Frisch Von Frisch, who was born in 1886, conducted studies on changes of color in fish and demonstrated that fish were capable of learning to distinguish among several colors and that their sense of color was fairly congruent with that of human beings. He later went on to study the color vision of bees.

Von Frisch's subsequent research was almost entirely concerned with the behavior of bees, and he is most widely known for his analyses of how they communicate with each other, that is, their language or what is known as their *dances*. His description of the complex behavior of bees prompted an investigation of information systems of other animal species.

Konrad Lorenz Born in 1903, Lorenz is known for his studies of animals, mainly birds, which he allowed to remain free but trained so that they would not be disturbed by his presence. Lorenz was a systematic observer who brilliantly described behavioral traits exhibited by animals. Many of his conclusions have been verified in experimental studies by himself and by other researchers. His interest focused from the beginning on instinctive actions, certain movements performed in a prescribed manner and provoked by certain key stimuli; these forms of behavior are now called *fixed motor patterns*. Lorenz showed that, in several animal species, a fixed motor pattern proceeds automatically once it has been provoked. It seems to be genetically programmed and, once started, is not affected by the environment. Fixed motor patterns presumably develop as a result of evolution, through the pressure of selection. Lorenz studied those patterns in several species, including jackdaws, ducks, and geese.

According to Lorenz, fixed motor patterns are provoked by stimuli specific to each pattern, which are called *key stimuli*. Those stimuli can be assumed to correspond to a particular organization of the central nervous system, originally called *das angeborene auslosende Schema*, and later, at Tinbergen's suggestion, the *innate releasing mechanism*. This mechanism is assumed to react to key stimuli by prompting or releasing corresponding fixed motor patterns. Lorenz has emphasized that not only instinctive actions but all kinds of learning have their basis in the genetically programmed equipment of the individual.

Lorenz is perhaps best known by psychiatrists for his studies of *imprinting*. During a certain short period of development, a young animal is highly sensitive to a certain type of stimulus that then, but not at other times, provokes a specific behavior pattern. Lorenz described how newly hatched goslings are programmed to follow a moving object, whereupon they rapidly become imprinted to follow it and possibly similar objects. Typically, the mother is the first moving object the young one sees, but should it see something else first, the gosling will follow it. For instance, a gosling imprinted by Lorenz followed him and refused to follow a goose (Fig. 5.4-3). Imprinting is an extremely important concept for psychiatrists to understand in their effort to link early developmental experiences with later behaviors.

FIGURE 5.4-3 In a famous experiment, Lorenz demonstrated that goslings would respond to him as if he were the natural mother. (Reprinted with permission from Hess EH: Imprinting: An effect of an early experience. Science *130:*134, 1959.)

Lorenz also studied the forms of behavior that function as sign stimuli (i.e., as social releasers) in communications between individuals of the same species. Many of the signals have the character of fixed motor patterns in that they appear automatically and provoke equally automatic reaction in other members of the species.

Lorenz is also well known for his interest in problems of aggression. He has written about the practical function of aggression, such as the defense of their territory by fish and birds. Aggression among members of the same species is common, but Lorenz has pointed out that, in normal conditions, it seldom leads to killing or even to serious injury. Although the animals attack one another, a certain balance appears between tendencies to fight and flight, with the tendency to fight being strongest in the center of the territory and the tendency to flight strongest at a distance from the center.

In many of his works Lorenz has tried to draw conclusions from his ethological studies of animals that can also be applied to human problems. Many of his suggestions are by now well known and provocative. The postulation of a primary need for aggression in humans, cultivated by the pressure of selection, is a primary example. That need might have served a practical purpose at an earlier time when human beings lived in small groups that had to defend themselves from other groups. Competition with neighboring groups became the most important factor of selection. However, Lorenz has pointed out how that need has survived the advent of weapons that can be used not merely to kill individuals but to wipe out all human beings.

Nikko Tinbergen Tinbergen, who was born in 1907, conducted a series of experiments to analyze various aspects of animal behavior. He also was successful in quantifying behavior and in obtaining measures of the power or strength of different stimuli in eliciting specific behavior. Tinbergen's first studies were of the digger wasp, *Philantus.* He determined that those insects dig individual nests into which they deposit captured bees to nourish their larvae. He was also able to show that they find their way back to their nests with the aid of various landmarks. Above all, they rely on their visual sense and learn the landmarks by means of an endogenously programmed aerial circuit.

Tinbergen's well-known studies of the various key stimuli that can provoke fixed motor patterns and of how they work together have been very valuable. Different stimuli can provoke the same motor pattern with different degrees of intensity. Particularly elegant is his analysis of the properties of the beak of the herring gull, which encourages its young to solicit food. For example, where the beak is narrow and yellow underneath, there is a contrasting red patch against which the young birds peck. By using dummies of different shapes and colors, and with different degrees of contrast, Tinbergen was able to measure the different degrees of force with which the stimuli prompted the young to peck.

Tinbergen's discovery of so-called displacement activities represents another key contribution. Those activities have been studied mainly in birds. For example, in a conflict situation, when the need for fight and the need for flight are of roughly equal strength, birds sometimes do neither. Rather, they display behavior that appears to be irrelevant to the situation; for example, a herring gull defending its territory may start to pick grass. Displacement activities of that kind vary according to the situation and the species concerned. It is well known that human beings can engage in displacement activities when under stress.

In one of his later works, Tinbergen and his wife studied early-childhood autism. They began by observing the behavior of normal children and children with autism when they meet strangers, employing the techniques used in observing animal behavior. In particular, they observed the conflict that arises in animals between fear and the need for contact and noted that it can lead to behavior that is similar to that of children with autism. They hypothesized that in certain specially predisposed children, fear can greatly predominate and can be provoked by stimuli that normally have a positive social value for most children. This innovative approach to studying infantile autism opened up new avenues of inquiry. Although the conclusions about preventive measures and treatment must be considered tentative, the methodology illustrates another way in which ethology and clinical psychiatry can relate to each other.

Future Directions Aspects of the interaction between psychiatry and ethology can be broadened in a number of ways, the first of which is methodology. Recent years have seen a beginning in the study of child behavior by ethological techniques similar to those used during the past quarter of a century in the study of primate behavior and involving operational definitions of specific behavior and the careful observation and recording of their occurrence.

The second aspect is the relative differences in interest in normal and abnormal behavior. The focus in medicine and psychiatry tends to be on the abnormal, whereas ethologists generally study the parameters of normal behavior for a given species. In a general sense, both ethologists and psychiatrists are interested in differences in adaptation—the ethologist in species differences as related to varying ecological niches and the psychiatrist in intraspecies differences in response to varying life situations. There has been a growing awareness in recent years of deficiencies in the objective understanding of normal human development, and more interaction with ethology could be useful in improving that situation.

The third issue that an interaction with ethology will force psychiatry to confront is that of the uniqueness of the human species. Psychiatry often assumes that humans are so different from other species that the study of those species is of little use in understanding human behavior. Although a phylogenetic point of view is acknowledged in human anatomy and physiology, it is certainly not emphasized in psychiatry.

The fourth aspect to be considered is the size of the behavioral units of interest to each area. Historically, ethologists have been interested in thoroughly studying the specifics of behavior to the point of a microscopic dissection, and, at the other extreme, through a more global approach. Psychiatry has been more interested in the behavior that takes place between these two extremes; that is, psychiatrists are not concerned about specific measurements of facial expression or difficulties in adaptation human beings are confronting today, but with the general behavior of individuals, families, and groups. Exceptions to the generalization include behavior modification at the more specific end of the spectrum and general systems theory at the more global end.

Inasmuch as ethology is a biological science, one might expect that the area of biological psychiatry is where the integration with ethology is most likely to occur. However, with the exception of the use of certain animal models for the understanding of the mechanism of action of a few psychopharmacological agents, biological psychiatrists have been among the least interested in the rich findings of that particular area of biology. Rather, biological psychiatry has tended to be quite reductionistic with its use of animal models. There is a growing body of literature on the effect of psychopharmacological agents in various species, but without much consideration of such factors as the phylogenetic status of the animal, its prior experience, and the effect of these agents on the animal in a natural setting.

A school of thought within psychiatry that has interesting parallels with an ethological perspective is that of psychoanalysis. The libidinous and aggressive drives about which Sigmund Freud and others have written could be viewed as analogous to some of the behavioral states studied in ethology. Much ethological literature deals with courtship and mating behavior, as well as aggression, whether expressed in hierarchical behavior or in territoriality. Much of Tinbergen's work deals with the problem of achieving reproductive success when tendencies for courtship and tendencies of aggression occur simultaneously between prospective mates. Bowlby has articulated the natural relationship between psychoanalytic and ethological thought, and his work demonstrates the usefulness of doing so. It has increased knowledge of the specific components of attachment behavior and has broadened the understanding of their existence.

Ethology seeks to understand behavior within an evolutionary or comparative framework and to use descriptive assessment techniques. There has been some interest in applying ethological descriptive techniques to assess social behaviors in psychiatric patients. For example, do patients with different types of psychiatric disorders show differences in their nonverbal social behaviors? Do those changes reflect the underlying illness or do they represent some key feature of the disorder? The use of some of the methods developed by ethologists would permit more definitive and potentially more specific characterization of disorders along those lines. Conventional psychiatric rating scales used in clinical research studies focus on individual behaviors, whereas the supplementation with ethologically based scales would permit the assessment of a broader range of key aspects of a person's functioning. For example, studies in depression have documented a reduction of the input and output of socially meaningful information, which in turn further isolates the person from others. Are such phenomena secondary to the illness (i.e., state related), or could they be evidence of traits that may characterize the baseline behaviors of such persons who may be prone to develop such disorders? These questions are parallel to the ones being asked in biological psychiatry, where state-trait distinctions are very common and where there is great interest in trait markers. The integration of data in man and animals using related rating scales and units of measurement is also important.

In a 1994 editorial in *Biological Psychiatry*, Brian Kirkpatrick highlighted certain areas as illustrating the important interface between psychiatric disease and the neurobiology of social behavior. These include:

1. Depression. Loss of significant social bonds increases the risk of major depressive disorders and there are human and animal models of the enduring neurobiological alterations associated with early social events.
2. The impairment of social relationships found in autism cannot be fully accounted for by the cognitive impairments found in these patients.
3. The neurobiology of social behavior may provide a useful conceptual framework for developing animal models relevant to the deficit syndrome of schizophrenia.
4. It may be possible to delineate a neuroanatomy of social behavior, including such fundamental behaviors as mating, paternal and maternal behavior, and the

processing of broad range of visual social stimuli.

Kirkpatrick's concluding paragraphs are worthy of a direct quote:

> Animal models of relevance to psychiatric disease are likely to account for specific aspects of human illness, and not for all the features of a disorder. For instance, models of social behavior relevant to schizophrenia might relate to the sociality found in patients with the defect syndrome, but not to the psychotic features they share with nondeficit schizophrenic patients. Similarly, social models might relate to the asociality of autism, but not to the cognitive impairments or stereotypies exhibited by autistic patients.
>
> Animal models must be used with caution. Human social behavior has unique aspects such as elaborate, flexible language, and the human brain is more complex than that of even our closest primate relatives. A superficial resemblance between human and animals behavior may also disguise great differences in the significance of the behavior. Nonetheless, current clinical research technologies, such as positron emission tomography and magnetic resonance imaging, are inappropriate for study of the structures that have been implicated in the control of social behavior in animals, due to the small size of those structures. With animal models, it is possible to use other methods to study such small structures, which are powerful determinants of behavior.
>
> As knowledge of the neural basis of social behavior progresses, this field will provide a basis for the development of rational hypothesis that could guide postmortem, pharmacological, and other clinical studies related to depression, autism, aspects of schizophrenia, and perhaps other problems.

CHAPTER 6. THEORIES OF PERSONALITY AND PSYCHOPATHOLOGY

6.1 PSYCHOANALYSIS

GLEN O. GABBARD, M.D.

Psychoanalysis has been one of the most influential intellectual movements in twentieth-century culture. It can be regarded as a theory of the personality, a method of investigation, a scientific discipline, and a form of treatment. Only a small subgroup of psychiatric patients receive formal psychoanalysis as a treatment, but the principles derived from psychoanalytic theory are broadly applicable to most patients seen in a general psychiatric practice. A systematic understanding of the unconscious mental life of the patient may illuminate reasons for noncompliance with a treatment plan, difficulties in establishing a therapeutic alliance with a clinician, and a patient's lack of interest in being helped. Hence an overarching psychoanalytically based framework is useful in the practice of psychiatry regardless of which specific treatment is being conducted.

It has been over 100 years since Sigmund Freud developed psychoanalysis as an investigative and therapeutic tool, and no body of knowledge approaches psychoanalytic theory in terms of its capacity to explain the mysteries of the human mind. Freud is ranked as the most cited twentieth-century thinker in all academic fields combined. Psychoanalysis has evolved to the point where Freud might be hard pressed to recognize it if he were alive today. Several fundamental controversies have sparked an intellectual fervor that is enriching psychoanalytic dialogues around the world. Psychoanalytic theory is now largely a pluralistic endeavor in which several useful theories compete with one another as explanations for specific human behaviors. Among the basic controversies in contemporary psychoanalysis are whether or not patients' difficulties are based in conflict or deficit, whether psychoanalysis is fundamentally a one-person (intrapsychic) or a two-person (interpersonal) psychology, whether the database in psychoanalysis is limited to a patient's subjective experience versus encompassing the analyst's experience as well, and whether psychopathology originates from traumatic reality events or largely from the role of fantasy in distorting real events.

The current controversies in theory and in the possible modifications of technique that follow from those theories can be traced to Freud's monumental work in the latter part of the nineteenth century and the first 40 years of the twentieth century. Freud himself modified his theory and practice repeatedly over the course of his career; nevertheless, he always preserved certain fundamental tenets that are still highly relevant today.

Freud articulated that any technique calling itself psychoanalytic had to involve the principles of *transference* and *resistance*. Transference is the patient's displacement onto the analyst of early wishes and feelings toward other people. Although patients may begin analysis with the understanding that their analysts are helpful professionals, they soon begin to experience the analyst as a significant figure from the past, such as a parent. Contemporary analysts also recognize that transference is partly affected by the analyst's real characteristics, so that the transference perception is an admixture of the real relationship with the analyst and relationships with figures from the past whom patients unconsciously bring into the present.

Freud originally identified resistance when he asked his patients to use the technique of *free association*, which involved saying whatever came to mind without censoring the thoughts. Freud noted that many patients could not carry out these instructions and in some cases would “go blank.” Ultimately he came to realize that such patients were unconsciously opposing the treatment every step of the way. Many patients are ambivalent about getting better and about cooperating with the clinician who is there to help them. Modern psychiatrists see resistance in the form of patients who forget to fill their prescriptions, refuse to take medications, miss their appointments, and otherwise engage in noncompliant behaviors.

These principles of technique, transference, and resistance derive from basic theoretical notions inherent in psychoanalysis.

THE UNCONSCIOUS

Foremost among these basic notions would be Freud's idea that much of mental life is unconscious. People like to think they are in control of their lives, but factors outside of conscious awareness often influence behavior. A simple example is the New Year's resolution that people have every conscious intention to keep but consistently undermine as they try to carry out their pledge. The unconscious is also revealed through slips of the tongue, termed *parapraxes*, which unwittingly exhibit to everyone what is going in the speaker's unconscious. A politician, who wants to say that his source is unimpeachable, instead blurts out, “I have this information from an impeachable source.” He blushes as everyone in the audience laughs. Nonverbal behaviors may also provide a glimpse of the individual's unconscious.

Dreams are one of the primary sources of information about unconscious conflict. Freud noted that long-forgotten memories reemerged in the process of the treatment, an observation that led him to conclude that the human mind has a form a censorship that deems certain memories, thoughts, and feelings unacceptable. The material is *repressed* or buried in the unconscious, so the person is no longer consciously aware of the phenomena that have undergone repression during conscious waking life. However, when the individual is asleep, the manifest or overt content of dreams often deals with material that would be entirely unacceptable in waking life. Freud demonstrated that a repressed childhood wish is often a motivating force that generates the content of the dream.

PSYCHIC DETERMINISM

Another central tenet of psychoanalytic theory is that behavior has meaning. Indeed, much of psychoanalytic clinical work can be described as the co-creation of meanings by patient and analyst. The meaning is partly determined by unconscious conflicts. Even when symptoms or behavior are influenced by biological factors and cultural considerations, the domain of psychoanalysis always involves meanings, and psychoanalysts are interested in how a patient uniquely interprets thoughts, feelings, and external events based on that individual's past experiences. A central feature of psychic determinism is that childhood experiences are repeated throughout life and are very much alive in terms of the adult's motivations, conflicts, and wishes. As Wordsworth noted, “The child is father of the man.”

In contemporary psychiatry, psychoanalytic theory and technique coexist with impressive advances in the neurosciences, knowledge of cultural influences on behavior, evolutionary theories, and social theories. To a large extent psychoanalytic theory has been enriched by engaging in a broad dialogue with these other disciplines, and the theory continues to evolve in an era of the greatest intellectual ferment the field has known since its inception 100 years ago.

HISTORY

The history of psychoanalysis is inextricably linked to the life of Sigmund Freud. He was born on May 6, 1856, in Freiburg, a small town in Moravia, which has since

become a part of Czechoslovakia. When Freud was 4 years old, his father, a Jewish wool merchant, moved the family to Vienna. He grew up there, was educated there, and practiced there almost his entire life. In 1938 Freud fled the Nazis by moving to England, where he died the next year (Fig. 6.1-1, Fig. 6.1-2, Fig. 6.1-3, Fig. 6.1-4, Fig. 6.1-5, Fig. 6.1-6, Fig. 6.1-7 and Fig. 6.1-8).

Freud's Career Freud was first and foremost an empirical scientist. He was convinced that the key to unlocking the secret of mental processes was to be found in the study of brain physiology. The dominant approach to human physiology in Europe during Freud's formative years was the Hermann Helmholtz school of physiology. According to the deterministic principles of that school, physiological and mental processes resulted from causal laws and sequences that could ultimately be reduced to the tenets of physics, such as the principles of inertia and conservation of energy. Freud was also influenced by the theories of Charles Darwin, which were much discussed in scientific circles in his day.

Coexisting with Freud's tendency to embrace scientific empiricism was his lifelong fascination with literature, particularly the writings of Johann Wolfgang von Goethe and William Shakespeare. Freud had a deep appreciation and respect for the word as a result of being raised in the Jewish tradition. Through his immersion in literature and religion, Freud became familiar with the complexities of the human psyche and the roles of symbolism and meaning in understanding human nature. Freud's thinking always displayed a romantic element, and it was no accident that he was ultimately awarded the Goethe Prize for literature.

Medical Training Freud's experience in medical school laid the foundation for his subsequent scientific orientation. It was during those years that he was exposed to the ideas of Darwin and Helmholtz. The intellectual currency of the day was scientific empiricism; an emphasis on measurement and observation was replacing the mysticism and romanticism that had pervaded scientific thought in central Europe in the first part of the nineteenth century.

During his medical school years Freud was profoundly influenced by two mentors, Ernst Brücke and Theodore Meynert. Those two figures—along with Sigmund Exner, who worked in Brücke's laboratory—dominated the physiological research in Europe during that era. Freud also worked in Brücke's laboratory and viewed Brücke in particular as a role model whose integrity and scientific discipline Freud strove to emulate.

Brücke, Meynert, and Exner all endorsed the idea that the nervous system operates through the transmission of quantitatively variable excitations from afferent to efferent nerve endings. Because the chemical basis of neural conduction was poorly understood, Brücke assumed that conduction is electrical in nature. Central to Brücke's thinking was the notion that the mind and the body are organized along principles of psychophysical parallelism. The reflex arc was his model of neural functioning. In other words, no spontaneous central activity exists in the nervous system; it merely functions as a passive instrument that remains quiescent until stimulated by exogenous energies. The end result of the stimulus is the reduction of incoming irritation to a minimum. That physiology of force and energies, drawing heavily from, the doctrine of conservation of energy, was to have a far-reaching effect on Freud's own thinking.

Medical Career After graduation from medical school, Freud continued to work in Brücke's laboratory for a year. There Freud developed his overriding scientific ambition to apply the principles of Helmholtz and Brücke to the nervous system. He was convinced that both psychopathological manifestations and normal mental functioning could ultimately be explained in terms of the forces and energies that regulate the nervous system.

Freud's research was interrupted when he realized that laboratory work could not generate sufficient income to support a family. He had fallen in love with Martha Bernays, and he was forced to enter medical practice to provide an adequate standard of living for his new bride. In 1882 he began work as a general physician in the Vienna General Hospital. After a stint in the surgical service, he served in Theodore Meynert's psychiatric clinic. Although Freud had some reservations about Meynert's clinical competence, his study of Meynert's amentia (acute hallucinatory psychosis) had a lasting effect on him and contributed to the concept of wish fulfillment, which later became a crucial part of Freud's theory of the unconscious.

Neurological Career Freud's exposure to neuroanatomy and neuropathology under the charismatic leadership of Meynert led him to choose neurology as a specialty. In 1885 he received a grant that allowed him to study for 19 weeks at the Salpêtrière in Paris. There his career was powerfully shaped by the great French neurologist, Jean-Martin Charcot.

Under Charcot's influence, Freud became fascinated with the problem of hysteria. Whereas most neurologists did not take hysterical phenomena seriously, Charcot viewed them as worthy of careful study. He viewed them as related to a congenital degeneration of the brain, but he placed considerable emphasis on the role of hypnosis in the treatment of hysterical disorders. When Freud observed the precipitation of hysterical manifestations through the use of hypnotic suggestion, he

began entertaining the possibility that hysteria has a psychological origin.

When Freud returned to Vienna in 1886, he was determined to pursue his dual interests in hypnosis and neurology. Hungering for more knowledge about the clinical applications of hypnosis, he journeyed to Nancy, France, to study with Ambroise-Auguste Liébault, who was attempting to remove neurotic symptoms through hypnotic suggestions. Liébault's associate, Hippolyte Bernheim, was also studying the characteristics of suggestibility and noted that it was present in patients with neurotic disorders other than hysteria. Freud's observations of the therapeutic uses of hypnosis used by Bernheim and Liébault convinced him that powerful unconscious forces were involved in human motivation and behavior. He also learned that physicians themselves may play significant roles as instruments of psychotherapeutic change.

Freud's first major neurological work appeared in 1891. Entitled *Aphasia*, it offered a functional explanation that accounted for variants of aphasic disorders in terms of disruptions of the radiating associative pathways. That same year with Oscar Rie, a pediatrician, he was coauthor of a major work on unilateral paralysis in children. Two years later he wrote a massive monograph on children's paralysis that received major acclaim.

Project for a Scientific Psychology The period between 1895 and 1897 represented a turning point in Freud's career. Intent on anchoring psychology to neurophysiology, Freud struggled to apply the principles of the Helmholtz school to the workings of the mind. The result was his pivotal work, *Project for a Scientific Psychology*. Freud was disgusted with what he had written and wanted it destroyed. It was finally published posthumously because of the recognition that it had a far-reaching influence on Freud's subsequent ideas.

Freud's explanation of the mechanisms of the nervous system revolved around the principles of neuronic inertia, which asserted that neurons tend to divest themselves of Q, the quantity of excitation. Pain can be related to an excess of nervous excitation, and pleasure can be viewed as the end result of the discharge of that excitation. At the root of the theory was a model of the nervous system as a passive recipient of stimulation from external forces and a concept of motivation in terms of tension or drive reduction.

Influenced by the principle of conservation of energy, Helmholtz had insisted that the sum of forces must remain constant in any isolated system. Freud elaborated on that principle of constancy in his *Project* by developing the idea that mental processes constantly strive for equilibrium or homeostasis. In 1893 Freud formulated the principle as follows: “If a person experiences a psychical impression, something in his nervous system, which we will for the moment call the sum of excitation, is increased. Now in every individual there exists a tendency to diminish this sum of excitation once more, in order to preserve his health.” This principle of constancy served as the economic foundation for Freud's theory of instincts.

Although many of Freud's ideas in his Project have been confirmed by more sophisticated neuropsychological studies, he was unable to forge the grand synthesis between the psychological and the neurological to which he had aspired. Nonetheless, in a number of his other works, “Preliminary Communication” (1893) and *Studies on Hysteria* (1895), the notions of the discharge of affect and cerebral excitation clearly derive from ideas generated in *Project for a Scientific Psychology*. Moreover, the model of the mind set forth in Freud's magnum opus, *The Interpretation of Dreams* (1900), also had clear roots in his *Project*. Finally, his understanding of the pleasure-unpleasure principle was profoundly influenced by the basic theorems of his Project. As late as 1920, in *Beyond the Pleasure Principle*, the derivatives are clearly in evidence.

EVOLUTION OF PSYCHOANALYSIS

During the decade from 1887 to 1897, Freud's interests in clinical neurology gradually waned. His collaboration with Josef Breuer, a distinguished older colleague with whom he had worked at Brücke's institute of physiology, led him into the nether regions of the unconscious mind, a subject that attracted his interest away from neurology and toward the evolution of psychoanalysis. As the two clinicians struggled together to understand the mysteries of hysteria, they gave birth to psychoanalysis as a therapeutic technique, as a scientific discipline, and as a method of investigation.

Collaboration With Breuer: The Case of Anna O. and Studies on Hysteria The body of theory, knowledge, and technique that is now referred to as psychoanalysis had its origins in one typical case treated by Breuer. The patient, Bertha Pappenheim, consulted Breuer in December 1880 and continued in treatment with him until June 1882. Referred to by Breuer as “Anna O.,” she was an intelligent and attractive woman of 21 years who presented a plethora of hysterical symptoms in association with her father's fatal illness. The symptoms included serious disturbances of sight and speech, inability to ingest food, paralysis of three extremities with contractures and anesthesias, and a nervous cough. She also manifested two distinct states of consciousness: one a relatively normal young woman, the other a troublesome and naughty child. Breuer observed that the shift between the two discrete personalities seemed to be induced by some form of autohypnosis, and he was able to bring about the transition by placing Anna O. in a hypnotic state.

Breuer knew that Anna had been very attached to her father and had nursed him alongside her mother while he was on his death bed. During her altered states of consciousness, Anna could recall vivid fantasies and powerful feelings she had experienced as her father lay dying. Breuer was astonished to note that his patient's recollection of the affect-laden circumstances during which her symptoms first appeared led those same symptoms to disappear. Anna O. dubbed this process the “talking cure.” She was so taken by it that she continued to discuss one symptom after another. For example, she remembered sitting at her father's side while her mother was absent and having a fantasy or daydream about a snake. In her vision the snake was about to bite her father. She tried to ward off the snake, but her arm had gone to sleep as a result of having been draped over the back of her chair. The paralysis remained until she was able to recall the scene under hypnosis and regain use of her arm.

Breuer became enchanted with his extraordinary patient. He spent so much time with her that his wife grew jealous and resentful. Frightened by the sexual connotations of his wife's complaints, he abruptly terminated the treatment of Anna O. Several hours after that termination, he was called to Anna's bedside in the midst of a crisis. He found her in an agitated state in the throes of hysterical childbirth. Although he had been unaware of any sexual feelings toward him, the phantom pregnancy (pseudocyesis) reflected Anna O.'s intense erotic longings for Breuer. He calmed his patient down by inducing a hypnotic trance, and in a state of extreme agitation he arranged for an immediate departure to Venice with his wife for a second honeymoon.

Although Breuer found the whole experience with Anna O. to be highly disconcerting, Freud was intrigued by the power of unconscious memories and suppressed affects to produce hysterical symptoms. Breuer was reluctant to publish his account, but Freud insisted that he write it up from memory some 13 or 14 years after it had occurred. The collaboration of Breuer and Freud resulted in the publication of “Preliminary Communication” in 1893. In that document they articulated the causal linkage between psychic traumata and hysterical symptoms.

In 1895, with the publication of *Studies on Hysteria*, Breuer and Freud presented a much more sophisticated clinical and theoretical treatise on the pathogenesis and treatment of hysterical symptoms. The hysterical patient suffers from “reminiscences,” according to Freud. In other words, a repressed incompatible idea is the source of the symptomatic manifestations. The patient had experienced a childhood trauma that stirred up overwhelming feelings of an intensely unpleasant nature. The traumatic experience represented an incompatible idea to the patient and was, therefore, intentionally dissociated or repressed from consciousness. The nervous excitation associated with the incompatible idea was transformed or converted into somatic channels that produced hysterical symptoms. As a result, all that was left in conscious awareness was a mnemonic symbol that was only remotely connected with the traumatic event, often through disguised links. Freud thought that, if the memory of the traumatic experience could be brought back into the patient's conscious awareness, along with the strangulated affect associated with it, the symptoms would disappear as the affect was discharged.

Evolution of Freud's Technique

Use of Hypnosis Although Freud had used hypnosis since he opened his practice in 1887, he had initially used the technique simply as a means to remove symptoms through suggestion. When he encountered disappointing results, he shifted to the cathartic method as a result of Breuer's account of Anna O. In 1889 Frau Emmy von N. consulted Freud for treatment of a variety of hysterical complaints, including anesthesia and pain in her leg, an ovarian neuralgia, delirium, hallucinations, phobias, and abulia. For the first time Freud used Breuer's cathartic method, attempting to remove the woman's symptoms through a process of recovering and verbalizing suppressed feelings with which they were associated. The method came to be known as *abreaction*.

Freud soon became dissatisfied with the abreactive approach when he observed that the therapeutic benefits lasted only as long as the patient maintained contact with the physician. The personal relationship with the physician appeared to have greater therapeutic importance than the specific hypnotic technique. His understanding of the doctor-patient relationship was expanded by an incident in which one of his patients awoke from a hypnotic trance and threw her arms around Freud's neck. Experiences such as those, coupled with Breuer's report of Anna O., led Freud to realize that the patient's attachment to the physician had an erotic

component. However, instead of fleeing in panic from such developments, as Breuer had done, Freud investigated them as he did any other phenomena encountered in treatment. Those early encounters led Freud to discover *transference*, a concept that was to become a corner-stone of psychoanalytic theory and technique. Transference refers to the displacement onto the analyst of thoughts, feelings, and behavior originally associated with significant figures from the past.

Freud's discovery of transference contributed to his abandonment of hypnosis. In his view, hypnosis concealed aspects of the transference, so that they could not be investigated as part of the process. He also felt that hypnosis encouraged the patient to please the hypnotist, instead of learning about the origins and the meanings of symptoms. Freud also observed that many patients were simply refractory to hypnosis.

Concentration Method and Development of Free Association One of the patients who was particularly resistant to the hypnotic abreactive technique was Elizabeth von R. Freud evolved his method of concentration as a way of dealing with the refractory nature of that patient. He remembered that Bernheim had asserted that all forgotten memories could be recalled consciously if the physician asked appropriate leading questions and urged the patient to remember.

Freud asked his patient to lie down on a couch and to close her eyes (Fig. 6.1-9). He asked her to concentrate on a particular symptom and to recall any memories that might assist in understanding the origin of the symptom. Freud would then press his hand on the patient's forehead and reassure her that she would indeed recall relevant memories when he questioned her about them.

Much to Freud's credit, he allowed himself to learn from his patients. Elizabeth von R., for example, responded to the concentration method by telling Freud, “I could have told you that the first time, but I didn't think it was what you wanted.” Freud then modified his technique by informing patients to simply ignore all censorship. When Elizabeth von R. reproached him for interrupting her flow of thoughts with his questions, Freud modified his technique again by reducing the frequency of his questions so as not to interfere with the natural flow of the patient's associations.

By the late 1890s Freud had come to realize that the concentration technique was more an impediment than a facilitator. He abandoned the procedures of directing the patient's attention, placing pressure on the forehead, directing the patient to close her eyes, and asking probing questions. Instead, he had the patient lie on the couch and say whatever came to her mind, the method of *free association*, which remains a central part of psychoanalytic technique today.

Repression and Resistance In addition to Freud's discovery of transference, two other seminal psychoanalytic concepts—resistance and repression—grew out of his clinical investigations of hysterical patients in the 1890s. In the evolution of his technique from hypnosis to the concentration method to free association, Freud noted that certain patients *resisted* the therapeutic technique. Some could not be hypnotized. Others were unable to recall memories of causative significance. Still others encountered a mental block when they attempted to free-associate. Freud discerned that a stubborn refusal to cooperate was not at the root of the resistance. Many of his patients who were genuinely distressed by their symptoms were also the most resistant to the therapeutic techniques. Freud concluded that active forces in the patient's unconscious mind were excluding unpleasant thoughts or memories from conscious awareness. He referred to that active force as *repression*.

Freud's studies of hysterical symptoms convinced him that repression was a pivotal force in the process of symptom formation. He described the mechanism in the following manner: A traumatic experience or a series of experiences, usually of a sexual nature, that had occurred in childhood had been forgotten or repressed because of its painful or unacceptable nature, but the excitement associated with the incident was not extinguished, and traces persist in the unconscious in the form of repressed memories. The memories may remain without pathogenic effect until a contemporary event, such as a disturbing love affair, revives them. The so far successful repression fails at that point, leading the patient to experience what Freud referred to as *the return of the repressed*. The original sexual excitement is revived and comes to the surface in the form of a neurotic symptom.

On the basis of his understanding of repression, Freud postulated that symptoms arise from a compromise between a repressed impulse and the countervailing forces of repression. In cases of hysteria, Freud believed that impulses that were unacceptable and therefore repressed were diverted into somatic pathways, resulting in such symptoms as paralysis, blindness, and disturbances of sensation. He speculated that similar mechanisms are involved in the development of paranoid ideation and obsessive-compulsive symptoms. The main thrust of treatment then was to assist patients in the retrieval of repressed memories of sexual experiences so that the excitations attached to them could emerge into conscious awareness and be discharged through verbalization.

Theory of Infantile Sexuality Freud's treatment of hysterics during the early years of the 1890s convinced him that childhood sexual seduction plays a major role in causing the neuroses. Many of his patients reported such seductions by nursemaids, fathers, and caretakers, and Freud believed that repressed memories of actual sexual traumas created neurotic symptoms.

In the latter half of the 1890s Freud began to reconsider his seduction hypothesis. The first glimpse that he had doubts about the viability of his etiological theory was contained in a September 1897 letter to his confidant and colleague Wilhelm Fliess. Freud was concerned that patients who were treated according to this theory often discontinued treatment while those who continued had poor outcomes. Freud also recognized that his theory of the traumatic etiology of neurosis strained credulity in that it required all fathers of neurotics, including Freud's own father, to be sexually perverse abusers of their own children. Also, some of the reports from his patients sounded preposterous. Emma Eckstein, for example, reported a “memory” of encountering the devil and being tortured by him as he inserted needles into her fingers. Stories of torture and possession linked to witchcraft were common among patients with hysteria.

Another factor that influenced Freud was his allegiance to Fliess. A theory based purely on environmental trauma was at odds with Fliess's idea that there were inborn cycles that unfolded in the natural course of development. Fliess carried his view of biological determination to the extreme, suggesting that the precise date of a person's death was predetermined. Freud disagreed, however, because a purely constitutional etiology would make a psychoanalytic intervention highly questionable.

Freud resolved the dilemma by rebuilding his theory of neurosogenesis around masturbation as being the cause of hysteria. Influenced by Havelock Ellis and the late–nineteenth-century sexological discourse, Freud wrote in 1899: “Not only dreams are wish fulfillments, so are hysterical attacks. This... probably applies to every product of neurosis.... The symptom is the wish fulfillment of the repressing thought, for example, in the form of a punishment; self-punishment is the final substitute for self-gratification, which comes from masturbation.” The emphasis on masturbation was a natural bridge to a shift toward intrapsychic fantasy rather than external trauma.

Although Freud's subsequent writings indicate that he never entirely abandoned his belief that actual sexual seductions by parents took place, by the late 1890s he had clearly moved to a position of stressing childhood sexual fantasies as the core of the neuroses. By adopting a psychodynamic theory of infantile sexuality in which the child's psychosexual life occupies center stage, psychoanalysis had taken a new direction, coming into its own as a depth psychology. The child was no longer portrayed as an innocent victim of wicked adults but was seen as a sexual being with powerful fantasies and wishes. By the waning years of the nineteenth century, Freud had completed his self-analysis, proposed a dynamic theory of infantile sexuality, developed the technique of free association, postulated the origins and the pathogenesis of the neuroses, and designed a theory of the mind that included the unconscious as its centerpiece. Psychoanalysis as it is known today was clearly recognizable at that point, and as the twentieth century approached, Freud was immersed in perhaps his most monumental work, *The Interpretation of Dreams*.

THE INTERPRETATION OF DREAMS

Significance of Dreams Freud became aware of the significance of dreams when he noted that patients frequently reported their dreams in the process of free association. Through their further associations to the dream content, he learned that the dreams were definitely meaningful, even though that meaning was often hidden or disguised. Most of all, Freud was struck by the intimate connection between dream content and unconscious memories or fantasies that were long repressed. That observation led Freud to declare that the interpretation of dreams was the royal road to the understanding of the unconscious.

Freud's self-analysis also contributed to his appreciation of the significance of dreams. One of his principal methods in conducting his own analysis was to rely on dreams and his associative exploration of those dreams. Indeed, Freud used many of his own dreams as illustrative examples in *The Interpretation of Dreams*, which appeared in 1900. Considered by many to be Freud's greatest work, the book still informs clinical psychoanalytic work with dreams today. In his magnum opus Freud put forth the notion that a dream is the disguised fulfillment of an unconscious childhood wish that is otherwise not readily accessible to conscious awareness in waking life.

In attempting to characterize the psychology of dreaming, Freud laid the foundations for ego psychology. He suggested that unconscious childhood wishes can be transformed into disguised conscious manifestations only if a censor exists in the mind. The censor, acting in the service of the ego, functions to preserve sleep. By disguising disturbing thoughts and feelings, the censor makes sure that the dreamer's sleep will not be disturbed. Moreover, early forms of defense mechanisms in the ego were delineated by Freud's investigation of the different methods of disguise used by the ego—for example, displacement, condensation, and symbolic representation. Freud also drew beginning parallels between the dream mechanisms and the pathological thoughts of psychotic patients in the waking state.

Analysis of Dream Content The dream, as it is recalled by the dreamer, is the result of the unconscious mental activity that occurs during sleep. Freud believed that dreaming is simply the conscious experience of thoughts during sleep. Contemporary research has revealed that the cognitive activity of sleep actually varies considerably. The dreaming activity described by Freud is probably more or less restricted to the stage 1 rapid eye movement (REM) periods of the sleep-dream cycle; those periods occur approximately every 90 minutes during the night. The thoughts that occur in non-REM sleep periods tend to be more logically organized, briefer, and more realistic.

Freud distinguished between two layers of dream content. The *manifest dream* refers to the content as it is recalled by the dreamer, including the mood and sensory experiences accompanying the dream and any commentaries on the dream that occur within the dream. The unconscious thoughts and wishes that threaten to awaken the dreamer constitute the *latent* content. Freud referred to the unconscious mental operations by which the latent dream content is transformed into the manifest dream as the *dream work*. Freud's technique of dream interpretation was based on free association, in which the patient would say whatever came to mind in response to aspects of the dream. Through this approach the manifest content of the dream would gradually give way to the underlying latent content in which the unconscious meaning of the dream is contained.

Freud initially believed that internal or external stimuli initiate dreaming. Modern dream research has demonstrated that endogenous patterns of activation in the central nervous system associated with particular phases of sleep are responsible for the onset of dreaming activity. A more contemporary understanding of what Freud viewed as initiating stimuli are that such phenomena are simply incorporated into dream content and influence the material in the dream to that extent.

Nocturnal Sensory Stimuli A variety of sensory impressions—including hunger, pain, thirst, and urinary urgency—may influence dream content. For example, a man whose thirst is beginning to interfere with his sleep may dream that he has risen from bed, gone to the bathroom, drunk a glass of water, and returned to bed as a way of safeguarding the continuity of sleep. Freud's view of dreaming as the guardian of sleep is still considered a valid function of dreaming, but recent research suggests that the function of dreams is considerably more complex in that the preservation of sleep is only one of many functions.

Day Residues Freud discerned that an important influence on the dream thoughts is the residues of feelings, ideas, and thoughts associated with experiences of the preceding day. The final form of the manifest content of the dream is shaped by those day residues, as well as by sensory stimuli. Seemingly innocuous or unimportant elements from the day residues may be used as the vehicle for the disguised expression of unconscious drives and wishes of an erotic or aggressive nature. Hence, events of the preceding day may effectively conceal the infantile impulse at the core of the dream.

Repressed Infantile Drives Following the dictum that a dream represents the disguised fulfillment of an unconscious childhood wish, Freud understood the driving forces behind dream activity as impulses or wishes from the earliest years of life. Those repressed wishes, usually sexual or aggressive and stemming from oedipal and preoedipal levels of development, are melded with day residues and nocturnal stimuli to produce the end result. Despite some challenges from discoveries of recent sleep research, Freud's observations continue to have clinical utility.

Dreams by young children are particularly unique because they show little distinction between infantile and current conflicts. In general, the dreams of young children are less disguised than the dreams of older persons and show much less distinction between manifest and latent dream content because of the relative immaturity of the defensive operations of the child's ego.

Dream Work As just noted, the dream work comprises several processes that transform latent dream content into manifest dream content. The theory of the nature of dream work, which Freud first put forth in *The Interpretation of Dreams*, became the fundamental description of the operation of unconscious processes. The mechanisms that Freud elaborated from his study of dreams proved to have broad applications to neurotic symptom formation and to a general psychology of the mind.

Dream Formation The basic problem of dream formation is to determine how the latent dream content represents itself through the manifest dream. In Freud's view the state of sleep leads to a relaxation of repression. With the repressive forces weakened, unconscious impulses and wishes are allowed to press for gratification and discharge. Since an outlet in motor expression is blocked by the sleep state, those repressed wishes and impulses have to find means of representation through mechanisms of thought and fantasy. Both elements of day residues and nocturnal stimuli are appropriated to express those latent wishes or impulses in the manifest dream.

The unconscious wishes and impulses that emanate from childhood are repressed because they are painful or unacceptable. Although repression is relaxed during sleep, Freud postulated that a dream censor is still actively involved in resisting the discharge of those impulses and disguising their true nature. The dream censor serves to attach impulses and wishes to neutral or innocent images from the residues of the dreamer's current psychological experience. Trivial or insignificant images from the dreamer's day residues are presumably linked on the basis of some resemblance that allows connections to be established. To enable those neutral images to surface in the dream, the dream work uses a set of disguised mechanisms that include condensation, displacement, symbolic representation, and secondary revision.

Condensation In condensation several unconscious impulses, wishes, or feelings can be combined and attached to one manifest dream image. For example, a composite character may appear in the dream that has the name of one person in the dreamer's life, a beard like another person, and a musical instrument that reflects a third person. The feelings associated with those three persons may be disguised in the resulting amalgam and may become apparent only through analysis of the various dream elements. The converse of condensation, diffusion, can also occur in a dream when a single latent wish or impulse is distributed through multiple representations in the manifest content.

Displacement In displacement the energy or intensity associated with one object is diverted to a substitute object that is associatively related but more acceptable to the dreamer's ego. Murderous wishes toward one's mother, for example, may be redirected toward a neutral or insignificant figure in one's life. In that manner the dream censor has displaced affective energy in such a way that the dreamer's sleep can continue undisturbed.

A special instance of displacement, projection, involves the attribution of the dreamer's own unacceptable impulses or wishes to another character in the dream. For example, a dreamer who finds homosexual impulses unacceptable may attribute them to his analyst in the dream. In some cases different aspects of the dreamer are represented in several characters in the dream.

Symbolic Representation Freud noted that the dreamer would often represent ideas or objects that were highly charged by using innocent images that were in some way connected with the idea or object being represented. In that manner an abstract concept or a complex set of feelings toward a person could be symbolized by a simple, concrete, or sensory image. Freud noted that symbols have unconscious meanings that can be discerned through the patient's associations to the symbol.

However, he also believed that certain symbols have universal meanings—for example, a flower as a symbol for female genitalia, a snake as a symbol for the penis.

Secondary Revision The mechanisms of condensation, displacement, and symbolic representation are characteristic of a type of thinking that Freud referred to as *primary process*. That primitive mode of cognitive activity is characterized by illogical, bizarre, and absurd images that seem incoherent. Freud believed that a more mature and reasonable aspect of the ego is at work during the dream to organize some of those primitive aspects of the dream into a more coherent form. He called that process *secondary revision*; in it intellectual processes of a more mature nature make the dream somewhat more rational. The process is related to more mature activity characteristic of waking life, which Freud termed *secondary process*.

Typical Dreams For the most part Freud believed that the underlying meaning of a dream reveals itself only through a proper analysis of the dreamer's associations. However, just as he made exceptions to certain universal symbols, he also thought that certain dreams are universal in their meaning, and he referred to them as *typical dreams*.

Anxiety Dreams Freud's dream theory preceded his development of a comprehensive theory of the ego. Hence, his understanding of dreams stressed the importance of discharging drives or wishes through the hallucinatory contents of the dream. He viewed such mechanisms as condensation, displacement, symbolic representation, projection, and secondary revision primarily as facilitating the discharge of latent impulses, rather than protecting the dreamer from anxiety and pain. Freud understood anxiety dreams as reflecting a failure in the protective function of the dream work mechanisms. In other words, the repressed impulses succeed in working their way into the manifest content in a more or less recognizable manner. The ego reacts to the emergence of the threatening content with intense anxiety; the dreamer often experiences severe distress or may even partially awaken.

Punishment Dreams Dreams in which the dreamer experiences punishment represented a special challenge for Freud because they appear to represent an exception to his wish-fulfillment theory of dreams. He came to understand such dreams as reflective of a compromise between the repressed wish and the repressing agency or conscience. In the punishment dream the ego anticipates condemnation by the dreamer's conscience if the latent unacceptable impulses are allowed direct expression in the manifest dream content. Hence, the wish for punishment by the patient's conscience is satisfied by giving expression to punishment fantasies. In that formulation Freud anticipated the concept of the superego and the interplay between the ego and the superego, which he did not elaborate into the structural model for some 20 years.

TOPOGRAPHIC MODEL OF THE MIND

The publication of *The Interpretation of Dreams* in 1900 heralded the arrival of Freud's topographic model of the mind. That model divides the mind into three regions: the conscious system, the preconscious system, and the unconscious system, each of which has its own unique characteristics. That theory of the psyche embraces four central assumptions. The first assumption is the notion of psychological determinism derived from Freud's Helmholtzian background. The second assumption is the existence of unconscious psychological processes. The third assumption postulates that neurotic symptoms are related to unconscious psychological conflicts and forces. Finally, the topographic theory assumes that some psychological energies originate in instinctual drives.

The Conscious The conscious system in the topographic model is characterized as the part of the mind in which perceptions coming from the outside world or from within the body or mind are brought into awareness. Consciousness is viewed as a subjective phenomenon whose content can be communicated only by means of language or behavior. Freud assumed that consciousness employs a form of neutralized psychic energy that he referred to as *attention cathexis*. In other words, one is aware of a particular idea or feeling as a result of the investment of a discrete amount of psychic energy in that particular idea or feeling. Until 1923 Freud viewed the conscious mind as being in control of motor activity as well. Freud devoted little of his own energies to the conscious system, so it is relatively undeveloped in his theory of the mind, as compared with the unconscious.

The Preconscious The preconscious system comprises those mental events, processes, and contents that are capable of being brought into conscious awareness by the act of focusing attention. Although most people are not consciously aware of the appearance of their first-grade teachers, they can ordinarily bring that image to mind by the deliberate focusing of attention on the memory. Conceptually, the preconscious interfaces with both the unconscious region and the conscious region of the mind. To reach conscious awareness, the contents of the unconscious must become linked with words and thus become preconscious. The preconscious also maintains the repressive barrier and censors unacceptable wishes and desires. Unlike the unconscious, which is characterized by primary process thinking, the preconscious is characterized by secondary process thinking and the delay of drive discharge.

The Unconscious The unconscious system is a dynamic one; the mental contents and processes of the unconscious are kept out of conscious awareness through the force of censorship or repression. The repressive force, sometimes referred to as *countercathexis*, manifests itself as the resistance to remembering. The essence of the unconscious can be captured in five key features:

1. The unconscious is closely related to instinctual drives. In Freud's theory of development, instincts were then thought to consist of sexual and self-preservative drives, and the unconscious was thought to contain primarily the mental representations and derivatives of the sexual instinct.
2. The content of the unconscious is limited to wishes seeking fulfillment. Those wishes provide the motivation for dream and neurotic symptom formation. That view is now considered reductionistic.
3. The unconscious system is characterized by primary process thinking, which has as its principal aim the facilitation of wish fulfillment and instinctual discharge. Primary process thinking is governed by the pleasure principle and, therefore, disregards logical connections, has no conception of time, represents wishes as fulfillments, permits contradictions to exist simultaneously, and denies the existence of negatives. The primary process is also characterized by extreme mobility of drive cathexis, meaning that the investment of psychic energy can shift from object to object without opposition. The mental mechanisms of displacement, condensation, and symbolic representation, discussed as part of the dream work, are part of the primary process as well. That form of thinking is also associated with creativity and with severe mental illness.
4. Memories in the unconscious have been divorced from their connection with verbal symbols. Hence, when words are reapplied to forgotten memory traits, as in psychoanalytic treatment, the verbal recathexis allows the memories to reach consciousness again.
5. The contents of the unconscious can become conscious only by passing through the preconscious, where censors are overpowered, allowing the elements to enter into consciousness.

DYNAMICS OF MENTAL FUNCTIONING

Freud conceptualized the psychic apparatus in the context of the topographic model as a kind of reflex arc. The arc consists of a series of segments arranged consecutively, with the perceptual or sensory system at one end and the motor system at the other. The memory and association systems were conceived of as occupying the segments between the two extremes. Perceptions are thus modified and stored in the form of memories, and the mental energy associated with unconscious ideas seeks discharge through thought or motor activity. Hence, the normal pathway of discharge in the waking state is from the perceptual to the motor end. Freud suggested that the flow of psychic energy can be reversed in sleep, moving from the motor to the perceptual end. That reversal of the normal flow of energy, which he called *topographic regression*, is the basis for the appearance of childhood images in dreams and the presence of hallucinations in psychoses.

When Freud subsequently abandoned the reflex arc model of the mind, he nevertheless retained the concept of regression as a key component to his theory. In neurosis, for example, the patient is thought to revert to earlier modes of instinctual discharge or to earlier levels of fixation. That form of regression is termed *libidinal* or *instinctual* regression.

FRAMEWORK OF PSYCHOANALYTIC THEORY

After the development of the topographic model, Freud turned his attention to the complexities of instinct theory. The *source* of the instinct refers to the part of the body from which it arises, to the somatic process that gives rise to stimuli that are represented in mental life as emotions, or to drive representations. The *impetus* or pressure refers to the amount of force or energy created by the instinctual stimulus. The *aim* refers to the action-directed gratification of the instinct. And the *object* is the target or recipient of the action-directed gratification and may be a person or a thing.

INSTINCT OR DRIVE THEORY

Freud was determined to anchor his psychological theory in biology. That choice led to terminological and conceptual difficulties when Freud used terms derived from

biology to denote psychological constructs. *Instinct*, for example, refers to a pattern of species-specific behavior that is genetically derived and, therefore, more or less independent of learning. Used primarily by students of animal behavior, the word “instinct” applies to such phenomena as migration, nesting, and maternal behavior.

Ethological studies have increasingly demonstrated that instinctual patterns are modified through experiential learning. The effects of adaptation on instinctually derived patterns have made Freud's instinctual theory problematic. Confusion also surrounds the translation of the German word *Trieb* into English; it does not have an unequivocal correlate. Freud was referring to powerful, imperative strivings, such as self-preservation and sexuality. Hence, *Trieb* has been translated as “drive,” “instinct,” and “instinctual drive.”

Confounding matters further is the fact that Freud himself shifted his view of instinct theory over time. His clearest definition appeared in his 1915 paper “Instincts and Their Vicissitudes,” in which he referred to an instinct as “a concept on the frontier between the mental and the somatic, as the psychical representative of the stimuli originating from within the organism and reaching the mind, as a measure of the demands made upon the mind for work in consequence with its connections with the body.” The ambiguity inherent in this concept on the borderland between the biological and the psychological has led to considerable debate about whether the mental representation aspect of the term and the physiological component should be integrated or separated.

Although “drive” may have been closer than “instinct” to Freud's meaning, he preferred not to translate *Trieb* in that manner because behavior theorists of his time had already appropriated the term “drive.” In contemporary usage, “drive” and “instinct” are often used interchangeably.

Classification of Instincts Freud's instinct theory grew out of clinical observations. The sexual drive, for example, appeared to be central to the pathogenesis of hysteria. Hence, Freud was primarily preoccupied with the sexual drive during the 1890s and into the early twentieth century. Although he originally postulated a self-preservative instinct in the 1890s, he did not elaborate it until some 20 years later. As psychoanalytic theory continued to evolve, his theorizing about the role of instincts became more and more abstract and divorced from clinical data.

Libido Freud defined *libido* as “that force by which the sexual instinct is represented in the mind.” The association of libido with sexuality is somewhat misleading in that Freud's intent was to encompass the general notion of pleasure, as well as sexuality, including both the physiological underpinnings and the mental representations. The linkage of genital sexuality with libido was viewed as the end result of a course of development in which libidinal expression takes a variety of forms, as is elaborated in the discussion of libidinal zones later in this section.

Ego Instincts From 1905 on, Freud maintained a dual-instinct theory subsuming sexual instincts and ego instincts connected with self-preservation. Until 1914, with the publication of “On Narcissism,” Freud had paid little attention to ego instincts. In that communication Freud invested ego instinct with libido for the first time. He postulated an ego libido and an object libido. Freud thus viewed narcissistic investment as an essentially libidinal instinct and called the remaining nonsexual components the ego instincts. In that rather confusing model Freud suggested that the clash between libido and ego instincts may produce symptoms of neurosis. At that point ego instincts connoted both the drives of self-preservation, such as hunger and thirst, and early aspects of the superego or conscience.

Aggression When psychoanalysts today discuss the dual-instinct theory, they are generally referring to libido and aggression. However, Freud originally conceptualized aggression as a component of the sexual instincts in the form of sadism. As he became aware that sadism has nonsexual aspects to it, he made finer gradations, enabling him to categorize aggression and hate as part of the ego instincts and to categorize the libidinal aspects of sadism as components of the sexual instincts. With that differentiation, the impulse to attack in order to defend oneself can be seen as aggression associated with the ego instincts, and sadism can be regarded as a fusion of sexual and aggressive instincts.

Freud ran into much greater difficulty when he attempted to explain self-destructive behavior with his newly developed taxonomy of instincts. How, for example, could he view the self-mutilation of masochistic patients as part of the ego instincts of self-preservation? Finally, to account for the clinical data he was observing, in 1923 he was compelled to conceive of aggression as a separate instinct in its own right. The source of that instinct, according to Freud, is largely in skeletal muscles, and the aim of the aggressive instincts is destruction. He also noted that aggression in response to the frustration of libido is secondary, rather than primary.

Life and Death Instincts Before the designation of aggression as a separate instinct, Freud, in 1920, subsumed the ego instincts under a broader category of life instincts. Life instincts were juxtaposed with death instincts, and the two were referred to as *Eros* and *Thanatos* in *Beyond the Pleasure Principle*. The life and death instincts were regarded as forces underlying the sexual and aggressive instincts. Although Freud could not provide clinical data that directly verified the death instinct, he thought it could be inferred by observing the *repetition compulsion*, the tendency of persons to repeat past traumatic behavior. Freud felt that the dominant force in biological organisms had to be the death instinct. He viewed it as a tendency of all organisms and their component selves to return to an inanimate state. Here again, Freud was linking psychology to principles of hard science—specifically, the notions of entropy and constancy from physics.

In contrast to the death instinct, Eros, the life instinct, refers to the tendency of particles to reunite or bind to one another. That counterpoint to entropy leads to organization and greater unities of systems. Sexual reproduction is the most obvious example. The death and life instincts are directly analogous to catabolism and anabolism. In modern psychoanalytic thinking the death instinct has been largely discounted except by followers of Melanie Klein. The current view is that the dual instincts of sexuality and aggression are sufficient to explain most clinical phenomena.

Pleasure and Reality As noted in the discussion of Freud's *Project*, the constancy principle, the tendency of an organism to maintain a particular state or equilibrium, was one of the cornerstones of the evolution of psychoanalytic theory. Freud's notion of the death instinct was clearly linked to the constancy principle and was also associated with what he termed the *Nirvana principle*, which postulates that an organism strives to discharge internal tension and to seek a state of rest. In 1911 Freud further elaborated the nature of the human organism's need to maintain a state of equilibrium when he described two basic tenets of mental functioning: the pleasure principle and the reality principle.

Freud essentially recast the primary process and secondary process dichotomy into the pleasure and reality principles, thus taking an important step toward solidifying the notion of the ego. Both principles, in Freud's view, are aspects of ego functioning. The *pleasure principle* is defined as an inborn tendency of the organism to avoid pain and to seek pleasure through the discharge of tension. The *reality principle*, on the other hand, is considered a learned function, closely related to the maturation of the ego, that modifies the pleasure principle and requires the delay or postponement of immediate gratification.

INFANTILE SEXUALITY

In 1905 Freud published *Three Essays on the Theory of Sexuality*. He regarded that work as second only to *The Interpretation of Dreams* in importance. Contrary to popular belief, Freud's ideas did not create much of an uproar among the scientific community or even among the public. The Vienna of his day was exposed to a great deal of popular literature that openly discussed an array of sexual problems. However, Freud's notion that children are influenced by sexual drives has made it difficult for some people to accept psychoanalysis throughout its 100-year history.

Freud's book was significant because it set forth three major tenets of psychoanalytic theory. First of all, Freud broadened the definition of sexuality to include forms of pleasure that transcend genital sexuality. Second, Freud established a developmental theory of childhood sexuality that delineated the vicissitudes of erotic activity from birth through puberty. Third, he forged a conceptual linkage between neuroses and perversions.

PSYCHOSEXUAL DEVELOPMENT

Freud's ideas about psychosexual developmental stages and libidinal zones have worked their way into popular culture. It is commonplace to hear someone who is greedy or voracious referred to as “oral.” Persons who are withholding and stubborn may be regarded as “anal.” The popular usage reflects the fact that Freud's identification of psychosexual stages also laid the groundwork for the subsequent psychoanalytic theory of character.

The earliest manifestations of infantile sexuality, in Freud's view, are basically nonsexual. They are associated with such bodily functions as feeding and bowel and bladder control. As the libidinal energy shifts from the oral zone to the anal zone to the phallic zone, each stage of development is thought to build on and to subsume the accomplishments of the preceding stage. The oral stage occupies the first 12 to 18 months of life. The anal stage picks up where the oral stage leaves off and extends to approximately 36 months of age. The phallic stage is usually associated with the period of time between ages 3 and 5.

Throughout each of the psychosexual stages, specific erotogenic zones, when stimulated, give rise to erotic pleasure. During the oral stage the infant derives

pleasure from nursing, in addition to satisfying the physiological need to assuage hunger. Karl Abraham, a disciple of Freud, divided the oral period into a sucking phase and a biting phase, thus incorporating aspects of aggression and sadism into the notion of sexual pleasure. Similarly, Abraham divided the anal stage into an anal-sadistic phase and an anal-erotic phase.

The phallic stage is initially focused on urination as the source of erotic activity. That urethral phase was briefly noted by Freud but was elaborated on by a number of later writers. During the urethral phase the primary eroticism is pleasure in urination and a secondary urethral retention pleasure. One may see derivatives of that phase in paraphilic activities involving sexual excitement associated with urinating on others or being urinated on by others.

Freud suggested that phallic erotic activity in boys is a preliminary stage leading to adult genital activity. Whereas the penis remains the principle sexual organ throughout male psychosexual development, Freud postulated that the female has two principal erotogenic zones, the vagina and the clitoris. He thought that the clitoris is the chief erotogenic focus during the infantile genital period but that erotic primacy shifts to the vagina after puberty. Studies of human sexuality have subsequently questioned the validity of that distinction.

Vicissitudes *Three Essays On the Theory of Sexuality* also discusses the vicissitudes of libido, by which Freud meant the different paths that the instinct can take within the sexual life of the person. Although in normal adult functioning sexual activity is dominated by the genital zone, pregenital libidinal zones continue to play a role, specifically during foreplay. Kissing, for example, constitutes a pleasurable stimulation of the oral zone, and stimulation of the anus may also accompany foreplay or be part of lovemaking. In healthy adults who have attained mature genital potency, the sexual act culminates in the pleasure of orgasm. Freud conceptualized infantile sexuality as *polymorphously perverse*—that is, composed of partial or component instincts that allow sexual excitation to occur from multiple sources. For example, oral and anal stimulation involves such component instincts as pleasure in watching *(scoptophilia)*, pleasure in showing *(exhibitionism)*, and pleasure in cruelty *(sadism)*. Those component instincts emerge as pairs of opposites. Scoptophilia and exhibitionism are instinctual pairs, as are sadism and masochism. Freud thought that all those components are combined into a unity at puberty under the primacy of the genital zone. Unacceptable components are either repressed or confined to foreplay. If the libido becomes irrevocably attached to one of the pregenital erotogenic zones or if a part instinct predominates, the result may be a perversion in which the normal act of intercourse is replaced by some other activity, such as fetishism or voyeurism. Freud termed the persistent attachment of the libido to a particular phase of genital development a *fixation*.

Neurosis and Perversion In studying perversions, Freud noted that perverse fantasies are ubiquitous in the human unconscious. He believed neurosis to be the negative of perversion. In other words, whereas persons with perversions express their fantasies and impulses in action, neurotic persons repress similar fantasies and impulses, which manifest themselves only as neurotic symptoms. Although that conceptualization continues to be valid in some cases, it perhaps oversimplifies the pathogenesis of perversions. Freud's formulation, for example, cannot explain why a part instinct in one person is repressed and transformed into a neurotic symptom whereas in another it is expressed overtly as a perversion. More theoretical sophistication was required to explain those individual differences.

OBJECT RELATIONS IN CLASSICAL THEORY

Although Freud's thinking is usually associated with drive theory and ego psychology, he also evolved his own version of object relations theory. He always held that early experiences with parenting figures have profound influences on subsequent development. He believed that adult relationships are later editions of childhood relationships. However, in Freud's opinion, the development of object relations is intimately connected with the sexual drive. Infants, in his view, have limited awareness of the mothering figure. Their main focus is on internal states of tension and relaxation. Hence, their longing for the object is, in fact, a longing for drive discharge or tension release. The object is viewed as a vehicle to satisfy drive pressures. As a result of that perspective on the infant's world, Freud's developmental line of object relations is intimately interwoven with psychosexual stages of development.

Oral Stage In the earliest months of life, the infant experiences hunger and frustration in the absence of the breast and the need-satisfying discharge of tension when the breast is present. Tension and hunger force the recognition and acceptance of persons in the outside world. In Freud's view, then, the first psychological awareness of an object arises from the intense physiological need for a familiar experience that provides gratification and relieves tension.

The mother's responsiveness to the child is critical in laying the foundations for the most rudimentary and essential basis for the subsequent development of object relations and the capacity for entering the world of human beings. She becomes the first love object for the infant in that she is recognized as the source of gratification of hunger and the provider of the erotogenic pleasure that the infant obtains from sucking. If a warm, trusting, and affectionate relationship has been established between mother and child during the first few months of life, the stage is set for the development of trusting and affectionate relationships with others throughout life.

Conversely, when the early mother-infant bond and the feeding experience are disturbed, the groundwork is established for subsequent problems in the area of object relations. If the mother is unavailable during the early sucking phase of the oral stage, frustration may be so intense that the infant grows up with intense longings to be nurtured and taken care of by others. If the fixation occurs during the biting phase of the oral stage, the child may be plagued with oral aggressive tendencies throughout life. Those impulses may be manifested in a voracious appetite or in a tendency to make biting comments about others that is destructive to relationships.

Anal Stage After infants pass through the oral stage during the first 18 months of life, they enter the anal stage, which lasts from about 18 to 36 months of age. One striking difference is that in the anal stage the child is much less passive than in the oral stage. Moreover, the demands of toilet training during the anal period lead to a struggle of wills between mother and child. The erotization of the anal stage involves both the pleasurable sense of excretion and, later, the erotic stimulation of the anal mucosa through the retention of feces.

Freud noted the connection between anal and sadistic drives. Initially, the object of anal-sadistic activity is the feces, and pinching off is regarded as a sadistic act. As the anal stage progresses, the sadism becomes more interpersonal in nature. In the developing struggles over toilet training, the child learns to exercise power over the parents by either giving up or retaining the feces. The sense of power over the environment that comes with sphincter control represents another sadistic element.

Before toilet training, elimination and pleasurable retention are essentially autoerotic because they do not require the presence or the assistance of an outside object. The act of defecation during that early period is imbued with a sense of omnipotence as a result. The feces become libidinized because they represent pleasure. Later, the child develops an ambivalent view of feces as body contents that are both external and internal. In other words, the child regards the feces as both “me” and “not me.” On the one hand, the feces are loved and retained or reinternalized; on the other hand, they are hated and pinched off.

The ambivalence associated with the anal stage may also be transferred to objects in the external environment. The stimulation associated with having the anal area cleansed may lead to strong erotic feelings toward the mother. Later, battles over toilet training lead to aggressive and hateful feelings toward parental figures. Freud suggested that obsessive-compulsive persons had regressed to the anal stage of development. The ambivalence associated with the feces in conjunction with the parental control led those persons to become compulsively neat, rigid, domineering, and pedantic. Freud also described them as intensely ambivalent, tormented by simultaneous feelings of love and hate and by simultaneous wishes both to control and retain the object and to expel and destroy it.

Urethral Stage Although Freud did not discuss the urethral psychosexual stage in any depth, some clinicians think it has particular relevance to issues of performance and control. The urethral stage is generally viewed as transitional between the anal and the phallic psychosexual stages. Pleasure in urination is referred to as *urethral erotism*, and urethral functioning may be associated with sadistic urges carried over from the anal stage. Competitiveness and ambition are often viewed as compensation for the shame associated with loss of urethral control.

Phallic Stage Around the age of 3 the child enters the phallic stage, in which the penis or the clitoris is the primary erotogenic zone. The phallic stage of psychosexual development heralds the arrival of the oedipal level of development, in which relationships become more complicated than they were in the past. The emphasis is on triangular or three-person relationships, instead of dyadic or two-person relationships. The phallic stage is also characterized by greater tolerance of ambivalence and the ability to withstand frustration in the absence of significant objects because of the ability to maintain an internal representation of the absent object.

Another major contrast between the pregenital psychosexual stages of development and the phallic stage is the nature of the child's libidinal activity. In the oral and anal stages, such activity is, for the most part, autoerotic in that the child's sexual impulses are directed toward the child's own body. Pleasure is still derived from one's own body in the phallic phase, but that period of development is also characterized by the fundamental task of finding a love object that will establish later patterns of object choice in adult life.

Oedipus Complex The period of life between ages 3 and 5 is known as the oedipal stage of psychosexual development because the culmination of infantile sexuality—the *Oedipus complex*—occurs at that time. Freud discovered this crucial cornerstone of psychological development during his own self-analysis and in his clinical work with patients in which fantasies of incest with the parent of the opposite sex emerged with regularity in association with feelings of jealousy and murderous rage toward the parent of the same sex. Drawing an analogy between such fantasies and the Greek myth of Oedipus, who unknowingly killed his father and married his mother, Freud termed the intrapsychic constellation the Oedipus complex.

The oedipal phase of development is of central importance in the pathogenesis of neuroses and many anxiety disorders. Oedipal issues are also prominent in the psychodynamics of character neuroses and high-level personality disorders, such as hysterical personality and obsessive-compulsive personality. The Oedipus complex presents a developmental challenge for the child, and the resolution of the child's dilemma differs according to the child's gender.

RESOLUTION FOR BOYS The first love object of the male child is his mother. Unlike the little girl, the little boy does not need to shift his affection to another parent at the beginning the oedipal phase. The male child essentially falls in love with his mother. He wishes to be at the center of her world, to sleep with her, to caress her, and to have all her attention. It becomes apparent that such plans are interfered with by the relationship of his mother and father. As a result, he begins to view his father as a rival and develops murderous wishes toward him. Those thoughts create a predicament for the little boy because he also loves his father. Murderous wishes produce guilt. They also produce fear of retaliation, accompanied by anxiety about that impending retaliation.

Freud repeatedly noted that the chief source of the boy's anxiety in the Oedipus complex is that the father will retaliate by removing the child's penis. The male child's investment in keeping his genitals intact supersedes his sexual wishes for his mother, and he renounces those wishes as a result. Freud termed the renunciation of oedipal strivings secondary to castration anxiety the castration complex. Hence, the Oedipus complex in boys is resolved by the castration complex. The male child identifies with his father and decides to find a woman like his mother so that he can become like his father. That resolution is often referred to as *identification with the aggressor*. One aspect of the male resolution of the Oedipus complex is that the retaliatory father is internalized to form the superego, which Freud regarded as heir to the Oedipus complex.

Freud viewed bisexuality as a fundamental aspect of the unconscious. Loving feelings for the father coexist with the view of him as a rival who must be murdered. At times, the mother is regarded as interfering with the father-son relationship, and the male child has murderous wishes about his mother. Freud referred to that constellation as the *negative Oedipus complex*, which he considered a universal aspect of psychosexual development.

RESOLUTION FOR GIRLS Freud was frank throughout his writings about his difficulty in understanding psychological development in girls. He often dealt with that difficulty by assuming that female development occurs along lines that are essentially analogous to male development. In attempting to explain the resolution of the Oedipus complex in little girls (called the *Electra complex*), Freud noted that, although the Oedipus complex in male children is resolved by the castration complex, in female children it is promulgated by an awareness of their “castrated” state. Freud believed that little girls feel like little boys during the preoedipal psychosexual stages until the age of 3, when girls discover the existence of the penis. He postulated that the discovery leads to feelings of inferiority and narcissistic injury and to penis envy. The little girl then blames her mother for bringing her into the world less well equipped than her male counterparts and turns to her father as her love object. The wish to have a baby with her father then replaces her wish for a penis.

The discovery of the little girl's “genital inferiority,” according to Freud, leads to one of three outcomes: (1) a defiant hypermasculinity, (2) a neurotic cessation of all sexuality, or (3) normal femininity, entailing the renunciation of clitoral sexuality. Whereas the fear of castration leads to the resolution of the little boy's Oedipus complex, fear of losing the mother's love leads the little girl to a satisfactory resolution of the Electra complex. When the female child realizes that her mother disapproves of her wishes toward her father, she decides to renounce her oedipal strivings to maintain her bond with her mother.

Freud's view of female development has undergone significant revision by modern psychoanalytic authors. It is now known that the sense of being female is present long before the onset of the phallic-oedipal stage of development. Child observational research suggests that both sexes become aware of anatomical genital differences at approximately 16 to 18 months of age. Also, studies of persons with chromosomal anomalies and ambiguous genitalia have persuasively demonstrated that the primary source of femaleness is not the nature of the genitalia but the parents' conviction about the nature of the child's gender. Moreover, penis envy is no longer regarded as a bedrock phenomenon that defies further understanding and analysis. Contemporary psychoanalytic writers regard penis envy as only one aspect of the development of feminine identity, not the origin of it. They point out that following a strictly Freudian model of development may lead a clinician to help a female patient regard herself as a genitally inferior form of male. The mysterious nature of the little girl's genitalia may provoke anxiety independent of their differences from the genitals of little boys, and those anxieties can be fruitfully explored in psychoanalysis.

SIGNIFICANCE OF THE OEDIPUS COMPLEX Freud viewed the Oedipus complex, along with its successful or unsuccessful resolution, as the nucleus for the pathogenesis of adult neurosis. He also thought that personality, fixations, object choices, and identifications are significantly influenced by the oedipal phase of development. Incestuous oedipal feelings reemerge in both sexes at puberty, and one of the tasks of adolescence is to withdraw libidinal urges from parental figures and direct them toward more suitable love objects.

Latency Stage This stage of development begins with the resolution of the Oedipus complex around the age of 5 or 6 and ends with the onset of puberty, somewhere between 11 and 13 years of age. The term “latency” derives from the fact that the sexual drive is relatively quiescent during those years. The inactivity of the sexual drive can be explained by the institution of the superego as the heir to the Oedipus complex. The control of instinctual impulses by the superego allows for further integration and consolidation of sex-role identity in sex roles. The latency stage of development is also associated with the development of a sense of industry and a capacity for mastery that enhances autonomous functioning.

Genital Stage This stage of psychosexual development corresponds with the adolescent phase that begins with the onset of puberty and ends with the achievement of young adulthood. Most clinicians who work with adolescents think it is useful to subdivide the period into preadolescent, early adolescent, middle adolescent, and late adolescent subphases. The most striking influence on this period of development is the physiological maturation of hormonal systems that results in an intensification of drives, particularly sexual drives. This rather extended psychosexual stage of development, without a doubt one of the most challenging in the life cycle, requires the development of psychological mastery over drive pressures. In addition, a key developmental task associated with the genital stage is the establishment of mature object relations and genital sexuality with an appropriate partner. A major aspect of that achievement is the psychological separation from one's own parents and the establishment of an independent life-style.

Freud's stages of psychosexual development are discussed in Table 6.1-1.

Table 6.1-1 Stages of Psychosexual Development

CONCEPT OF NARCISSISM

The first systematic discussion of narcissism in Freud's work was published in 1914. Freud was dissatisfied with the paper and wrote to Karl Abraham, “The

narcissism was a difficult labor and bears all the marks of a corresponding deformation." Nevertheless, Freud's thinking about narcissism led him to important modifications in his understanding of libido and instinct theory in general.

Theoretical Basis According to the Greek myth, Narcissus was a young man who fell in love with his own reflection in the water of a pool and drowned in his attempt to embrace the beloved image. Freud used the term *narcissism* to describe situations in which a person's libido is invested in the ego itself, rather than in other people. That conceptualization of narcissism presented Freud with vexing problems for his instinct theory. It essentially violated his distinction between libidinal instincts and ego or self-preservative instincts. Freud's understanding of narcissism led him to use the term to describe a wide array of psychiatric disorders, very much in contrast to the contemporary usage of the term to describe a specific kind of personality disorder. For example, in 1908 Freud noted that in cases of schizophrenia (which was then known as *dementia precox*), the person's libido is withdrawn from objects and turned inward. He believed that the withdrawal of libidinal attachment to objects accounted for the loss of reality testing in psychotic patients. Grandiosity and omnipotence in such patients reflected excessive libidinal investment in the ego.

Freud did not limit his use of narcissism to psychoses. In states of physical illness and hypochondriasis, he observed that libidinal investment is frequently withdrawn from external objects and from outside activities and interests. Similarly, he suggested that, in normal sleep, libido is withdrawn and reinvested in the sleeper's own body. Homosexuality, which Freud regarded as a perversion, was understood as an instance of a narcissistic form of object choice, one in which a person falls in love with an idealized version of himself or herself projected onto another person. He also found narcissistic manifestations in the beliefs and myths of primitive people, especially those involving the ability to influence external events through the magical omnipotence of their own thought processes. In the course of normal development, children also exhibit a belief in their own omnipotence.

Narcissism and Object Relations According to Freud, the infant is born into a state of primary narcissism in which the libido is stored in the ego. He viewed the neonate as completely narcissistic, with the entire libidinal investment in physiological needs and their satisfaction. He referred to that self-investment as *ego libido*.

The infantile state of self-absorption changes only gradually, according to Freud, with the dawning awareness that a separate person—the mothering figure—is responsible for the gratification of the infant's needs. That realization leads to the gradual withdrawal of the libido from the self and the redirection toward the external object. Hence, the development of object relations in the infant parallels the shift from primary narcissism to object attachment. The libidinal investment in the object is referred to as *object libido*.

If the developing child suffers rebuffs or trauma from the caretaking figure, object libido may be withdrawn and reinvested in the ego. Freud called this regressive development *secondary narcissism*.

One of the confusing aspects of Freud's conceptualization of narcissism is that his use of the term varied according to context. At times, he discussed narcissism as a perversion in which persons use their own bodies or body parts as objects of sexual arousal. At other times, he used the term to describe a developmental phase, as in the state of primary narcissism, when there is no differentiation of self and other and when autoeroticism predominates. That use is particularly problematic because narcissism operates at all stages of psychosexual development, from the deprivation of oral needs during the earliest months of infancy to the losing out to a rival during the oedipal phase. In still other instances, Freud used the word "narcissism" to refer to a particular type of object choice. He distinguished love objects who are chosen "according to the narcissistic type," in which case the object resembles the subject's idealized or fantasied self-image, from objects chosen according to the "anaclitic type," in which case the love object resembles a caretaking figure from early in life. And Freud occasionally used the word "narcissism" interchangeably and synonymously with "self-esteem."

Freud's developmental view of narcissism and object relations has caused considerable controversy in the field. Part of the difficulty stems from the fact that a certain amount of narcissistic libido is necessary for healthy self-regard. Freud's maturational model implies that, in the course of healthy development, one should outgrow investment in oneself and devote one's libidinal energies primarily to others. Others have noted that Freud's model implies that investment of the libido in a love object results in depletion of libidinal investment in oneself. That conceptualization does not explain how it is that persons are likely to feel the greatest sense of self-esteem when they are in love. And Freud's model does not lend itself well to the differentiation between normal narcissism and pathological narcissism. Subsequent psychoanalytic theorists, discussed later in this section, have dealt with some of those difficulties.

EGO PSYCHOLOGY

Although Freud had used the construct of the ego throughout the evolution of psychoanalytic theory, ego psychology as it is known today really began with the publication of *The Ego and the Id* in 1923. That landmark publication also represented a transition in Freud's thinking from the topographic model of the mind to the tripartite structural model of ego, id, and superego. He had repeatedly observed that not all unconscious processes can be relegated to the instinctual life of the person. Elements of the conscience, as well as functions of the ego, are clearly unconscious as well. From 1923 to 1937 Freud developed both his theory of ego psychology and his later theory of anxiety. After his death, such psychoanalytic contributors as Heinz Hartmann, Ernst Kris, David Rapaport, and Erik Erikson continued the general thrust within psychoanalysis away from the instinctual life toward a greater emphasis on ego functioning and development and toward social and cultural perspectives.

Early Concepts of the Ego Freud's concept of the ego was ill-defined and imprecise during the formative years of psychoanalysis. He used the term to refer to the dominant place of the person's conscious thoughts and values, as opposed to the domain of repressed impulses and wishes. The ego's primary function is defensive, which at that time denoted repression. Impulses and wishes, primarily of a sexual nature, are barred from conscious awareness because of the counterforce provided by the ego. In the early years of the 1890s, Freud viewed the memories of sexual trauma as the main source of the defensive response. Those memories arouse unpleasant affect, which leads to repression, which in turn causes a damming up of energy that produces anxiety. That formulation, however, produces a contradiction in the nature of the ego's function. On the one hand, the ego reduces tension and avoids unpleasant affects through repression; on the other hand, the process of repression *produces* anxiety, which is an equally unpleasant affect. When Freud shifted in 1897 from his emphasis on actual seduction to the role of childhood fantasy, he also suspended his thinking about the function of the ego.

During the ensuing years, Freud devoted much of his attention to the instinctual drives and their vicissitudes. His studies led him back to consideration of the ego. In his 1915 work "Instincts and Their Vicissitudes," Freud noted that the sexual instinct is subjected to repression, sublimation, turning on oneself, and reversal into its opposite (a sadistic impulse transformed into a masochistic one). Those vicissitudes came to be understood as defense mechanisms of the ego.

Topographic theory failed to provide Freud with all the answers he needed to explain the functioning of the mind. For example, since neither the preconscious nor the ego instincts can be viewed as solely responsible for regression or censorship, how can repression be explained? Freud tried to explain repression by postulating that certain ideas remain in the unconscious as a result of libidinal withdrawal. He suggested that the withdrawal is a repetitive process of countercathexis that operates on an unconscious basis. He eventually assigned that function to the ego.

Freud's Ego Psychology Freud's first comprehensive theory of the ego appeared in *The Ego and the Id*. There, although the ego is primarily organized around the perceptual conscious system, it also includes the structures responsible for *unconscious* defenses and resistance in the clinical setting. The ego is regarded as the agency that organizes mental processes and functions. It is one of three major functional subdivisions of the mental apparatus—one that responds in a mostly passive way to pressures from the other two, the id and the superego. The ego has its origins in the id, in Freud's view, and is later depicted by him as a helpless rider on the id's horse, going in whichever direction the id dictates. The ego also responds to reality influences.

In 1926 Freud introduced the notion of signal anxiety in *Inhibitions, Symptoms and Anxiety*. There the ego is no longer viewed as a passive servant of the id. Signal anxiety is seen as an autonomous function of the ego that initiates defensive maneuvers in response to the threatened emergence of unacceptable wishes and impulses from the unconscious.

The concept of the ego was further expanded to include adaptation as a result of Freud's continued elaboration of the reality principle. Adaptation enables the ego to control instinctual drives when real danger prompts those drives into action. Intrinsic to the maturation of the ego is the substitution of the reality principle for the pleasure principle. In addition to reducing tension from the id, the reality principle gauges the limitations, requirements, and possibilities of the environment with an eye to attaining greater pleasure in the future. By the last decade of his life, Freud viewed the ego as the executive organ of the psyche, a powerful regulatory force for the integration and control of impulses, and as an agent of adaptation in relation to reality. In 1937 Freud made it clear that the ego evolves independently of the id.

STRUCTURE OF THE PSYCHIC APPARATUS

Contemporary psychoanalytic ego psychology is based on Freud's structural theory, which divides the psychic apparatus into the id, the ego, and the superego. The id encompasses the mental representations of the instinctual drives and some but not all the contents of the unconscious system in Freud's topographic theory. The id operates according to primary process and to the dictates of the pleasure principle. The ego occupies the position between the drives and the demands of the outer world. It evaluates, perceives, coordinates, and integrates perceptions in the service of taming the intensity of drives. The ego attempts to achieve optimal gratification of instinctual striving while maintaining good relations with the superego and with external reality. The superego assists the ego in the regulation of tensions arising from the id. It encompasses internalized moral values, prohibitions, and standards of parental figures.

Id Freud referred to the id as “the dark inaccessible part of our personality.... We approach the id with analogies: we call it a chaos, a cauldron full of seething excitation.” Freud borrowed the term from Georg Groddeck, a psychoanalytically informed internist, who coined the term “id” to mean all that was ego-alien. It was viewed as a reservoir of the unorganized instinctual drives. Operating under the domination of the primary process, the id lacks the capacity to delay or modify the instinctual drives with which the infant is born. The id should not, however, be viewed as synonymous with the unconscious because both the ego and the superego have unconscious components.

Ego The ego spans all three topographic dimensions of conscious, preconscious, and unconscious. Logical and abstract thinking and verbal expression are associated with conscious and preconscious functions of the ego. Defense mechanisms reside in the unconscious domain of the ego. The most comprehensive definition of the ego can be found in Freud's *An Outline of Psycho-Analysis*, which he wrote in 1938:

> Here are the principal characteristics of the ego. In consequence of the pre-established connection between sense and perception and muscular action, the ego has voluntary movement at its command. It has the task of self-preservation. As regards external events, it performs that task by becoming aware of stimuli, by storing up experiences about them (in the memory), by avoiding excessively strong stimuli (through flight), by dealing with moderate stimuli (through adaptation) and finally by learning to bring about expedient changes in the external world to its own advantage (through activity). As regards internal events, in relation to the id, it performs that task by gaining control over the demands of the instincts, by deciding whether they are to be allowed satisfaction, by postponing that satisfaction to times and circumstances favorable in the external world or by suppressing their excitations entirely. It is guided in its activity by consideration of the tension produced by stimuli, whether these tensions are present in it or introduced into it.

In essence, then, the ego controls motility, perception, contact with reality, and, through the mechanisms of defense available to it, the delay and modulation of drive expression.

Origins of the Ego In Freud's view, the neonate has no ego to speak of, and the coherent system of functions now associated with the concept is regarded as an outgrowth of the id. Specifically, the ego arises out of the modification of the id created by the demands of the external world. The ego forms in tandem with the increasing influence of external reality on the infant, gradually replacing the pleasure principle with the reality principle. The role of conflict, first between the id and the outside world and later between the id and the ego, Freud viewed as central to ego development.

Later contributors to ego psychology—such as Hartmann, Kris, and Loewenstein—made significant modifications to the theory of ego development. Hartmann, in particular, stressed the adaptational aspects of the ego. In his view, one can delineate a line of ego development that is independent of instinctual drives. He postulated the existence of primary autonomous ego functions that do not have their origins in the id. Those functions include perception, motility, memory, and intelligence; all are present from birth and therefore determined, at least in part, by genetic factors. In that expanded view of the ego, the origins of both the ego and the id were thought to be in a common undifferentiated matrix present at birth. That shift toward the primacy of the ego was instrumental in the movement within psychoanalytic theory away from drive theory and toward a greater focus on the complexities of the ego.

Functions of the Ego Although Freud periodically used the term “ego” to mean self, the concept is best viewed as a structure within the personality. It is an agency or an organization of functions that have in common the task of mediating between the instincts and the outside world. Ego psychologists have identified a set of basic ego functions that characterize the ego. The following descriptions reflect the activities that are generally regarded as basic and fundamental to the operation of the ego:

1. Control and regulation of instinctual drives. The development of the capacity to delay or postpone drive discharge, like the capacity to test reality, is closely related to the progression in early childhood from the pleasure principle to the reality principle. That capacity is also an essential aspect of the ego's role as mediator between the id and the outside world. Part of the infant's socialization to the external world is the acquisition of language and secondary process or logical thinking, both of which assist in the control of instinctual drives. The capacity to think in a logical and abstract manner allows for the representation of drives in fantasy, which may circumvent the need to discharge them in action.

The ego's capacity to regulate thinking and to control drive discharge is intimately connected with its defensive functioning. One example of the linkage between control of drives and defensive functioning can be seen in the ego's use of signal affects. Affect states such as guilt, anxiety, shame, and depression serve as signals of the potential breakthrough of threatening impulses from the unconscious. Those signals then act to mobilize defenses in the ego to prevent the breakthrough. That function of the ego is also instrumental in building a capacity to tolerate pain, anxiety, and frustration within manageable limits.

2. Judgment. A closely related ego function is judgment, which involves the ability to anticipate the consequences of one's actions. As with the control and regulation of instinctual drives, judgment develops in parallel with the growth of secondary process thinking. The ability to think logically allows for an assessment of how one's contemplated behavior may affect others. The consequences to oneself can also be ascertained through the use of secondary process thinking. The ego function of judgment may assist regulatory aspects of the ego in the avoidance of impulse discharge. Both those ego functions are commonly impaired in impulsive personality disorders.
3. Relation to reality. The mediation between the internal world and external reality is a crucial function of the ego. The relationship with the outside world can be divided into three aspects: the sense of reality, reality testing, and adaptation to reality. The sense of reality develops in concert with the infant's dawning awareness of bodily sensations. The ability to distinguish what is outside the body from what is inside is an essential aspect of the sense of reality, and disturbances of body boundaries, such as depersonalization, reflect impairment in that ego function.

Reality testing is an ego function of paramount importance in that it differentiates psychotic persons from nonpsychotic persons. Reality testing refers to the capacity to distinguish internal fantasy from external reality. That function of the ego gradually develops in parallel with the increasing dominion of the reality principle over the pleasure principle.

The third aspect, adaptation to reality, involves the ability to use one's resources to develop effective responses to changing circumstances on the basis of previous experiences with reality. One may perceive reality accurately but not use one's full resources to make an informed judgment about the necessary response. In that sense, adaptation is closely linked to the concept of mastery with respect to both control of drives and accomplishment of external tasks. Adaptation to reality is also intimately connected with defensive functions of the ego. One commonly calls on a variety of defensive maneuvers to master situations that may produce anxiety or other affects. To deal with overwhelming trauma, for example, one may use temporary denial to get through the crisis.

4. Object relationships. The significance of object relationships in normal psychological development and in psychiatric disorders was not fully appreciated until relatively late in the evolution of classical psychoanalysis. The capacity to form mutually satisfying relationships is in part related to patterns of internalization stemming from early interactions with parents and other significant figures. That ability is also a fundamental function of the ego in that satisfying relatedness depends on the ability to integrate positive and negative aspects of others and oneself and to maintain an internal sense of others, even in their absence. Similarly, mastery of drive derivatives is crucial to the achievement of satisfying relationships.
5. Synthetic function of the ego. First described by Herman Nunberg in 1931, the synthetic function refers to the ego's capacity to integrate diverse elements into an overall unity. Different aspects of oneself and others, for example, are synthesized into a consistent representation that endures over time. The function also involves organizing, coordinating, and generalizing or simplifying large amounts of data.
6. Primary autonomous ego functions. A direct outgrowth of the work of Hartmann, the primary autonomous functions refer to rudimentary apparatuses that are present at birth and that develop independently of intrapsychic conflict between drives and defenses, provided that what Hartmann referred to as an *average expectable environment* is available to the infant. As noted previously, those functions include perception, learning, intelligence, intuition, language, thinking, comprehension, and motility. In the course of development, some of those conflict-free aspects of the ego may eventually become involved in conflict if they

encounter opposing forces.

7. Secondary autonomous ego functions. Hartmann originally used the concept of the conflict-free sphere of ego functioning to identify areas of primary autonomy. However, that area may be enlarged by functions that originally arise in the service of defense against drives but subsequently become independent of them. Those functions are referred to as *secondary autonomous ego functions*. For example, a child may develop caretaking functions as a reaction formation against murderous wishes during the first few years of life. Later, the defensive functions of the style may be neutralized or deinstinctualized when the child grows up to be a social worker and cares for the homeless. That neutralization, leading to desexualization of libidinal drives or deaggressivization of aggressive drives, provides the ego with independent energies that were formerly used to deal with drive pressures.
8. Defensive functions of the ego. Freud acknowledged the existence of several defense mechanisms, but his writings focused predominantly on repression, which he regarded as the queen of the defenses. In many of his contributions, defense and repression are used almost synonymously. Repression provides a barrier against the direct expression of impulses and wishes from the unconscious. With the ascent of the structural model, Freud shifted the function of defense to the ego. However, defense mechanisms could not be systematically studied until after 1926, when Freud formulated his theory of signal anxiety and the mobilization of defenses in response to danger signals.

The first comprehensive study of defense mechanisms was written not by Sigmund Freud but by his daughter Anna in her landmark 1936 work, *The Ego and the Mechanisms of Defense*. Anna Freud (Fig. 6.1-10) expanded her father's work by providing detailed descriptions of a number of individual defense mechanisms, including regression, reaction formation, undoing, introjection, identification, projection, turning against the self, reversal, and sublimation. She pointed out that everyone uses a characteristic repertoire of defense mechanisms that are intimately related to that person's character. She also insisted that the ego should be the focus of psychoanalytic treatment, in addition to the uncovering of repressed drive derivatives. Her famous observation that “there is depth in the surface” reflected her appreciation of the complexity of the defensive aspects of the ego.

Evolution of Defense Mechanisms In the course of development, defenses emerge as a reflection of the ego's attempts to mediate between the pressures of the id, on the one hand, and the demands of external reality, on the other hand. At each phase of psychosexual development, then, the specific drive components evoke specific ego defenses. For example, defense mechanisms like introjection and projection are seen in concert with the development of oral incorporative impulses; reaction formations such as shame and disgust develop in response to anal impulses and pleasures. Pregenital defense mechanisms may persist into adult life, lending an infantile cast to the adult personality. In the course of normal development, mechanisms like repression and intellectualization supersede immature defenses.

The defense mechanisms most commonly used by a person to deal with unpleasant situations or distressing internal affective states constitute a significant component of that person's character. Obsessive-compulsive character traits, such as excessive orderliness and miserliness, may initially develop in response to instinctual drives, but they are subsequently divorced from them as they take a central role in the person's overall functioning, even in conflict-free situations. The defenses may be adaptive and healthy, as well as pathological; in normal functioning they are crucial to the preservation of psychological well-being.

In psychopathological states, one may see various alterations of normal defensive functioning. In hysterical and obsessive-compulsive persons, for example, one sees hypertrophied development of particular defenses, as though the dangers from infantile impulses were just as threatening in adulthood as they were in childhood. Exaggerated repression is characteristically associated with hysterical patients; such defenses as reaction formation, undoing, isolation of affect, and intellectualization are associated with obsessive-compulsive patients. Persons who are fixated at the oral psychosexual stage may rely on such defense mechanisms as denial and projection. The failure of defenses may lead to a breakthrough of direct drive expression with obvious regression in the ego's control of thought and affect, a condition most clearly manifested in the schizophrenias.

Classification of Defenses The defenses of the ego can be classified in a variety of ways. Psychoanalysts themselves disagree as to the best taxonomy, and most acknowledge that any one classification is inadequate in its capacity to take into account all the relevant factors. Defense mechanisms can be categorized according to the psychosexual stage with which they are associated, but that system does not address the fact that some defense mechanisms (such as regression) are used in every developmental stage.

Other systems assign defenses according to the nature of the psychopathology with which they are associated. According to that taxonomy, hysterical defenses include conversion, repression, somatization, and dissociation. Freud himself classified defenses according to severity of psychopathology. Denial, distortion, and projection, he believed, are defense mechanisms associated with psychosis. The neurotic defense mechanisms include repression, isolation, undoing, displacement, and reaction formation. He considered mature defenses to be sublimation, altruism, humor, and suppression. A classification that draws both on the level of psychopathology and on developmental maturity is provided in Table 6.1-2, along with definitions of commonly recognized defense mechanisms.

Table 6.1-2 Classification of Defense Mechanisms

Although analysts disagree on the total number of defense mechanisms, most agree with Freud's assessment that defense mechanisms must possess the following properties: (1) they manage instinct, drive, and mood; (2) they are unconscious; (3) they are discrete; (4) they are dynamic and reversible; and (5) they can be adaptive or pathological.

Superego The third component of the tripartite structural model is the superego. The superego establishes and maintains the person's moral conscience on the basis of a complex system of ideals and values internalized from one's parents. As noted previously, Freud viewed the superego as the heir to the Oedipus complex; it is, therefore, influenced by the resolution of oedipal conflict. It conducts an ongoing scrutiny of the behavior, thoughts, and feelings of the person; makes comparisons

with expected standards; and offers approval or disapproval. Criticisms and reproaches lead to a variety of painful feelings; praises and rewards raise the person's self-esteem. Those activities occur unconsciously to a large extent, reflecting the clinical observation that self-criticism operates as much outside conscious awareness as aggressive and sexual drive derivatives do.

The idea of the superego first appeared in 1896 with Freud's *Further Remarks on the Neuro-Psychoses of Defence*, in which he described "self-reproaches which have reemerged in transmuted form and... relate to some sexual act that was performed with pleasure in childhood." In early discussions of dreams, Freud commented on the activities of a self-criticizing agency that censors the entry of unacceptable ideas into consciousness because the ideas are morally offensive. In his 1914 paper "On Narcissism," Freud spoke of a special self-critical agency and of a hypothetical state of narcissistic perfection originating in children's idealized views of themselves. As that idealized version of self is tarnished through the slings and arrows of development, the child attempts to recover the lost narcissism by creating an ego-ideal. Having postulated that construct, Freud needed to create a special agency whose function it was to be sure that the person's behavior and thoughts measure up to the expectations of the ego-ideal. The construct of the superego grew out of the need for monitoring and preserving the ego-ideal.

Ego-Ideal The distinction between the superego and the ego-ideal has always been ambiguous. The most common usage today is to refer to the ego-ideal as an agency that *prescribes* what one should do and to refer to the superego as an agency of moral conscience that *proscribes*—that is, dictates what one should *not* do. Freud, however, did not always make that distinction. In 1921 he referred to the self-critical agency responsible for guilt and self-reproaches in melancholia and depression as the ego-ideal. In *The Ego and the Id* 2 years later, he assigned both the conscience and the ego-ideal to the superego. Today most analysts conceptualize the ego-ideal as comprising a set of functions contained within the structure of the superego.

The ego-ideal is best conceptualized as an amalgam of internalized representations. The ideal object, stemming from internal images of an admired and omnipotent parent, is one such representation. The ideal self, based on fantasies of a self-image that would result in maximal parental approval, is another representation contained within the concept. Representations of actions that should be done to attain an ideal relationship with significant figures in one's life are also involved.

The ego-ideal becomes an internal standard of what one should be. In this regard it is intimately connected with shame, which is a response to an internal perception that one has not lived up to one's ego-ideal. Although guilt is a closely related affect, it is generally regarded as a response to the transgressions of superego prohibitions, particularly sexual or aggressive wishes toward others.

Origins of the Superego As described earlier, the superego is a relatively mature structure resulting from the resolution of the Oedipus complex. In the case of the little boy, his love for his mother engenders murderous wishes toward his father. His observation of the genital differences between males and females leads him to fear that his oedipal wishes will be punished with castration. Under the influence of the perceived threat from his father, the little boy renounces his incestuous longings for his mother and identifies with his father. That resolution involves the installation of the parental moral values as the superego structure.

In the case of the little girl, she renounces oedipal strivings for her father because she realizes that a victory over her mother would result in the loss of her mother's love. Freud initially postulated that little girls grow up with less moral conviction and character as a result of the absence of the castration threat. That view is no longer held by contemporary psychoanalysts. Recent empirical studies suggest that moral developmental differences between boys and girls do exist but along different lines. Boys tend to place high moral value on achievement and fair play; girls are more likely to develop a moral code based on affiliation and relatedness to others.

Evolution of the Superego Primitive superego precursors are formed early in life from the internalization of frightening and aggressive perceptions of parental figures. In some cases those perceptions are based on real behaviors of the figures; in other cases the perceptions are influenced by distortions deriving from fantasies by the child and from projections of the child's rage and sadism onto external objects. As a child matures and resolves the Oedipus complex, identifications with both parents become integrated to form an intricate and well-rounded internal object representation within the ego that interacts with the other contents of the ego as a superego. The parental identification is further reinforced by the child's struggles to repress unacceptable sexual and aggressive wishes and by the child's identification with the parent's superegos.

The ego originates to a large extent through interactions with the external world. The superego, however, is much more closely related to the id in its origins. It emerges from a powerful struggle with the drive pressures emanating from the id and is, therefore, more internal in its origins than is the ego. The identifications constituting the superego continue to undergo modification as role models and authority figures in one's life become incorporated into a set of internal standards, values, aspirations, and ideals.

As the oedipal phase of psychosexual development is resolved, the child moves into the stage known as *latency*. That stage, ranging from age 5 or 6 until the onset of puberty, is a period of relative quiescence, when the pressures from instinctual drives are more or less under control. Punishments and restrictions previously imposed by the parents are now firmly ensconced in the superego, which judges and guides behavior even in the absence of external authorities.

With the onset of puberty and the entry into adolescence, sexual and aggressive drives resurge. The superego is undermined as abandoned incestuous strivings are rekindled. The well-known phenomenon of adolescent rebellion can be understood as both an instinctual mutiny against the prohibitions of the superego and an attempt to take flight from the forbidden impulses toward parents arising from the hormonal changes of puberty. A major developmental task of adolescence is to modify the superego from a rigid and overly punitive structure to one that allows and sanctions an adult sexual object choice.

THEORY OF ANXIETY

The development of Freud's understanding of anxiety is of fundamental importance to the theory and the practice of psychoanalysis. His clinical observations in the 1890s led him to regard anxiety as the result of "dammed-up libido." In other words, a physiological increase in sexual tension leads to a corresponding increase in libido, the mental representation of that physiological event. The normal outlet for such tension is, in Freud's view, sexual intercourse. However, abnormal sexual practices, such as abstinence and coitus interruptus, prevent tension release and result in *actual neuroses*. Those conditions of heightened anxiety related to libidinal blockage include neurasthenia, hypochondriasis, and anxiety neuroses, all of which Freud regarded as having a biological basis.

Freud differentiated the actual neuroses from the *psychoneuroses*—hysteria, phobias, and obsessional neuroses. He understood those conditions and the anxiety associated with them to be primarily related to psychological factors, rather than physiological factors. Intrapsychic conflict is responsible for anxiety in psychoneuroses, and Freud observed that the resulting anxiety is less intense and dramatic than what he observed in actual neuroses.

Freud's early theory of anxiety cannot account for objective anxiety related to the threat of real danger that is unrelated to accumulated sexual tensions. That gap in Freud's theory led him to expand his conceptual framework of the pathogenesis of anxiety to include self-preservation and the adaptive function of anxiety.

Anxiety as a Signal With the publication of *Inhibitions, Symptoms and Anxiety* in 1926, Freud created a new theory of anxiety that reflects the ascendence of the structural model over its topographic predecessor. Accordingly, the role of instinctual drives and physiological pressures is of less importance in that theory. Instead, the new theory accounts for both real external anxiety and neurotic internal anxiety as a response to a danger situation.

Freud identified two types of anxiety-provoking situations. One situation involves overwhelming instinctual stimulation, the prototype of which is the experience of birth. In such situations, the excessive amount of drive pressure penetrates the protective barriers of the ego, producing a state of helplessness and trauma. The second and more common situation involves anxiety that develops in *anticipation* of dangers, rather than as the result of those dangers. That warning to the organism, known as *signal anxiety*, operates at an unconscious level and serves to mobilize the ego's resources to avert the danger. Either external or internal sources of danger may produce such a signal that leads the ego to marshal specific defense mechanisms to guard against or to reduce the degree of instinctual excitation.

Freud's new theory of anxiety explains neurotic symptoms as a partial failure of the ego to cope with distressing stimuli. The drive derivatives associated with danger have not been adequately contained by the defense mechanisms used by the ego. In phobias, for example, Freud explained the fear of an external threat (such as dogs or snakes) as an externalization of an internal danger. In psychotic conditions the breakdown of ego-defensive functioning is so thoroughgoing that associated distortions of ego functioning take place in an effort to accomodate the idiosyncratic distortions of the external world perceived by the patient.

Although Freud focused much more of his attention on signal anxiety in the latter part of his career than in his early career, he always maintained that physiologically based actual neuroses exist alongside the psychoneuroses. Freud's differentiation of two forms of anxiety—one biologically mediated and the other psychologically generated—proved to be remarkably prophetic. That distinction parallels what we now view as panic disorder and generalized anxiety disorder. Panic disorder may be

mediated by stimulation of the locus ceruleus, the largest noradrenergic nucleus of the brain. Dysregulation of the g-aminobutyric acid system seems to trigger that form of anxiety; psychological factors, unrelated to the locus ceruleus, appear to trigger a milder form of anticipatory or generalized anxiety. It has been postulated that an underlying neural structure may lead to a diathesis for the more severe form of anxiety and that the absence of such a neural structure leads to a milder form of expression, signal or anticipatory anxiety.

Developmental Hierarchy of Anxiety Freud realized that each stage of psychological development contains a characteristic danger situation involving phase-specific issues. Hence, a developmental hierarchy of anxiety can be constructed based on the specific fears associated with each stage. The earliest danger situation is a fear of disintegration or annihilation, often associated with concerns involving fusion with an external object. As one matures to the recognition of the mothering figure as a separate person, separation anxiety or fear of the loss of the object becomes more prominent.

During the oedipal psychosexual stage, the girl child is most concerned about losing the love of the most important figure in her life, her mother. The male child is primarily anxious about bodily injury or castration. After the resolution of the oedipal conflict, a more mature form of anxiety occurs, often termed *superego anxiety*. That latency-age concern involves the fear that internalized parental representations, contained in the superego, will cease to love the child or will angrily punish the child. The symptoms of anxiety may have determinants from several of those developmental stages. A major task for the psychoanalytic clinician treating anxiety is to understand the particular danger situations and their associated developmental phases that have contributed to the anxiety of a particular patient in a particular situation.

Implications of Theory Freud's theory of signal anxiety heralded a decisive shift in his formulation of the ego. Before the introduction of the structural theory in 1923, Freud regarded the ego as a passive, weak, and fragile agency that responds to the bidding of the instinctual drives from the id and the punitive demands of the superego. In his revision of his anxiety theory, however, the ego is an executive agency that exerts control over the forces of the id. Anxiety appearing before repression is operative, and the ego is endowed with sufficient autonomy to exercise certain functions on its own.

The conceptualization of anxiety as a signal also has important clinical implications. Anxiety should not be viewed simply as a pathological symptom to be removed. A healthy ego must develop the capacity to use anxiety signals to mobilize ego resources in efforts at mastery and control. Indeed, psychoanalysts view a person's capacity to tolerate anxiety as a significant sign of ego integration and psychological health.

PSYCHOANALYTIC CONCEPT OF CHARACTER

Although the term “character” has moral overtones in popular usage, in psychoanalysis, *character* refers to the enduring patterns of functioning typical of a person. Others know a person's character by that person's habitual way of behaving, feeling, speaking, and thinking. A variety of theoretical underpinnings have been proposed to explain character formation. As previously noted, Freud linked certain character traits with certain psychosexual stages. For example, persons who are developmentally fixated at the anal stage are likely to manifest orderliness, obstinacy, and miserliness. In a classic paper on anal eroticism and character, Freud concluded that permanent character traits represent “unchanged prolongation of the original instincts, or sublimation of those instincts, or reaction formation against them.”

Freud was faced with a challenge in differentiating neurotic symptoms from character traits. He suggested that neurotic symptoms represent a “return of the repressed,” reflecting his formulation that the failure to repress drive derivatives leads to neurotic symptom formation. In contrast, he postulated that character traits are the end result of the *successful* use of repression and other defenses, particularly reaction formation and sublimation. Freud's development of the structural model allowed him to expand his understanding of character formation further by including identification as a defense. He observed that a person may be able to relinquish an object attachment only by a process of identification, in which the lost object is firmly established inside the ego. Through a series of identifications, children develop their own characters. The formation of the superego is a related identificatory process that also contributes to the end result of a unique character structure.

Karl Abraham delineated character traits linked to oral, anal, and genital roticism and, in so doing, advanced Freud's rudimentary ideas to a much more sophisticated and detailed description of character. Wilhelm Reich also made significant contributions by identifying the close relationship between resistance to psychoanalytic treatment and the nature of the patient's character traits. Reich's observations about character resistance remain useful today in the work of contemporary psychoanalytic clinicians.

Current Concepts of Character Today the concept of character and that of personality are used interchangeably, particularly in discussions concerning Axis II personality disorders and traits. Psychoanalytic interest has expanded beyond specific character traits to a broadened understanding of character as a series of compromise formations between instinctual wishes and opposing defenses, on the one hand, and constellations of internal representations of self and others, on the other hand. Increasing evidence from studies of twins and other research indicate that genetic and constitutional factors play key roles in the development of character. The unique stamp of personality of any one person appears to be the final common pathway of a complex mixture of innate biological predispositions and environmental-psychological factors. For example, recent research suggests that shyness involves an inherited diathesis that requires particular environmental circumstances to attain phenotypic manifestations.

Discussions of character lead directly to related concepts of self, ego, and identity—all of which have developed varied meanings in contemporary psychoanalytic usage. The following discussion of object relations theory attempts to explicate those terms in more detail.

OBJECT RELATIONS THEORY

The ego-psychological approach to psychoanalysis, often referred to as the classical view, is one of three major theoretical frameworks that are widely used by modern psychoanalytic clinicians. The other two theoretical schools, object relations theory and self psychology, are both emblematic of a trend within psychoanalysis away from an emphasis on drives and defenses and toward an increasing interest in relationships. Self psychology, which is discussed later in this section, derives from the interpersonal tradition established by Harry Stack Sullivan but most eloquently formulated and elaborated by Heinz Kohut and his followers. Object relations theory originated in the work of Melanie Klein and members of the British school, including D.W. Winnicott and W.R.D. Fairbairn.

Basic Concepts The ego-psychological perspective conceptualizes drives as primary and object relations as secondary. In that model the infant is motivated by the wish to discharge tension under the pressure of instinctual drives. By contrast, object relations theory stresses the fact that all drives emerge in the context of a mother-infant relationship; therefore, object seeking must be considered a motivation equal to or of even greater importance than drive discharge.

Freud made many references to the importance of internalized objects. For example, in his 1923 landmark work on the structural model, *The Ego and the Id*, he noted that “the character of the ego is a precipitant of abandoned object-cathexes and... contains the history of these object choices.” In other words, he firmly believed that a person's ego results from identification with such external objects as parental figures. Similarly, the superego and the ego-ideal are conceptualized as internalizations of aspects of one's parents.

Freud laid the groundwork for a theory of object relations within the framework of the structural model, but his followers began to notice certain limitations of the model. For example, it became increasingly apparent that the id is not simply an amorphous cauldron of explosive drives. Aggressive and sexual wishes are connected with fantasies and meanings organized around relationships. Similarly, the view of the ego as subservient to an internal critical agency called the superego is seen as having limited clinical usefulness. The superego has both loving and critical aspects to it, and the complexity of its interaction with the ego can most usefully be conceptualized as an internal object relationship. Conceptualizing an object relationship strictly in terms of its cathexis with drive energy does not do justice to the full range of needs and moods associated with relationships. Such wishes and needs as affirmation, safety, reassurance, and self-esteem are not easily subsumed under the dual-instinct theory.

In strict terms, object relations theory is not an interpersonal model of psychoanalysis. It is a theory of unconscious internal object relations involving the transformation of interpersonal relationships into internalized structures. As infants grow and develop, they internalize an experience of a self in relationship to an other. The feeding experience is perhaps the best prototype of the process. While a hungry infant is screaming for its mother, a template of unpleasant experience is laid down in its brain, involving an experience of the self as greedy, demanding, and angry and an experience of an object (the mother) as frustrating, unavailable, and inattentive. That self-object constellation is also accompanied by powerful moods.

When the mother finally feeds the baby, the self-object-moods unit is transformed into a positive experience of the self, a positive view of the object as nurturant and attentive, and a positive affective experience of pleasure and satiation. At around 16 months of age, the infant's cognitive and perceptual apparatuses have

sufficiently developed so that those two experiences are internalized as two opposing sets of self-object-mood units.

That examination of the feeding experience illustrates a basic tenet of object relations theory—namely, that object relations always involve an interaction between a self and an object associated with an affect. Internalized representations of self and object do not occur in isolation. A second point of crucial importance is that the structures laid down by the child are significantly determined by the child's fantasy life. For example, the mother who is not responding to her child's demands to be fed may actually be a perfectly competent mother who is simply occupied with other siblings. However, the infant's fantasies may involve a mother who is evil, rejecting, and abandoning, so that the internal structure laid down by the child may include such distorted characteristics. Freud was clearly aware of that phenomenon when he noted in 1940, “It is a remarkable thing that the super-ego often displays a severity for which no model has been provided by the real parents.” Hence, a one-to-one correlation may not exist between the real external object and the internalized object.

Object relations theory also views motivation differently from Freudian ego-psychological theory. For example, the infant transforms its mother into an internal soothing presence as a way of dealing with its fear of losing its mother. In that manner both the external mother and the internalized version of the mother represent safety and an enhanced sense of well-being for the child, independent of drive discharge. Internalizing bad or negative aspects of the mother is more complex and involves the fantasy of gaining control over the bad object by capturing it within oneself, developing mastery through repetitive traumatic experiences with the object, yearning to transform the bad object into a good object, and needing to hang on to the bad object because it is preferable to no object at all.

The development of the self-object units in the child's internal world reflects the operation of two distinct internalization mechanisms. *Introjection* involves the taking in of an object that continues to exist as an other, an internal presence that may be experienced as a soothing companion or a critical parent, as in the case of the superego. Introjects, then, continue to be experienced as *objects*, rather than as parts of the child's self. *Identification*, in contrast, involves a modification of the self on the basis of the internalization of a significant external figure who is used as a model. That assimilation process in identification leads to the child's experience of those parental qualities as part of the self, rather than as a foreign body, as in the case of introjection. Identification with an introject may also take place over the course of development.

Whereas ego psychology regards conflict as struggles between wishes and defenses or between intrapsychic agencies, such as the id and the superego, object relations theory views conflict quite differently. Unconscious conflict is perceived as a struggle between different self-object–affect units striving for center stage in the psyche. The notion of character is also conceptualized in a different manner. Instead of the ego-psychological view that the end result of instinctual drives and specific defensive operations deals with those drives, character is viewed as heavily influenced by the predominant constellations of self-representations and object representations deriving from introjections and identifications.

Historical Evolution Object relations theory as a separate school of psychoanalytic thought originated in the United Kingdom. The British Psychoanalytic Society is divided into three segments as a result of disagreements that took place before and during World War II. Those three discrete groups, still in existence today, include the A group, followers of Melanie Klein; the B group, followers of Anna Freud; and the independent group, who are often referred to as the middle groupers. The third group—consisting of such notable clinicians as Winnicott, Fairbairn, Harry Guntrip, Michael Balint, Margaret Little, and John D. Sutherland—are responsible for the theory of object relations as it is known today. They formed the British school of object relations out of a wish to avoid taking sides with either the Kleinians or the Anna Freudians. However, they owe a substantial debt to Melanie Klein, who is generally acknowledged to be the pivotal figure in the shift from classical theory to object relations theory.

Melanie Klein Heavily influenced by Freud, Klein evolved a theory of internal object relations that was intimately linked to drives. She arrived in England in 1926, having emigrated from Budapest and Berlin. Her unique perspective largely grew out of her psychoanalytic work with children, in which she became impressed with the role of unconscious intrapsychic fantasy. She believed that a fear of annihilation associated with Freud's death instinct was a key factor in the first few months of the infant's life. She postulated that the ego undergoes a splitting process to deal with that terror; derivatives of the death instinct—such as aggression, hatred, sadism, and all other forms of “badness”—are disavowed and projected onto the mother.

Klein viewed projection and introjection as the primary defensive operations at that stage of life. After projecting the death-instinct derivatives into the mother, the infant begins to suffer from persecutory anxiety, in which the infant lives in dread of an invasive attack from the mother. In that terrifying fantasy, the “bad mother” created by the infant's projections gets inside the infant (i.e., the “bad mother” is reintrojected) and destroys the remaining “goodness” (i.e., libidinal derivatives) that were originally protected by the splitting and projection of the “badness.”

That persecutory anxiety characterized what Klein called the *paranoid-schizoid position*, the infant's mode of organizing experience in which all aspects of the infant and the mother are split into good and bad elements. Klein thought that external and internal objects cannot be clearly distinguished because the actual figures in the external world are heavily colored by the infant's projections and ensuing perceptions are distorted. She conceptualized oscillating cycles of introjection and projection to keep bad aspects of the self separated from good aspects of the self and to keep the bad aspects of objects separated from the good aspects. In that manner the child can prevent good, loving aspects of its experience from being destroyed by bad, hateful aspects of experience. In the second half of the first year of life, according to Klein's developmental timetable, the child's part-object world (i.e., a world containing an “all-bad” mother and an “all-good” mother) begins to change. The child becomes aware that the hateful, rejecting mother and the loving, nurturing mother are simply aspects of the same person. As those disparate views are integrated, the infant becomes concerned that it may have harmed or destroyed its mother through its hostile and sadistic fantasies directed toward her. At that developmental point the child has arrived at the *depressive position*, in which the mother is viewed ambivalently as having both positive and negative aspects and as being the target of a mixture of loving and hateful feelings.

In contrast to the paranoid-schizoid position, in which the primary concern of the infant is external attack, in the depressive position the infant's primary concern is that it may harm love objects, particularly the mother. The possibility of losing the good object through sadistic and aggressive impulses produces guilt feelings in the child. Anxiety about loss of the love object through one's own destructiveness is known as *depressive anxiety*. To deal with guilt feelings, the child engages in a process of *reparation*, in which efforts are made to ensure that love prevails over hate and that damage done through one's own destructiveness is repaired through loving behavior. Because the maternal object is recognized as a whole object in the depressive position, Klein postulated that the Oedipus complex begins in the second half of the first year, and she recast the whole oedipal constellation as an effort to resolve depressive anxieties and guilt through reparation.

Kleinian theory has been criticized for its significant shortcomings. One of its primary difficulties is the assumption that an infant in its first year of life possesses a highly sophisticated capacity for abstract and conceptual thinking. The infant's perceptual-cognitive development is actually too rudimentary when that young to be capable of elaborating the sophisticated fantasies that Klein postulates. Hence, her developmental timetable, which compresses preoedipal and oedipal phases into the first year, is no longer tenable.

Klein's emphasis on envy and greed have considerable clinical utility, but her view that such states, as well as aspects of sadism and aggression, derive from the death instinct has fallen out of favor. Klein has also been criticized for relying too heavily on fantasy and thereby discounting the role of actual environmental trauma on children and the influence of real parental objects on the child's development. Post-Kleinian theorists have suggested that the paranoid-schizoid and depressive positions are not developmental phases that are outgrown but, rather, two modes of generating experience that continue in a dialectic with one another throughout adult life. Viewed from that perspective, Klein's formulations have a great deal of clinical value, particularly in the treatment of highly disturbed patients.

Independent Group The British analysts who constitute the middle group had several key features in common. First, like Klein, they were involved in the psychoanalytic treatment of patients who were more severely disturbed than the classical neurotic patient. As a consequence of that particular clinical experience, they tended to focus on preoedipal development and dyadic object relations, rather than the triangular oedipal constellation. Also, they counterbalanced Klein's focus on intrapsychic fantasy with detailed attention to the actual environment provided by the mothering figure in the earliest months of life. The group was also intensely interested in a theory of *deficit*—that is, a theory that encompassed the effects of insufficient maternal nurturance on the developing child and that conceptualized certain forms of psychopathology as involving the absence of or an insufficiently developed intrapsychic structure, rather than interagency conflict. Each of the leading figures of the British school of object relations theory made unique contributions.

W.R.D. FAIRBAIRN Although heavily influenced by Klein, Fairbairn (Fig. 6.1-11) reversed her focus on the role of fantasy in the infant's creation of its objects. He saw the causes of his patient's difficulties in their mothers' failure to provide appropriate nurturance, rather than in the frustration of drives. He thought that infants have a basic need for a kind of love and acceptance from the mother that assures the infants that they are persons in their own right. In that regard he conceptualized the need for the recognition of personhood as primary and the physiological needs related to the drives as secondary. He did not deny the existence of libido and aggression but thought that they are fundamentally object-seeking, rather than pleasure-seeking.

FIGURE 6.1-11 W.R.D. Fairbairn. (Courtesy of John D. Sutherland, Edinburgh, Scotland.)

Although Klein stressed that fantasy is the earliest and most basic activity of the infantile mind, Fairbairn regarded fantasy as substitutive rather than primary. The welfare of the developing child lies fundamentally in the experience of the mother's acceptance of it, and internal objects are elaborated only in compensation for unsatisfactory relationships with real external objects.

Fairbairn is particularly known for his insight into the primacy of the schizoid condition. He suggested that, when the mothering figure fails to fulfill the baby's basic needs, the infant splits the object and the ego into various components, leading to a schizoid state. Hence, in contrast to classical theory, the Fairbairn theory views the ego as whole at birth, only to become split as it encounters unfavorable experiences with early mothering figures. In the Fairbairn model, libidinal object-seeking is primary, and aggression occurs as a natural defensive reaction to the frustration of the libidinal drive.

D.W. WINNICOTT Of all the middle groupers, Winnicott is probably the best known. Like Fairbairn, he was a Kleinian revisionist who gave greater credence to the role of external reality in development. He was particularly interested in the creation of a *holding environment* by the mother that made it ultimately possible for the child to develop awareness as a separate person. In Winnicott's view the mother plays a key role in bringing the world to the child and in offering empathic anticipations of the infant's needs. The mother provides a fundamentally crucial relationship that enables the nascent self of the infant to emerge. Trained as a pediatrician, Winnicott gave primary attention to the mother-infant dyad. Little of importance was written about the father in Winnicott's work.

Winnicott coined the term *good-enough mothering* to designate a mothering figure who is able to provide an optimal amount of comfort and constancy for the infant, so that the infant can proceed along normal developmental lines. Such a mother tunes in to the infant and meets the child's omnipotent needs without challenging them and offers her support according to the infant's own timetable, rather than imposing herself on the child as a consequence of her own needs. She also lets the infant separate at the appropriate time and allows for an optimal disillusionment of the child's omnipotence.

Winnicott was also responsible for the concept of the *transitional object*, the infant's not-me possession, usually a reassuring blanket or toy. The object, often suffused with the mother's scent, enables the child to separate emotionally from the mother without undue anxiety. The transitional object preserves the illusion of the comforting maternal object, even in her absence. Winnicott described *transitional phenomena* as objects, sounds, sights, and smells that exist in an intermediate realm that has elements both of external reality and of the child's own subjectivity. Art, religious experience, and creativity may well derive from that sphere of experience.

Winnicott's distinction between the *true self* and the *false self* is widely used in clinical discussions. The true self refers to the inherited potential that constitutes the kernel of the child. The true self is the child's authentic being that will emerge if a good-enough mothering experience with an appropriate holding environment is offered. The false self is a facade constructed by the child in reaction to a self-involved mother who insists on certain responses from her child. The false self may develop to protect the true self by complying with the maternal demands.

Winnicott's conceptual framework of the mother-infant relationship led to a form of psychoanalytic treatment that radically departed from the classical approach. He thought that the analyst must provide the appropriate facilitating environment that was missing during the patient's early development. Only then can the true self, which was frozen in a state of developmental arrest, continue its growth and overtake the false self constructed by the patient. Like Fairbairn, Winnicott thought that psychopathology results from the mother's failures, rather than from interagency conflict or intrapsychic fantasy. His own technique took on a unique character in that he advocated a prolonged holding period before making interpretive interventions.

MICHAEL BALINT Balint thought that the search for the primary love object underlies virtually all psychological phenomena. The infant wishes to be loved totally and unconditionally, and, if the mother is not forthcoming with appropriate nurturance, the child devotes its life to a search for the love that was missed in childhood. Balint described the feeling in many patients that something is missing as *the basic fault*. Like Fairbairn and Winnicott, Balint understood that deficit in internal structure to be the result of maternal failures. He viewed all psychological motivations as stemming from that failure to receive adequate maternal love.

Unlike Fairbairn, Balint did not entirely abandon drive theory. He suggested that libido, for example, is both pleasure-seeking and object-seeking. He also worked with primitively organized patients, and, like Winnicott, he felt that certain aspects of psychoanalytic treatment occur at a more profound level than verbal explanatory interpretations. Although some material involving genital psychosexual stages of development can be interpreted from an intrapsychic conflict perspective, Balint believed, certain preverbal phenomena are reexperienced in analysis, and the relationship itself is decisive in dealing with that realm of experience.

Mixed Models When object relations theory began to cross the Atlantic and to influence North American thinkers, attempts were made to integrate American ego-psychological concepts with the object relations perspectives of Klein and members of the British school. Two prominent contributors to that mixed-model approach are Edith Jacobson and Kernberg. The melding of ego psychology and object relations theory typical of their work has led Jacobson and Kernberg, as well as those influenced by them, to be categorized as American object relations theorists.

Edith Jacobson In contrast to members of the British school, Jacobson understood the infant's disappointment with the maternal object to be not necessarily related to actual failure by the mother. In Jacobson's view, disappointment is always related to a specific, drive-determined demand, rather than to a global striving for contact or engagement. She viewed the infant's experience of pleasure or unpleasure as the core of the early mother-infant relationship. Satisfactory experiences lead to the formation of good or gratifying images, whereas unsatisfactory experiences create bad or frustrating images. Normal and pathological development are based on the evolution of these self-images and object images. As far as Jacobson was concerned, the concept of fixation refers to modes of object relatedness, rather than modes of gratification.

Jacobson believed that the structural model and an emphasis on object relations are not fundamentally incompatible. She thought that the ego and self-images and object images exert a reciprocal influence on one another's development. The ego, as it matures, integrates early pleasure-unpleasure experiences into partial primitive images of the self and the object. Subsequent events continue to be divided into either gratifying or frustrating experiences.

By the second year of life, with further maturation of the ego, the child is able to distinguish specific features of the love object and to entertain the notion of being like the admired object, rather than of becoming the object. If conditions are favorable, selective identification, the tendency to be like the object, gradually replaces the tendency to regress into merger fantasies. Eventually, competition with peers and the same-sex parent contributes to stable ego identification and the establishment of an ego-ideal. Jacobson viewed the ego-ideal as a fusion between ideal self-images and ideal object images that partially compensate for the lost fantasies of merger.

For Jacobson the superego develops in three phases. The early superego consists of archaic, sadistic images formed on the basis of introjective and projective processes. The second phase involves the fusion of ideal self-images and ideal object images into the entity of the ego-ideal. The third and final stage involves the internalization of realistic parental demands, values, and prohibitions.

Otto Kernberg Perhaps the most influential of the American object relations theorists, Kernberg was substantially influenced by both Klein and Jacobson. Much of his

theory was derived from his clinical work with patients suffering from borderline personality disorder (discussed later). In brief, Kernberg places great emphasis on the splitting of the ego and the elaboration of good and bad self-configurations and object configurations. Although he continues to use the structural model, he views the id as composed of self-images, object images, and their associated affects. Drives appear only to manifest themselves in the context of internalization of interpersonal experience. Good and bad self-relationships and object relationships become associated, respectively, with libido and aggression. Not only do object relations constitute the building blocks of structure, but they are also the building blocks of drives. Goodness and badness in relational experiences precede drive cathexis. In other words, the dual instincts of libido and aggression arise from object-directed affective states of love and hate.

The influence of Klein on Kernberg is apparent in his view of infantile development as moving from splitting toward integration. Idealized or good images of self and object are gradually integrated with devalued or bad self-images and object images, leading to ambivalent, whole-object configurations of self and other. That integration leads to feelings of guilt, concern, and mourning, much as Melanie Klein described the process. Kernberg's view of the superego follows Jacobson's model in delineating three layers based on the three developmental phases of Jacobson.

The principal features of the major object relations theorists are summarized in Table 6.1-3.

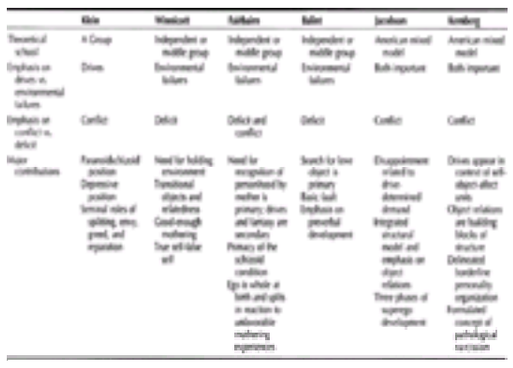

Table 6.1-3 Object Relations Theorists

Defense Mechanisms in Object Relations Theory Although the clinical work of ego psychologists has focused primarily on neurotic defense mechanisms, the object relations theorists have traditionally worked with more disturbed patients. That clinical perspective has delineated a set of primitive defense mechanisms characteristic of severe personality disorders and psychoses that are in common usage by object relations theorists.

Splitting Although Freud described splitting of the ego in his discussions of fetishism, Klein was the first analyst to recognize the universal importance of splitting in early development. It can be defined as an unconscious process that actively separates contradictory self-representations, contradictory object representations, or contradictory feelings from one another. Splitting is crucial for emotional survival because it allows the infant to separate the negative views of the mother as a rejecting, unavailable figure from the positive views of the nurturing, feeding mother, so that the feeding experience itself is not contaminated by the terrifying anxieties about the “bad mother.” Splitting helps the developing child separate love from hate, pleasure from unpleasure, good from bad, and positively colored experience from its negative counterparts. Splitting may also be viewed as a basic mode of ordering experience into separate compartments on the basis of the fear that all that is good will be destroyed by all that is bad unless the good and the bad are kept separate. Splitting is secondarily elaborated into a psychological defense.

Kernberg has been instrumental in making the defense of splitting clinically relevant to the diagnostic understanding and treatment of severe personality disorders. He has identified four common clinical manifestations of splitting: (1) the coexistence of contradictory and alternating self-representations that cause the patient to look quite different from day to day, (2) the division of persons in the environment into an idealized or all-good group and a devalued or all-bad group, (3) selective problems with impulse control, and (4) the expression of behaviors and attitudes that alternate and are contradictory but are regarded by the patient with lack of concern and bland denial. Although Kernberg has cited splitting as the key defensive operation in borderline patients, it may also be found in psychotic patients and those with neurotic or higher-level personality disorders.

Projective Identification Splitting works hand in hand with the second defense mechanism, projective identification, which is an unconscious three-step process by which object representations or self-representations are disavowed and attributed to someone else. The three steps involve the following:

1. The patient unconsciously projects an object representation or self-representation into the clinician.
2. The clinician unconsciously identifies with what is projected and begins to behave or feel like the patient's projected object representation or self-representation in response to interpersonal pressure exerted by the patient's behavior. That step in the phenomenon has been referred to as *projective counteridentification*.
3. The clinician psychologically processes the projected contents, which are, therefore, modified to some extent before finally returning to the patient through reintrojection. When those modified projected contents are returned to the patient, there is a corresponding modification of the patient's internal object relatedness.

This model is somewhat artificially linear for purposes of explication, but in the crucible of clinical work, the projective and identificatory aspects may occur virtually simultaneously. Moreover, the patient's mental contents are not mystically transferred to the clinician's internal world. A more accurate description of what actually happens is that the patient's interpersonal behavior evokes repressed aspects of the clinician that ordinarily are not regarded by the clinician as part of his or her continuous experience of self. Hence clinicians in the throes of projective identification may experience themselves as having been taken over by “alien” forces, that is, their experience is one of “I am not acting like myself.” In reality, they are simply under the sway of aspects of themselves that are ego-dystonic. In other words, there is a repressed and unconscious aspect of the clinician that is a “good fit” with what is being projected by the patient; the patient does not project into an empty container. The pre-existing aspects of the clinician may help to determine why some clinicians are more easily “provoked” by certain patients.

Projective identification as defined in this three-step model can be viewed as both an intrapsychic defense mechanism and an interpersonal process. Splitting and projective identification work in tandem to separate good and bad elements from one another. For example, a woman who has introjected a physically abusive parent may use projective identification to keep the internal bad object representation outside herself, so that she can control it. Her behavior may coerce treaters to assume the role of the abusive parent and to struggle with feelings of anger and hatred toward her. The treater's feeling of being controlled or bullied into assuming a specific role vis-à-vis the patient is a hallmark of projective identification. Although Melanie Klein originated the concept of projective identification, Wilfred Bion elaborated it to encompass a developmental situation in which the infant projects unacceptable aspects of itself into the mother, who serves as a container for the infant's projections before returning them in a modified form.

Projective identification is a controversial term, and some authors have limited its use to describe an intrapsychic defense that may or may not result in a complementary response from the clinician. In that model the identification process is regarded as occurring within the patient, rather than within the clinician who is the target of the projection. By maintaining the empathic bond or identification with the projected contents, the patient can maintain a fantasy of complete control over the target of the projection and over the projected material itself.

The distinction between projection and projective identification is also somewhat controversial. However, if one assumes that the three-step model involves both an intrapsychic defense and an interpersonal process, projective identification requires a transformation of the target of the projection. Projection does not require such a transformation. Paranoid patients, for example, may assume that people who are walking up and down the street are members of the Central Intelligence Agency, but that projection of malevolence does not alter the feelings or the behaviors of those people.

Primitive Idealization and Devaluation Primitive idealization and devaluation also occur in concert with splitting. External objects are viewed as either all good or all bad as a way of preventing the destruction of the loving aspects of others and of the self by their hateful counterparts. Hence, by attributing omnipotence and perfection to certain figures in the environment, a patient may bask in the reflected glory of the object and defend against feelings of contempt and envy toward the object. Similarly, by devaluating another person as thoroughly worthless, the patient may defend against painful feelings of envy and inferiority.

Concept of the Self Whereas ego psychologists concentrated their efforts on the ego, object relations theorists have sought to clarify the role of the self in psychoanalytic theory. The confusion between the self and the ego goes back to Freud's ambiguous usage of *Ich*, which James Strachey translated as “ego” in *Standard Edition of the Complete Psychological Works of Sigmund Freud*. Freud used the term to connote both the person and the intrapsychic agency within the person. In other words, a term that can be literally translated from the German as “I” was used interchangeably to refer both to subjective self-experience and to a collection of organizing functions within the psyche. However, the self-experience meaning gradually became lost in the increasingly preferred usage of “ego” as an impersonal executive organ of the psyche.

Hartmann attempted to distinguish the two meanings of *Ich* by defining the interactional context. The self interacts with objects, and the ego interacts with the id and the superego. That clarification was useful because it stresses the fact that the self evolves in relational configurations to objects. Hence, one's experience of oneself is discontinuous in that the nature of the self varies with the nature of the object to which it is relating. In that regard the person's self embodies the history of many internalized relationships. The concept of the self should then refer to a multiplicity of points of view from which one experiences, observes, and feels. Everyone behaves differently from others and has a different sense of internal experience, depending on the figure with whom the person is relating.

Despite the presence of that array of selves responding to diverse environmental contexts, a person has some sense of continuity over time. The sum of the component selves is regarded as one's *identity*, a term defined by Erik Erikson as a conscious sense of inner solidarity that endures over time.

If one considers a sentence such as, “I think about myself,” one becomes aware that the self is used to describe both an object of reflection and an experiential consciousness that is doing the thinking. That distinction has been the source of another major controversy surrounding the self—namely, whether the word “self” should be used to refer to an intrapsychic representation, conscious or unconscious, or to an initiator of action in its own right. Ego-psychological thinkers have traditionally viewed the self as representational, but members of the British school have preferred a concept that includes subjective experience or personal agency. Kernberg has suggested that there is room for both the self-as-agency view and the self-as-representation perspective. The self-as-agency is embedded in the ego and may be conceptualized as the end result of the integration of a myriad of self-representation.

Contemporary psychoanalytic theory has been enhanced by conceptualizing the self as a content of the ego. The ego is useful for understanding and dealing with drive-defense conflicts, character, and compromise formations, but the self offers a subjective side to the ego that is relevant to such issues as narcissism, identity, self-other differentiation, and internal object relations. Moreover, the notion of self is important in clinical work with primitively organized patients who use such defenses as splitting and projective identification. Kohut's view of the self as a primary, supraordinate entity implying motivational status is discussed under the heading “Self Psychology.”

Infant Observation Studies Object relations theory has been bolstered by the findings of infant observation studies conducted by Margaret Mahler (Fig. 6.1-12) and her colleagues. Those investigations focused on both normal and abnormal mother-infant pairs during the first 3 years of life. The investigations were specifically designed to study the manner in which a child achieves an intrapsychic sense of separateness from its mother. As a result of the research, three developmental phases in mother-infant object relations have been described.

FIGURE 6.1-12 Margaret S. Mahler, M.D. (Courtesy of Margaret S. Mahler, M.D.)

An *autistic* phase occurs during the first 2 months of life, during which the infant spends most of its day in a half-sleeping, half-waking state, more concerned about physiological matters than relatedness. From 2 to 6 months of age, the infant enters the phase of *symbiosis*, a term Mahler used to describe an undifferentiated state of fusion between infant and mother. The onset of that phase is heralded by the infant's smile response and the baby's dawning awareness of a dimly perceived source of need satisfaction in its environment, although that maternal source is viewed as within the orbit of an omnipotent dual unity.

Most of Mahler's research focused on the third phase of the development of object relations, which she termed *separation-individuation*. That period extends from around 6 months to 36 months of age and involves the infant's psychological birth as a separate person apart from the mother. Observational data indicated that the third phase can be divided into four subphases. The first subphase, *differentiation*, occurs between 6 and 10 months of age and is linked to the child's awareness that the mother is a separate person. That awareness often results in the child's attachment to a transitional object, as described by Winnicott, to substitute for the mother when she is not available.

The second subphase, which Mahler termed *practicing*, occurs between the ages of 10 and 16 months and is characterized by elated investment in the child's newfound autonomy that results from acquiring locomotor skills. Toddlers explore their environment as though their mothers were no longer important, only to return for periodic refueling through physical contact.

The third subphase of separation-individuation, known as *rapprochement*, occurs between 16 and 24 months of age. In contrast to the toddler's relative obliviousness of the mother's presence during the previous subphase, in rapprochement the toddler shows a marked increase in its awareness of vulnerability to separations from its mother. Children at that age demonstrate a seemingly constant concern about the actual location of their mothers and display a wish for their mothers to be involved in sharing new experiences. A great need for maternal love can also be observed during the third subphase. Rapprochement is crucial in the development of object relations in which the child uses splitting of self-representations and object representations. The toddler's anger at its mother is viewed as dangerous because of the risk that the anger will destroy the positive internal representation of the mother, and the absence of the child's mother during the third subphase leads to a predominance of bad self-representations and object representations, which may be quite frightening to the child.

The fourth subphase of separation-individuation is marked by the beginnings of object constancy and the consolidation of the child as a separate person. The period corresponds to the third year of the child's life and involves the integration of the good and bad aspects of both self-representations and object representations. Moreover, the major accomplishment of the fourth subphase is the development of *object constancy*, by which the mother becomes introjected as an integrative whole object that is felt as a soothing internal presence. Because an internal image of the mother is sustained during periods of separation, the child no longer feels threatened by the comings and goings of the mother.

The empirical data gathered by Mahler and her colleagues demonstrate the crucial importance of object-seeking in the course of development. Clinicians have shown that the concepts of separation-individuation, object constancy, and, particularly, the rapprochement subphase have considerable applicability in the understanding of primitively organized patients, such as those with borderline personality disorders. The implications of that research on the understanding of pathogenesis is discussed under the heading “Psychoanalytic Psychopathology.”

SELF PSYCHOLOGY

The third major theoretical school in modern psychoanalysis is self psychology. (The other two schools are ego psychology and object relations theory, discussed above.) Derived from the work of Heinz Kohut (Fig. 6.1-13), the self psychology model of the mind regards the person as needing particular kinds of responses from others in the environment to develop and maintain a sense of self-esteem and well-being. Although object relations theory and self psychology have some similarities,

object relations theory stresses the importance of internalized relationships between self-representations and object representations, and self psychology focuses on the role of actual external relationships in creating self-cohesion and self-esteem.

FIGURE 6.1-13 Heinz Kohut. (Courtesy of AP/Wide World Photos.)

Kohut's self psychology departs from classical ego psychology in a number of ways. Defects or deficits, rather than conflicts, take center stage in self psychology. Faulty structures are viewed as responsible for faulty functioning, and the emphasis is on infantile needs, rather than repressed wishes and drives. Hence, the analyst's therapeutic goals involve understanding those needs and partially meeting them in the treatment, rather than frustrating infantile wishes that must ultimately be renounced. Building the psychic structure and repairing self-defects are seen as more important than the resolution of conflict.

Kohut's Double-Axis Theory Self psychology evolved out of psychoanalytic work with narcissistically disturbed patients. In treating those patients, Kohut noted that ego psychology based on the structural model lacks sufficient explanatory power with those patients. Instead of having discrete neurotic symptoms, those narcissistic patients had vague complaints related to disappointing patterns in relationships and a hypersensitivity to slights from others.

Kohut thought that a new theory was required to provide a conceptual framework for the analytic treatment of such patients. His theory evolved directly from clinical observations, specifically the tendency of his patients to form one of two kinds of transference: the mirror transference and the idealizing transference. The mirror-transference patients seem in desperate need of the analyst's approval and will do whatever is necessary to gain that affirmation or validation from the analyst. Those patients often appear to be performing or showing off to obtain the analyst's admiration. Kohut viewed mirror transference as a revival of an infantile situation in which the child shows off to capture the gleam in the mother's eye that makes the child feel confirmed and validated. Kohut referred to that developmental arrest as the *grandiose-exhibitionistic self*, a term he used nonpejoratively to describe a normal developmental phase in which the child's self-worth is dependent on empathic mirroring responses from the mothering figure. Without that empathy, children cannot maintain their sense of self-cohesion or wholeness, and their sense of self fragments. That sense of fragmentation of the self can be experienced along a continuum from mild anxiety or distress to full-blown panic associated with feelings of disintegration. Those children who are not provided with adequate maternal empathy are regarded as developmentally frozen and doomed to go through life seeking mirroring responses from others.

In the idealizing transference the patient regards the analyst as a perfect and omniscient parent who meets all the patient's needs. The patient may show little interest in insight or understanding in such cases because the patient's primary wish is to bask in the reflected glory of the idealized analyst. Kohut viewed that transference manifestation as similar to the developmental arrest in which the child has not been provided with a parental model worthy of idealization. As a result, the analyst is needed to perform the function that was missing in childhood.

Kohut's observations led him to postulate a double-axis theory that takes into account both narcissistic needs and object love. Kohut was impressed that narcissistic needs are never outgrown but, rather, persist throughout life in parallel development with the person's needs for object love. On the basis of that perspective, he postulated a separate axis for narcissistic development that exists alongside the classical line of development leading to object love, as depicted in Figure 6.1-14. In that model the self begins as a set of fragments that gradually achieve cohesiveness if the child's phase-appropriate developmental needs are greeted with maternal empathy.

FIGURE 6.1-14 Kohut's double axis theory (1971). (Reprinted with permission from Gabbard GO: *Psychodynamic Psychiatry in Clinical Practice*. American Psychiatric Press, Washington, DC, 1990.)

At some point in development, a point that Kohut left unspecified, children are threatened by losing the blissful perfection of the mother-infant bond and resort to one of two strategies to recapture the perfection. In one scenario the perfection is assigned to a grandiose self within the infant, in which case the adult manifestation in the psychoanalytic setting is the mirror transference. In the other scenario the infant assigns perfection to an idealized parental imago, in which case the idealizing transference appears in the analytic setting. In the course of normal development, the grandiose self evolves into healthy ambitions, and the idealized parent imago is eventually internalized as a structure akin to Freud's ego-ideal or superego—that is, a set of values and ideals that lead to moral conduct. If, however, the child's developmental needs for mirroring or idealization or both are met with maternal failures of empathy, a developmental arrest occurs at the point of the grandiose self or the idealized parental image. Those two poles of self-development Kohut termed the *bipolar self*.

Inherent in Kohut's double-axis theory is an acceptance of narcissistic needs. He thought that Freud's model of the progression from primary narcissism to object love as an expectation in the normal maturational process contains a moralizing, pejorative tone toward narcissism. In other words, Freud's view suggests that narcissism should be outgrown and that the mature adult should be primarily devoted to the needs and concerns of others. Kohut regarded that attitude as hypocritical; after all, everyone has narcissistic needs that are crucial to one's sense of personal happiness and fulfillment. Indeed, one of Kohut's major contributions was his insistence that, in addition to the dual drives of sexuality and aggression, needs for self-esteem also occupy a place of central importance in the psyche. Self psychology, then, provides a conceptual framework for the analyst that advocates empathy for the patient's narcissistic needs, instead of viewing them as immature and contemptible. Another implication of the double-axis model is that the development of a cohesive sense of self may in and of itself be a legitimate goal for psychoanalytic treatment, regardless of the patient's capacity for object love.

Selfobject Concept Throughout the evolution of self psychology, Kohut struggled with the extent to which his new theory would depart radically from the classical model in which he had been trained. He initially tried to incorporate drive theory by suggesting that narcissistically disturbed patients invest objects with a special form of narcissistic libido. However, as his theory evolved, he eventually found that mixed models were unsatisfying to him, so he made a complete break from classical theory. He also thought that his theoretical formulations were no longer limited to narcissistic personality disorders. He greatly expanded the scope of self psychology

to include all forms of psychopathology.

Within that broadened view, the term “selfobject” became a central tenet of his theory. *Selfobjects* are viewed as fundamental needs of all persons that are required for normal development. Selfobjects may best be conceptualized as functions (such as mirroring, validating, soothing, idealizing, and affirming), rather than actual persons. As the term “selfobject” implies, other people are not viewed as separate objects with their own centers of autonomy and their own distinct needs. Rather, they are viewed as present only to gratify the needs of the nascent self. Kohut believed that selfobjects are necessary for emotional survival in the same way that oxygen in the atmosphere is needed for physical survival. Throughout life all persons are dependent on others to maintain their sense of self-esteem and well-being.

At the time of his death in 1981, Kohut had conceptualized a third area of selfobject needs, which he termed the *twinship* or *alter ego*. Originating in a childhood wish to merge with the mothering figure, this dimension of selfobject needs makes its appearance in the transference in the form of a wish or need to be exactly like the analyst. Infantile antecedents of that transference development can be found in such commonplace occurrences as a little girl's pretending to feed her doll as her mother is busy nursing a younger sibling. Hence, Kohut's bipolar self became a *tripolar self*.

As a result of this expansion of the theory, Kohut observed that all forms of psychopathology can be traced to disturbances of the self-selfobject relationship in childhood. The Oedipus complex is regarded as secondary in importance in the light of the self-psychological view that all psychiatric disorders are based on distortions of the self, weakness of the self, or defects in the structure of the self. Oedipal conflicts involving castration anxiety, inhibition of aggression, and other neurotic symptoms are regarded as breakdown products of preoedipal failures in the provision of selfobject needs. An adequate self-selfobject matrix during the early years of life should allow the developing child to weather the oedipal constellation without residuals of neurotic symptoms. Moreover, most forms of pathological behavior—including perversions, binge eating, sexual promiscuity, and drug abuse—are regarded as efforts to restore or maintain a cohesive sense of self under the threat of fragmentation. In that conceptual model, disintegration anxiety, involving the concern that the failure of adequate selfobject responses from persons in the environment will lead to fragmentation of the self, becomes the fundamental fear leading to emergency attempts to restore harmony to the self through pathological behaviors.

Despite the central importance of the self in Kohut's theory, Kohut himself never offered a simple definition of the self. He seemed to think that an overarching structure of such fundamental importance defied definition. If one follows the development of his theory from the late 1960s to the time of his death in 1981, however, his view of the self appears to have undergone a transformation from that of a self-representation to a supraordinate center of initiative and experience that was regarded as the main motivating agency in the primary constellation of the psyche. In that regard the self in Kohut's self psychology is both an experiential self and a center of initiative that establishes and repairs self-esteem. Hence, even self psychology cannot escape the dialectic of self as simultaneously subject and object. That theoretical perspective can also be characterized by a marked deemphasis on the ego and its functions and a corresponding increase in the importance of conscious subjective experience. Also, in the light of the minimization of the role of drives and defenses, aggression is viewed as a secondary reaction to selfobject failures, rather than as an instinctual drive of a primary or innate nature.

Although Kohut was always vague about the developmental timetable appropriate to his theory, certain implications can be drawn. First, Kohut believed that a psychological connection to a mothering figure is present from birth, an idea in stark contrast to Mahler's autistic phase. The infant, in Kohut's view, is born into a self-object bond that is much closer to Mahler's concept of the symbiotic phase. Second, Kohut's emphasis on the lifelong need for appropriate selfobjects suggests that psychological separation is a myth. He regarded Mahler's object relations view, which revolves around the notion that the child moves in the direction of autonomy from supportive caretakers, as containing a moralistic stance. Kohut's notion of lifelong dependence on selfobjects places him in opposition to Mahler's developmental framework. His view was that dependency itself does not diminish; instead, the quality of the selfobjects needed by the self moves from archaic to more mature and appropriate.

Infant Observation Data Infant research, particularly that of Daniel Stern, has provided considerable support for the developmental premises of self psychology. Stern's observations convinced him that the infant does not emerge from the womb into a state of autistic self-absorption. From the first days of life, the infant appears to be aware of the mothering figure. Moreover, affirmation and validation from the caretaker is crucial for the development of the infant's sense of self. In that regard Stern stressed that what develops is a sense of self-with-other, and the role of fantasy, as in Klein's theory, is viewed as of only minimal significance. The infant primarily experiences reality, in Stern's view, and relates to the real presence of the mother, whose responses allow the infant to grow. Stern believed that the infant is an adept observer of reality and that it is the older toddler who uses fantasy and distortion to alter what is perceived. He argued that secondary process thought precedes primary process thought and is the bedrock of normal development.

Stern delineated five discrete senses of self. He regarded them as different domains of self-experience, rather than as phases that are subsequently eclipsed by the succeeding phase. Each domain, once formed, remains for the entire life span and operates in concert with the other coexisting senses of self. During the first 2 months of life, an emergent self appears; it is predominantly a bodily self based on physiological needs. A core sense of self emerges from 2 to 6 months of age; it is associated with greater interpersonal relatedness. Stern viewed the third sense of self, appearing between 7 and 9 months, as a major advance. He called it the sense of subjective self because it involves the matching of intrapsychic states between mother and infant. The fourth sense of self, the verbal or categorical sense of self, emerges between 15 and 18 months of age and coincides with the ability to think symbolically and to communicate verbally. The arrival of a fifth sense of self, a narrative sense of self, appears between 3 and 5 years of age. Stern believed that the fifth sense of self, the historical view of the self, is the one encountered when patients present their life stories in the analytic setting.

Stern identified four essential features of the sense of self: agency, coherence, affectivity, and continuity (or historicity). He also noted that such fundamental issues as attachment, trust, and security transcend phase specificity and are issues for the entire life span. He also questioned the notion of symbiotic merger postulated by Mahler as occurring in the first 6 months of life. In Stern's view, such wishes for and fears of union are the product of a much more mature mind, one that is capable of thinking abstractly about such concepts as fusion and merger. A central tenet of Stern's work is that the infant develops as a result of sensitive affective attunement by the mothering figure. Kohut and other self psychologists argue that the same kind of empathic resonance is necessary in the analytic situation to repair the patient's self-defects.

Post-Kohut Contributions After Kohut's death in 1981 self psychology has continued to expand its vision. The three selfobject transferences of Kohut have come to be regarded as insufficient to account for all the transference phenomena observed in the clinical setting. Ernest Wolf, a colleague and collaborator of Kohut, has described two additional selfobject transferences. The *adversarial* selfobject transference functions so as to provide an experience with a benevolent, but opposing force while also allowing confirmation of partial autonomy for the self through active opposition. The *efficacy* selfobject transference provides an experience of having an effective impact on another individual, in that it evokes necessary selfobject functions from that individual.

Robert Stolorow and his colleagues have taken Kohut's emphasis on empathy and suggested that psychoanalytic work is confined to aspects of the patient's experience that are accessible to empathy and introspection. They emphasize the nature of the intersubjective field created by analyst and patient and view extratransference information as of minor importance to the analytic process. In this regard, they are inclined to regard psychopathology as involving a two-person interplay. Analysts who fail to meet the specific selfobject needs of the patient may significantly influence the psychopathology they perceive in the patient. Other analysts influenced by self psychology believe that information outside the empathic-introspective mode of perception must be integrated into the analyst's knowledge base. Joseph Lichtenberg regards knowledge of “model scenes” prototypical of childhood and infant experiences as extremely relevant to understanding and reconstructing the patient's early experience. He also argues that five distinct motivational symptoms must be taken into account to fully understand forces at work in the patient. These five systems include exploratory assertiveness, sensual-sexuality, aversiveness, attachment-affiliation, and most psychological aspects of physiological pressures. Lichtenberg regards mainstream self psychology as reductive in its relegation of sexuality and nonsexual pleasure to a relatively peripheral position.

In other post-Kohut developments, Howard Bacal and Kenneth Newman have sought to integrate self psychology with object relations theory. They note that although Kohut failed to acknowledge being influenced by the British School of object relations, he has much in common with their thinking. They also stress that in its applications to the clinical setting, self psychology is basically a variant of object relations theory. Whereas Kohut argued that the self alone was the center of his theory, Bacal and Newman point out that the self in connection with its object is the true basic unit of self psychology. A sophisticated understanding of the selfobject was not articulated by Kohut, so these authors have sought to fill that void by regarding the relationship between patient and analyst as a true object relationship.

POSTMODERN TRENDS

In recent years the hegemony of ego psychology in American psychoanalysis has been challenged by a number of postmodern trends in psychoanalytic thought. The unifying factors in postmodernism include the view that reality inevitably grows out of social and linguistic construction and a basic skepticism about any

unquestionable or fundamental truths. Freud is often regarded as representing modernity, characterized by a positivist orientation and a dispassionate search for an absolute or objective truth in the patient that will ultimately be revealed if the patient adheres to the method of free association. By contrast, postmodern schools of thought, such as social constructivism, perspectivism, intersubjectivity, relativism, and mutuality argue that no absolute objectivity exists and that perceptions in the analysand are inevitably influenced by the analyst's own subjectivity.

Of all the forms of postmodernism, the most extreme variation would be that of relativism. According to this school of thought, truth about the patient is impossible, and both analyst and analysand are mired in uncertainty. A more moderate view that is endorsed by a number of contemporary psychoanalytic thinkers is that of realism and perspectivism. The realist-perspectivist school differs from relativism by acknowledging the existence of a clinically useful and significant reality in the patient that requires articulation and understanding in the course of the treatment. Nevertheless, this theoretical orientation stresses that each participant in the analytic dyad has a subjectivity that ultimately results in a jointly constructed reality. In this two-person frame of reference, both analyst and analysand are regarded as having plausible perceptions of the emerging reality.

Social Constructivism The social constructivist perspective of Merton Gill and his collaborator Irwin Hoffman has been highly influential in the evolution of recent psychoanalytic thinking in America. Central to social constructivism is the notion that the analyst's *real* behavior continuously affects the patient's transference. The analyst is no longer regarded as a dispassionate observer of the intrapsychic functioning of the patient but rather a mutual and full-fledged partner in the exploration of what transpires between the two people involved in the analysis. Moreover, a central tenet of the social constructivist view is that analysts can never know the full extent of the way that their irreducible subjectivity influences patients and the analytic process.

Countertransference is viewed as continuous and unconscious so that the analyst is incapable of keeping up with unconscious emotional reactions to the patient. Another basic tenet of this perspective is that the patient may see something that the analyst is resisting in the same way that the analyst observes resistance in the patient. Hence the analyst needs to take seriously the patient's interpretations of the analyst's conscious and unconscious influences on the patient. The social constructivist view emphasizes both spontaneity and personal engagement with the patient that fully acknowledges the contributions of the analyst to the transference.

Postmodern trends in psychoanalytic thought often lead to a deconstruction of the analyst's authority, but social constructivists like Gill and Hoffman have argued that the authority of the analyst is to some extent inescapable by virtue of the asymmetry of the analytic situation. The analyst always has the benefit of knowing more of what is going on in the patient's mind than the patient knows about what is going on in the analyst's mind. In addition, by virtue of their training analysis, analysts should be more aware of biases and more capable of reflecting on those biases.

American Relational Theory Of all the postmodern schools, American relational theory has probably had the most profound impact on contemporary psychoanalytic discourse. In 1983 Jay Greenberg and Stephen Mitchell identified two distinct approaches to psychoanalytic theory: the drive-structure model and the relational model. They argue that these two perspectives are essentially incompatible because drive theory stems from a philosophical tradition that regards man as an essentially isolated individual whereas relational theory derives from a view of man as a social being. Conflict occurs in a relational context in this theory rather than between intrapsychic agencies. The similarities to the British Middle Group have been acknowledged by the fact that relational theory is sometimes regarded as the “American Middle School.”

Relational theorists acknowledge the intrapsychic but view it as the internalization of interpersonal experience that is also mediated by biologically based constraints. Physiological pressures, such as sexuality, are not ignored, but are recognized as occurring in a relational context.

Central to the relational view is the notion of mutuality (i.e., the inevitability of a two-way influence between patient and analyst). Meaning is not construed simply by the analyst's clinical acumen but through a dialogue between patient and analyst involving negotiation and joint construction. Relational theorist Lewis Aron has stressed that mutuality does *not* imply symmetry or equality. Despite the mutuality and reciprocity of the relationship, analysis is a relatively asymmetrical relationship where one person seeks help from another and pays that professional a service that is rendered under ethical guidelines.

Feminism has played an important role in the development of relational theory. Classical psychoanalysis has been viewed by feminist critics as embodying masculine ideals of objective science and detachment from the object of study. Feminist views that attachment and relatedness are as important as independence and autonomy have contributed to a shift towards a more relational perspective within analysis. Jessica Benjamin has pointed out that in most developmental theories within psychoanalysis, the mother of the infant is viewed only as an object rather than a subject. She is seen as provider, caregiver, source of nurturance, and empathic selfobject but rarely viewed as someone with a subjectivity that involves a purpose apart from taking care of the child. Benjamin has stressed that intersubjectivity is a developmental achievement involving the recognition of the mother (or other person) as a separate subject rather than merely as an object. Much like Winnicott, Benjamin emphasizes that in the course of psychoanalytic work, the analyst becomes less of an object and more of a subject to the patient, paralleling the nature of subjectivity and objectivity in the course of child development.

Lacanian Theory A discussion of postmodernism would not be complete without a survey of the theory of the French psychoanalyst Jacques Lacan (1901–1981). Although abstruse, elusive, deliberately provocative, and unorthodox, Lacan has made a lasting impression on French psychoanalysis as well as on literary and film criticism in academic departments throughout the world. Lacan's reading of Freud relies heavily on linguistics. The notion that the human being is constituted by language is one of three basic principles endorsed by Lacan. The unconscious is structured like a language that consists only of signifiers—biology and drives have no place in his theory. Second, the ego does not exist as an autonomous structure. The third principle is that an individual is inevitably embedded in political and societal structure that cannot be transcended.

Lacan preferred to speak of “orders” rather than stages of development, and he identified three orders relevant to understanding the human condition. From 6 to 18 months there is an imaginary order involving a mirror stage, during which infants delight in identifying with their reflection. This preverbal and presymbolic order gives way to a symbolic order involving the acquisition of language and a split between the inner and the outer world. The inner world is connected with a misrecognition in the mirror stage where the “I” or the self is identified with the father's laws and the cultural standards associated with those laws. The final order is that of the “real,” which is stark factual reality and exists somewhere outside of language; this is viewed as unreachable and indefinable by Lacan.

Lacan thrived on being unorthodox. He denied the significance of diagnoses, rules, or established schools of thought. He saw the analytic process as an effort to recognize the alienation from one's true self. Analysis was also designed to bring out underlying structures and contexts in the unconscious. Historical reconstruction is downplayed whereas desire for the “Other” is examined in all its many forms.

Lacanian analysis has had little influence on the clinical practice of psychoanalysis in North America, although literary critics within American universities have made many applications of Lacan in their analyses of texts. Its antiempirical basis, its denial of the importance of preverbal human experience, and the impenetrability of much of the prose written by Lacan and Lacanian disciples has made it less popular among American clinicians than those in Europe and South America.

EMPIRICAL BASIS OF PSYCHOANALYSIS

Freud and psychoanalysis are regularly pronounced dead in articles appearing in popular periodicals. In many cases these funeral notices are accompanied by challenges to the basic scientific premises of Freud's theory. Many of the attacks on Freud have centered on his early views—formulated in the 1890s—about the importance of uncovering repressed memories in the course of analysis to accomplish the therapeutic goals of the treatment. Few of the attacks have demonstrated any significant degree of understanding about the contemporary practice of psychoanalysis and how it has evolved over the last 100 years.

Clinical psychoanalysis has progressed far beyond the theory of therapeutic action advanced by Freud in the 1890s. The de-repression of long-forgotten memories shifted first to an emphasis on recovering memories of fantasies. The next major shift was towards an emphasis on exploring resistances to free association, which eventually gave way to a direct examination of transference constellations. The field has now moved into a systematic examination of both transference and countertransference because they are viewed as critical aspects of the two-person field created when an analyst and an analysand meet together in the consulting room. Critics of psychoanalysis have failed to keep up with these changes in the field so that much of the criticism is leveled at specific historical models of treatment that are no longer applicable in contemporary practice.

Many psychoanalytic critics claim that there is no empirical validation of basic psychoanalytic principles or of the psychoanalytic treatment method. Many of those critics are completely unaware of a substantial body of psychological research that has confirmed the fundamental validity of the basic psychoanalytic principles. The most central of all psychoanalytic propositions, that much of mental life is unconscious, is the most challenged by critics of psychoanalysis but ironically is best

validated by extensive literature from experimental psychology.

Subliminal presentation of stimuli that are psychodynamically meaningful to subjects can affect a wide range of behavior even though the subjects do not have any conscious awareness of the stimuli. Individuals with no capacity to recognize faces, a condition called *prosopagnosia*, can respond emotionally to someone standing in front of them about whom they consciously know nothing. Similarly, they may have differential electrophysiological responses to familiar versus unfamiliar faces. Subliminal stimuli have been studied in connection with brain evoked-related potentials, and this research has demonstrated differences in amplitude of these potentials in response to emotional versus neutral words when presented subliminally.

Recent research demonstrates that unconscious affective signals may well factor into decisionmaking before conscious thought enters in. In work by Damasio and his colleagues, the ventromedial prefrontal cortex appears to be part of a system that stores information about past punishments and rewards; signals from this area of the brain trigger the unconscious emotional responses that are registered as a “gut feeling” or intuition.

These conclusions were based on a study involving two decks of cards—one, a “good” deck, produced greater monetary rewards than the other, a “bad” deck. Normal subjects showed physiological responses (measured by skin conductance) before choosing cards from the “bad” deck. This autonomic response occurred *before* they could verbally describe their understanding of why it was better to pick from the “good” deck. A comparison group of patients with lesions in the ventromedial prefrontal cortex did not have the same physiological responses, nor did they have the “hunch” or “gut feeling” manifested by the normal subjects.

Freud's views on the role of unconscious memories have also been confirmed by experimental psychologists. His conclusions, which are often misrepresented by critics, include the following: (1) unconscious memories can indeed be recovered; (2) some recollections are true whereas others are false; (3) even memories that are essentially accurate may be distorted in various ways.

Unconscious transference processes have also been documented experimentally. In one study subjects were asked to provide a description of a significant other in their lives. A component of that description was subsequently incorporated into a depiction of a fictional character. When the subjects were later asked to recall everything they could about the fictional character, they embellished their description with other elements drawn from the characteristics of their significant other.

Although the accumulated research from the experimental psychology literature confirms that Freud was correct in his central tenet regarding the influence of unconscious thoughts, feelings, and motives on a behavior, the evidence for the efficacy of psychoanalytic treatment is more problematic. Uncontrolled studies of persons in analysis suggest that 60 to 90 percent are substantially improved after treatment. However, no randomized controlled study of analysis has yet been conducted so this evidence cannot be considered definitive. Without a control group, investigators cannot be certain if the patients would have improved to the same extent with the passage of time.

On the other hand, there are formidable methodological obstacles entailed in designing a randomized, controlled study of psychoanalysis. First, patients are not randomly assigned to analysis as a treatment. Patients who do well in analysis typically seek it out because of high motivation to understand themselves. Second, the appropriate control group for a process that takes 5 years or more is a challenge for the research design. How many patients are willing to be in a no-treatment control group for such an extended period of time? Third, if 10 percent of patients in a 16-week randomized, controlled trial of brief therapy drop out of the project, there is no substantial loss to the project because 90 percent have continued. However, if in a 5-year study of psychoanalysis, 10 percent of the patients drop out every 4 months, the sample size would be depleted to the point where the statistical power would be severely compromised in any comparisons performed by the researchers. Intercurrent life events, such as deaths of significant others, divorce, and serious illness, are much more likely to become crucial factors influencing outcome in a 5-year study than in a brief therapy project confined to 16 weeks of treatment.

An overriding problem is that a randomized, controlled study would fail to capture the essence of psychoanalytic treatment. Random assignment bypasses the fact that patient and analyst find each other through a poorly understood process of “patient-analyst matching.” For some reason, both members of the dyad feel that they can work with each other. Also, good analysis is characterized by flexibility, and a treatment manual has the potential to restrict the analyst so that the treatment being studied is different from the treatment occurring in a naturalistic setting.

Nevertheless, there are numerous studies, some using randomized, controlled design, demonstrating that psychotherapies based on psychoanalytic principles are efficacious.

PSYCHOANALYTIC PSYCHOPATHOLOGY

In an age in which neuroscience research has made giant strides in the understanding of many Axis I disorders, psychoanalytic theory still has much to contribute to the overall understanding of causes and pathogenesis. Although biological factors play major roles in such illnesses as schizophrenia and mood disorders, environmental and psychological stressors are influential in triggering the underlying biological diathesis. Moreover, the clinical management of Axis I disorders is greatly enhanced by a psychoanalytically based understanding of the personality factors that contribute to the illness. In the following survey of the psychoanalytic contributions to the understanding of psychiatric disorders, the emphasis is on psychological and environmental factors. However, whenever appropriate, the interaction between those factors and biological determinants of the illness is pointed out.

Schizophrenia Freud thought that patients with psychotic disorders are not amenable to psychoanalytic treatment, so he did not accumulate the kind of clinical experience with psychoses that he did with neuroses. Nevertheless, he attempted to place psychotic disorders in a psychodynamic conceptual framework. Freud thought that the sine qua non of schizophrenia is the withdrawal of object cathexis, by which he meant that schizophrenia patients detach themselves from any libidinal or emotional investment in external objects or their intrapsychic representations. He regarded schizophrenia as a regression from object love to an autoerotic stage of development in which one does not have to deal with the frustrations and conflicts encountered in interpersonal relationships.

Freud's decathexis theory underwent revision after the structural model had been developed. In his revised view of schizophrenia, he contrasted neurosis and psychosis on the basis of the nature of the conflict involved. He regarded neurosis as a conflict between the ego and the id, but in psychosis the conflict occurs between the ego and the external world; reality is remodeled to conform to the patient's internal distortions. Even after that substantial revision, Freud continued to write about withdrawal of object cathexis and used that concept to assert that patients suffering from schizophrenia cannot form transference attachments to treaters.

Subsequent psychoanalytic writers have demonstrated that schizophrenia patients do develop transference, although it is qualitatively different from the variety seen in the psychoanalytic treatment of neurotic patients. Harry Stack Sullivan and Frieda Fromm-Reichmann, who spent their professional careers involved in the psychoanalytic treatment of psychotic patients, regarded schizophrenia as arising from early interpersonal difficulties in the child-parent relationship that required understanding and repair in the context of a therapeutic relationship. In their view, faulty mothering led to anxiety and distrust of others, causing persons with schizophrenia to withdraw from interpersonal relatedness. This parent-blaming view has been discredited by recent research.

One controversy in the psychoanalytic literature involves whether or not the conflict theory used to explain neuroses is sufficient to explain schizophrenia as well. Jacob Arlow and Charles Brenner believed that psychosis can be explained by the same compromise-formation model that is applied to neuroses and that the two conditions may differ quantitatively, but qualitatively they are fundamentally alike. Arlow and Brenner conceptualized the quantitative differences as schizophrenia's involving greater disturbances of ego and superego functioning, more severe regression, and more intense conflicts revolving around aggression. They regarded schizophrenic symptoms, such as delusions and hallucinations, as compromise formations developed in response to conflict, much in the same way that neurotic symptoms are developed. Similarly, Arlow and Brenner viewed the withdrawal of object cathexis that Freud emphasized as simply a defensive retreat from conflict.

Biological research on schizophrenia has identified primary difficulties with information processing and attention in schizophrenia; both difficulties are improved by antipsychotic medication. Indeed, most schizophrenia patients experience themselves as being bombarded by a variety of external and internal stimuli. Approaching the illness from a deficit model, James Grotstein suggested that the schizophrenic inability to screen out incoming stimuli is the fundamental problem in the illness of schizophrenia. The defective stimulus barrier makes it extremely difficult for patients with schizophrenia to deal with the chaotic feelings within, so unacceptable impulses and affects are projectively disavowed and placed in the mothering figure.

Mood Disorders Biological factors play major roles in the causes and pathogenesis of mood disorders. A vast literature on genetic transmission and neurotransmitter changes attests to that fact. Nevertheless, research suggests that intrapsychic and environmental stressors are involved in the onset of major depressive episodes in the majority of cases. It is useful in the light of that perspective to separate cause from pathogenesis. Environmental factors, such as the loss of a loved one, and intrapsychic factors, such as falling short of internal standards, may be crucial causative determinants of a particular depressive episode. The ensuing response to

those environmental and intrapsychic triggers, however, occurs at the level of brain chemistry. Hence, the stressor interacts with a genetic vulnerability.

Depression Freud originally understood depression as internally directed anger. In his view the self-reproaches and the loss of self-esteem commonly experienced by depressed patients are directed not at the self but, rather, at an introject. He noted that in some cases the only way the ego can give up an object is to introject it, so the anger directed at the ambivalently held object takes on the clinical manifestations of depression. After his development of the structural model, he expanded his understanding of depression to include a harsh superego that punishes the person for harboring destructive wishes toward parental figures and other loved ones.

Melanie Klein suggested that depression is linked to a reactivation of the depressive position; depressed patients are convinced that they have destroyed their internal good objects because of their own aggression and greed. As a result, they feel persecuted by internal bad objects while longing for the lost love objects.

Contemporary psychoanalytic contributors have downplayed the role of aggression in the development of depression. They are likely to view depression as a disturbance of self-esteem in the context of interpersonal relationships. A consistent observation is that depressed patients feel that they have not lived up to their internal standards of conduct. The depressed patient's awareness of the disparity between their actual performance and those high internalized expectations leads them to feel helpless and powerless. Often, their internal expectations involve eliciting a certain kind of response from important persons in the environment. Depressed persons often live their entire lives for others, rather than for themselves. Depression may begin when they feel hopeless about their life plans because they realize that their efforts have been wasted in living for someone else.

From an object relations perspective, many depressed patients unconsciously experience themselves to be at the mercy of a tormenting internal object that is unrelenting in its persecution of them. In cases of psychosis, that primitive forerunner of the superego may actually be hallucinated as a voice that is unrelentingly critical. From the self-psychological point of view, depression is related to a sense of despair about ever getting one's selfobject needs met by people in the environment.

Mania Empirical research has demonstrated that genetic and biological factors play a key role in bipolar I disorder. Nevertheless, psychodynamic issues are highly relevant to the overall treatment. Psychological and environmental stressors are often involved in precipitating a manic episode, and psychotherapeutic interventions may help to identify and reduce those stressors to increase the chances that the patient will remain euthymic. Also, the psychodynamic conflicts of the patient may use the manic episodes in the service of expressing specific aspects of those conflicts. For example, manic episodes often serve a defensive function so that the patient does not get in touch with the painful affects associated with the undercurrent of depression. The variant of dysphoric mania, when depressive feelings break through the manic episodes, reflects this defensive function of mania. Melanie Klein noted that manic defenses have several functions: to deny that one is dependent on love objects, to disavow the presence of internal objects, and to restore and rescue lost love objects. Manic episodes frequently occur in response to significant losses as a way of denying the grief associated with the losses.

There are also a number of psychodynamic themes that are consistently problematic in the treatment of patients with bipolar I disorder. Denial and lack of insight into the illness is a regular accompaniment of the disorder, and generally persists even when the patient is euthymic. As a result, compliance with medication is a major problem in the management of these patients. The denial is also accompanied by a form of intrapsychic discontinuity manifested in splitting of the self-representation. In other words, euthymic patients will often disavow any connection with the aspect of themselves associated with the manic episode. They may deny that their behavior was part of an illness or completely minimize the extent to which the behavior was problematic. Moreover, since they see no connection between the euthymic self and the manic self, they may not see the need for ongoing treatment. Finally, grief and loss are often part of the aftermath of the destructive behavior connected with the manic episode. The patient may struggle with feelings of guilt and the need to do the work of mourning to assimilate the losses and work through the feeling that he or she has been destructive to loved ones.

Anxiety Disorders and Neuroses Freud's famous psychoneurotic cases are summarized in Table 6.1-4. In brief, his early view included a heavy emphasis on the traumatic consequences of childhood seduction and on the physiological buildup of libido. As Freud shifted to a model based on psychic conflict, he viewed neurotic symptoms as reflecting the breakthrough of infantile sexual impulses in response to failures of repression. With the advent of the structural model, Freud understood neurotic symptoms to be compromise formations between unconscious wishes and defenses against those wishes produced as a result of conflict between intrapsychic agencies. That view was further refined in 1926, when anxiety became understood as a signal of the presence of danger in the unconscious that mobilized ego defense mechanisms to bolster repression. The relabeling of neuroses as anxiety disorders in the third, revised third, and fourth editions of the American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders (DSM-III, DSM-III-R, and DSM-IV) has led to an unfortunate tendency for clinicians to think about anxiety as an illness to be eliminated with pharmacological intervention, rather than as an overdetermined symptom of unconscious conflict that requires understanding.

	Conversion Reaction (Dora)	Phobic Reaction (Hans)	Obsessive-compulsive Reaction (Rat Man)	Mixed Psychoneurotic Reaction (Wolf Man)
Family history	Striking family history of psychiatric and physical illness	Both parents treated for neurotic conflict but not severe	No family history of mental illness	Striking family history of psychiatric and physical illness
Symptoms	Enuresis and masturbation at 6–8 yrs. Onset of neurosis at 8. Migraine, nervous cough, and hoarseness at 12. Aphonia at 16. "Appendicitis" at 16. Convulsions at 16. Facial neuralgia at 19. Change of personality at 8 from "wild creature" to quiet child	Compulsive questions at 3–2½ yrs. on regard to sex differences. Jealous reaction to sibling birth at 2½. Overt castration threat. Overt masturbation at 3½. Overeating and constipation at 4–5. Phobic reaction at 4–5. Attack of flu at 5 worsens phobia. Tonsillectomy at 5 worsens phobia	Naughty period at 3–4 yrs. Marked timidity after a beating by Father at 4. Recognizing people by their smells as a child ("Bonellius"). Precocious ego development. Onset of obsessive ideas at 6–7	Irritable and quiet up to 2½ yrs. "Naughty" period at 2½–4 yrs. Phobias at 4–5 with nightmares. Obsessional reaction at 6–7 (pious ceremonials). Disappearance of neuroses at 8
Causes	Seduction by older man. Father's illness. Father's affair	Seduction case by mother. Sibling birth at 2½	Seduction by governess at 4. Death of sibling at 4. Beating by Father at 4	Seduction by older sister at 2½. Mother's illness. Conflict between maid and governess

Table 6.1-4 Classical Psychoneurotic Reactions

Panic Disorder Recent biological research has borne out Freud's early observations that there are two forms of anxiety, one involving a purely psychological cause and the other more clearly related to an underlying neurophysiological substrate. Psychological anxiety is now regarded as a milder form of anticipatory or signal anxiety, and neurophysiological anxiety takes the form of panic disorder. Many patients who experience episodes of panic feel that the attacks come out of the blue and are therefore psychologically contentless. Nevertheless, psychodynamic investigations of those attacks find that many of them have psychological meaning. The experience of them as coming out of the blue may only reflect the fact that the psychological triggers are unconscious. A number of studies have demonstrated a close link between separation anxiety and panic disorder. In addition, as many as 43 percent of all panic-disordered patients show improvement after taking a placebo; that finding suggests that the interpersonal involvement with a physician who is concerned about the symptoms may ameliorate certain psychological factors involved in the onset of panic attacks.

One of the clearest examples of psychologically precipitated panic attacks can be found in patients who have not attained object constancy, as described in Mahler's developmental scheme. Patients with borderline personality disorder often cannot internalize a soothing image of the therapist at times of distress. That incapacity may precipitate panic attacks that have all the physiological symptoms of the disorder, accompanied by the thought that the therapist has died or abandoned them. At such times a brief telephone conversation with the therapist reassures them that they have not been abandoned and immediately quiets the panic attack. Such clinical instances illustrate how psychodynamic factors may trigger neurotransmitter disturbances and how psychotherapeutic interventions may calm those disturbances.

Phobias The classical psychodynamic understanding of phobias is based on the mobilization of ego defense mechanisms in response to signal anxiety. An unacceptable aggressive or sexual thought begins to enter conscious awareness, and the phobic person worries about the possibility of retaliatory punishment for such thoughts. The result is the activation of signal anxiety, which enlists the ego's help in deploying three defense mechanisms—displacement, projection, and avoidance—that work in concert. The unconscious impulse is displaced and projected outward onto a neutral stimulus, such as a dog or an elevator, which is then avoided.

Obsessive-Compulsive Disorder Freud regarded obsessive-compulsive neurosis as reflecting a defensive retreat from the presence of oedipal conflicts in response to the threat of castration anxiety. In Freud's model obsessive-compulsive patients regress to the preceding psychosexual stage, the anal stage, because they feel relatively safe from the threats associated with the oedipal constellation. That regression leads to an unraveling of the smooth fusion between the sexual and the

aggressive drives, so that obsessive-compulsive neurotic patients suffer from intense ambivalence. The patients often feel paralyzed with doubt and indecision because of the simultaneous presence of hateful and loving feelings. To defend against aggressive and sexual impulses that are experienced as on the verge of being out of control, obsessive-compulsive patients use reaction formation, intellectualization, isolation, and undoing.

Recent research suggests that the psychodynamic explanation is only partially explanatory. Because patients with obsessive-compulsive disorder have smaller caudate nucleus volumes than do healthy controls and have almost no placebo responses in controlled medication trials, biological factors appear to play major roles in causing the disorder. However, even biologically based disorders have psychological meanings, and the elucidation of those meanings may be instrumental in the clinical management of those patients.

Posttraumatic Stress Disorder Freud originally placed great importance on trauma in the development of neurosis. Contemporary psychodynamic understanding of anxiety states reflects a rediscovery of the pivotal role of actual environmental trauma in many patients suffering from severe anxiety. Posttraumatic stress disorder became a legitimate diagnostic entity in the official nomenclature as a result of the substantial evidence accumulated regarding the severe and disabling effects of trauma on Vietnam War veterans and on victims of incest, sexual abuse, and rape. One contribution of psychoanalytic thinking has been to understand the meaning of the environmental stressor to a particular patient. Different persons respond differently to the same stressor. Seemingly minor stressors can produce major symptoms in one person, but overwhelming trauma may have minimal effects on another person.

Modern studies on the effects of psychic trauma in childhood have shown that an arrest of affective development occurs in response to such trauma. However, trauma in adulthood tends to produce a regression in affective development. The end result is that trauma victims are unable to use affects as signals. A kind of psychic numbing occurs because any intense emotion is internally regarded as a threat that the original trauma is returning. Consequently, affects are somatized, and many patients who have experienced trauma have psychosomatic illnesses accompanied by an inability to identify emotional states, a condition known as *alexithymia*. Associated with those developments, patients with posttraumatic stress disorder are often incapable of soothing themselves, so that they are in a permanent state of hyperarousal.

Many patients who experience childhood sexual abuse learn to dissociate under the duress of the trauma. They thus convince themselves that the trauma is happening to someone else who has a different name and a different identity. In that manner dissociative identity disorder, which many view as a form of chronic posttraumatic stress disorder, develops.

Generalized Anxiety Disorder Patients with generalized anxiety disorder may experience mild symptoms of autonomic discharge but nothing comparable to the experience of patients with panic disorder. Anxiety in cases of generalized anxiety disorder is a signal of an unconscious danger or threat to the person. The psychodynamic meaning of the signal can be discerned only by a careful evaluation of the source of the patient's fear. Anxiety stems from various developmental levels, each of which has its own characteristic fear. If anxiety stems from oedipal conflicts, a male patient may fear castration or physical harm in response to forbidden wishes or thoughts. Preoedipal concerns may lead to separation anxiety in which patients fear that an important loved one is about to abandon them. At higher developmental levels patients may suffer from superego anxiety, in which case the concern is that they are not living up to the internalized ideals and standards of their parents.

Paraphilias The classical view of the origin of the paraphilias or perversions is that they serve the function of denying castration. For example, a male exhibitionist may display his genitals in public as a way of reassuring himself that he has not been castrated. Freud noted that perversions are complex and multilayered, observing that passive and active counterparts of perverse activity ordinarily coexist in the same person. For example, sadists have a flip side that is masochistic, and exhibitionists are unconsciously voyeuristic.

From a self-psychological perspective, paraphilias are regarded as desperate responses to the absence of appropriately emphatic selfobjects. Perverse sexual activity may restore a sense of cohesiveness to the self in the paraphilic patient. Similarly, sexual acting out during a psychoanalytic process may relate to empathic failures in the analyst.

Contemporary views of the paraphilias have stressed the role of object relatedness in their cause and pathogenesis. Robert Stoller has noted that the essence of perverse sexual activity is the conversion of a passively experienced trauma into an adult act of triumph and mastery. For example, if parents dress a little boy as a girl, he may seek to master his humiliating childhood traumas by becoming a transvestite as an adult. Joyce McDougall has viewed deviant sexual behavior as resulting from unconscious scripts stemming from a complicated set of identifications and counteridentifications with the erotic desires and conflicts of one's parents. She has also noted a fear of self-disintegration involved with much perverse activity, so that certain deviant sexual practices may be experienced as medicating the internal fear of dissolving into nothingness.

Anorexia Nervosa Patients with anorexia nervosa typically lack a sense of autonomy and selfhood. Many patients with the disorder experience their bodies as somehow under the control of their parents. Self-starvation may be an effort to gain validation as a unique and special person. Only through acts of extraordinary self-discipline can the anorexic patient develop a sense of autonomy and selfhood.

Psychoanalytic clinicians who treat patients with anorexia nervosa generally agree that those young patients have been unable to separate psychologically from their mothers. The body may be perceived as if it were inhabited by an introject of an intrusive and unempathic mother. Starvation may have the unconscious meaning of arresting the growth of that intrusive internal object and thereby destroying it. Often, a projective identification process is involved in the interactions between the patient and the patient's family. Many anorexic patients feel that oral desires are greedy and unacceptable, so that those desires are projectively disavowed. Parents respond to the refusal to eat by becoming frantic about whether the patient is actually eating. The patient can then view the parents as the ones who have unacceptable desires and projectively disavow them. Others are voracious and ruled by desire but not the patient.

Bulimia Nervosa Patients suffering from bulimia nervosa lack the superego control and ego strength of their counterparts with anorexia nervosa. The bulimic patients' difficulty in controlling impulses is often manifested by chemical dependency and self-destructive sexual relationships, in addition to the binge eating and purging that are hallmarks of the disorder. Many bulimic patients have histories of difficulty in separating from caretakers manifested by the absence of traditional objects during their early childhood years. Some clinicians have observed that bulimic patients use their own bodies as transitional objects. The struggle for separation from the maternal figure is played out in the ambivalence toward food; eating may represent a wish to fuse with the caretaker, and regurgitating unconsciously expresses a wish for separation.

Psychodynamic treatment of patients with bulimia nervosa has revealed a tendency to concretize introjective and projective defense mechanisms. In a manner analogous to splitting, food is divided into two categories: those items that are nutritious and those that are unhealthy. Food that is designated as good may be ingested and retained within because it unconsciously symbolizes good introjects. But junk food is unconsciously associated with bad introjects and is, therefore, expelled through vomiting, with the unconscious fantasy that all destructiveness, hate, and badness are being evacuated. Patients may temporarily feel good after vomiting because of the fantasized evacuation, but the associated feeling of being all good is short-lived because it is based on an unstable combination of splitting and projection.
